The network used as a teacher in this paper is a modified version of the HRNet+OCR+PSA architecture [23]. It comprises the HRNet+PSA backbone, a version of HRNetV2 [26] with the Polarized Self Attention (PSA) block as the attention block. High Resolution Net V2 (HRNetV2) is an ad-hoc architecture for semantic segmentation, derived from HRNet. It consists of four stages, each of which produces high-resolution features. The stages consist of repeated multi-resolution blocks. Each block consists of a multi-resolution group convolution and a multi-resolution convolution. The multi-resolution group convolution is an extension of the group convolution. It separates the input channels into multiple subsets of channels and applies a standard convolution to each subset at different spatial resolutions. In a multi-resolution convolution, on the other hand, the input and output subsets are fully connected, and each connection is a standard convolution. The output channels for each subset are the sum of the results of the convolutions on each subset of input channels.

The HRNet features are then transmitted to the decoder, which serves as the OCR (Object Contextual Representation) module [27]. The central concept of the OCR module is that the label assigned to each pixel must match the label of the object containing it. To achieve this goal, the OCR module first extracts soft object regions from feature maps and then, using an attention mechanism, computes representations of the object regions together with the pixel representations. These representations are used to improve the final representations employed to predict the segmentation map.

Starting from the basic architecture, we modified it specifically to solve the weed mapping problem (see Fig. 1). In particular, to handle additional input channels, we modified the first input layer so that it can accept not only visible channels but also non-visible channels.

B. Student

Like the teacher and other semantic segmentation models, Lawin includes an encoder and a decoder. The encoder is a type of architecture called Mix Transformer (MiT) [28], explicitly designed for semantic segmentation as an alternative to the original ViT. MiT can produce multilevel features with different resolutions, similar to CNNs, and outputs a feature map for each Transformer block. This hierarchical representation provides high-level coarse-grained and low-level fine-grained features that generally improve performance in semantic segmentation. For example, starting from an RGB image of size $3 \times H \times W$, the first Transformer block generates a feature map of size $C_1 \times \frac{H}{4} \times \frac{W}{4}$, where C_1 is the chosen embedding dimension. Then, each subsequent transformer block takes as input the feature maps of the previous block and produces a feature map $F_i \in \mathbb{R}^{C_i \times \frac{H}{2^{i+1}} \times \frac{W}{2^{i+1}}}$, where i is the index of the block.

The decoder uses a technique called Large Window Attention Spatial Pyramid Pooling (LawinASPP), which consists of five different branches, including a pooling layer, a shortcut connection, and three large window attentions with different

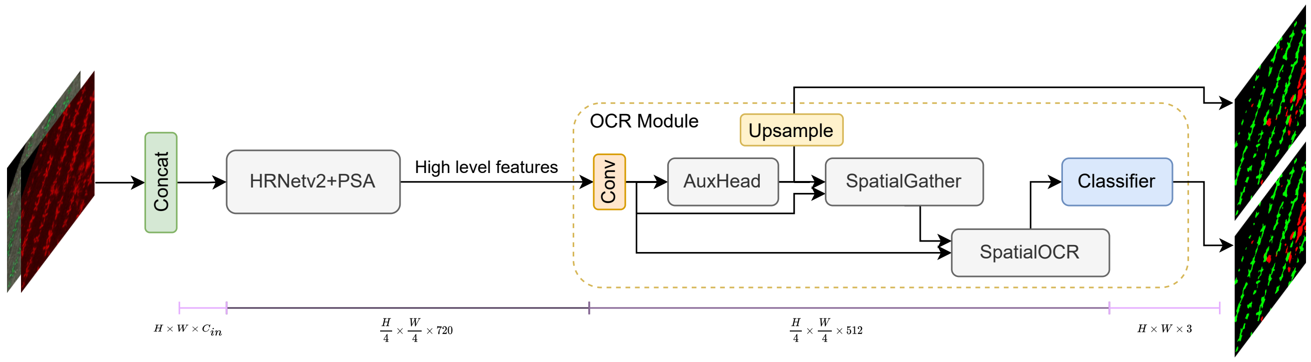

Fig. 1. HRNet+OCR+PSA modified for weed mapping ("Conv" is a convolutional layer with a 3×3 kernel, while H, W, and C_{in} are the height, width, and channels of the input images, respectively). Unlike the original version, the model accepts both visible and non-visible channels as input.

context sizes. The pooling branch handles the global context, while the three window attentions serve as local context extractors. The last two outputs of the encoder are processed with a standard multilayer perceptron and an upsampling operation. However, the first output is not processed by LawinASPP but concatenated with its output. A final linear transformation is applied to create the final segmentation map, followed by an upsampling operation. The resulting map is a probability distribution that assigns each pixel to a specific class.

As for HRNet+OCR+PSA, starting from the basic architecture of Lawin, we modified it to accept visible and non-visible channels. Moreover, to further improve performance, we propose a lighter variant of Lawin, Lawin-L0, which uses SegFormer as the encoder [28]. SegFormer, in turn, has five variants based on embedding size and model depth (B0, B1, B2, B3, B4). Lawin-L0 has a halved embedding size and a halved number of blocks in each phase compared with Lawin-B0. In addition, Lawin-B0 repeats each of the four stages twice, while Lawin-L0 repeats them only once. The embedding size in Lawin-B0 is (32, 64, 160, 256), while in Lawin-L0 it is (16, 32, 80, 128). The decoder also reflects these sizes, further reducing the computational cost. Lawin-L0 is shown in Fig. 2.

C. Vanilla Knowledge Distillation

In precision agriculture using drones, obtaining lightweight models is critical. Knowledge distillation can help achieve higher accuracy on lighter models. In particular, for weed mapping, we want to show that lightweight models can achieve comparable performance to large models when adequately trained.

In *vanilla KD*, the loss is a weighted sum of a task loss and a distillation loss:

$$\mathcal{L} = (1-\alpha)\mathcal{L}_{task} + \alpha\mathcal{L}_{KD}$$

where $\mathcal{L}_{task}$ is the task-specific loss function for the student model, $\mathcal{L}_{KD}$ is the distillation loss, and α is a hyperparameter controlling the relative weighting between the two losses.

D. Teacher Assistant Knowledge Distillation (TAKD)

This variant of KD consists of two distillation stages [13], where the first stage involves the teacher model distilling its knowledge to an intermediate assistant model, and the second stage involves the assistant model further distilling knowledge to the final student model. This approach is designed to leverage the expertise of the teacher model while mitigating the impact of the capability gap between the teacher and student models. Introducing the assistant model as an intermediary aims to minimize the loss of information and enable a more effective transfer of knowledge to the student model. As an assistant, we used Lawin, specifically the B0 variant, which falls between the teacher and student models in terms of complexity.

E. Annealing Knowledge Distillation

This technique tries to solve the capacity gap problem by modifying the KD loss and introducing a dynamic temperature function to make the student's training gradual and smooth [14]. The process is divided into two phases: Stage I, gradual training of the student to imitate the teacher using the annealing KD loss; Stage II, fine-tuning the student with hard labels using the task loss. The resulting loss can be defined as:

$$\mathcal{L} = \begin{cases} \mathcal{L}_{KD}^{annealing}(i), & \text{Stage I: } 1 \leq \mathcal{T}_i \leq \tau_{max} \\ \mathcal{L}_{task}, & \text{Stage II: } \mathcal{T}_n = 1 \end{cases}$$

where i denotes the epoch index in the training process with n maximum epochs for Stage I and $\mathcal{T}_i$ the corresponding temperature value. At epoch (i), $\mathcal{L}_{KD}^{annealing}(i)$ is defined as:

$$\mathcal{L}_{KD}^{annealing}(i) = ||z_s(x) - \Phi(\mathcal{T}_i)z_t(x)||_2^2$$

$$\Phi(\mathcal{T}) = 1 - \frac{\mathcal{T}-1}{\tau_{max}}, 1 \leq \mathcal{T} \leq \tau_{max}, \mathcal{T} \in \mathbb{N}$$

In this case, the distillation loss is a mean squared error (MSE) between the student's logits ($z_s(x)$) and an annealed version of the teacher's logits ($z_t(x)$), obtained by multiplying them by the annealing function Φ. The annealing function is a monotonically decreasing function $\Phi : [1, \tau_{max}] \in \mathbb{N} \to [0,1] \in \mathbb{R}$. τ_{max} represents the hyperparameter for the maximum temperature.

As before, unlike the original version, the model accepts both visible and non-visible channels as input and has a reduced number of hidden channels.

F. Continuation Knowledge Distillation

This technique is based on continuation optimization, a method for solving optimization problems by gradually increasing the complexity of the objective function [15]. The idea is to start with an easy-to-train objective function that becomes increasingly complex as the training progresses, allowing the student model to learn and gradually improve its performance. The loss function is defined as:

$$\mathcal{L} = \psi(i)\mathcal{L}_{task} + (1 - \psi(i))\mathcal{L}_{KD}$$

where $\psi(i)$ is a monotonically increasing linear function $\psi : \mathbb{N} \to [0, 1] \in \mathbb{R}$. The ψ function is defined as:

$$\psi(i) = \begin{cases} \frac{i}{N_{epochs}} & \text{if } i \leq N_{epochs} \\ 1 & \text{if } i > N_{epochs} \end{cases}$$

where i is the epoch index and N_{epochs} is the number of epochs the student model will learn from the teacher.

$\mathcal{L}_{KD}$ is the distillation loss, defined as the MSE between the student's logits $(z_s(x))$ and the annealed teacher's logits $(z_t(x))$ similarly to annealing KD, but with a defined margin m:

$$\mathcal{L}_{KD} = \max\{0, ||z_s(x) - \Phi(\mathcal{T}_i)z_t(x)||_2^2 - \Phi(\mathcal{T}_i)m\}$$

where $\Phi(\mathcal{T}_i)$ is the annealing function.

V. Experiments

This section presents our experimental setup, followed by the quantitative and qualitative results of crop and weed segmentation.

A. Experimental Setup

For the Rheinbach subset, we used the same train-test subdivision applied in [8] and [29], namely [000, 001, 002, 004]–[003]. Due to the limited number of images containing weeds in the Eschikon subset test set, we opted for a different split to ensure more reliable results, i.e., [005, 007]–[006]. All channels provided in the two subsets are fed to the models. We used Adam as an optimizer for model training, with batch size 6, a maximum number of epochs of 500, and an early stop with patience 25. Specifically, the validation sets were randomly extracted from the training sets for early stopping. We used the regional mutual information [30] as the task loss, weighted by the frequency of pixel classes, as done in [8]:

$$\mathcal{L}_{RMI} = \lambda w_c \mathcal{L}_{ce}(y, p) + (1 - \lambda)\frac{1}{B}\sum_{b=1}^{B}\sum_{c=1}^{C}(-I_l^{b,c}(\mathbf{Y}; \mathbf{P}))$$

where $\lambda \in [0, 1]$ is a weight factor, $\mathcal{L}_{ce}$ is the cross-entropy, B denotes the batch size, C the number of classes, $I_l^{b,c}(\mathbf{Y}; \mathbf{P})$ is the mutual information between the ground truth and the prediction, and $\mathbf{Y}$ and $\mathbf{P}$ are the ground truth and the prediction, respectively. w_c are the class weights, calculated as:

$$w_c = \frac{FoA(c)}{\widetilde{FoA(c)}}$$

$$FoA(c) = \frac{I_c}{I}$$

where $f(x)_c$ is the probability of the true class c predicted by the model, $\widetilde{FoA(c)}$ is the median of $FoA(c)$ by varying c, I_c is the number of pixels in c, and I is the total number of pixels. The eventual application of these weights is a hyperparameter in the experiments.

In addition, we used Kullback-Leibler divergence and MSE for vanilla KD as the distillation loss, with $\alpha = 0.8$. The same hyperparameters were used for TAKD. As for annealing KD, we used an initial temperature of 0.9. In addition, it is not possible to use early stopping because the temperature is a function of epochs, so we set 50, 100, and 150 as the maximum epochs. For continuation KD, we used the same hyperparameters as for annealing KD, but given the way ψ

TABLE I
COMPARISON OF DIFFERENT KD TECHNIQUES WITH THE TEACHER AND THE UNDISTILLED MODEL FOR BOTH SUBSETS OF DATA

	Rheinbach				**Eschikon**			
	F1	**F1 Background**	**F1 Crop**	**F1 Weed**	**F1**	**F1 Background**	**F1 Crop**	**F1 Weed**
Teacher	0.868	0.990	0.877	0.737	0.656	0.995	0.816	0.155
No distillation	0.843	0.989	0.847	0.696	0.565	0.995	0.653	0.046
Vanilla KD	0.855	0.989	0.855	0.719	0.624	0.990	0.668	0.215
TAKD	0.850	0.988	0.842	0.720	**0.631**	0.992	0.763	0.138
Annealing KD	0.853	0.989	0.849	0.722	0.581	0.994	0.691	0.059
Continuation KD	**0.863**	0.990	0.862	0.736	0.553	0.987	0.666	0.005

is defined, the early stopping technique can be used. The experiments were performed on an RTX 3080 Ti with 12 GB of VRAM.

We used the F1 score for each class and macro-averaged to assess the models quantitatively. It was calculated as follows:

$$F1 = \frac{2TP}{2TP + FP + FN}$$

where TP stands for true positives, FP for false positives, and FN for false negatives.

B. Quantitative Results

The study's results are presented in Table I, which compares the performance of the teacher model used alone, the student model without teacher knowledge distillation, and the student model with knowledge distillation. We do not show the results obtained with all possible hyperparameter configurations for better readability, but only the best ones obtained. Furthermore, it is worth noting that the different KD methods did not modify the number of parameters of the resulting models but only the training procedure.

The study found that in both subsets, the use of knowledge distillation improved performance. Interestingly, the vanilla KD approach was sufficient to improve the score. Continuation KD outperformed the other models for the Rheinbach subset, with an average F1 score of only 0.005 lower than the teacher model and 0.001 lower for the weed class. On the other hand, the Eschikon subset presented difficulties due to the differences between the crops of the three collected fields, highlighting the difficulty of generalization in weed mapping. However, the teacher assistant technique showed promise, improving performance by up to 7%. The F1 score for weeds also showed a substantial increase, from 0.046 without KD to 0.138 with TAKD. In addition, the F1 score for crop class showed a significant increase from 0.653 to 0.753. Although there was a reduction in the background class score, the score was still high enough to make the reduction insignificant. State-of-the-art models for the WeedMap dataset include DeepLabV3 [11], which obtained an F1 score of 0.81 on the Rheinbach subset. Instead, while not using F1 in their experiments [8], replicating SegNet scores 0.445 on Eschikon and 0.836 on Rheinbach. Therefore, our lightweight model outperforms even the dataset's state-of-the-art.

Regarding computational time and complexity, Lawin-L0 has a relatively low amount of computational operations, measured in GMacs (giga multiply-accumulated operations), equal to 0.5 GMacs, and a relatively low number of parameters, measured in millions, equal to 0.98 million parameters. On the other hand, HRNet+OCR+PSA has significantly higher computational requirements, with 42.04 GMacs and 75.74 million parameters. Despite the substantial reduction in parameters, a satisfactory level of accuracy can be achieved.

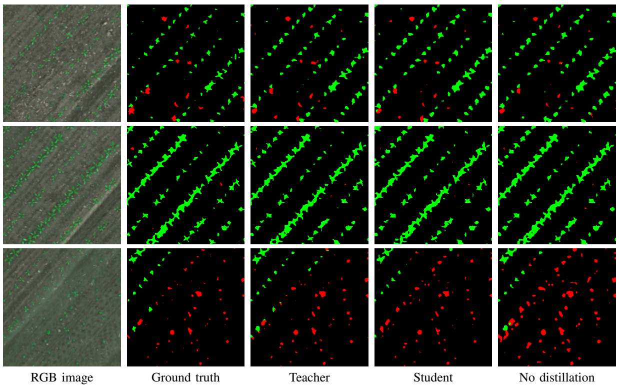

Fig. 3. Segmentation examples performed on test field [003] (black = background, green = crop, red = weed).

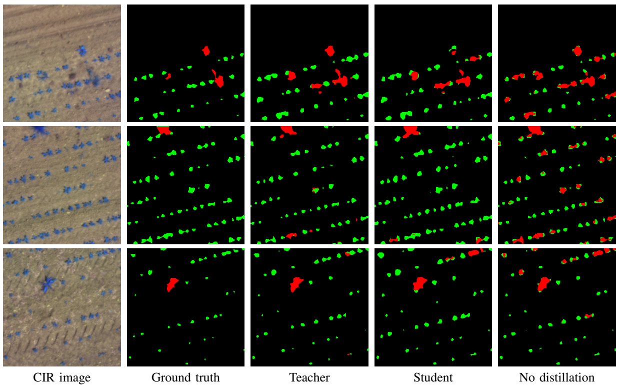

Fig. 4. Segmentation examples performed on test field [006] (black = background, green = crop, red = weed). CIR stands for color infrared.

C. Qualitative Evaluation

A qualitative assessment of weed mapping found that the segmentation maps obtained from the students' model were the same quality as those obtained from the teacher model. This is reflected in the F1 score obtained from both models. This indicates that the students' model can learn effectively from the teacher model and produce accurate weed mapping results. Examples of segmentation maps obtained as output from the best execution of student Lawin-L0 and teacher HRNet+OCR+PSA on Rheinbach are shown in Fig. 3. In the Rheinbach subset, the segmentation maps reveal no apparent visual difference in the F1 score, despite all models performing well. However, distinct differences are observed for the weed class in the Eschikon subset, shown in Fig. 4. The models show an imbalance toward the weed class, with high recall, low precision, and many false positives. In particular, this phenomenon is more pronounced in the undistilled model than in the distilled model. The segmentation maps produced by the distilled model resemble those of the teacher model, indicating the significant influence of the teacher model on students' predictions.

VI. Conclusion

Our study demonstrated that knowledge distillation in the context of drone-based weed mapping could be effectively used to train an extremely lightweight model with only 0.5 GMacs. Our results indicate that this model can provide high-level performance while maintaining a short inference time. This makes them ideal for mobile platforms such as drones or ground control stations, which can also be smartphone devices. In particular, we have shown that the student model can learn from the teacher model and produce accurate results. Applying knowledge distillation to the Rheinbach subset resulted in a relatively modest 2% increase in the F1 score. However, the technique proved more effective for the more challenging Eschikon subset, where a significant 7% improvement was achieved. This highlights the practical value of knowledge distillation in this particular context. A potential future direction of this research could be to apply knowledge distillation to other tasks similar to weed mapping. This would allow us to evaluate the effectiveness of our approach further and explore its potential applications in a broader range of contexts where lightweight models are critical (for example, in crowd flow detection [31]).

In conclusion, developing effective and efficient computer vision algorithms on drones can significantly improve weed management practices, leading to more sustainable and efficient farming practices. By enabling farmers to quickly and easily identify infested areas and prioritize control efforts, this technology has significant implications for precision agriculture, ultimately increasing profitability and environmental sustainability.

Abstract— **Mutual learning is a machine learning algorithm where multiple machine learning algorithms share knowledge among themselves to improve themselves. The utilization of mutual learning algorithms can effectively enhance the efficiency of machine learning and neural networks within a multi-agent system. This approach is particularly useful in scenarios where the system cannot be adequately trained with a large dataset. By exchanging data in a dynamic teacher-student network system, mutual learning can result in efficient learning outcomes. Typically, a large network serves as a static teacher and transfers data to smaller networks, referred to as student networks, to improve their efficiency. In this study, we aim to demonstrate that two small networks can dynamically alternate between the roles of teacher and student to share knowledge, resulting in improved efficiency for both networks. To exemplify this concept, we apply a mutual learning algorithm using convolutional neural networks (CNNs) and Support Vector Machine (SVM) to accurately identify the kidney diseases – cyst, tumor and stone using image classification algorithm.**

Index Terms—**Mutual learning, teacher-student network, CNN, model distillation, Kidney Disease, Cyst, Tumor, Stone**

I. Introduction

MACHINE learning has a great potential to revolutionize the medical science. It can be a big aid to the current medical system specially in disease diagnosis in early stage. Moreover, in many third world countries, there is extreme shortage of doctors and hence, the doctors do not have the ample time and energy to invest behind a patient. In those cases, machine learning algorithm can provide work as a 'second brain' for the doctor to aid him in disease diagnosis. Even in the first world countries the machine learning algorithms can provide a third eye to the doctors. Couple of recent studies [1][2] shows that an estimated 5% of the outpatients get wrong diagnosis in US every year. Particularly when a patient is in serious medical condition, the misdiagnosis is common. A study shows that almost 20% of the serious patients are misdiagnosed at the level of primary care [3]. Misdiagnosis can result in serious harm of the patient and almost one-third of the misdiagnosed patient face harmful consequences [4].

Nevertheless, use of machine learning in medical diagnosis is still limited due to several facts. Experiments proved that for attaining considerable accuracy level, machine learning training dataset requires abundant amount of patient data [5][6][7][8][9][10]. However, the machine learning diagnostic algorithms could not reach the accuracy of the doctors in differential diagnosis [11][12][13] yet specially where there can be multiple possible causes of a patient disease symptoms. Lots of research has been done in disease diagnosis but few has shown considerable accuracies (accuracy>90%) because as stated earlier, wrong diagnosis can be potentially dangerous for the patient. For example, machine learning algorithms for heart disease detections show accuracies in the range between 80% to 90% [14][15][16][17] while only one result shows accuracy of 94% [16] using SVM algorithm. Machine learning algorithm for diabetes detection shows accuracies between the 70% to 80% [18][19][20] [21][22] while only one result using Naïve Bayes algorithm shows accuracy of 95%. Lever disease detection algorithms [23][24] [25] shows even poorer accuracies (around 70%) while only couple of results shows accuracies over 96% [25] using Naïve Bayes and functional tree algorithm. Research [26] [27][28] shows poor accuracies for Hepatitis detection also (ranges between 70% to 90%) while only one result [26] shows accuracy of 96% using Naïve Bayes algorithm.

Medical diagnosis AI must have very high accuracy (>97%) on unknown dataset [29][30]. For that, medical diagnosis AI must have training dataset greater than 10000 to build reliable system [29][30]. But building a big and comprehensive dataset in medical sector is not easy because patient data sharing has lots of confidentiality and legal bindings. Moreover, a key step in machine learning is to train the algorithm/network properly to achieve good accuracy. Most often, in order to achieve good enough accuracy, machine learning algorithms have to be trained using fairly large number of training datapoints. It may require large memory to execute and get power and computation resource hungry training algorithms which can be a tremendous problem in many systems. Hence, there is a big demand to find small and fast training mechanisms. Mutual learning [31][32][33] is one of the interesting concepts explored to execute faster and efficient training of machine learning algorithm and share knowledge among the algorithms.

Mutual learning algorithm is a machine learning algorithm where multiple machine learning algorithms learns from different sources and then share their knowledge among themselves (fig 1) so that all the agents can improve their classification and prediction accuracies simultaneously. Mutual learning algorithm can be an efficient mechanism for improving the machine learning and neural network efficiency in a multi-agent system. Most of the model distillation systems use a big network, known as teacher network, to pass its learning to a smaller network to train the later [34][35][36]. Static teacher-student network data passing is one-way which incurs several issues like mimicry loss [37]. Furthermore, the teacher network does not see any improvement in efficiency. On the other hand, in mutual learning, a variation of model distillation, there is no static teacher-student network. Rather, role of teacher and student network can change dynamically based on the training sample, and both networks can train each other (fig 1). Thus, efficiencies and accuracies of both

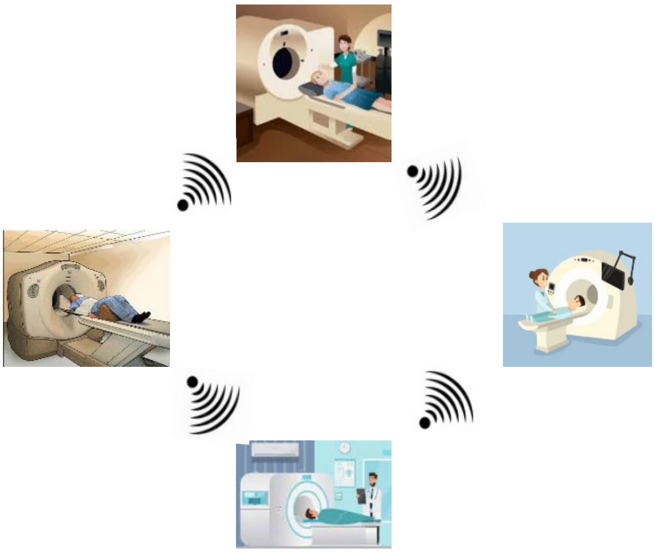

Figure 1: Medical diagnosis machines sharing knowledge.

networks improve. The concept can be particularly useful to increase the efficiency of multiple small networks simultaneously which can be used to do parallel processing. Furthermore, mutual learning can be particularly useful when a big single training dataset is not available. Rather, small, distributed sets of training data are available and some of the training data may need to be relabeled. In this way mutual learning can be very helpful in the field of machine learning for medical diagnosis. Since the machines are sharing data among themselves in non-human readable format, the issue of privacy breaching can also be avoided and gradually over the time the machine will improve their accuracy levels to an acceptable threshold for medical diagnosis.

In this paper, we demonstrate the concept of such mutual learning via the different kidney disease (cyst, tumor and stone in kidneys) detection using scanned kidney images in ref[38] dataset. We used CNN and SVM algorithm to implement the kidney image pattern recognition. We show how the mutual learning can improve the efficiency of both the networks simultaneously and how it can reduce the overall training time significantly. The accuracy keeps improving over the time as more and more training data is shared between machine learning algorithms. We also show that the increasing the number of networks in mutual learning can significantly improve the efficiency of all the networks involved without significantly increasing the training time. The mutual learning is implemented between both homogeneous and heterogeneous agents and comparison between relative accuracy improvements are discussed and analyzed in detail.

II. Background on Mutual Learning

For centuries, philosophers have delved into the study of learning theory, while psychologists, engineers, and computer scientists have joined this exploration over the past seventy years. As a vast, multidisciplinary field, learning theory has been the subject of investigation using a multitude of methods. Historically, the majority of research has focused on a single agent, typically a learner or student, operating in a deterministic or stochastic environment. However, this report marks a significant departure from traditional learning approaches as it investigates the dynamics of multiple agents learning from each other.

The fundamental inquiry, posed in various iterations, revolves around how two or more agents or entities, operating within the same or similar environment and attempting to solve the same or similar problem, can share information to increase operational efficiency.

Mutual learning problems are prevalent and encompass a wide spectrum, ranging from straightforward deterministic optimization to exceedingly complex ones that are challenging to articulate accurately. The problems addressed in this report span multiple areas, such as deterministic optimization in high-dimensional spaces, stochastic reinforcement learning in static/stationary environments (learning automata), employing both deterministic and stochastic schemes, learning in dynamic environments, such as those defined by Markov Decision Processes, and learning/adaptation by multiple agents in dynamic environments described by deterministic or stochastic difference and differential equations.

Mutual learning can occur between two humans, a human and a machine, or between two machines. Researchers in fields such as social psychology are particularly interested in the former. However, the importance of human-machine interactions has become increasingly evident, especially in the context of interactions between human-driven and fully autonomous vehicles. We anticipate that machine-machine learning will lead to complex yet intriguing problems that will keep investigators occupied for many years. The quantitative approach used in this and future reports will not only facilitate efficient collaboration between machines, but also shed light on the limitations of such collaboration. Specifically, the study aims to address the question of whether two agents, each utilizing schemes that result in optimal behavior in stationary environments, may arrive at an incorrect conclusion when learning from one another.

A. *Related Research*

In the study conducted by Ikemoto *et al* [39], human-robot mutual learning and co-adaptation were explored, inspired by human parenting behavior. In the context of artificial neural networks, Zhang *et al* [37] examined the problem of a group of deep neural networks learning from each other for a classification task. The researchers concluded that small neural networks with mutual learning could outperform a single powerful teacher network. Nie *et al* [40] investigated mutual learning to achieve superior performance in two related yet distinct computer vision tasks, namely human parsing and pose estimation. Another relevant research theme is multi-agent learning systems, where agents focus on different subtasks of a complex problem and work together to solve it, similar to mathematical game theory. Panait and Luke [41] provide an overview of this well-established field, emphasizing inter-agent communication, task decomposition, and scalability in multi-agent systems. In contrast to multi-agent systems, mutual learning involves agents that collaborate to solve the same or similar tasks and act as (partial) teachers to each other to enhance their learning.

III. Kidney Disease Diagnosis with Machine Learning : Literature Review

In literature, many machine learning studies has been done on pattern recognition-based kidney diseases detection.

However, most of the work focused on chronic kidney disease detection [42][43][44] since it can be fatal for the patient. Few works [45][46][47] has been done on machine learning based kidney cyst, tumor and stone detection. Ref [45] used CNN to show an accuracy of 99.52% while ref [46] showed 99.30% accuracy using VGG16. Ref [47] showd impressive 99.98% accuracy using DenseNet201. All these works are conducted on a certain dataset and parameters are optimized for maximum accuracy. The principle concern is, how these trained networks would behave for a new unknown set of data. It is unlikely that they will show similar accuracy for unknown dataset. For achieving good universal accuracy, the algorithms are needed to be trained over times by datasets from various sources and types.

IV. THE PATTERN RECOGNITION PROBLEM

For every pattern recognition problem, there is a sample space S consisting of elements. These elements, also known as pattern samples or samples, are the focus of a specific problem. For example, in character recognition, a sample would refer to a specific character, while in medical diagnosis, it would be a set of symptoms. The goal of a pattern recognizer is to develop a rule that divides the sample space into partitions where all elements belonging to the same partition are equivalent. Essentially, the sample space S is divided into equivalence classes.

A. Design of a Pattern Recognizer

The basic structure of the pattern recognizer consists of the following three stages:

1) Physical Measurement: In the first stage, each sample (converted from physical measurements) corresponds to a set of ordered numbers.

2) Feature Extraction: In the second stage those features which are judged to be important for the recognition problem are derived from the elements in stage 1 (this is more of an art than a science).

3) Classification : This is the crucial part of the procedure in which the elements are classified on the basis of their features.

The above separation of the problem into the three stages of physical measurement, feature extraction and classification is mainly for convenience. The choice of the features is critical to the success of the classification process, but the former depends on the physical measurements made on the samples. If the original set S can be expressed as $S = \cup_i \ C(i)$, where C(i) is an equivalence class, the objective of pattern recognition is to find a mapping such that all elements of C(i) are mapped to the same class.

B. Methods for Pattern Recognition

Historically, the methods proposed for pattern recognition , belong to two distinct periods. During the 1960s,70s, and part of 80s most of the methods assumed that the two sets could be separated by a hyperplane in the feature space. Hence the problem was to determine the orientation of the hyperplane based on the test samples. A very large number of outstanding text books exist in which the convergence of the hyperplane to the desired orientation, based on the information contained in the training samples, is rigorously proved.

The rise of methods based on artificial neural networks followed the period referred to earlier. Significantly more complex decision surfaces than hyper-planes (manifolds in the feature space) could be used to perform pattern classification. The methods were significantly less analytic in nature, but the success of the methods in real problems eventually made them the preferred methods in practical applications. In much of the literature in the 1960s, 70s, and 80s, the discriminant surfaces were linear hyperplanes and the classification rule was based on whether a sample lies above or below the hyperplane (i.e., whether the projection of the sample on the normal to the hyperplane is positive or negative). In such situations, classification is the process by which the hyperplane is determined by the training samples, and, if a solution exists, using the hyperplane to classify test samples whose classifications are unknown.

Pattern recognition based on the above methods are well known. When 'Mutual Learning' is used for such problems, it is assumed that agents (or machines) with different training sets (datasets) are attempting to solve the same problem. Our interest lies in the questions that can arise when they communicate with each other and whether they can improve their performance in some sense by such communication.

V. THE MUTUAL LEARNING ALGORITHM

In this section, we describe our main contribution of the paper, i.e., the mutual learning algorithm. As stated earlier, we propose two different algorithms for mutual learning.

A. Algorithm I - Similarity Matching Based Mutual Learning

In this algorithm, the two agents take turns in serving the other agent's teacher, i.e., there are no predefined assigned roles as teacher and student between the two agents. When an agent encounters a novel data-point that is not present in either agent's dataset, the two agents engage in mutual communication where each one looks for points that are 'similar' in its training set, and the corresponding data labels. The agent that wins this competition, i.e., has (labeled) examples that are more 'similar' to the novel data point than the other agent, serves as the teacher and the other agent takes the role of the student for the novel data point. The two agents augment their training with their respective (labeled) training datasets intermittently with such mutual learning with exploratory 'novel' datapoints not included in the training set.

The expectation in such mutual learning is that, by leveraging the 'expertise' of the other agent on specific 'unseen' examples, an agent may be able to overcome the inadequacy of its training data, and will be able to learn faster. That is, each agent will be able to achieve superior classification performance than what is possible without such mutual learning. The following describes the proposed mutual learning algorithm in a more precise manner.

Let D be a (training) dataset of ground truth with N examples. At each iteration k, each agent picks an example from D with probability p(k). With probability (1-p(k)) they choose a random input with unknown class label. If they choose an example from D, learning proceeds as in the isolated learning case. If they choose a random input X, each agent A_1 and A_2 determines their output classification for M <= N examples in D that are closest to X. Whichever agent A_i has higher number of correct labels for these M ground truth examples, is considered the teacher, with the other agent A_j

being the student. The student A_j then updates itself for X treating the output label generated by the teacher A_i for X as the target. X can be viewed as an off-line experiment, while choosing any example from D is an on-line experiment. p(k) starts at k=1 with a value of 0.5 (say) but is increased towards 1 with increasing k as, say,

$$p(k) = 0.5*(2- 1/\sqrt{k})$$

Therefore, eventually both agents only use ground truths. This provides the guarantee that eventually both agents will only use on-line experiments, i.e., isolated learning with ground truths, and therefore is guaranteed to perform no worse than isolated learning. What we hope to demonstrate that with an appropriate scheduling of p(k), the mutually learning team can achieve a given high level of accuracy with fewer total online experiments than that required by an isolated learning agent, by making used of the off-line experiments.

Fig.2 shows a pictorial representation of algorithm 1. Fist, two agents are trained with different training datasets first (fig 2 top). When an agent encounters a novel datapoint, it matches the novel data point with all the datapoints in both the training datasets of agent1 and agent2. In this way it tries to find the ’most similar’ and previously seen datapoint. The new novel datapoint is labeled the same as the ’most similar’ datapoint (fig 1 bottom). All the novel datapoints are labelled in the same way and both the agents are retrained with new novel dataset and their respective old training dataset (fig 2 bottom).

B. Algorithm II - Previous Knowledge Based Mutual Learning

In this algorithm the two agents are trained with different training datasets first (fig 3 top). When an agent encounters a novel data point, both the agents predict the label of the data point based on their own knowledge and previous training. The confidence level or the prediction accuracy probability for each agent are also calculated at the same time (fig 3 top). The agent with higher confidence wins the competition and the novel data point is labeled according to the winner agent’s prediction (fig 3 bottom). The winner agent then works as the teacher and the other agent becomes the student for that particular new data point. In this way, for a particular unseen data point, we are trying to see which agent has the most capability to predict based on previous knowledge and training. In this way the ‘less capable’ agent for that particular agent learns something new and as a result, it will be able to predict for similar datapoint faster and with better accuracy in future. The two agents augment their training with their respective (labeled) training datasets intermittently with such mutual learning with exploratory ‘novel’ datapoints not included in the training set.

Assuming there are total ‘N’ number of classes in a multiclass classification problem. For a particular unseen new data point the probability of predictions from output neurons can be written as follows according to Gibb’s measure

$$\sum_{k=1}^{N} Pr(Y_i = k) = \sum_{k=1}^{N} \frac{1}{Z} e^{\beta_k \cdot X_i} = \frac{1}{Z} \sum_{k=1}^{N} e^{\beta_k \cdot X_i} = 1$$

Here we assumed softmax activation function. Solving for Z (normalization constant) gives

$$\sum_{k=1}^{N} e^{\beta_k \cdot X_i} = Z$$

Therefore, the prediction confidence for different classes are given as

$$Pr(Y_i = 1) = \frac{e^{\beta_1 \cdot X_i}}{\sum_{k=1}^{N} e^{\beta_k \cdot X_i}}, \quad Pr(Y_i = 2) = \frac{e^{\beta_2 \cdot X_i}}{\sum_{k=1}^{N} e^{\beta_k \cdot X_i}}$$

$$\dots\dots\dots\dots\dots\dots\dots\dots$$

$$Pr(Y_i = N) = \frac{e^{\beta_N \cdot X_i}}{\sum_{k=1}^{N} e^{\beta_k \cdot X_i}}$$

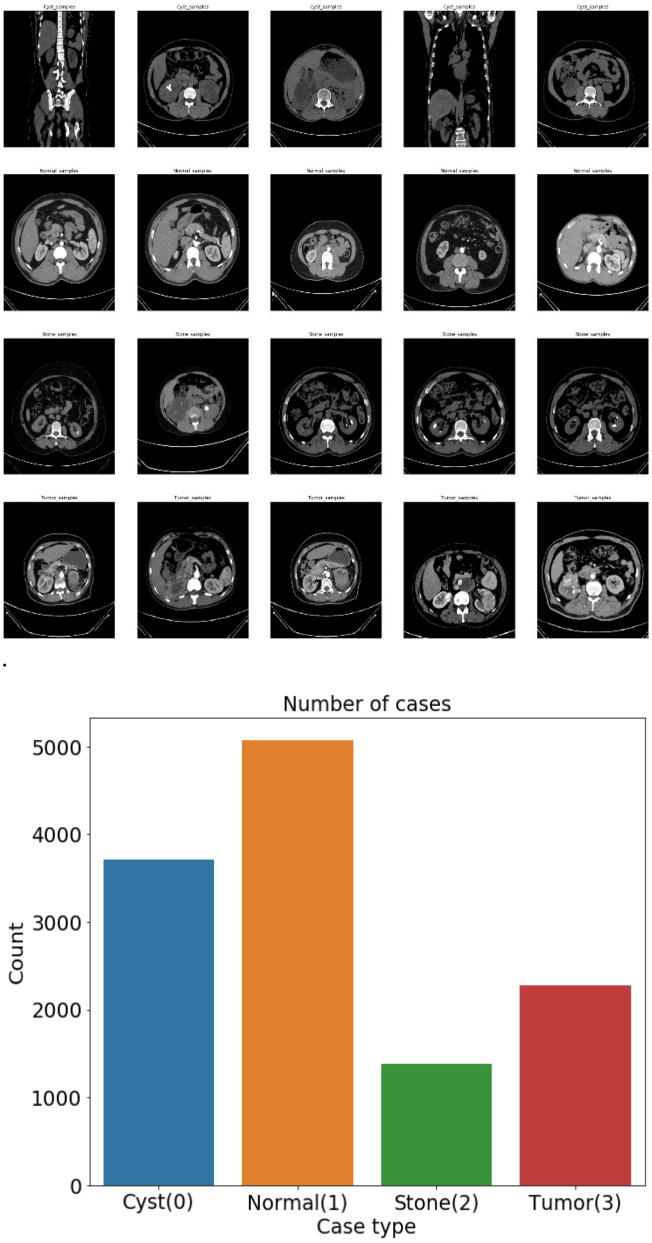

Figure 4 : (top) Samples of Kidney images. The first row shwos kidney images with Cyst. Second row are the scans of nomal kidneys. The third row contains the scans of kidneys with stone. The last row shows the scans of kidneys with tumors. (bottom) Histogram plot showing the number of samples in different data types in full training dataset.

The maximum probability is the predicted class for the unseen new data point. In this algorithm we determine the probabilities of predicted class from different agents and consider the prediction of the most ‘confident’ agent.

VI. Simulation Framework for Mutual Learning Demonstration in CNN

A. *Training Data*

The dataset is a collection of 12,446 unique data within it in which the cyst contains 3,709, normal 5,077, stone 1,377, and tumor 2,283 [38]. The size of each image is 865x700 pixels (figure 4-top). The training dataset contains 10,000 images and the testing dataset contains 2,446 images. The images roes through one hot encoding and the pixel values are normalized. The dataset is not well distributed especially if you consider the individual data points for different kidney diseases. Nevertheless, in our real world, we rarely have well distributed dataset rather it is expected that the we will see skewed data distribution. We intentionally kept the raw dataset in the same way so that we can demonstrate that our proposed mutual learning algorithm is not strongly affected by the skewness of the data.

The training dataset is equally divided into 4 smaller datasets – each containing 2,500 training points. The CNN is trained separately with the full training dataset and small training datasets and accuracy is tested against the testing dataset.

B. *CNN Model*

The CNN model consists of two parts - the data preprocessing part and the artificial neural network. The CNN preprocessing steps contains several layers. First, there is a 2D convolution layers both with 28 output filter with 3x3 kernel and ReLU activation function. The output of the convolution layer goes through a 2x2 maxpool layer. The input images again goes though a convolution layers both with 64 output filter with 3x3 kernel and ReLU activation function. The output from the convolution layer goes through a 2x2 maxpool layer, another convolution layers both with 64 output filter with 3x3 kernel and ReLU activation function. Then finally there is a flatten layer to convert the 2D data to 1D array.

The second layer in CNN is a fully connected artificial neural network (ANN). The ANN basically consist of four layers -three hidden dense layers and the output layer. The first hidden dense layer contains 640 neurons. Output from the first hidden layer goes through a dropout layer to avoid overfitting. Second hidden dense layer consists of 264 neurons, third hidden dense layer consists of 64 neurons and the output layer consists of 4 neurons. Each output neuron indicates a probability of kidney with cyst, normal kidney, kidney with stone and kidney with tumor respectively. The output neuron indicating highest probability is the final result.

C. *SVM Model*

In this work we used two types of SVM network – SVM with linear kernel and non-linear (sigmoid) kernel. The hyperparameters are optimized for both linear and non-linear SVM to achieve good accuracy with full training dataset.

VII. Results and Discussion

First, the CNN network is trained with the complete training dataset and tested for efficiency using the testing dataset. Next, the CNN network is trained with each of the smaller training datasets, and efficiency is tested against the testing dataset each time. Two CNN networks are then trained simultaneously using different small and randomly chosen training datasets, followed by interaction between the networks for data exchange and mutual training. The efficiency of both CNN networks is then tested using the testing dataset. The experiment is further repeated with four teacher-student networks.

A. *CNN Network Testing Efficiency with Full Training Dataset and One-fourth Training Dataset*

The CNN is first trained with the full training dataset first and the accuracy is tested against the testing dataset. Training with the full dataset is a time and memory hungry procedure. The whole process took almost 35 minutes in a machine with 1.6 GHz dual-core processor and 8GB 2,133 MHz RAM. The

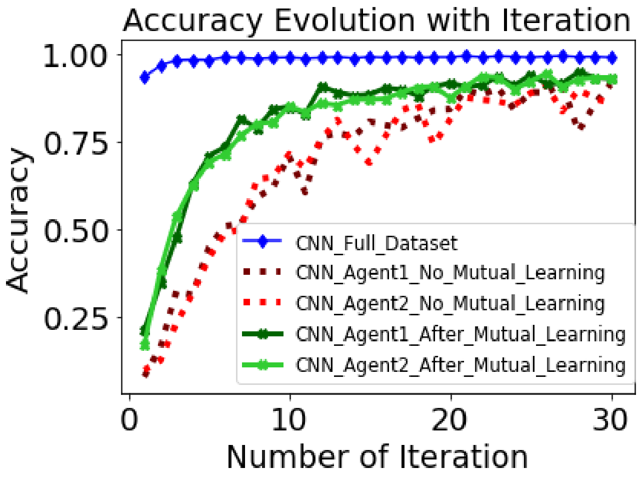

Fig. 5. CNN network accuracy plot with iteration for mutual learning. The top blue plot indicates the accuracy when the CNN is trained with the full training dataset. The light green and dark green plots indicates the CNN network accuracy with iteration after mututal learning. The light red and dark red lines are the accuracy plots before mutual learning.

maximum accuracy is 99.54%. The accuracy plot with iteration for full training dataset is shown in fig. 5 (top blue curve). The CNN is then trained with the each of the small datasets and accuracy is tested every time. In fig. 5 accuracy plots are shown for two of the small training sets. The maximum accuracy for all the training sets is found to be 84.1%.

B. Mutual Learning with Two Teacher-Student Networks Using Algorithm I

Two CNN networks are trained with two randomly selected small training sets (dataset 1 and dataset 2) first. The two networks then share their knowledge with each other and get trained further. For that, the labels are removed from another small training dataset (dataset 3).

Each datapoint (kidney scnas) are compared with the data points of dataset 1 and dataset 2 that are used to train the two CNNs. The comparison is done by comparing each corresponding pixels of the image and calculating the root mean square value of the difference. The closest data point from the two training datasets is assumed to contain the right label, The rest of the data points in dataset 3 are relabeled in this way and the two CNNs are trained accordingly.

Fig. 5 shows the accuracy plots before and after the mutual learning. The accuracy clearly got better after applying the mutual learning algorithm. The maximum accuracy before mutual learning was 84.1% while the maximum accuracy increased to 90.45% after mutual learning. In this way, mutual learning can help when system cannot be trained with big single dataset or there is scarcity of single big training dataset. Here both the network accuracy increases simultaneously which adds to the benefit of dynamic teacher-student network instead of static teacher-student network.

C. Mutual Learning with Two Teacher-Student Networks Using Algorithm II

Two CNN networks are trained with two different, randomly selected small one-fourth training sets again (dataset 1 and dataset 2). The two networks then share their knowledge with each other using the second mutual learning algorithm and get trained further. For that, the labels are removed from the another small training dataset (dataset 3).

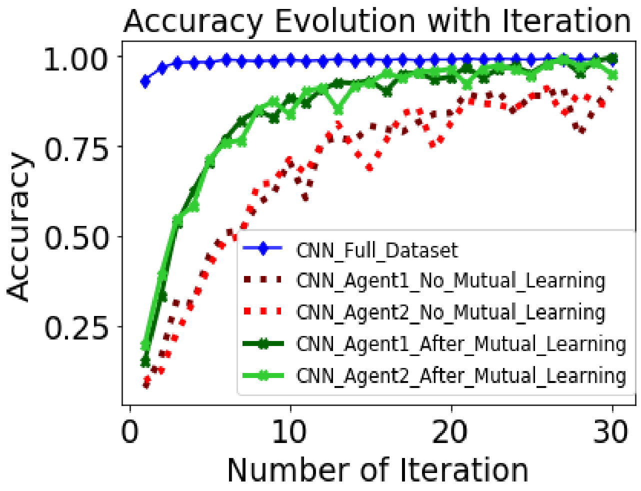

Fig. 6. CNN network accuracy plot with iteration for mutual learning. The top blue plot indicates the accuracy when the CNN is trained with the full training dataset. The light green and dark green plots indicates the CNN network accuracy with iteration after mututal learning. The light red and dark red lines are the accuracy plots before mutual learning.

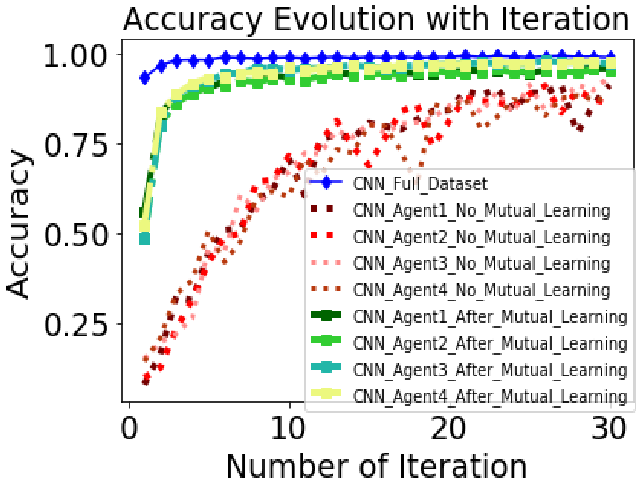

Fig 7. Accuracy plot with iteration for four CNN agents with mutual learning and without mutual learning

The new training data point labels are predicted using both the CNN agents along with their prediction confidence. Each data point in the dataset 3 set is relabeled according to more confident agent and both the agents are retrained after the labeling is finished. Fig. 6 shows the accuracy plots before and after the mutual learning. The accuracy clearly got better after applying the mutual learning algorithm. The maximum accuracy before mutual learning was 84.1% while the maximum accuracy increased to 93.6% after mutual learning. The accuracy is improvement is better than first algorithm. This is because the proximity calculation between figures can be more prone to error. Since, the accuracy of agents are already quite high, the confidence based relabeling is more accurate. But if the pre-mutual learning accuracy is low for the agents then algorithm I should work better than algorithm II. The most appropriate algorithm therefore depends on the pre-mutual learning accuracies of the agents and input types.

D. Mutual Learning with Four Teacher-Student Networks Using Algorithm I

Model distillation can be more efficient and the accuracy can be further improved if more agents share information

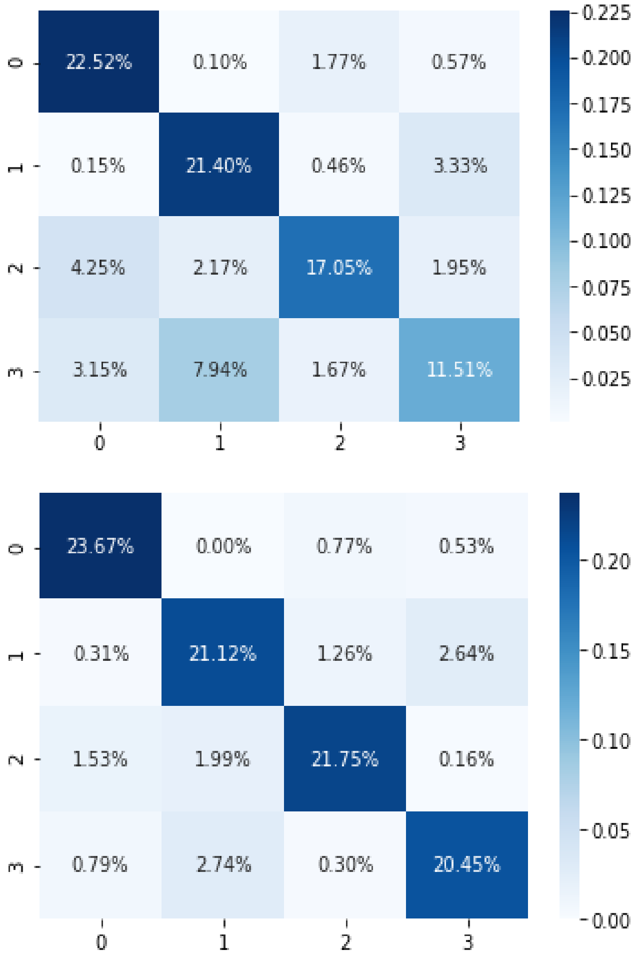

Fig. 8. Heatmap of confusion matrix for linear and non-linear SVN trained with full training dataset.

among themselves. To demonstrate the fact, we repeated the mutual learning algorithm with four networks. All the networks dynamically play the role of teacher and student. When one network plays the role of teacher, the three other networks play the role of student. Since four networks can share a lot more information with each other compared with two networks, all the networks become more well-trained and hence, the efficiency of all the networks increases simultaneously.

Fig. 7 shows the accuracy plots before and after machine learning for ten agents. The maximum accuracy achieved in this case is 94.78% compared to 90.45% for two network mutual learning. The green curve set represents the mutual learning with ten teacher-student networks in fig. 7.

E. SVM Network Testing Efficiency with Full Training Dataset and One-fourth Training Dataset

The SVM with linear and non-linear kernel is first trained with the full training dataset first and the accuracy is tested against the testing dataset. Training with the full dataset is a time and memory hungry procedure. The whole process took couple of hours in a machine with 1.6 GHz dual-core processor and 8GB 2,133 MHz RAM. The maximum accuracy for SVM with linear kernel is 76.59% while maximum accuracy for SVM with non-linear kernel is 85.9% after 30 iteration. The heatmap of the confusion matrix for linear and non-linear SVM is shown in fig 8.

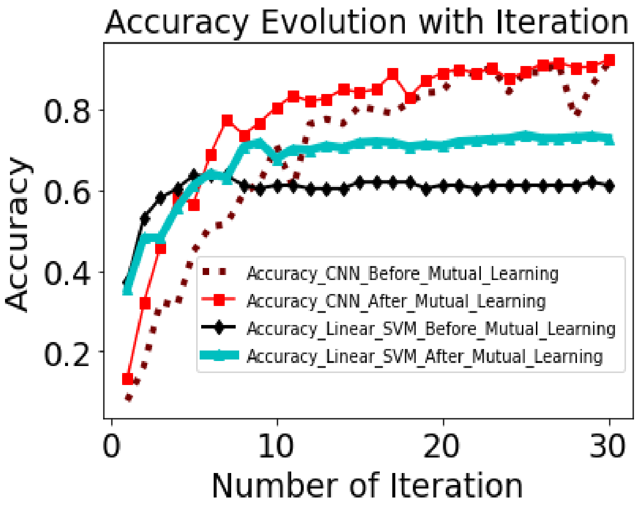

Fig. 9. Linear SVM anc CNN network accuracy plot with iteration for mutual learning. The brown and black plots indicates the CNN and linear SVM network accuracy cosecutively with iteration before mututal learning. The red and pastle lines are the accuracy plots after mutual learning for CNN and linear SVM network cosecutively.

Both SVM agents are then trained with small dataset and accuracy is tested every time. The maximum accuracy for linear SVM with small training set is 59.63%. while the accuracy is 44.1% for non-linear SVM.

F. Mutual Learning with Two SVM Networks Using Algorithm I

Homogeneous mutual learning is applied between two linear SVMs in the same ways as it was applied between two CNN agents. The linear SVM accuracy went up to 61.97% after mutual learning. Similarly, the accuracy went up to 55.74% after mutual learning between two non-linear SVMs.

G. Heterogeneous Mutual Learning with CNN and SVM Networks Using Algoritm II

Model distillation between homogeneous agents has been shown in literature. We have shown here that mutual learning is possible between heterogenous agents and the result is exciting. In figure 9, we have shown the accuracy plots before and after the mutual learning for linear SVM and CNN. The accuracy clearly got better after applying the mutual learning algorithm II. The maximum accuracy for linear SVM before mutual learning was 59.63% while the maximum accuracy increased to 74.04% after mutual learning. The maximum accuracy for CNN before mutual learning was 84.1% while the maximum accuracy increased to 85.76% after mutual learning. In this way, mutual learning can help both the agents get better accuracy.

One worth mentioning point is that we chose simple CNN and SVM algorithm because the basic purpose of the paper is not to show impressive accuracy of kidney disease diagnostic with machine learning. Rather our intention is to show that our proposed mutual learning algorithm works with different machine learning and neural network algorithm. Also most often we see that a particular algorithm is showing excellent accuracy for a particular dataset but might show poor accuracy for other dataset. A comprehensive way to avoid this fundamental issue is to keep training the algorithm with new datasets over the time. The mutual learning enables the machine learning algorithm to keep learning over time.

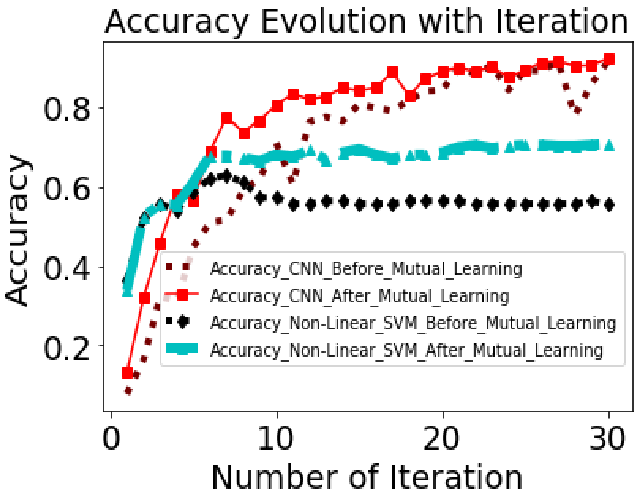

Fig. 10. Non-linear SVM anc CNN network accuracy plot with iteration for mutual learning. The brown and black plots indicates the CNN and non-linear SVM network accuracy cosecutively with iteration before mututal learning. The red and pastle lines are the accuracy plots after mutual learning for CNN and non-linear SVM network cosecutively.

In figure 10, we have shown the accuracy plots before and after the mutual learning for non-linear SVM and CNN. The accuracy clearly got better after applying the mutual learning algorithm. The maximum accuracy for non-linear SVM before mutual learning was 44.1% while the maximum accuracy increased to 72.21% after mutual learning. The maximum accuracy for CNN before mutual learning was 84.1% while the maximum accuracy increased to 84.79% after mutual learning.

An important observation is that the accuracy of SVM linear agent increased by 14.41% while accuracy of CNN only increased by 1.66%. Similarly, the accuracy of SVM linear agent increased by 28.11% while accuracy of CNN only increased by 0.69%. This is because CNN has already a much higher accuracy that SVM. Therefore, when they are engaged in mutual learning and trying to teach each other, the SVM learns a lot from CNN. But since the SVM accuracy was not high before mutual learning, it is not able to teach the CNN much and hence the CNN is less benefited from the mutual learning. Furthermore, the accuracy of CNN increases less in figure 9 vs in figure 10 because the non-linear SVM agent used in figure 10 has lower accuracy than the linear SVM agent used in figure 9. The machines here replicate our real life experience quite nicely.

H. Accuracy and Timing Comparison

The timing and accuracy comparison is shown below in table I. Clearly mutual learning gives a great advantage rather than training with big dataset because it significantly reduces the time and computational resource. It can give the flexibility to train multiple networks in parallel.

TABLE I. ACCURACY AND TIMING COMPARISON FOR CNN

	Single big training dataset	*Two small one-fourth Dataset*	*Mutual learning two agents Algorithm I*	*Mutual learning two agents Algorithm II*	*Mutual learning with four agents*
Maximum Accuracy	99.54%	84.1%	90.45%	93.6%	94.78%
Execution Time	~35 minute s	~6 minutes	~ 17 minutes	~ 15 minutes	~ 30 minutes

TABLE II. ACCURACY AND TIMING COMPARISON FOR SVM

	Single big training dataset	*Two randomly selected small one-fourth Dataset*	*Mutual learning with two SVM agents*	*Mutual learning with CNN and SVM agents*
Linear SVM Maximum Accuracy	76.59%	59.63%	61.97%	74.04%
Non-linear SVM Maximum Accuracy	85.9%	44.1%	55.74%	72.21%
Execution Time	~8 minutes	~2.5 minutes	~ 6 minutes	~ 6.5 minutes

VIII. CONCLUSION

This paper explores mutual learning in pattern classification, where two agents, P and Q, have separate sets of learning samples (patterns A and B) that require classification. The primary objective is to ensure that both agents classify all learning samples correctly, and the exchange of all samples is one possible solution. However, the paper seeks more efficient ways to determine misclassified samples between the two agents.

The paper concludes that detailed discussion between the two agents is necessary for successful classification, particularly regarding samples near the discriminant surfaces of the classifiers. When one agent misclassifies a learning sample of the other, the latter must continue its learning process until it correctly classifies the sample. Both agents then store different learning samples to accelerate the mutual learning process.

Furthermore, the paper presents a detailed description of a classification problem with simulation results that demonstrate the proposed mutual learning algorithm significantly enhances the participating agents' performance compared to isolated learning without mutual learning.

To summarize, the mutual learning algorithm has several benefits for machine learning systems. It not only improves the accuracy of all the networks involved, but it also enhances the speed of learning. This feature makes it a suitable option for practical systems with memory and computation resource constraints. Moreover, it enables many small networks to operate simultaneously, making it compatible with GPU-based systems. By increasing the number of networks, the accuracy of the system can be enhanced, providing the flexibility to adjust the system size as per the need. In short, the mutual learning algorithm can make machine learning faster, more flexible, and require fewer memory and computing resources.

Abstract—**Software technology has exponentially evolved leading to the development of intelligent applications using artificial intelligence models and techniques. Such development impacts all scientific and social fields: home automation, medicine, communication, etc. To make those new applications useful to a larger number of people, researchers are working on how to integrate artificial intelligence into real world while respecting the notion of calm technology. This paper fits in the context of the development of intelligent systems termed "wise systems" that aim at satisfying the calm technology requirement. Those systems are based on the concept of "Wise Object": a software entity – object, service, component, application, etc. – able to learn by itself how it is expected to behave and how it is used by a human or another software entity. During its learning process, a Wise Object constructs a graph that represents its behavior and the way it is used. A major weakness of Wise Objects is that the numerical information that they generate is mostly meaningless to humans. Therefore the objective of the work presented in this paper is to extend Wise Objects with semantic that enable them communicate with humans whose attention will consequently be less involved. In this paper, we address the issue of how to relate two different views using two state-based formalisms: State Transition Graph for views generated by the Wise Objects and Input Output Symbolic Transition System for conceptual views. Our proposal extends previous work done to extend the generated information with the conceptual knowledge using a matching algorithm founded on graph morphism. The first version of the algorithm has several limitations and constraints on the graphs that make it difficult to use in realistic cases. In this paper, we propose to generalize the algorithm and raise those restrictions. To illustrate the complete process, the construction of a sample graph matching on a home-automation system is considered.**

I. Introduction

To ENABLE usability and accessibility of intelligent systems to a large number of people, researchers are working on how to integrate artificial intelligence (AI) into real world while respecting the notion of calm technology. Calm technology represented by Mark Weiser and John Seely Brown [1] in 1995, intends to lightly involve humans within the work process by requiring the smallest possible amount of their attention [2], minimizing therefore system intrusion into their life. Furthermore as software systems usage varies depending on users and time, they should be able to autonomously adapt to evolving such usages. To meet those requirements, we realised a software framework to develop intelligent systems termed "Wise Systems" (WS), based on the concept of "Wise Object" (WO) [3].

A WO is a software entity – object, service, component, application – able to learn by itself how it is expected to behave and how it is used by a human or another software entity. This is enabled by introspection and reflection mechanisms (more details in [4]). WOs compose a WS that may be considered as a multi-agent system [5] [6] where a WO is a self-learning agent that autonomously monitors its internal changes and that does not know the other WOs in the system. Thus, a WO informs the WS about its state changes, so that other WOs react accordingly.

Based on the behaviour of the WS and the internal monitoring of each WO, the collected monitoring data can feed a learning process able to determine usual and unusual behaviors (for instance). As the development of WSs is non-trivial, we developed an object based framework, known as the Wise Object Framework (WOF [4]) to help developers design, deploy and evolve WSs. Generally, knowledge in AI-enabled systems can be provided according to two approaches: (*i*) describing a priori the arrangement of activities to be performed by the system, or, (*ii*) letting the system acquire by its own the required knowledge using different learning mechanisms:

- *In the former approach*, ontologies or scenarios are usually used to describe the arrangement of activities to achieve a goal as in [7] and [8]. In [7], functional behavior as well as inter-operation of system entities are described a priori using state-diagrams. In [8], the authors go a step forward combing ontologies to design ambiant assisted living systems with an unsupervised learning before system deployment to create relevant scenarios. In those approaches, the end user is at the heart of the scenario creation process as described in [9] and [10].
- *In the second approach*, knowledge is provided by the AI-enabled system in representations and views not necessarily understandable by humansand to the distance

between the business domain and technological domain views [11].

According to the calm technology [12], the WO embedded AI fits in the second approach. By self-monitoring, a WO acquires raw knowledge (logs) about its behavior. Based on IBM's 4 state loop (MAPE-K) [13] [14] architecture, WOF provides a plugin system to add analyzers that produce new knowledge from existing knowledge (i.e., logs or knowledge produced by the analyzers). Different analyzers already exist like statistical, Markovian, etc. In this paper, we focus on the State Transition Graph (STG) analyzer, it analyzes logs and produces an STG. This graph is useful for a WO to know in which state it stands and to determine the consequences on its state when it performs an action (a method invocation in the object oriented paradigm of WOF). This graph can also be used by the WO to determine the sequence of methods to call to reach a specific state. As previously stated, and because it is built in a completely unsupervised way, this graph does not carry useful semantic, the states only carry numbers, that is a problem to communicate with end-users.

Although initiated in the 18th century with Euler's work on the famous problem of Königsberg bridges [15], graph theory remains a powerful tool for software-intensive system development. Graphs are present at the software design stage, such as Input/Output Labelled Transitions Systems (IOLTS) or Input/Output Symbolic Transitions Systems (IOSTS) which are often used to model the system behavior, especially to build systems based on oracle, controller synthesis [16] [17] or to test a system by executing the various possible behaviors of this system [18], as well as during the data collection phase, to connect data from different sources [19]. As these graphs are conceptual, dedicated to human to human communication, they bring semantic. Since the STG built at runtime by a WO is close to IOLTS, a WO can use knowledge from its design stage, the IOSTS for example, to attach semantic to its STG. These graphs are obtained by combining two research methods (quantitative and qualitative). On the machine side, behavioral data (i.e., logs) is autonomously collected by WOs which dynamically analyse it and build an STG. On the human side, a developer/expert expresses the expected behavior of a system in a conceptual model using a human vocabulary. A qualitative behavioral view is provided using an IOSTS.

Our proposal in this paper is to present a new matching algorithm between both types of graphs. As the problem was simplified in our previous work [20], it has many limitations, the strongest being the number of equivalent attributes/variables in STG/IOSTS, another limitation is the constraint on the existence of only one matching between an STG and an IOSTS. This new algorithm will extend more further the generated knowledge with conceptual knowledge, based on the graph morphism [21] [22]. Thus, many variables from both knowledge will be taken into account this time, resulting in many different matching. This provides the ability to make WSs' generated knowledge understandable by human and to enable human evaluation of WSs' outputs. Explicitly, the contribution presented in this paper attempts to relate both views: (a) a conceptual view relying on knowledge given by developers to either describe or control the system behavior, and, (b) behavior-related knowledge acquired during WS's learning process, this process is illustrated through a concrete example. Consequently, we are in the process of establishing a machine-human communication (MHC). In this way, we use two state-based formalisms:

- *STG* for representing behavior-related knowledge generated by the WSs,
- *IOSTS* for modelling conceptual views of developers/experts.

This paper is organised as follows: Section II presents the basic idea, describes the architectural overview and gives the definition of important terms. Section III presents STG and IOSTS formalisms, and illustrates them through examples. Finally, Section IV presents our graph matching algorithm, before Section VI concludes the paper.

II. Basic idea & architectural view

The basic idea underlying the WO concept is to give a software entity the core mechanisms for learning behaviors through introspection and analysis. Our aim is to go further by enabling software to execute MAPE-K loops [4]. On the top of this concept, we built the WOF [3] with design decisions mainly guided by reusability and genericity requirements: the framework should be maintainable and used in different application domains with different strategies (e.g., analysis approaches).

Seeking clarity, we borrowed some terms used for humans to refer to abilities a WO possesses. Awareness and wisdom both rely on knowledge. Inspired by [23], we give some definitions of those terms commonly used for humans and present those we chose for WOs.

Knowledge: refers to information, inference rules and information deduced from them, for instance: "Turning on a heater will cause temperature change".

Awareness: represents the ability to collect - ability to provide internal data - on itself by itself. For instance, it is when an entity/object/device collects information and data about capabilities *(what is intended to do)* and its use *(what it is asked to do)*. Capabilities are the services and functionalities the WO may render.

Wisdom: is the ability to analyse collected information and stored knowledge related to their capabilities and usage to output useful information for end users. It is worth noticing that a WO is highly aware, while the converse is false. Wisdom implies awareness, but awareness does not imply wisdom.

Semantic: is the meaning given to something so that it can be understood by humans as mentioned in the Cambridge dictionary. This definition also applies to objects/devices, as semantic is used to communicate with humans.

From the conceptual view, according to the target application, a WO may be considered as:

- a stand-alone software entity (object, component, etc.),
- a software avatar designed to be a proxy for a physical device (e.g., a heater, vacuum cleaner, light bulb),

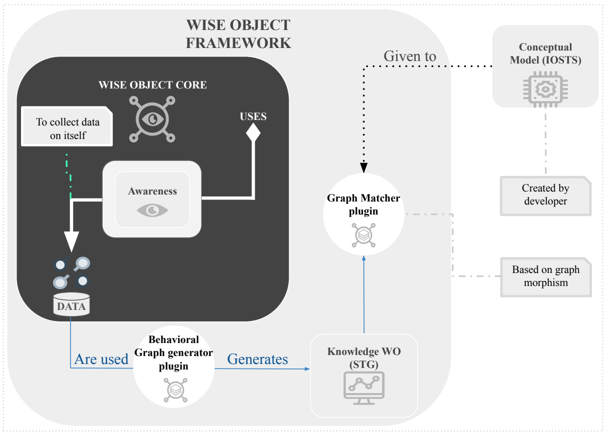

Fig. 1: Generic functional architecture of a WO in the WOF [20].

- a software avatar designed to be a proxy for an existing software entity (object, component, etc.).

A WO is characterised by its:

- autonomy: it is able to operate with no human intervention,
- adaptability: it changes its behavior when its environment evolves,
- ability to communicate (send its state changes and receive requests): with its environment according to a publish-subscribe paradigm.

Fig. 1 illustrates a partial view of a WO's functional architecture defined in the WOF. As depicted, the WO uses awareness to collect data on itself. It analyses those data thanks to the behavioral graph generator plugin (Also termed analyzer) and generates a behavioral graph represented by an STG (Section III-A). On the other hand, when designing an application, developers can provide a conceptual model describing/specifying the way they view the behavior of the system's entities associated to WOs. Such models are represented using IOSTS and contain the semantic given by developers to WOs (Section III-B). The IOSTS formalism is mostly known in simplifying system modelling by allowing symbolic representation of parameters and variable values instead of concrete data values enumeration [24].

The semantic carried by the IOSTS will be used by the graph matcher plugin to extend the STG using the algorithm proposed in this paper.

III. Complex Behavioral Models, Definitions and Illustrations

Modeling the behavior of a system is enabled by tools and languages that result in informal, semi-formal or formal representations: semi-formal notations like UML or more abstract behavior representations based on proven theories [25] like graph theory. In our case, STGs and IOSTSs respectively generated by WOs and provided by developers are used.

A. Definition of an STG

An STG is a directed graph where vertices represent the different states of an object and transitions represent the execution of its methods. Let us consider an object defined by its set of attributes A and its set of methods M. According to this information (A and M) on the object, the STG definition is given in Definition 1.

***Definition** 1:*

An STG is defined by the triplet $G(V, E, L)$ where:

- V is the set of vertices, with $|V| = n$ where each vertex represents a unique state of the object, and conversely, each state of the object is represented by a unique vertex. Therefore $v_i = v_j \Leftrightarrow i = j$ with $v_i, v_j \in V$ and $i, j \in [0, n[$.
- E is the set of directed edges where $\forall e \in E$, e is defined by the triplet $e = (v_i, v_j, m_k)$, such that $v_i, v_j \in V$ and $m_k \in M$. This triplet is called a transition labeled by m_k. The invocation of method m_k from state v_i switches the object to state v_j.
- L is a set of vertex labels where any label $l_i \in L$ is associated to v_i. A label l_i is the set of pairs $(att_j, value_{i,j})$ $\forall att_j \in A$, with $value_{i,j}$ the value of att_j in the state v_i and $Dom(att_j)$ the value domain of att_j, i.e., the set of $value_{i,j}$ for all i. By definition, 2 states v_i and v_j are different $v_i \neq v_j$, $iff \quad \exists att_k \in A$, such that $value_{i,k} \neq value_{j,k}$. Conversely, if $\forall k \in [0, |A|[\quad value_{i,k} = value_{j,k}$, the states v_i and v_j are considered the same, i.e., $v_i = v_j$, thus $i = j$.

The STG must comply with certain constraints:

- The number of attributes is finite:

$$|A| \in \mathbb{N}^*.$$

- The domain $Dom(att_i)$ of each attribute $att_i \in A$ is bounded and discrete:

$$\begin{gathered} \forall att \in A, \min(Dom(att)) \neq -\infty, \\ \max(Dom(att)) \neq \infty, \\ |Dom(att)| \in \mathbb{N}^*. \end{gathered}$$

The matching algorithm we propose in Section IV takes as input an STG with a specific property we name exhaustiveness. Definition of "exhaustive STG" is given in Definition 2

***Definition** 2:* An exhaustive STG is an STG such that from each vertex v_i there exist $|M|$ transitions, each labeled by a method m_k in M:

$$\begin{gathered} \forall v_i \in V, \forall m_k \in M, \\ \exists v_j \in V | (v_i, v_j, m_k) \in E. \end{gathered} \tag{1}$$

It is worth noting that v_i and v_j may be different or same states ($v_i \neq v_j$ or $v_i = v_j$).

According to Definition 2, an exhaustive STG is deterministic, i.e., from any state, on any method invocation, the destination state is known. Moreover, the number of transitions $|E|$ in an exhaustive STG depends on the numbers of vertices $|V|$ and methods $|M|$ such that:

$$|V| \times |M| = |E|. \tag{2}$$

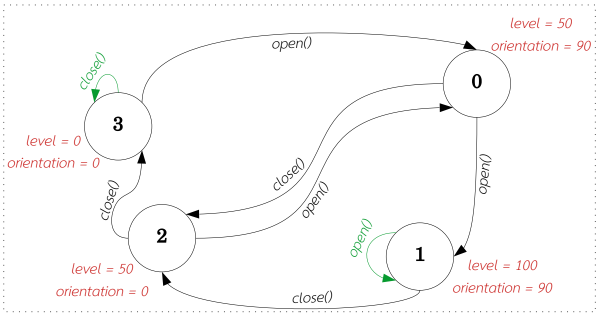

Fig. 2: An exhaustive STG presentation of a roller shutter.

As each vertex represents a state and a unique set of attribute values, an attribute is defined according a discrete and bounded domain and the set of attributes is naturally finite, the number of vertices $|V|$ is bounded:

$$\prod_{i=1}^{|A|} |Dom(att_i)| \geq |V|. \tag{3}$$

The inequality is due to the fact that some attribute value combinations may not be compatible. In other words the number of possible states is $\prod_{i=1}^{|A|} |Dom(att_i)|$, but all are not necessary reachable.

Fig. 2 illustrates an exhaustive STG of the behavior of a simplified roller shutter with adjustable slats. It is defined by the attributes "level" and "orientation" ($A = \{level, orientation\}$) and 2 methods "open" and "close" ($M = \{open(), close()\}$). The methods "open" and "close" respectively increase and decrease the level by 50, the slats orientation is adjusted automatically to have values 0 or 90. This STG was automatically generated and State 0 corresponds to the first discovered state, State 1 the second, etc., consequently, except the methods that give semantic to the transitions, the states have no semantic. According to the domains of the level and orientation, and Property 3, the STG has 4 reachable states, and according to Property 2 the number of edges is 8. Point out that State 0 has nothing to do with the initial values of the roller shutter, they correspond to the first state found during the automatic generation of the STG.

Let us note that a WO, never stores the whole STG due to an evident combinatorial explosion. Only a useful sub-graph is stored and mechanisms for forgetting sub-parts that are no longer useful are implemented. These memory problems are out of the scope of this paper, and we consider here only exhaustive STG to highlight the algorithm.

B. Definition of an IOSTS

An IOSTS is a directed graph whose vertices, called localities represent different states of the system (in our case, the system is a software object) and whose edges are transitions. The localities are connected by transitions triggered by actions. An IOSTS allows the definition of an infinite state transition system in a finite way, unlike an STG. In the literature, IOSTS are used to verify, test and control systems. Verification and testing are formal techniques for validating and comparing two views of a system while control is used to constrain the system behavior [16] [26]. The definition of IOSTS given in Definition 3, is taken from [27] [16] and especially from the use case given in [24].

Definition 3: An IOSTS is a sixfold $\langle D, \Theta, Q, q_0, \Sigma, T\rangle$ such as:

- D is a finite set of typed data consisting of two disjoint sets of: variables X and action parameters P. Let an element $d \in D$, $Dom(d)$ determines the value domain of d.
- Θ an initial condition expressed as a predicate on variables X.
- Q is a non-empty finite set of localities with $q_0 \in Q$ the initial locality. A locality q is a set of states such that statesOf(q) $\subseteq Dom(X)$, with $Dom(X)$ the cartesian product of the domains $Dom(x)$ of each $x \in X$:
$$Dom(X) = \prod_{x \in X} Dom(x). \tag{4}$$
Let us note that a state is defined by a unique tuple of values for the whole variables.
- Σ is the alphabet, a finite, non-empty set of actions. It consists of the disjoint union of the set $\Sigma^?$ of input actions, the set $\Sigma^!$ of output actions, and the set $\Sigma^\mathcal{T}$ of internal actions. For each action a in Σ, its signature $sig(a) = \langle p_1, \dots, p_k\rangle | p_i \in P$ is a tuple of parameters. The signature of internal actions is always an empty tuple.
- T is a finite set of transitions, such that each transition is a tuple $t = \langle q_o, a, G, A, q_d\rangle$ defined by:
  - a locality $q_o \in Q$, called the origin of the transition,
  - an action $a \in \Sigma$, called the action of the transition,
  - a boolean expression G on $X \cup sig(a)$ related to the variables and the parameters of the action, called the transition guard, transition guards allows us to distinguish transitions that have same origin and action but disjoint conditions to their triggering,
  - an assignment of the set of variables, of the form $(x := A^x)_{x \in X}$ such that for each $x \in X$, A^x is an expression on $X \cup sig(a)$, it defines the change of variable values during the transition,
  - a locality q_d, called the transition destination.

According to this definition, each variable has a subdomain in each locality. Thus, let us define the function $dom(q, x)$ that returns the definition domain of the variable $x \in X$ in the locality $q \in Q$, consequently $dom(q, x) \subseteq Dom(x)$. By extension, $dom(q, X)$ is the cartesian product of domains of all x in q:

$$\begin{gathered} dom(q, X) = \textstyle\prod_{x \in X} dom(q, x), \\ dom(q, X) \subseteq Dom(X). \end{gathered} \tag{5}$$

Fig. 3 illustrates the IOSTS given by a developer to control a roller shutter with adjustable slats. This IOSTS expresses that the roller shutter expects an input $up?/down? \in \Sigma^?$ carrying the parameter $step \in]0, 100]$, the relative elevation to increase or decrease the shutter level. In addition, the roller shutter slats can be rotated between 0 and 90 degrees during the elevation.

Let us mention that the roller shutter used in this example adapts automatically its $angle$, while the elevation is between 0 and 100 steps. Thus, end-users only control the elevation (height). The IOSTS contains two localities:

- The locality where the system is closed (i.e., both variables are equal to 0, see Equation 6). In this locality, if the system receives the $up?(step)$ command, the transition will be made from the $Closed$ to $Open$ locality by increasing the value of the $height$ variable by $step$. If the system receives the $down?(step)$ action, it will perform no operation (NOP).
- The locality where the system is open (i.e., one of the variables is different from 0, see Equation 7). In this locality, if the system receives the action $up?(step)$, the transition will be reflexive from $Open$ to itself and will compute the value of the variable $height$ by executing this assignment $height := min(height + step, 100)$, the shutter elevation cannot be increased more than the maximum of elevation. If it receives the $down?(step)$ action and the action closes the shutter less than it is open ($step < height$), $height$ is decreased by $step$, otherwise the transition will be from the locality $Open$ to the locality $Closed$ by assigning 0 to the variable $height$.

As illustrated in Fig. 3, and according to the Definition 3, the IOSTS is composed of:

- $Q = \{Closed, Open\}$, the set of localities.
- $X = \{height, angle\}$, the set of variables.
- $P = \{step\}$, the set of parameters.
- $\Sigma = \{up?, down?\}$, the set of actions where the signatures of the actions are $sig(up?) = sig(down?) = \langle step\rangle$.
- $Dom(height) = [0, 100]$, $Dom(angle) = [0, 90]$ and $Dom(step) =]0, 100]$ are respectively the domains of $height$, $angle$ and $step$.
- According to Equation 4, $Dom(X)$ is:

$$Dom(X) = [0, 100] \times [0, 90].$$

- The states of closed locality, defined by Equation 5, are:

$$\begin{gathered} statesOf(Closed) = \{(0, 0)\}, \\ \{(0, 0)\} \subset Dom(X). \end{gathered} \tag{6}$$

- The states of open locality are defined as follows:

$$\begin{gathered} statesOf(Open) = Dom(X) \backslash statesOf(Closed), \\ Dom(X) \backslash statesOf(Closed) \subset Dom(X). \end{gathered} \tag{7}$$

Thus:

$$statesOf(Closed) \cap statesOf(Open) = \emptyset. \tag{8}$$

As IOSTS is classical reference modeling formalism for model-based testing of reactive systems [28], it provide a convenient abstraction of the behaviors of such systems, which are beneficial and playing an important role in the matching algorithm.

IV. Graph matching algorithm

This section introduces our algorithm that relates the generated STG to developers' semantic expressed in an IOSTS formalism. The generated STG in Fig. 2 is composed of states automatically labelled by the WO: 0, 1, 2 and 3 and the localities of the IOSTS are labelled "Open" and "Closed". As both represent the same roller shutter, the main challenge is how to match states 0, 1, 2 and 3 to the localities of the IOSTS, in other words, which attribute of the STG corresponds to which variable of the IOSTS.

A. Matching constraints

The STG and IOSTS must meet certain criteria to correctly apply the matching algorithm.

1) Considering that we have in the set of attributes A a non empty subset called $A_e \neq \emptyset$ and in the set of variables X a non empty subset called $X_e \neq \emptyset$. Furthermore, let us consider $\mathcal{R}$ the binary relation of A_e in X_e, which is a bijection ($\rightarrowtail\!\!\!\!\twoheadrightarrow$) [29]:
   - each member of A_e must be linked exactly to one element of X_e,
   - each element of X_e must be linked exactly to one member of A_e.

   $$\begin{gathered} \exists! A_e \subseteq A, \exists! X_e \subseteq X | A_e \rightarrowtail\!\!\!\!\twoheadrightarrow X_e \\ \Leftrightarrow \\ (A_e, X_e), \end{gathered} \tag{9}$$

   where (A_e, X_e) means that both A_e and X_e represent the same information. The matching solution is given by $(A_e, X_e, \mathcal{R})$. Therefore, any couple att_e, x_e such that $att_e \mathcal{R} x_e$ will be featured by (att_e, x_e) as they represent the same information, thus:

   $$Dom(att_e) \subseteq Dom(x_e). \tag{10}$$

   Let us note that $Dom(att_e)$ is a subset of $Dom(x_e)$ due to the fact that $Dom(x_e)$ can be defined as a continuous domain and $Dom(att_e)$ is defined as a discrete and bounded set of values. Furthermore, from Equation 10 we deduce the following:
   - In case of $Dom(att_e) \subset \mathbb{R}$:

   $$\begin{gathered} (att_e, x_e) \\ \Leftrightarrow \\ min(Dom(att_e)) \geq min(Dom(x_e)) \\ \wedge \\ max(Dom(att_e)) \leq max(Dom(x_e)). \end{gathered}$$

   - In case of $Dom(att_e) \subset \mathbb{S} \mid \mathbb{S}$ is the set of strings:

   $$\begin{gathered} (att_e, x_e) \\ \Leftrightarrow \\ \forall value_i \in Dom(att_e), value_i \in Dom(x_e). \end{gathered}$$

2) Every locality in the IOSTS must be unique taking into account just the set variables X_e. Thus, the domains of X_e in the different localities in the IOSTS are disjoint:

   $$\begin{gathered} \forall q, q' \in Q \mid q \neq q' \\ \Leftrightarrow \\ dom(q, X_e) \cap dom(q', X_e) = \emptyset. \end{gathered}$$

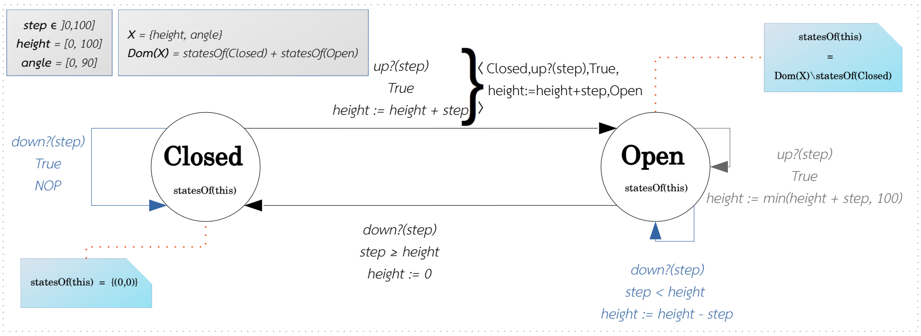

Fig. 3: An IOSTS representation of a roller shutter.

B. Algorithm

The matching algorithm will automatically run through several steps summarized in Fig. 4. The algorithm will receive two types of knowledge representation (STG and IOSTS). It is divided into three parts. The former produces all possible attribute-variable matching pairs P. The result will be used in the second part to build all longest combinations $\mathcal{P}_m$, which will be used to construct the matching between states and localities in the third part.

As validation of the algorithm is NP-complete, reducing the matching cost is planned as future work through the use of ontology and the matrix structure of graphs.

Let us detail the algorithm:

- As a starting point, P is the set that contains all potential equivalent attribute-variable pairs according to their domains:
$$P = \{(att, x) \mid att \in A, x \in X, Dom(att) \subseteq Dom(x)\}.$$
- $\mathcal{P}(P)$ is the power set of P [30], it contains all subsets c of P:
$$\forall c \subseteq P, c \in \mathcal{P}(P),$$
thus, $|\mathcal{P}(P)| = 2^{|P|}$. As A_e and X_e are not empty, the empty set can be removed from $\mathcal{P}(P)$:
$$\mathcal{P}\not\emptyset = \mathcal{P}(P) \backslash \{\emptyset\}.$$
- $\mathcal{P}_v$ is all valid combinations c of pairs attribute-variable in $\mathcal{P}\not\emptyset$. A combination c_i is valid if and only if it represents a bijection between its attributes and variables.
$$\mathcal{P}_v = \{c \mid c \in \mathcal{P}\not\emptyset, \forall (att_i, x_j) \in c,$$
$$(att_i, x_k) \notin c \wedge (att_l, x_j) \notin c\},$$
with $i \neq l$ and $j \neq k$.
- $\mathcal{P}_m$ is all maximized combinations[1] c_i of pairs attribute-variable in $\mathcal{P}_v$:
$$\mathcal{P}_m = \{c \mid c \in \mathcal{P}_v, \forall c_j \in \mathcal{P}_v, c \not\subset c_j\}. \tag{11}$$
$\mathcal{P}_m$ stores the maximized combinations according to the definition domain of attributes and variables.

As for each vertex it exists a unique locality such that for any couple attribute-variable of a combination, the values of the attribute are included in the domain of the locality, we keep from $\mathcal{P}_m$ only the combinations that satisfy such property. Therefore, $\mathcal{P}_{VQ}$ stores the possibles combinations c_i that correspond to a valid matching between vertices V and localities Q.

$$\begin{aligned}\mathcal{P}_{VQ} = \{c \mid c \in \mathcal{P}_m, \exists! v \in V, \exists! q \in Q, \forall (att, x) \in c,\\ dom(v, att) \subseteq dom(q, x)\}.\end{aligned} \tag{12}$$

From $\mathcal{P}_{VQ}$, all the possible matching $\mathcal{M}_{VQ}$ that stores the sets of vertex-locality couples can be deduced:

$$\begin{aligned}\mathcal{M}_{VQ} = \{m_i \mid \forall c_i \in \mathcal{P}_{VQ}, \exists! v \in V, \exists! q \in Q,\\ \forall (att, x) \in c_i, dom(v, att) \subseteq dom(q, x),\\ (v, q) \in m_i\}.\end{aligned} \tag{13}$$

These matching $\mathcal{M}_{VQ}$ are valid regarding the couples attribute att variable x and the couples vertex v locality q. Since the matching algorithm is based on the graph morphism, it needs to respect the structure of the matched graphs [31]. In our context, the images of the vertices of the STG in the IOSTS – the localities – must respect the *adjacency relations (neighboring)* present in the STG (i.e., the transitions). In other words, two adjacent vertices must match the same or two adjacent localities. Consider $\mathcal{S}$ is the surjective application of the STG in the IOSTS respectively between the vertices V and localities Q (see Equation 14), i.e., each vertex matches one locality and a locality is matched by at least one vertex. For any transition $(u, v) \in E$ of STG, then $(\mathcal{S}(u), \mathcal{S}(v)) \in T$ is a transition of the IOSTS. The STG → IOSTS matching is a surjective homomorphism, i.e., an epimorphism [31].

$$\begin{aligned}\mathcal{S} \colon STG &\to IOSTS,\\ V &\twoheadrightarrow Q = \mathcal{S}(V),\end{aligned} \tag{14}$$

implies:

$$\begin{gathered}\mathcal{S}_E \colon E \to T,\\ \mathcal{S}_E((u, v)) = (\mathcal{S}(u), \mathcal{S}(v)),\\ (\mathcal{S}(u), \mathcal{S}(v)) \subset T.\end{gathered} \tag{15}$$

.

According to Equation 15, if state v' is the neighbor of v and the locality q matches with v, v' must match with q or a neighbor of q:

$$\mathcal{M}_{\mathcal{S}} = \{m \mid m \in \mathcal{M}_{VQ}, \forall (v, q) \in m, \forall v' \in neighbors(v), \\ \exists q' \in neighbors(q) \cup \{q\}, (v', q') \in m\}. \tag{16}$$

C. Matching illustration

In the previous example, the STG in Fig. 2 is automatically generated by a WO and the IOSTS in Fig. 3 is provided by a developer. Both represent the same simplified roller shutter behavior. The behavior is simplified to highlight the algorithm, the implementation can deal with complex behaviors. The STG uses discrete values with a level of opening of 50% and a slats orientation of 90%, while the IOSTS use continuous intervals, without any constraint on the step that is a real value.

Fig. 5 and Fig. 6 illustrate all possible matching results of the API developed in the LISTIC laboratory of both (STG and IOSTS) graphs. Localities in the IOSTS are *Closed* and *Open*, each contains variables with disjoint domains (see Equation 8), in our example, both variables *height* and *angle*.

According to the constraints of the matching algorithm given in Section IV-A:

1) there is potential equivalent attributes/variables between the STG and the IOSTS, more precisely between the attributes "level, orientation" and the variables "height, angle". According to Equation 10, the following pairs represent potential attributes/variables equivalences:

$$(level, height), \\ (orientation, angle), \\ (orientation, height),$$

2) the domains of both localities *Closed* and *Open* respect Equation 8. Thus, *Closed* and *Open* are disjoint.

On the STG side, there are four vertices, each one labeled with a set of attribute-value pairs $(att, value)$. In our case, the pair $(level, orientation)$ takes the values $[(50, 90), (100, 90), (50, 0), (0, 0)]$ respectively for

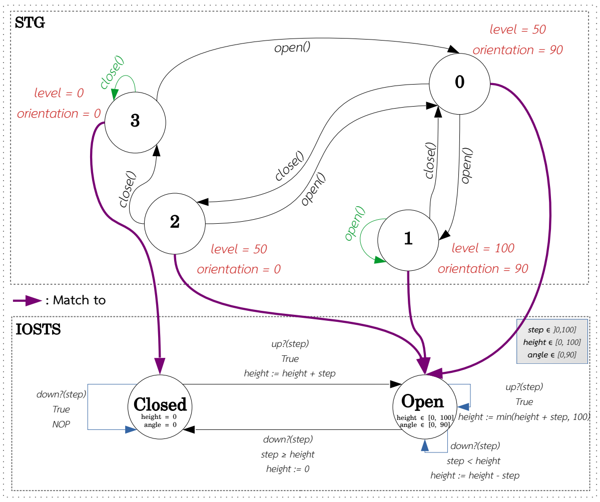

Fig. 5: Algorithm result of the graph matching $\mathcal{P}_m^1 = \{(level, height), (orientation, angle)\} \in \mathcal{P}_{VQ}$.

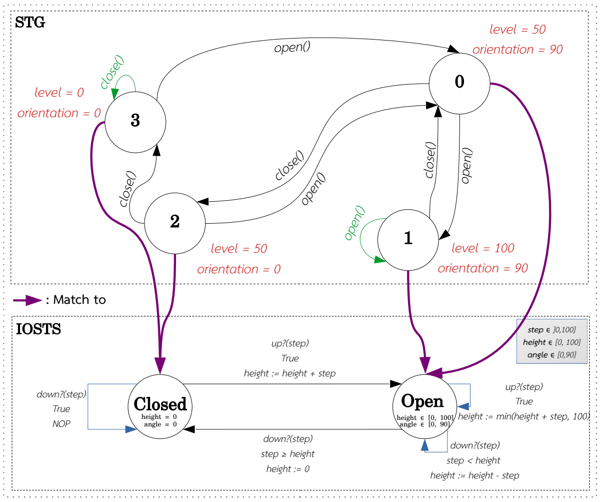

Fig. 6: Algorithm result of the graph matching $\mathcal{P}_m^2 = \{(orientation, height)\} \in \mathcal{P}_{VQ}$.

(v_0, v_1, v_2, v_3). Therefore, to establish a correspondence between the two graphs, for all combinations $\mathcal{P}_m(P)$, the definition domain of the pair $(level, orientation)$ in each vertex of the STG must be compared to the definition domain of the variables pair $(height, angle)$ in each locality of the IOSTS. This comparison gives $\mathcal{P}_{VQ}$, which consequently implies $\mathcal{M}_{\mathcal{S}}$. In detail, the following sets are obtained:

$$P = \{(level, height), (orientation, angle),\\ (orientation, height)\}.$$

The powerset of P:

$$\mathcal{P}\emptyset(P) = \{\{(level, height)\}, \{(orientation, angle)\},\\ \{(orientation, height)\},\\ \{(level, height), (orientation, angle)\},\\ \{(level, height), (orientation, height)\},\\ \{(orientation, angle), (orientation, height)\},\\ \{(level, height), (orientation, angle),\\ (orientation, height)\}\}.$$

Therefore:

$$\mathcal{P}_v = \{\{(level, height)\}, \{(orientation, angle)\},\\ \{(orientation, height)\},\\ \{(level, height), (orientation, angle)\}\}.$$

Thus:

$$\mathcal{P}_m = \{\{(orientation, height)\},\\ \{(level, height), (orientation, angle)\}\}.$$

As $\mathcal{P}_{VQ} \equiv \mathcal{P}_m$ in this illustration, it contains two combinations, which gives two matches

$$\mathcal{M}_{VQ} = \{\\ \{(v_0, Open), (v_1, Open), (v_2, Open), (v_3, Closed)\},\\ \{(v_0, Open), (v_1, Open), (v_2, Closed), (v_3, Closed)\}\\ \}.$$

Since both matching are surjective in this illustration, $\mathcal{M}_{VQ} \equiv \mathcal{M}_{\mathcal{S}}$.

This example provides two possible matches and the algorithm cannot determine, which one corresponds to (A_e, X_e). More information is required to determine the good matching. This information can be provided by the end user or, as we intend to do in future work, determined from the meaning of attributes, variables, methods and actions using an ontology.

V. Related work

For many years, graphs have been used in several fields to represent complex problems in a descriptive way (e.g., maps, relationships between people profiles, public transportation, scene analysis, chemistry, molecular biology, the quest for evolutionary conserved pathways thought protein-protein alignment, etc.). This has been done for various purposes: analysis, operation, knowledge modeling, pattern detection, etc. Although initiated in the 18th century with Euler's work on the problem of Königsberg bridges [15], graph theory remains a powerful tool for software-intensive system development and an effective way to represent objects as in [32]. Since then, several approaches of graph matching have been developed and the first formulation of the graph matching problem was proposed by [33] and dates back to 1979. Afterwards, several formulations appeared like convex-concave programming formulation, maximum common subgraph (MCS), the use of the Frobenius norm that uses the adjacency matrices of corresponding graphs to express the maximization or the minimization of the non-overlapping edges between two graphs, graph matching using dummy vertices that consist of finding a matching with the exception of some vertices in the data graph, which have no correspondence at all. In general, there exist two major formulations of the graph matching problem [34] [35]:

- *Exact Matching* is divided into two categories, (a) graph isomorphism, checks whether two graphs are the same. (b) subgraph isomorphism, checks whether the smallest graph is a subgraph of the biggest one. Both techniques are overly complex and rely on graph/subgraph isomorphism, whether or not they check the one-to-one or many-to-one matching.
- *Inexact Matching* is a term used where it is impossible to find an isomorphism between two graphs, and it comprises many approaches:
  - the maximum common subgraph, used in searching the similarity between the graphs to know how different they are instead of a binary answer [36]
  - least square formulation, used in the case of weighted graphs to search for a match that minimizes the total difference between all aligned edges through the use of the Frobenius norm for instance [36].
  - graph edit distance, used to find in a low cost the sequence of operations (i.e., deletion, insertion and substitution of vertices and edges) that transform one graph into another [37]. As this procedure is a hard combinatorial problem, another alternative called "beam search" is explained in details in [38]

In real applications, we often want to match graphs of different sizes, which results in new techniques and norms as depicted in [34]. Moreover, the problem is more extensive than one might imagine, as graphs are used to represent objects, images, regions in maps, also, many formalisms have emerged so far, such as the correspondence between different representations of knowledge as an STG and an IOSTS, which, to our knowledge, no paper has addressed. Until now, the most well-known operations on graphs is the comparison of two or more graph representations that requires many theoretical and complex concepts [21], like graph matching, which is a more constrained version of the graph isomorphism problem that is at the basis of our proposal. Finally, we mention that graph/sub-graph isomorphism and homomorphism are considered to be the most complex problems in graph matching, they are NP-complete. These problems have been studied in [39] [21] [40]. It is worth to mention that for certain types of graphs under certain constraints, the complexity of the isomorphism has been proven to be of polynomial type with a huge cost [41].

The matching of two knowledge representations (STG - IOSTS) led us to two problems: exact matching and inexact matching. To understand the problems, we need to see the matching from both perspectives: machine (i.e., numerical and structural) and human (i.e., semantic). According to the machine, and since the matching preserves the structure and the transitions between both formalisms, the matching is always exact between "states" and "localities", which gives an epimorphism (Equations 14, 15). However, from the human perspective, in most real-life cases, there will be at most one exact matching according the semantic. As illustrated in the illustrations (Fig. 5 and Fig. 6), only one matching is exact. The exact matching problem is a great challenge, our work focuses on this problem by taking into account, in addition to the numerical perspective, the semantic perspective.

VI. Conclusion and future work

Our research work on software intelligent systems, namely WSs, tackles the issue of bringing closer knowledge generated by AI and human semantic. Indeed a major weakness of WOs composing a WS is that they generate numerical information mostly meaningless to humans. Our proposal is to extend knowledge issued by WOs (expressed in STGs) at runtime with knowledge (expressed in IOSTs) provided by developers at design time. Such extension is based on graph matching.

We have proposed in this paper an algorithm to face the problem of matching an STG and an IOSTS. The goal of this work is to extend WOs with the behavior semantic defined at software design time. From the end user's perspective, the algorithm provides the system with the ability to communicate with him using human semantic. From the developer's perspective, the resulted matching may help him discover errors or inconsistencies between the conceptual view and the system implementation. The results of the algorithm provide a set of valid matching according to the numerical and structural information stored in both behavioral graphs.

As illustrated in the paper, the algorithm provides a set of valid matching, however, it cannot determine the valid one from the end user perspective. Besides, the algorithm has neither an idea of the meaning of variables that represent the same information at different scales, nor of variable names. Thus, one of our future work will address this problem: How to take semantic into account in the matching problem? From the end user perspective, this problem is a semantic one, the natural solution is therefore to rely on ontologies. Approaches we are currently considering consist in semantic graph matching based on an ontology merged with the results presented in this paper.

In this respect, we have initiated a France-Canada innovation project with the University of Sherbrooke to investigate matching algorithms based on other semantic formalisms than IOSTSs, such as ontologies and scenario-based [8] [7]. The main idea is to bind the algorithm matching results with an ontology to provide a human level communication with users according to the context of the application. Moreover, this collaboration brings us the medical context as a new application domain, namely ambient assistance systems for elderly people.

***Abstract*—A polynomial-size mixed integer linear programming model for the Precedence-Constrained Minimum-Cost Arborescence Problem with Waiting-Times was recently proposed in the literature, that uses a smaller number of variables and constraints compared to previously proposed polynomial-size models. In this work, we extend this model with constraint programming constructs to further enhance its performance. An extensive computational study support that modern constraint programming solvers are the best tool available at solving the models proposed. Several improvements to state-of-the-art results are finally reported.**

***Index Terms*—Combinatorial Optimization; Arborescences; Precedence-Constraints.**

I. Introduction

THE *Minimum-Cost Arborescence* (MCA) problem involves finding a directed minimum-cost spanning tree, rooted at vertex r, in a given input directed graph. Jack Edmonds [1], and Yoeng-Jin Chu and Tseng-Hong Liu [2] independently introduced the first polynomial time algorithm for solving the problem. Gabow and Tarjan [3] improved the running time of the algorithm by using *disjoint-sets* and a special implementation of *Fibonacci heaps*.

Several variations of the MCA problem with different objective function and/or constraints were introduced in the literature since its introduction. Given a finite resource associated with each vertex in the input graph, the *Resource-Constrained Minimum-Weight Arborescence problem* [4] is an $\mathcal{NP}$-hard problem which asks to find an arborescence with minimum total cost where the sum of the costs of outgoing arcs from each vertex is at most equal to the resource of that vertex. Given an integer Q and non-negative integer vertex demand q_j associated with each vertex, the *Capacitated Minimum Spanning Tree problem* [5] is an $\mathcal{NP}$-hard problem which asks to find a directed minimum spanning tree rooted at r, such that the sum of the weights of the vertices in any subtree off the root is at most Q. Given a weighted directed acyclic graph with each vertex having a specified color from a set of colors, the *Maximum Colorful Arborescence problem* [6] is an $\mathcal{NP}$-hard problem which asks to find an arborescence of maximum weight, in which no color appears more than once. Given an integer rank associated with each vertex, the *Restricted Fathers Tree problem* [7] asks to find a minimum-cost arborescence rooted at r, such that the path between each vertex and the root contains only vertices with same rank or higher.

Constraint programming (CP) is paradigm for solving combinatorial problems by representing them as *constraint satisfaction problems* (CSP) [8]. A CSP is represented as a set of variables each with a defined domain of values, and a set of relations/constraints on the subsets of these variables. A CP solver takes a CSP and finds an assignment to all the variables that satisfies the constraints, and can also extend the problem to finding optimal solutions according to an optimization criteria. A CP solver searches the solution space systematically using a branch-and-bound algorithm with inference techniques which consists of propagating the information contained in one constraint to the neighboring constraints. Such techniques reduce the size of the solution space that needs to be explored [9]. CP has been used to solve a wide range of problems in the literature. Hande [10] proposed a CP model for the *Open Vehicle Routing problem with Heterogeneous Vehicle Fleet* (HFOVRP). In [10] the CP model is compared with a mixed-integer linear programming (MILP) model of the HFOVRP, and they showed that the CP model is effective for providing good-quality solutions for small-sized instances of the HFOVRP in short computational times compared to the MILP model. Kasapidis et al. [11] presented a MILP model and a CP model for the *Multi-Resource Flexible Job-Shop Scheduling problem with Arbitrary Precedence Graphs*. The computational experiments conducted in [11] has shown that the CP model is more effective and achieves the best

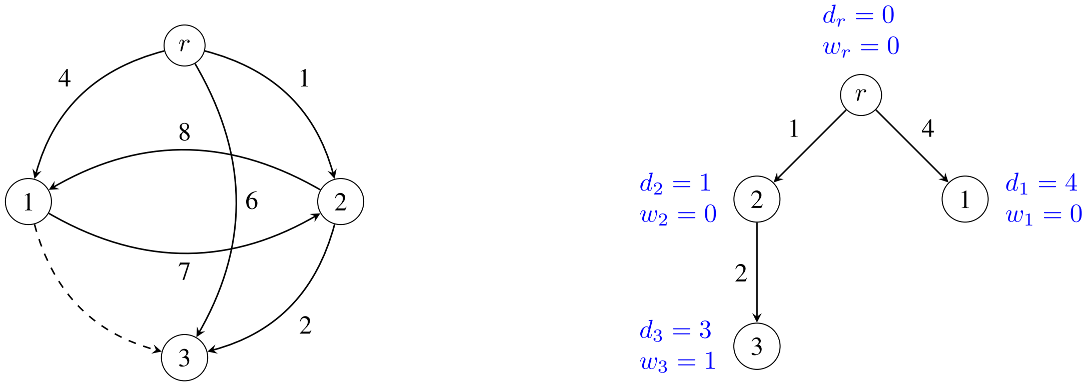

Fig. 1: Example of an instance solved as a PCMCA-WT. The graph on left shows the instance with its respective arc costs, and the precedence relationship $(1, 3) \in R$ marked as a dashed arrow. The graph on the right shows an optimal PCMCA-WT solution of cost 8.

results compared to the MILP model, although more time-consuming on some instances. Kirac et al. [12] proposed a CP approach for solving the *Team Orienteering problem with Time Windows and Mandatory Visits*, and they showed that the CP-based approach finds 99 of the best-known solutions and explores 64 new best-known solutions for the benchmark instances. Kizilay et al. [13] proposed a novel CP model for the *Mixed-Blocking Permutation Flow Shop Scheduling problem with Batch Delivery* that minimizes the total tardiness and batch cost. The results of their study has shown that due to the complexity of the problem, the developed CP model can solve only small-sized instances in reasonable computational time. Montemanni and Dell'Amico [14] proposed a CP model for the *Parallel Drone Scheduling Traveling Salesman problem*, and showed that by exploiting multi-threading computation, the method was able to optimally solve all the instances considered in the literature.

The *Precedence-Constrained Minimum-Cost Arborescence* (PCMCA) problem is an $\mathcal{NP}$-hard problem [15] that was first introduced by Dell'Amico et al. [16]. The PCMCA problem is an extension to the MCA problem, in which precedence constraints must be satisfied as follows. Given a set R of ordered pairs of vertices, then for each precedence relationship $(s, t) \in R$, a path in the solution which covers both s and t, must visit vertex s before visiting vertex t. The objective is to find an arborescence of minimum total cost satisfying the precedence constraints. The PCMCA problem has applications in the design of commodity distribution networks where certain paths are not allowed in the network due to logistical constraints [16]. Several MILP models of the problem were proposed in [15], [16], [17].

The *Precedence-Constrained Minimum-Cost Arborescence Problem with Waiting-Times* (PCMCA-WT) is an $\mathcal{NP}$-hard problem that was recently introduced by Chou et al. [15]. The PCMCA-WT is a variation on the PCMCA problem characterized by the following differences. Given arc costs indicating the time required to traverse an arc, suppose there is a flow which starts at the root vertex r, that must reach every vertex in an arborescence T. For each precedence relationship $(s, t) \in R$, the flow must enter vertex s at the same time step, or before entering vertex t, which means that the flow can stop at any vertex and wait. The waiting time at vertex t is defined as the difference between the time at which the flow enters s and the time at which the flow reaches t. The objective of the problem is to find an arborescence T of minimum total cost, plus total waiting times, where the flow never enters s after entering t for all $(s, t) \in R$. Several MILP models for solving the problem were proposed in [15].

The PCMCA-WT problem can be formally defined as follows. Given a directed graph $G = (V, A, R, r)$, where $V = \{1, \dots, n\}$ is the set of vertices, $A \subseteq V \times V$ is the set of arcs, $R \subset V \times V$ is the set of precedence relationships, and $r \in V$ is the root of the arborescence. Let c_{ij} be a cost associated with each arc $(i, j) \in A$ which represents the time required for the flow to travel from vertex i to vertex j. Let d_j be the time step at which the flow enters vertex $j \in V$, and let w_j be the waiting time at vertex $j \in V$. The objective of the problem is to find an arborescence T rooted at vertex r, that has a minimum total cost plus total waiting time, where the flow never enters t before entering s for all $(s, t) \in R$ (i.e. $d_t \geq d_s$ for all $(s, t) \in R$).

Figure 1 presents an example of an instance solved as a PCMCA-WT. The instance graph (left graph) shows the precedence relationship $(1, 3) \in R$ marked as a dashed arrow, while the solution graph (right graph) shows an optimal solution of that instance, with the corresponding d_i and w_i value written next to each vertex. The graph on the right shows an optimal PCMCA-WT solution of cost 8 (sum of all the arcs cost plus total waiting time at each vertex), with a resulting waiting time of value 1 at vertex 3, since $d_1 = 4$, while $d_3 = 3$ and $(1, 3) \in R$.

The rest of this paper is organized as follows. Section II introduces the MILP model used in this study. Section III introduces a CP model that extends the MILP model introduced in Section II by introducing redundant constraints for a subset of the original inequalities and describing them in terms of

CP constructs, in order to further exploit the capabilities of the CP solver. Section IV summarizes computational results, while some conclusions are outlined in Section V.

II. A Mixed Integer Linear Programming Model

A polynomial-size MILP model for the PCMCA-WT was recently proposed by Dell'Amico et al. [18]. The model extends a classical formulation for the MCA problem [19], through the addition of precedence-enforcing constraints. The precedence-enforcing constraints detect a precedence violating path by propagating a value along all the paths of the solution starting from t for all $(s,t) \in R$ [16], [17].

A different version of the model that contains a smaller number of variables and constraints was also proposed in [18]. The reduction is achieved by exploiting the special property of the PCMCA-WT, that is for any precedence relationship $(s,t) \in R$, the flow must enter vertex t at the same time step or after entering vertex s. This implies that it is possible to remove a precedence relationship $(s,t) \in R$ when the input graph does not contain a zero-cost path that starts from t and ends in s. The reduced model for the PCMCA-WT proposed in [18] is summarized as follows. For further details the reader can refer to [18].

Let x_{ij} be a variable associated with every arc $(i,j) \in A$ such that $x_{ij} = 1$ if $(i,j) \in T$, and 0 otherwise. Let y_i be a variable associated with every vertex $i \in V$ that indicates the order in which vertex i is visited on the path connecting vertex i to the root r. Let u_j^t be a variable associated with every vertex $j \in V$, and vertex $t \in V$ where t is part of a precedence relationship (i.e. $\exists (s,t) \in R$). Let d_j be the time at which the flow enters vertex $j \in V$, and let w_j be the waiting time before the flow enters vertex j. Let $P_{ij} \subset A$ be a simple directed path that starts from i and ends at j, and let $c(P_{ij}) = \sum_{(i,j)\in P} c_{ij}$ be the cost of that path. For each $s \in V$, let $V_s = \{t \in V \backslash \{r\} \,|\, \exists\, (s,t) \in R, c(P_{ts}) = 0\}$. The PCMCA-WT can be formulated as the following MILP model.

$$\text{minimize} \quad \sum_{(i,j)\in A} c_{ij}x_{ij} + \sum_{i\in V} w_i \qquad (1)$$

$$\text{s.t.:} \quad \sum_{(i,j)\in A} x_{ij} = 1 \qquad \forall j \in V\backslash\{r\} \qquad (2)$$

$$y_i - y_j + 1 \leq n(1 - x_{ij}) \qquad \forall (i,j) \in A : j \neq r \qquad (3)$$

$$u_s^t = 0 \qquad \forall (s,t) \in R : t \in V_s \qquad (4)$$

$$u_t^t = 1 \qquad \forall t \in V_s \qquad (5)$$

$$u_j^t - u_i^t - x_{ij} \geq -1 \quad \forall (s,t) \in R : t \in V_s, (i,j) \in A \qquad (6)$$

$$d_r = 0 \qquad (7)$$

$$w_r = 0 \qquad (8)$$

$$d_j \geq d_i - M + (M + c_{ij})x_{ij} \qquad \forall (i,j) \in A \qquad (9)$$

$$w_j \geq d_j - d_i - M + (M - c_{ij})x_{ij} \qquad \forall (i,j) \in A \qquad (10)$$

$$d_t \geq d_s \qquad \forall (s,t) \in R \qquad (11)$$

$$x_{ij} \in \{0,1\} \qquad \forall (i,j) \in A \qquad (12)$$

$$y_i \geq 0 \qquad \forall i \in V \qquad (13)$$

$$u_j^t \geq 0 \qquad \forall t \in V_s, j \in V \qquad (14)$$

$$d_i, w_i \in \mathbb{R}^+_{\leq M} \qquad \forall i \in V \qquad (15)$$

The set of constraints (2) impose that every vertex excluding the root must have exactly one parent. Constraints (3) are the subtour elimination constraints, which enforce that any feasible solution is acyclic. The set of constraints (2) and (3) guarantee that any feasible solution is an arborescence rooted at vertex $r \in V$. Constraints (4) and (5) fix the values of u_s^t and u_t^t to 0 and 1 respectively, for all $(s,t) \in R$, where $t \in V_s$. Constraints (6) impose that if $x_{ij} = 1$ then $u_j^t \geq u_i^t$ (see Figure 2 for further explanation). Constraint (7) sets the time step at which the flow enters the root to 0. Constraint (8) sets the waiting time at the root r to be equal to 0. Constraints (9) impose that when arc $(i,j) \in A$ is selected to be part of the solution, then the flow enters vertex j at a time step that is greater than or equal to the time step at which the flow enters vertex i plus c_{ij}. Constraints (10) enforce that the waiting time at vertex j is greater than or equal to the difference between the time at which the flow enters vertex j and the time at which the flow enters vertex i plus c_{ij}. Constraints (11) enforce that the time at which the flow enters vertex t is greater than or equal to the time at which the flow enters vertex s for all $(s,t) \in R$. Finally, constraints (12)-(15) define the domain of the variables, and M is an upper bound on the value of an optimal solution.

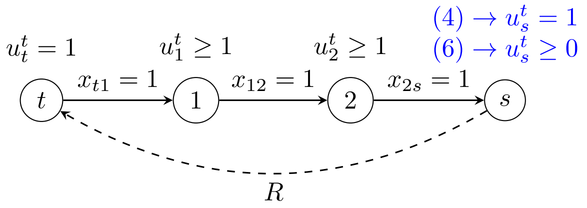

Fig. 2: An example on how a precedence relationship $(s,t) \in R$ can be enforced by propagating the value of u_t^t along every path starting from t, and if the solution contains a path from t to s, then we are propagating a value of one to vertex s and imposing that $u_s^t \geq 1$. However, we enforce $u_s^t = 0$, and therefore the solution violates the precedence relationship $(s,t) \in R$.

III. A New Constraint Programming Model

The CP solver used in this study, CP-SAT [20] is a solver that utilizes integer programming techniques (linear relaxation, presolve, cuts, and branching heuristics) to enhance its performance [21] and has recently been shown to successfully deal with different combinatorial optimization problems [22], [23]. Furthermore, the computational results in Section IV show that for the model considered in this work, the CP solver outperforms the MILP solver on a subset of the instances considered in terms of achieved average optimality gap, solution time, and the quality of the solutions obtained. Therefore, we introduce a CP model in this section that extend the MILP model introduced in Section II by adding the set of constraints

(3) and (6) formulated as logical constraints, and merging the two sets of constraints (9) and (10) into one set of logical constraints. By doing so, we further exploit the capabilities of the CP solver. Since the CP solver used utilizes integer programming techniques, it is beneficial to include both the logical and linear form of the constraints in the model, so that when the logical constraint is not enforced by the SAT solver (i.e. the logical constraint is not included in the model by the solver), their equivalent linear constraint is included in the program when computing its linear relaxation.

Using a set of implication constraints which enforce the implied constraint when the value of the variable is true, the MILP model introduced in Section II can be extended using the following set of constraints.

$$x_{ij} \implies y_j = y_i + 1 \qquad \forall (i,j) \in A : j \neq r \qquad (16)$$

$$x_{ij} \implies u_j^t \geq u_i^t \qquad \forall t \in V_t, j \in V \backslash \{r\} \qquad (17)$$

$$x_{ij} \implies d_j = d_i + w_j + c_{ij} \qquad \forall (i,j) \in A \qquad (18)$$

Constraints (16) are the subtour elimination constraints modelling the nonlinear relationship $y_j = (y_i + 1)x_{ij}$. Constraints (17) are the precedence-enforcing constraints modeling the nonlinear relationship $u_j^t \geq u_i^t x_{ij}$. Constraints (18) combine the two constraints (9) and (10) into a single equality constraint that model the nonlinear relationship $(d_j - d_i - w_j - c_{ij})x_{ij} = 0$. Note that variables d_i and w_i are defined as integers (compared to the MILP model), since a CP solver only accepts integer variables and coefficients. This means that c_{ij} for all $(i,j) \in A$ should be integer or to be discretized before solving the model. The value of c_{ij} can be discretized by multiplying every c_{ij} by a constant k, and then considering only the integer part of the result. In order to compute the correct solution cost, the objective function value should be divided by k. A higher k value leads to higher numerical precision, whereas a low k value leads to a lower numerical precision and thus faster execution. Therefore, a k value which balances the two factors should be considered. In this study we only consider instances with integer coefficients. However, the interested reader can refer to [14] where the authors show how changing the k value can affect the computation time.

IV. Experimental Results

The computational experiments are based on the benchmark instances of TSPLIB [24], SOPLIB [25], [26], and COMPILERS [27], originally proposed for the *Sequential Ordering Problem* (SOP) [28], [29], [30]. The benchmark instances are the same instances previously adopted in [15], [18] for the PCMCA-WT with the following characteristics. The benchmark sets contain a total of 116 instances (81 open instances) ranging in size between 9 and 700 vertices, with an average of 248 vertices. Finally, all instances have integer coefficients (i.e. the weight of the arcs of the cost graph is integer). All the experiments are performed on an Intel Xeon Platinum 8375C processor with 8 cores running at 2.9 GHz with 16 GB of RAM. For all instances an upper bound on the value of the optimal solution (i.e. M), is set to the value of the solution cost of solving the instance as a SOP, using a nearest neighbor algorithm [27]. This is a valid upper bound for the cost of the optimal solution of the PCMCA-WT, being a feasible solution for the SOP a simple directed path that includes all the vertices of the graph, such that t never precede s for all $(s,t) \in R$. This implies that $d_t \geq d_s$ for all $(s,t) \in R$, with a waiting time equal to zero at each vertex by definition.

The computational results are generated using two solvers: a *MILP Solver* and a *CP Solver*. The MILP Solver is CPLEX v12.8 [31], and is run with 8 thread standard B&C algorithm, with the two parameters *NodeSelect* and *MIP emphasis* are set to *BestBound* and *MIPEmphasisOptimality* respectively. The CP Solver is Google OR-Tools [20] v9.5 CP-SAT solver, and is run with its default parameters with all 8 threads available are allocated for the solver. A time limit of 1 hour is set on the computation time of both solvers. For the rest of this section we will be referring to the MILP model introduced in Section II as *BM* (Basic Model), while the CP model introduced in Section III will be referred to as *RM* (Reinforced Model).

Tables I, II and III show the complete results of each model and solving method, where we report the following. For each instance, columns *Name* and *Size* report the name and size of the instance. Column $\rho(R)$ reports the density of arcs in the set of precedence relationships computed as $\frac{2 \cdot |R|}{|V|(|V|-1)}$. Column *Best-Known* reports the best-known bounds on the optimal solution for each instance as $[LB, UB]$, where *LB* is the lower bound on the optimal solution, and *UB* is the best-known solution. The best-known solutions are obtained from the results appeared in [18], generated using the same computational setup and configuration used in this study. For each model solved with the corresponding solver, we report the following columns. Columns *LB* and *UB* report the lower/upper bound on the optimal solution achieved by the corresponding solving method of that model. Column *Gap* reports the optimality gap computed as $\frac{UB-LB}{UB}$. Column *Branches* reports the number of branches created in the search-decision tree, and is only reported when the models are solved with the CP Solver. Finally, column *Time [s]* reports the solution time in seconds and is only reported for the instances that are solved optimally within the time limit. In the tables, bold numbers indicate that a new best-known lower/upper bound is found.

A. Multi-threading Computation

The performance of CP solvers can often be greatly improved by the use of multi-threading computation, usually more than MILP solvers due to the different approaches used to solve the mathematical model. In this section, we assess the effect of multi-threading on the performance of the CP Solver and MILP Solver at solving the model introduced in Section II. The four instances *ft53.1, prob.42, ESC78*, and *jpeg.4753.54* were selected as both solvers are able to optimally solve those instances within the time limit using 8 threads.

Figure 3 reports the time required to optimally solve the different instances considered using a number of threads

TABLE I: Computational results for TSPLIB instances.

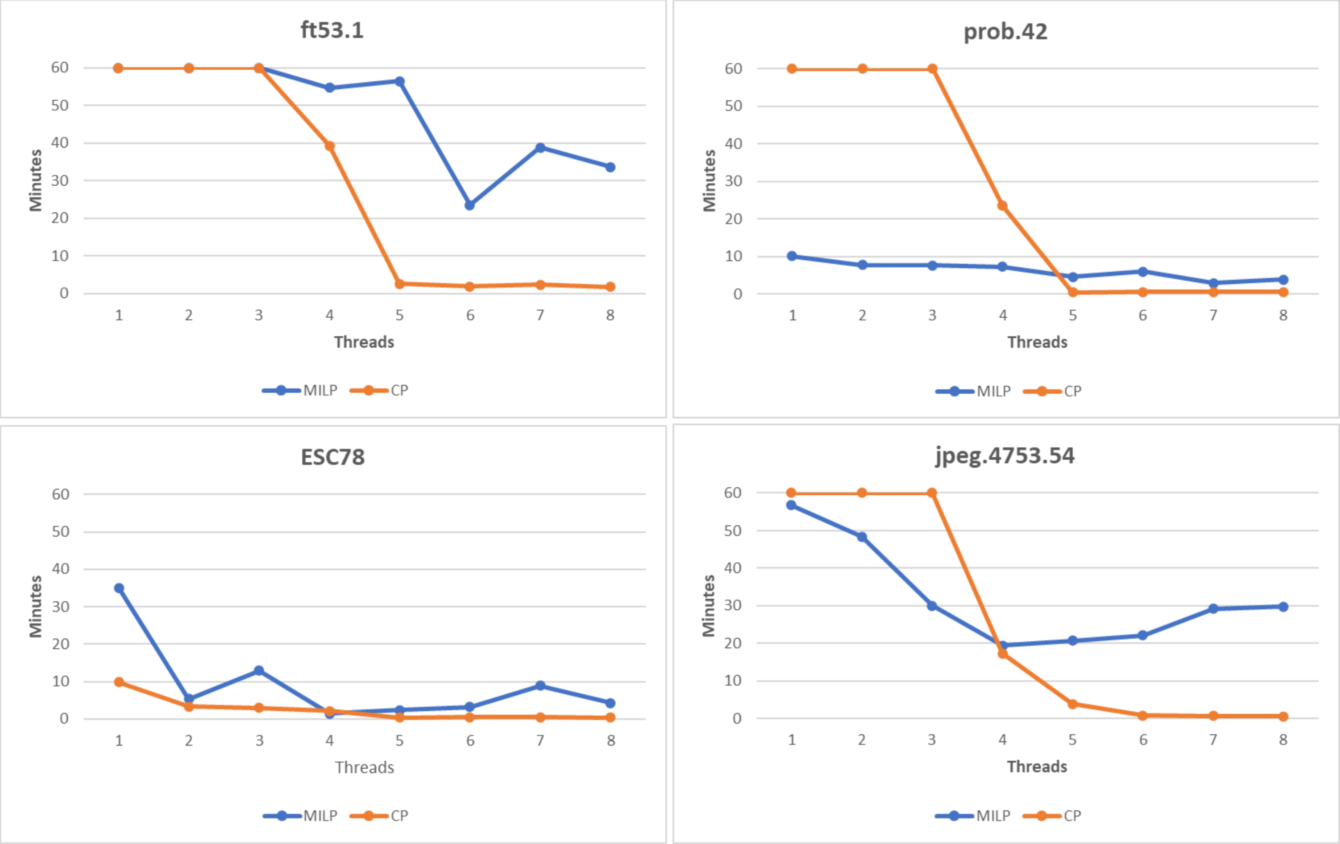

Fig. 3: Time required by the MILP Solver and CP Solver to optimally solve different instances with different number of threads. A time of 60 minutes reported means that the respective solver was not able to optimally solve the instance within the time limit.

between 1 and 8. In the figure, a time of 60 minuets reported means that the respective solver was not able to optimally solve the instance within the time limit of one hour.

The results reported in Figure 3 show that the CP Solver substantially benefits from the use of multi-threading computation. Furthermore, the results show that the CP Solver is not able to optimally solve three out of four instances within the time limit when less than four threads are allocated for the solver. However, when allocating four or more threads, the CP Solver is able to optimally solve those instances. Furthermore, a drastic change in performance can be observed between four and five threads, reaching a speedup up to 93.5%. On the other hand, the MILP Solver does not seem to benefit as much from multi-threading for the instances considered, possibly due to the overhead of task distribution, and the waiting time incurred by the variety of methods run in parallel. Furthermore, we can notice less consistent gain when increasing the number of threads used by the MILP Solver compared to the CP Solver. It should be noted that the differences between the two solvers might be less extreme when more challenging instances are considered, but this is difficult to investigate as most instances are hard to solve optimally, even with longer computational time limit (hours) is allowed, and with eight threads allocated for the solvers.

In conclusion, the CP Solver appears to greatly benefit from multi-threading computation; therefore, all the experiments reported in this section were run on eight cores.

B. *Analysis of the Results*

In this section, we first compare and discuss the results achieved by the MILP and CP Solvers by solving the model *BM*. We then compare and discuss the results achieved by the CP Solver by solving the models *BM* and *RM*.

TABLE IV: Summary of the results achieved by solving the model *BM* with the MILP Solver and CP Solver.

	MILP Solver	CP Solver
Average optimality gap	0.340	0.301
Average solution time	297.6	89.7
New best-known lower bounds	0	9
New best-known upper bounds	0	19
New optimal solution	0	1

Table IV summarizes the results of solving the model *BM* by the MILP Solver and CP Solver, where we report the following. The *Average optimality gap* is computed with respect to all the instances where both solvers find a feasible/optimal solution before reaching the time limit when solving the model *BM*. The *Average solution time* is computed on all the instances that are solved optimally by the both solvers. The *New best-known lower bounds* and *New best-known upper bounds* rows report the number of instances where solving the model by each solver resulted in an improved lower or upper bound. Finally, *New optimal solution* row reports the number of instances where an optimal solution is found for an instance that was previously open, by each solver.

Considering the model *BM*, the MILP Solver achieves an average optimality gap of 0.340 across all the instances, but fails to solve a single instance (marked bold in the table) as it runs out of memory while solving the linear relaxation of the model. On the other hand, the CP Solver achieves an average optimality gap of 0.301 (a 11.5% improvement) when excluding the instance that is not solved by the MILP Solver, and an average optimality gap of 0.298 (a 12.4% improvement) across all the instances. By further inspecting the results, we notice that the CP Solver achieves a smaller average optimality gap within the time limit for instances with density less than 0.85 and size smaller than 400.

For a total of 27 instances that are optimally solved by both solvers, the MILP Solver has an average solution time of 297.6 seconds, while the CP Solver has an average solution time of 89.7 seconds (a 69.9% improvement). We should note that the CP Solver generally finds the optimal solution in less time compared to the MILP Solver on small to medium sized instances.

Finally, out of a total of 81 open instances, the CP Solver is able to find an improved lower bound for 9 instances (11.1%), an improved upper bound for 19 instances (23.5%), and finds the optimal solution of one instance that was previously open. On the other hand, the MILP Solver is not able to improve the best-known solution of any instance. Based on the experiments performed on the model *BM* presented in Section II, we can conclude that the CP Solver has an overall better performance at solving the given MILP model.

TABLE V: Summary of the results achieved by solving each model with the CP Solver.

	BM	RM
Average optimality gap	0.298	0.287
Average solution time	146.9	99.4
New best-known lower bounds	9	4
New best-known upper bounds	19	27
New optimal solution	1	1

The rest of this section discusses the results achieved by the CP Solver by solving the two models *BM* and *RM*. The results are summarized in Table V where we report the following. The *average optimality gap* reports the Average optimality gap of all the instances where the solver finds a feasible/optimal solution before reaching the time limit by solving both models. The *Average solution time* reports the average solution time in seconds of all the instances that are solved optimally by the solver when solving both models. The *New best-known lower bounds* and *New best-known upper bounds* rows report the number of instances where solving each model resulted in an improved lower/upper bound. Finally, *New optimal solution* report the number of instances where an optimal solution is found for an instance that was previously open.

In terms of achieved average optimality gap, the CP Solver achieves an average optimality gap of 0.287 (a 3.7% improvement) when solving the model *RM*, compared to solving the model *BM*. Furthermore, for a total of 36 instances that are solved optimally when solving both models, the CP Solver generates 57.9% less branches in the search-decision tree when solving the model *RM* compared to solving the model *BM*. By further inspecting the results, we notice that the CP Solver achieves a smaller average optimality gap within the time limit when solving the model *RM* for instances with density less than 0.89 and size less than 500, which means that the CP Solver performs better on a larger subset of the instances compared to solving the model *BM*.

For a total of 36 instances that are solved optimaly by the CP Solver when solving both models, the CP Solver has an average solution time of 146.9 seconds when solving the model *BM*, and an average solution time of 99.4 seconds (a 32.4% improvement) when solving the model *RM*.

Finally, out of a total of 81 open instances, when solving the model *BM* the CP Solver finds an improved lower bound for 9 instances (11.1%), an improved upper bound for 19 instances (23.5%), and finds the optimal solution for one instances that was previously open. On the other hand, when solving the model *RM* the CP Solver finds an improved lower bound for 4 instances (4.9%), an improved upper bound for 27 instances (33.3%), and finds the optimal solution for the same instance that was previously open. Based on the computational experiments and the improvements in the results achieved by the CP Solver when solving the model *RM*, we can conclude that duplicating the constraints can indeed improve the performance of the solver for the given model.

V. Conclusions

The computational experiments has shown that the CP Solver outperforms the MILP Solver at solving instances with sizes up to 500 with precedence relationships density that is less than 0.89. Furthermore, the CP Solver achieves a smaller average optimality gap and solution time compared to the MILP Solver. By adding constraint programming constructs to the MILP model, we were able to further exploit the capabilities of the CP Solver, and improve its performance at solving the instances. In terms of solution quality, and out of a total of 81 open instances, the CP Solver was able to find the optimal solution to an instance that was previously open, provide new best-known lower bounds for 13 instances, and establish new best-known solution for 46 instances. Based on the computational experiments performed, we have shown that the CP Solver performs better on average for the given models. Furthermore, duplicating constraints by defining them in their linear form and logical form further pushes the performance of the CP Solver. Future work will consider investigating new valid constraints/inequalities for the PCMCA-WT that can be used within a constraint programming paradigm to further utilize its potential.

Abstract—**In this paper we consider filtering and processing large data streams in intelligent data acquisition systems. It is assumed that raw data arrives in discrete events from a single expensive sensor. Not all raw data, however, comprises records of interesting events and hence some part of the input must be filtered out. The intensity of filtering is an important design choice because it determines the complexity of filtering hardware and software and the amount of data that must be transferred to the following processing stages for further analysis. This, in turn, dictates needs for the following stages communication and computational capacity. In this paper we analyze the optimum intensity of filtering and its relationship with the capacity of the following processing stages. A set of generic filtering intensity, data transfer, and processing archetypes are modeled and evaluated.**

I. Introduction

SENSOR technology has developed rapidly over the past decades. Numerous surveys can be found, each limited to a specific sensor technology type. An important research topic is the computational and communication integration of multiple sensors in a network [1], [2], [3], [4], [5]. There is an implicit assumption here that the economics of constructing, deploying and operating such a system are such that the use of multiple sensors is plausible within project budget constraints.

In this paper we envision a problem with a different emphasis where there is a single, very expensive “sensor”. Examples of such a device include detectors for particle accelerator experiments such as the CERN Large Hadron Collider [6], or the recently announced Electron Ion Collider [7] to be built at Brookhaven National Laboratory. Another example is the use of a large radar equipped drone for monitoring ocean traffic. A final example is the use of imaging satellites for ocean, weather, environmental monitoring and earth resources sensing [8]. Note that what we generically consider a “sensor", may consist of a large number of individual sensing elements (as in a particle detector) but we refer to the ensemble collection as a sensor.

The commonality in all these examples is that the sensor increasingly can generate raw data at rates that are much faster than the data can be downloaded over a communication channel(s) onto servers for processing. Moreover, not all data collected by the sensor is valuable enough to be retained for further processing. The generally proposed solution for this problem is to have onboard pre-processing of the data at the detector, the drone or the satellite. This processing is not classical data compression but more so the use of data analysis, machine learning (ML) or other type of broadly understood artificial intelligence techniques to pre-process the raw data for a much smaller processed summary that is more amenable to transmit. Thus, only interesting particle tracks, ship tracks and weather patterns may be transmitted, but the majority of the raw data isn’t. For simplicity of exposition we will say that the ML algorithm serves as a filter on the raw data, independently of the field of origin of the actually applied filtering technique. Clearly this situation has similarities with edge computing where sensors/actuators at the network edge do local processing in order to reduce the amount of network traffic to distant cloud facilities. Again, the specification of a single sensor here makes our problem have a unique character.

In this paper we analyze the intensity of data filtering in the first stages of data processing necessary for the shortest time to obtain results. The intensity of filtering is important for the following reasons: (i) filtering algorithms are often hardware-implemented, and consequently, have costly realization, their changes are less flexible than in software (especially in remote posts like satellites); (ii) the higher intensity of filtering, the more complex algorithm is applied which results in longer filtering time and/or more extensive hardware system; (iii) the size of data emerging from the filtering stage determines needs for capacity in the further stages of data processing pipeline where more sophisticated algorithms are executed; (iv) and vice versa the speed of communication between the stages of data pipeline and processing in the stages following the initial filtering have impact on the required intensity of raw data filtering. For the purpose of analyzing systems of the above nature, an extensive set of the single expensive sensor (SES) models for filtering and processing problem will be examined. These cases are meant to illustrate the modeling and solution possibilities and be representative in a generic way. A common sense expectation is that high intensity of initial data filtering reduces amounts of the data analyzed in the pipeline and thus reduces the time to obtaining the results. However, more intensive filtering is also more time-consuming. Thus, due to interaction between nonlinear speed of filtering and complexity of processing the data in

SUMMARY OF NOTATIONS

α_i	size of load part assigned to stage 2 processor i [byte]
A_0	reciprocal of the first stage processing speed [e.g. s/byte]
A_i	reciprocal of the heterogeneous second stage processing speed on processor i [e.g. s/byte]
A	reciprocal of the second stage processing speed for identical processors [e.g. s/byte]
C_i	reciprocal of the communication speed between stage 1 and heterogeneous stage 2 processor i
C	reciprocal of the communication speed between stage 1 and stage 2 for identical processors [e.g. s/byte]
F	fraction of retained data
m	number of machines (a.k.a. servers, processors) in the second stage
T	execution time of the whole filtering and processing workflow
V	size of input data (at the front-end of the system)

the later stages, the processing time may have a minimum at a certain filtering intensity. We investigate such minima in this paper. Furthermore, options for combining advanced processing algorithms of various complexity classes in the data processing workflow are analyzed.

Our models are largely tractable. Parts of the evaluation of the models use concepts from the theory of divisible (i.e. partitionable) loads, a well established concept, that provides elegant solutions particularly for linear models [9], [10], [11], [12], [13]. The divisibility of the loads means that big volumes of data are processed and the discrete units of data are small in relation to the whole data size. It is also assumed that the loads can be divided into parts processed independently in parallel.

Further organization of this paper is the following. In the next section related literature is outlined. The filtering and parallel processing problem is formally defined in Section III. Section IV is dedicated to analytical derivation of the formulas guiding selection of the optimum filtering intensity. Results of numerical modeling of filtering and processing systems are provided in Section V. The last section is dedicated to conclusions. The notations are summarized in Table I.

II. Related Work

In the literature on sensor networks, particularly wireless sensor networks, there are general surveys [14] and surveys on specific technological aspects of sensor networks such as transport and routing [15], fault detection [16], security solutions [17], optimizing sensor-source geometries and minimizing the number of sensors [18], the use of swarm intelligence for performance optimization [19] and numerous applications.

There has been some work on analytical models of sensor data generation, communication and computation. For instance, an early work is [1] which examined scheduling for measurement and data reporting in wireless sensor networks. Data gathering networks have been the subject of research by Berlińska and recently by Luo et. al. Data gathering networks have been studied in connection with background communication [3], limited base station memory [4], data compression [5], [20], [21], energy minimization [22] and in the case of tree data gathering networks [2]. The case when the load is processed in a pipeline fashion has been studied in [23], [24].

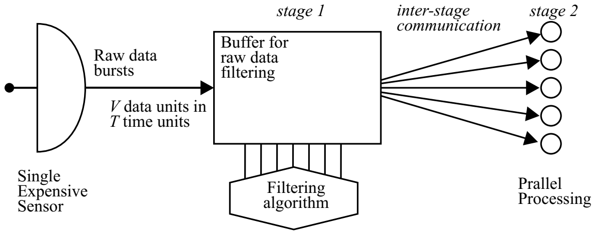

Fig. 1. Data filtering and processing system architecture.

Most work to date has involved multiple sensors, unlike the single expensive sensor paradigm of this paper. An LHC data acquisition system [6] is a good example of a single expensive sensor with data filtering and parallel processing. In LHC protons circulate in bunches and opposing beams that cross each other resulting in collisions with 40MHz frequency. Only data from particle collisions with sufficient energy and momentum are allowed to proceed from the so-called level-1 trigger to the second stage of processing (so called high-level trigger) for further reconstruction of particle trajectories and analysis.

III. Problem formulation

It is assumed that there is a two-stage workflow: (1) the first stage is related to sensor data filtering, (2) the second stage conducts further data processing. An overview of the system architecture is shown in Fig.1. The data from the sensor arrive in discrete events each delivering V units of data. The arriving chunk of data is intercepted in the input buffer, and all filtering algorithms use this buffer. The same buffer is used to send the filtered data to the second stage of processing. The use of a single buffer in this model is an aggregate representation of specialized buffer architectures that may be needed in practice to handle the influx, staging and filtering of massive amounts of data. The data chunks may arrive repetitively, then it is assumed that at most V units of data arrive in a chunk once in T time units. The first stage filtering is done in linear time, but the intensity of filtering, i.e. fraction F of the initial data transferred to the second stage, is related to the speed of filtering.

In the second stage more intricate, than filtering, data processing is conducted requiring machines with substantial computing power, memory and storage. Hence, these can be dedicated data centers or cloud systems. The machines running in the second stage will be referred to as servers or processors. Many different algorithms may be executed in parallel in the second stage. For example, different algorithms discovering unrelated artifacts may be run in parallel. In such a case it is assumed that each specific data-processing algorithm receives the same data set, has its own set of processors, and all the many algorithms are executed independently of each other. The longest path in the data-processing would always go to the processor(s) running the most time-consuming algorithm. Consequently, in the following we analyze only one of the possibly many parallel paths in data-processing. Namely, the longest one.

A. First Stage Filtering Intensity and Complexity

The intensity of filtering is expressed by fraction $F \in (0, 1]$ controlling the amount of produced results. The amount of results delivered from stage 1 to stage 2 is FV, where V is the size of data injected into the first stage from the sensor. This volume of data is filtered in time A_0V. It is assumed that the intensity of filtering F and speed of filtering are interdependent. Precisely, the inverse of filtering speed is some function $A_0(F)$. Depending on the application, $A_0(F)$ may assume various forms. Here we list a few possibilities:

Case 1: $\mathbf{A_0(F) = 1/F^c}$, where $c > 0$ is some constant. This kind of relationship may emerge as a consequence of iterative filtering. Let i be the number of iterations that are executed on each data unit, then A_0 and F can be expressed as

$$F = f^i \tag{1}$$

$$A_0 = a^i, \tag{2}$$

where $f \in (0, 1)$ is the fraction of data remaining after each iteration of filtering, and f and $a > 1$ are some given constants determined by the filtering algorithm. This means that an iterative filtering algorithm is executed on *each* data unit, and extending the algorithm by each new iteration takes exponentially longer to process a data unit. This can be the case when each data unit (e.g. a picture) is rectified with increasing resolution. From equation (1), we get $i = \frac{\ln F}{\ln f}$. From (2), $\ln A_0 = i \ln a$, and hence, $\ln A_0 \ln f = \ln F \ln a$. Equivalently, we have $\ln A_0 = \ln F \ln a/\ln f$, and hence, $A_0 = F^{\frac{\ln a}{\ln f}}$. Since $f \in (0, 1), a > 1$, we have $\frac{\ln a}{\ln f} < 0$ and $A_0(F) = \frac{1}{F^c}$, where $c = -\frac{\ln a}{\ln f} > 0$.

Case 2: $\mathbf{A_0(F) = c\ln(1/F)}$. Again all filtering iterations are executed on each data unit, each iteration takes the same time and reduces output data size $f \in (0, 1)$ times. Then as in the previous case $F = f^i$, $i = \frac{\ln F}{\ln f}$, but since each iteration takes the same time, we have $A_0 = ai$, and hence we obtain $A_0(F) = c\ln(1/F)$, where $c = -\frac{a}{\ln f} > 0$.

Case 3: $\mathbf{A_0(F) = c(1 - \ln F)}$. Suppose the filtering is a *sieve*, i.e., the filtering algorithm sifts data in some buffer and with each iteration part of the data is dropped. Suppose $\frac{1}{j}$-th of the initial data is removed in iteration j. Thus, after i iterations $V \times \frac{1}{2} \times \frac{2}{3} \times \cdots \times \frac{i-1}{i} = V/i = FV$ data units remain. Hence, $F = 1/i$. The filtering time T_1 is proportional to the diminishing data sizes: $T_1 = aV(1+\frac{1}{2}+\frac{1}{3}+\cdots+\frac{1}{i}) = aH_iV = A_0V$, where H_i is the ith harmonic number. Since $H_i \le 1 + \ln i$, $A_0(F) = aH_i \le a(1 + \ln 1/F) = c(1 - \ln F)$, where $a = c$ is some constant.

Case 4: $\mathbf{A_0(F) = c(1 - F)}$. The data filtering is a sieve again, and after i iterations the remaining data size is $FV = f^iV$ where $f \in (0, 1)$. Filtering time is $T_1 = A_0V = aV\sum_{j=1}^{i} f^i = aV\frac{1-f^i}{1-f}$. Hence, $F = f^i$, $A_0 = a\frac{1-f^i}{1-f}$. Consequently, $A_0(F) = \frac{a(1-F)}{1-f} = c(1 - F)$ where $\frac{a}{1-f} = c$ is constant.

Let us observe that in all the above cases $A_0(F)$ decreases with F which means that more intensive filtering (F decreases) requires longer computation ($A_0(F)$ increases).

B. Inter-Stage Communication

The flow of results from stage 1 to stage 2 can be organized in a number of ways. Here we assume two alternatives:

A. Sequential communication – time to transfer x_i bytes to server i and x_j bytes to server j is $C_ix_i + C_jx_j$.

B. Parallel communication – stage 1 to server connections are mutually independent. Time to transfer x_i bytes from stage 1 to server i and x_j bytes to server j is equal to $\max\{C_ix_i, C_jx_j\}$.

C. Computational Complexity of the Second Stage

Computational complexity of the second stage depends on the executed algorithms, necessary result integration and storage. We adopt divisible load theory assumption [10], [12], [13] that the data processed in the second stage is arbitrarily divisible and can be processed in parallel. Potential ways of parallelization are determined by a particular algorithm. Since the variety of possible second stage algorithms and ways of parallelizing them seems unlimited, we will consider a limited set of archetype algorithms as examples of typical computational complexity functions:

Linear – The time to process x units of data is A_ix on processor i. Typical examples are searching for patterns, compression, message digest (e.g. MD5) calculation or scoring data units (like in the LHC example). Here we assume that result collection time is negligible because the size of output data is small or the results are left on the servers and storing is included in the algorithm run time. Since result return is neglected, it can be shown that in the optimum schedule all servers must finish computations at the same moment [10], [12], [13].

Loglinear – Sorting is a typical example of an algorithm with loglinear complexity. Classic sequential sorting algorithms like heapsort, quicksort have complexity $O(n \log n)$, where n is the number of sorted items. We will assume that a parallel version of these algorithms consists in splitting the volume of data into parts, sorting the parts in parallel, and then sequentially merging the results. Thus, on m identical processors the complexity of this method would be $O((n/m)\log(n/m) + n \log m)$.

Quadratic - Computing a similarity matrix can serve as an example of an algorithm with quadratic computational complexity. Its sequential complexity is $O(n^2)$. In the case of parallel processing, the square area of work, e.g. a similarity matrix, may be partitioned into $\ell \times \ell$ squares distributed to processors, where integer ℓ is a tunable parameter of the algorithm. There are ℓ^2 tiles each of of size n^2/ℓ^2. Sending and processing one square takes $O(n^2/\ell^2)$ time. If equal numbers of ℓ^2/m tiles are assigned to each of m processors, then receiving and processing them can be executed in time $O(n^2/\ell^2 \times \ell^2/m)$ which is $O(n^2/m)$. Note that tile distribution may be different, that is, it may depend on the communication and computing speeds of the processors.

IV. Optimum Filtering Intensity

Our goal in this section is to derive close-form solutions (i.e. formulas) linking optimum filtering intensity F with other system parameters to minimize the time required to transmit and process all data. In many cases the obtained formulations are not amenable to analytic solutions. In such a situation further study is delegated to numerical modeling described in the next section.

A. Parallel Communication, Linear Second Stage

In the optimum schedule, all servers communicate and process in parallel, finishing at the same time T. Hence, we have

$$\alpha_1(A_1+C_1) = \alpha_i(A_i+C_i) \qquad i=2,\dots,m \quad (3)$$

$$FV = \sum_{i=1}^{m}\alpha_i \quad (4)$$

In the above equation system all processors communicate and compute in the same interval by (3), and all work is done by (4). From (3) we get $\alpha_i = (A_1+C_1)/(A_i+C_i)\alpha_1$ and

$$FV = (A_1+C_1)\sum_{i=1}^{m}\frac{\alpha_1}{A_i+C_i} = K(A_1+C_1)\alpha_1, \quad (5)$$

where

$$K = \sum_{i=1}^{m}\frac{1}{A_i+C_i} \quad (6)$$

is a constant. The schedule length is a sum of filtering, communication and processing times:

$$T = A_0(F)V + (A_1+C_1)\alpha_1 = A_0(F)V + FV/K. \quad (7)$$

Thus, in order to minimize T, we have to minimize the function

$$t(F) = A_0(F) + F/K. \quad (8)$$

We will now compute the optimum value of F for the considered functions $A_0(F)$. Note that practical values of F belong to some interval $[F_{min}, F_{max}] \subset (0,1]$. Thus, if the computed optimum value F^* is larger than F_{max}, we should set $F = F_{max}$. Similarly, if $F^* < F_{min}$, then the smallest possible value of F should be chosen.

1) $\mathbf{A_0(F) = 1/F^c}$, where $c > 0$ is a constant. Then,

$$t(F) = F^{-c} + F/K, \quad (9)$$

$$t'(F) = -cF^{-(c+1)} + 1/K \quad (10)$$

and

$$t''(F) = c(c+1)F^{-(c+2)} > 0. \quad (11)$$

Thus, $t(F)$ is minimized when $t'(F) = 0$, i.e., for

$$cF^{-(c+1)} = 1/K, \quad (12)$$

$$F = (Kc)^{1/(c+1)}. \quad (13)$$

2) $\mathbf{A_0(F) = c\ln(1/F)}$, where $c > 0$ is a constant. We have

$$t(F) = -c\ln F + F/K, \quad (14)$$

$$t'(F) = -c/F + 1/K \quad (15)$$

and

$$t''(F) = c/F^2 > 0. \quad (16)$$

Hence, $t(F)$ is minimized when

$$F = cK. \quad (17)$$

3) $\mathbf{A_0(F) = c(1 - \ln F)}$, where $c > 0$ is a constant. Then,

$$t(F) = c(1 - \ln F) + F/K, \quad (18)$$

$$t'(F) = -c/F + 1/K \quad (19)$$

and

$$t''(F) = c/F^2 > 0. \quad (20)$$

The minimum value of $t(F)$ is obtained for

$$F = cK. \quad (21)$$

4) $\mathbf{A_0(F) = c(1 - F)}$, where $c > 0$ is a constant. Now we have

$$t(F) = c(1-F) + F/K, \quad (22)$$

$$t'(F) = -c + 1/K. \quad (23)$$

Thus, $t'(F)$ does not depend on F. If $c > 1/K$, then $t(F)$ is decreasing, and the maximum possible value of F should be chosen. If $c < 1/K$, then $t(F)$ is increasing and the smallest possible F should be selected.

B. Sequential Communication, Linear Second Stage

We assume that the sensor communicates with the processors in the order of their identifiers. Hence, we have

$$\alpha_i(A_i+C_i) = \alpha_{i-1}A_{i-1} \qquad i=2,\dots,m \quad (24)$$

$$FV = \sum_{i=1}^{m}\alpha_i \quad (25)$$

Equations (24) mean that communication to and computation on processor i is preformed in parallel with computation on processor $i-i$. It follows implicitly that processor i is started after activating processor $i-1$. Hence, we obtain

$$\alpha_i = \frac{\alpha_1\prod_{j=1}^{i-1}A_j}{\prod_{j=2}^{i}(A_j+C_j)} \qquad i=2,\dots,m, \quad (26)$$

$$FV = \alpha_1\sum_{i=1}^{m}\frac{\prod_{j=1}^{i-1}A_j}{\prod_{j=2}^{i}(A_j+C_j)} \quad (27)$$

and

$$T = A_0(F)V + (A_1+C_1)\alpha_1 = A_0(F)V + FV/L, \quad (28)$$

where

$$L=\sum_{i=1}^{m}\frac{\prod_{j=1}^{i-1}A_j}{\prod_{j=1}^{i}(A_j+C_j)}. \tag{29}$$

Equation (28) has the same form as (7), and hence, the considerations from Section IV-A can be also applied in the case of sequential communication.

C. Parallel Communication, Loglinear Second Stage

In the case of loglinear complexity of the second stage, it is assumed that processing consists of three steps: parallel communication, parallel processing chunks of data, and sequential merging of the results. The latter can be executed in time $FVC_M \log m$, where FV is the amount of data that has to be collected, C_M is reciprocal of merging speed (e.g. in sec/byte) which is taking into account the speed of communication between the servers providing data to merge and the merging server, $\log m$ is a factor representing time to elect the smallest value among m servers in the merging step. The former two steps (parallel communication and processing) take the same time T_1 on all servers. Hence we have:

$$T_1 = C_i\alpha_i + A_i\alpha_i \ln\alpha_i \qquad i=1,\dots,m. \tag{30}$$

Let us define

$$y_i = \frac{C_i}{A_i} + \ln\alpha_i. \tag{31}$$

We have

$$\begin{aligned} y_i e^{y_i} &= \left(\frac{C_i}{A_i} + \ln\alpha_i\right) e^{\frac{C_i}{A_i}}\alpha_i = \\ &= \frac{1}{A_i}\left(C_i\alpha_i + A_i\alpha_i \ln\alpha_i\right) e^{\frac{C_i}{A_i}} = \frac{T_1}{A_i} e^{\frac{C_i}{A_i}}. \end{aligned} \tag{32}$$

Recall that if $ye^y = x$ then $y = W(x)$, where W is the Lambert function [25]. Thus, we have

$$y_i = W\left(\frac{T_1}{A_i} e^{\frac{C_i}{A_i}}\right), \tag{33}$$

and (30) can be written as

$$T_1 = A_i\alpha_i W\left(\frac{T_1}{A_i} e^{\frac{C_i}{A_i}}\right). \tag{34}$$

Hence, the load chunk sizes are:

$$\alpha_i = \frac{T_1}{A_i W\left(\frac{T_1}{A_i} e^{\frac{C_i}{A_i}}\right)}. \tag{35}$$

The Lambert function cannot be expressed in terms of elementary functions, but T_1 can be found numerically by solving

$$FV = \sum_{i=1}^{m} \frac{T_1}{A_i W\left(\frac{T_1}{A_i} e^{\frac{C_i}{A_i}}\right)}. \tag{36}$$

The above equation is easier to solve in homogeneous systems because all processors have the same parameters and load to process is split equally. Then, each processor receives load of size $\alpha_i = \frac{FV}{m}$ and equation (36) becomes:

$$FV = \frac{mT_1}{AW\left(\frac{T_1}{A} e^{\frac{C}{A}}\right)}. \tag{37}$$

Moreover, we get from (33)

$$\begin{aligned} W\left(\frac{T_1}{A} e^{\frac{C}{A}}\right) &= \frac{C}{A} + \ln\alpha_i = \frac{C}{A} + \ln\left(\frac{FV}{m}\right) = \\ &= \ln\left(\frac{FVe^{\frac{C}{A}}}{m}\right) \end{aligned} \tag{38}$$

and hence,

$$T_1 = \frac{AFV}{m} \ln\left(\frac{FVe^{\frac{C}{A}}}{m}\right). \tag{39}$$

The schedule length including filtering, communication and processing is

$$T(F) = A_0(F)V + \frac{AFV}{m} \ln\left(\frac{FVe^{\frac{C}{A}}}{m}\right) + FVC_M \ln m \tag{40}$$

We will now compute the optimum value of F for which T is minimum.

1) $\mathbf{A_0(F) = 1/F^c}$, where $c > 0$ is a constant. Then,

$$\begin{aligned} T'(F) = -cVF^{-(c+1)} + \frac{AV}{m}\left[\ln\left(\frac{FVe^{\frac{C}{A}}}{m}\right) + 1\right] + \\ + VC_M \ln m \end{aligned} \tag{41}$$

$$T''(F) = c(c+1)VF^{-(c+2)} + \frac{AV}{mF} > 0 \tag{42}$$

Hence, $T(F)$ is a minimum when $T'(F) = 0$.

2) $\mathbf{A_0(F) = c\ln(1/F)}$, where $c > 0$ is a constant. We have

$$\begin{aligned} T'(F) = -cV/F + + \frac{AV}{m}\left[\ln\left(\frac{FVe^{\frac{C}{A}}}{m}\right) + 1\right] + \\ + VC_M \ln m \end{aligned} \tag{43}$$

and

$$T''(F) = cV/F^2 + \frac{AV}{mF} > 0 \tag{44}$$

Again, for F satisfying $T'(F) = 0$, $T(F)$ is minimum.

3) $\mathbf{A_0(F) = c(1 - \ln F)}$, where $c > 0$ is a constant, is dealt in the same way as the previous case because $[c\ln(1/F)]' = c(1 - \ln F)' = -c/F$.

4) $\mathbf{A_0(F) = c(1 - F)}$, where $c > 0$ is a constant.

$$T'(F) = -cV + \frac{AV}{m}\left[\ln\left(\frac{FVe^{\frac{C}{A}}}{m}\right) + 1\right] + VC_M \ln m \tag{45}$$

and

$$T''(F) = \frac{AV}{mF} > 0 \tag{46}$$

and $T(F)$ is a minimum when $T'(F) = 0$.

D. Sequential Communication, Loglinear Second Stage

In this case communications and parts of processed load are linked by the system of equations:

$$C_{i+1}\alpha_{i+1} + A_{i+1}\alpha_{i+1}\ln\alpha_{i+1} = A_i\alpha_i\ln\alpha_i \qquad i = 1,\dots,m-1 \tag{47}$$

$$FV = \sum_{i=1}^{m}\alpha_i \tag{48}$$

Equations (47) ensure that work on processor $i-1$ is processed in parallel with communication to and computation on processor i. This set of nonlinear equations does not seem to have an easy analytical solution. Therefore, we will recourse to numerical methods to solve (47)-(48) and find F for which the processing time is minimum.

E. Parallel Communication, Quadratic Second Stage

As mentioned in Section III we assume that the quadratic amount of work is shared between the m processors. This amount of work can be split into ℓ^2 work units, each of size $(FV/\ell)^2$. We will assume that ℓ is large and hence work can be sufficiently flexibly divided as in the linear case. Yet, mind that the amount of work, i.e. data to be processed, grows proportionately to $(FV)^2$. Furthermore, a homogeneous system is considered. Similarly to the linear case (Section IV-A), results are not explicitly merged. We have

$$T_1 = \alpha_i\left(A\left(\frac{FV}{\ell}\right)^2 + 2C\left(\frac{FV}{\ell}\right)\right) \qquad i = 2,\dots,m \tag{49}$$

$$\ell^2 = \sum_{i=1}^{m}\alpha_i \tag{50}$$

Equations (49) mean that communication and processing is performed in the same interval on all processors. Since the system is homogeneous, $\alpha_i = \ell^2/m$, for $i = 1,\dots,m$, the whole schedule length is

$$T(F) = A_0(F)V + \frac{\ell^2}{m}\left(A\left(\frac{FV}{\ell}\right)^2 + 2C\left(\frac{FV}{\ell}\right)\right) \tag{51}$$

We will now compute the optimum value of F for which T is minimum.

1) $\mathbf{A_0(F) = 1/F^c}$, where $c > 0$ is a constant. Then,

$$T'(F) = -cF^{-(c+1)}V + \frac{2FAV^2}{m} + \frac{2CV\ell}{m} \tag{52}$$

$$T''(F) = c(c+1)VF^{-(c+2)} + \frac{2AV^2}{m} > 0 \tag{53}$$

Hence, $T(F)$ is minimum when $T'(F) = 0$. Unfortunately, equation (52) does not seem to have an easy analytical solution for $T'(F) = 0$ and has to be solved numerically.

2) $\mathbf{A_0(F) = c\ln(1/F)}$, where $c > 0$ is a constant. We have

$$T'(F) = -cV/F + \frac{2FAV^2}{m} + \frac{2CV\ell}{m} \tag{54}$$

$$T''(F) = cV/F^2 + \frac{2AV^2}{m} > 0 \tag{55}$$

Again, $T(F)$ is minimum when $T'(F) = 0$ and

$$F = \frac{\sqrt{4C^2V^2\ell^2/m^2 + 8cAV^3/m} - 2CV\ell/m}{4AV^2/m} \tag{56}$$

3) $\mathbf{A_0(F) = c(1 - \ln F)}$, where $c > 0$ is a constant, is dealt in the same way as the previous case because $[c\ln(1/F)]' = c(1-\ln F)' = -c/F$.

4) $\mathbf{A_0(F) = c(1 - F)}$, where $c > 0$ is a constant.

$$T'(F) = -cV + \frac{2FAV^2}{m} + \frac{2CV\ell}{m} \tag{57}$$

and

$$T''(F) = \frac{2AV^2}{m} > 0. \tag{58}$$

Hence, $T(F)$ is minimum when $F = \frac{mc-2C\ell}{2AV}$.

F. Sequential Communication, Quadratic Second Stage

We have a set of equations determining work distribution:

$$2C\alpha_{i+1}\left(\frac{FV}{\ell}\right) + A\alpha_{i+1}\left(\frac{FV}{\ell}\right)^2 = A\alpha_i\left(\frac{FV}{\ell}\right)^2 \qquad i = 1,\dots,m-1 \tag{59}$$

$$\ell^2 = \sum_{i=1}^{m}\alpha_i \tag{60}$$

Unfortunately, this set of nonlinear equations does not seem to have an easy analytical solution for F minimizing the schedule length. Therefore, we will recourse to numerical methods to solve (59)-(60) and find F for which the processing time is minimum.

V. Numerical Modeling

This section is dedicated to showing tendencies in the system parameters when the filtering intensity is optimum with respect to the minimum total processing time. In cases not amenable to representation with a closed-form formula, the optimum value of F was found by use of Python method `scipy.optimize.fsolve`. We assume that the amount of input data is $V = 1\mathrm{E}6$. We will analyze recurring patterns in performance rather than particular numbers. Therefore, only representative examples of the cases introduced in Section III-A are extensively discussed. For simplicity, only homogeneous systems are analyzed.

A. Parallel Communication, Linear Second Stage

Fig. 2 presents the relationship between the retained data fraction F and the schedule length T in case 2, i.e. $A_0(F) = c\ln(1/F)$, for $m = 100$ and several combinations of A, C and c values. The smallest value of F for which T is shown in Fig. 2 is 0.01, because F must be greater than 0. When $A = C = 5$ and $c = 0.001$, filtering is fast, while data transfer and processing in the second stage are rather slow. Hence, the smaller amount of data is retained, the shorter schedule is obtained. Contrarily, when $A = C = 1$ and $c = 0.3$, filtering

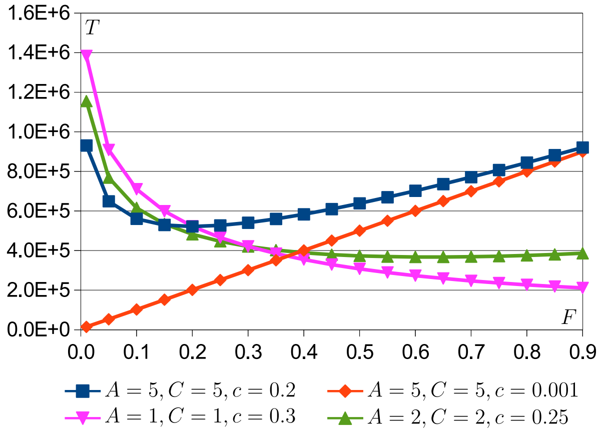

Fig. 2. T vs. F for parallel communication, linear second stage, case 2, $m = 100$.

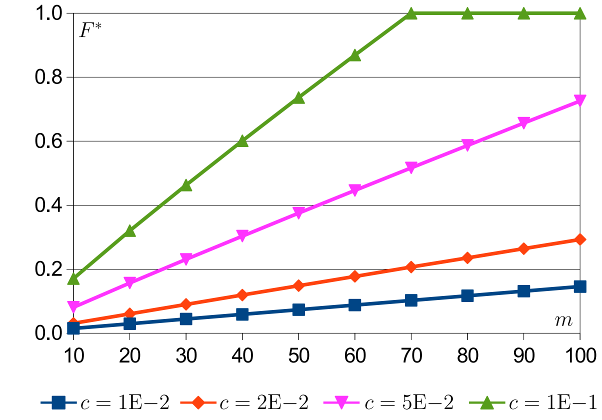

Fig. 3. F^* vs. m for parallel communication, linear second stage, case 1, $A = 5$, $C = 2$.

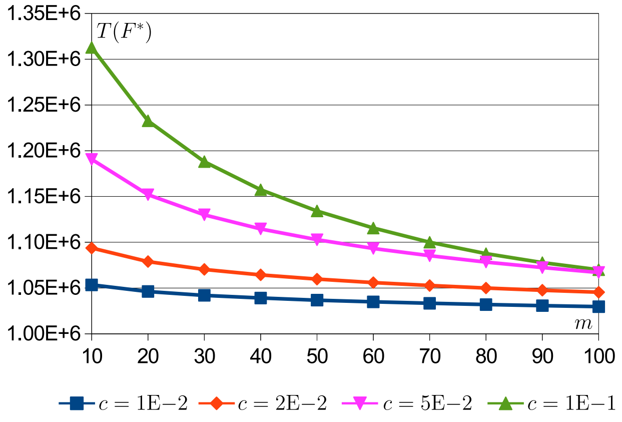

Fig. 4. $T(F^*)$ vs. m for parallel communication, linear second stage, case 1, $A = 5$, $C = 2$.

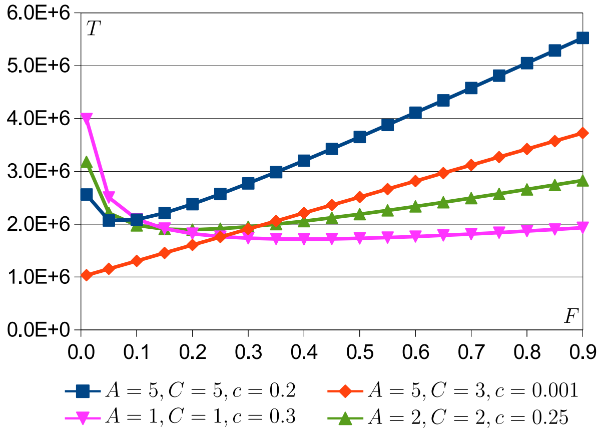

Fig. 5. T vs. F for sequential communication, linear second stage, case 1, $m = 10$.

is slow, while data transfer and processing are rather fast. In consequence, larger F (i.e. lower filtering intensity) results in a smaller schedule length T. In the remaining two presented cases, the optimum value of F is neither the minimum possible (close to 0) nor the maximum possible (1). For $A = C = 5$ and $c = 0.2$, the best value of F is 0.2, and for $A = C = 2$, $c = 0.25$ it is 0.65.

Fig. 3 shows how the optimum value of retained data fraction F^* depends on the number m of second stage processors, for case 1 ($A_0(F) = 1/F^c$) with $A = 5$ and $C = 2$. When m grows, parallel data transfer and processing take less time in comparison to the filtering stage. Therefore, a larger fraction of data should be retained, in order to decrease the filtering time. Naturally, the optimal filtering intensity decreases when filtering is slow, i.e., for large c. In particular, when $c = 1\text{E}{-1}$ and $m \geq 70$, no filtering should take place.

The total processing time resulting from filtering the optimum size of data for different values of c and m is depicted in Fig. 4. Naturally, the schedule length decreases when more processors are used. This effect is stronger when c is large. Indeed, in this case, decreasing filtering intensity (F increases, $A_0(F)$ decreases), which is possible because of using a larger number of processors, has a large impact on the filtering time.

B. Sequential Communication, Linear Second Stage

When communication is sequential, a smaller number of second stage processors can be effectively used than in the case of parallel communication. Therefore, in Fig. 5, we present the schedule lengths obtained for different values of F and network parameters, $m = 10$, and for filtering case 1. In general, the visible tendencies are similar to the ones in Fig. 2. However, even when $A = C = 1$ and $c = 0.3$, the optimum value of F is much smaller than 1, i.e. filtering must be more intensive than for parallel communication. The best among values analyzed here is 0.4. Indeed, sequential communication is a bottleneck, and even very costly filtering can be beneficial, because it decreases the communication time.

The optimum data fractions F^* for $A = 5$ and $C = 2$ are presented in Fig. 6. The values are much smaller than in the case of parallel communication (see Fig. 3). As we already explained, intensive filtering decreases the communication time, which dominates in the schedule length. The fraction

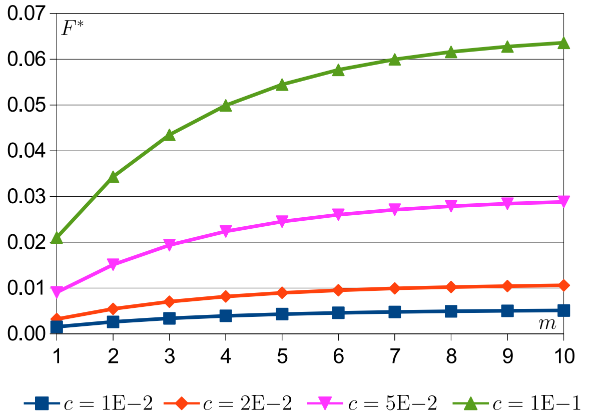

Fig. 6. F^* vs. m for sequential communication, linear second stage, case 1, $A = 5$, $C = 2$.

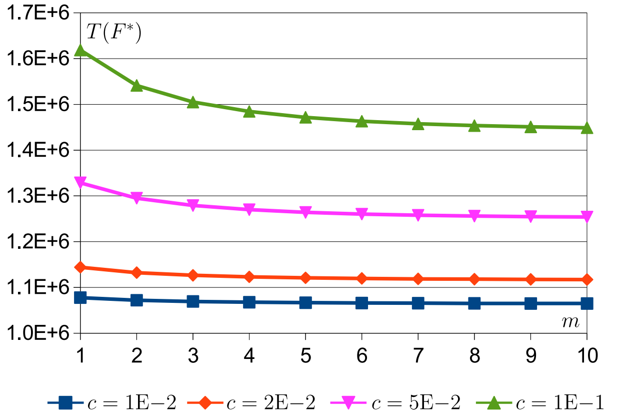

Fig. 7. $T(F^*)$ vs. m for sequential communication, linear second stage, case 1, $A = 5$, $C = 2$.

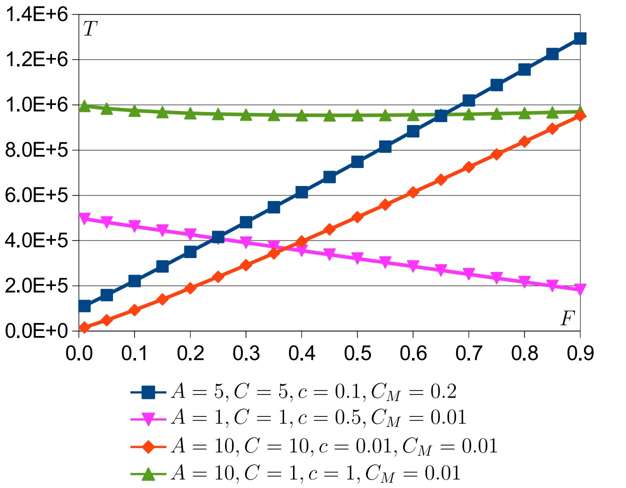

Fig. 8. T vs. F for parallel communication, loglinear second stage, case 4, $m = 100$.

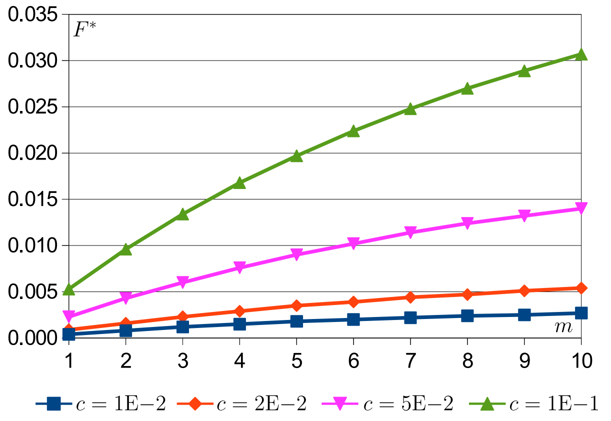

Fig. 9. F^* vs. m for sequential communication, loglinear second stage, case 1, $A = C = 3$, $C_M = 1\text{E}{-}2$.

of retained data grows with increasing m at a slower pace than in the case of parallel communication.

The optimum schedule lengths are shown in Fig. 7. Using a larger number of servers results in a shorter processing time, but the impact of changing m is smaller than in Fig. 4, because using more processors m does not decrease the communication time.

C. Parallel Communication, Loglinear Second Stage

Fig. 8 presents the schedule lengths T obtained for different values of F and network parameters, for parallel communication, loglinear second stage case 4. i.e. $A_0(F) = c(1 - F)$. Recall that in the case of linear second stage and case 4, the function $T(F)$ was always monotonous (Section IV-A, equations (22, 23)). It can be seen in Fig. 8 that when the second stage complexity is loglinear, $T(F)$ is also monotonous for many choices of network parameters, but not for all of them. In particular, when $A = 10$, $C = 1$, $c = 1$ and $C_M = 0.01$, the best among analyzed values of F is 0.45.

In cases 1 and 2 of data filtering complexity, the impact of increasing the number of processors m on the optimum value of F and schedule length is similar as for linear processing complexity. The main difference is that the time of merging the results also influences the results. When C_M is big, the merging stage becomes a bottleneck. Hence, more intensive filtering is required to reduce its duration and thus to obtain an optimum schedule.

D. Sequential Communication, Loglinear Second Stage

The differences between systems with sequential and parallel communication in the case of loglinear second stage are similar to those present when the second stage is linear. Since sequential communication is a bottleneck, optimum schedules are obtained by more intensive data filtering. Fig. 9 shows that even if m is large and filtering is slow, the fraction of retained load should be at most several percent in case 1 of filtering complexity. The optimum fractions obtained for cases 2, 3 and 4 are even smaller.

E. Parallel Communication, Quadratic Second Stage

When the second stage complexity is quadratic, intensive data filtering is required to obtain a short schedule by de-

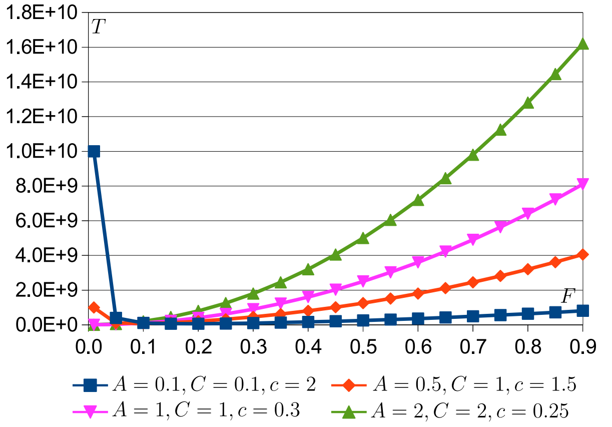

Fig. 10. T vs. F for parallel communication, quadratic second stage, case 1, $m = 100$.

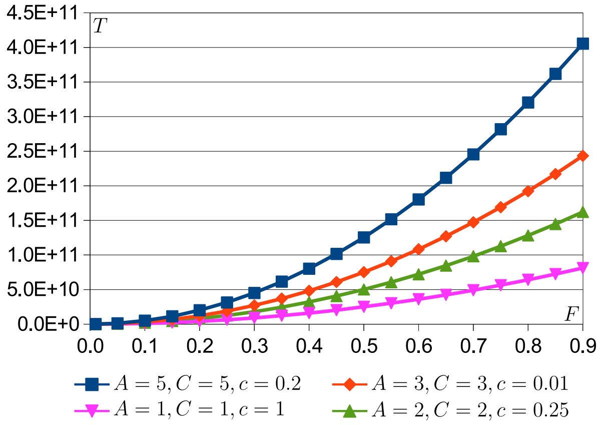

Fig. 11. T vs. F for sequential communication, quadratic second stage, case 1, $m = 10$.

creasing the duration of processing. It can be seen in Fig. 10, representing case 1 of the filtering complexity, that only when c is really large (i.e. $c > 1$), it may not be beneficial to decrease the data size as much as possible. In cases 2, 3 and 4 the fraction of retained data should be practically always as small as possible.

F. Sequential Communication, Quadratic Second Stage

When communication is sequential and the second stage complexity is quadratic, very intensive filtering should be used, even if it is costly. For all combinations of parameter values we studied, $T(F)$ is an increasing function (see Fig. 11). Although the optimum fraction F^* increases slightly with growing m, it stays below 0.01 for all settings we tested. Taking into account the practical limitations on F, this means that the smallest possible amount of data should be retained.

VI. Conclusions

In this paper we analyzed impact of data filtering intensity on the performance of systems with single expensive sensors. The analysis covered two-stage systems with generic representations of filtering algorithms, communication patterns and data processing methods. It appears that due to the interaction of nonlinear complexity of filtering, transmission time and further data processing stages, there exists filtering intensity which is optimum for the overall processing performance. These optima were investigated both analytically and computationally. It appeared that the communication subsystem and the second stage algorithm complexity have a large impact on the first stage filtering intensity. The ability of certain combinations of the system designs to scale is very limited. In systems with sequential communication gains from using parallel processors in the second stage are quickly diminishing because data transfer easily becomes a bottleneck. Processing with algorithms of high complexity (loglinear, quadratic) should be delegated to even further stages of data processing workflows because they incur needs for filtering intensities which may be hard to realize. Thus, by exposing scalability issues we demonstrated in this paper that designers of workflows with data filtering and distributed processing should strive for parallel data transfers and linear processing algorithms when handling large volumes of data from the sensors.

***Abstract*—Solving systems of linear equations is a critical component of nearly all scientific computing methods. Traditional algorithms that rely on synchronization become prohibitively expensive in computing paradigms where communication is costly, such as heterogeneous hardware, edge computing, and unreliable environments. In this paper, we introduce an s-step Approximate Conjugate Directions (s-ACD) method and develop resiliency measures that can address a variety of different data error scenarios. This method leverages a Conjugate Gradient (CG) approach locally while using Conjugate Directions (CD) globally to achieve asynchronicity. We demonstrate with numerical experiments that s-ACD admits scaling with respect to the condition number that is comparable with CG on the tested 2D Poisson problem. Furthermore, through the addition of resiliency measures, our method is able to cope with data errors, allowing it to be used effectively in unreliable environments.**

I. Introduction

Solving a system of linear equations $A\mathbf{x} = \mathbf{b}$ is a critical kernel in many applications, studied in great detail across applications, as well as for both iterative [1], [2] and direct solves [3], [4], [5], [6]. However, even iterative methods such as Krylov subspace methods, which have reduced serialization [7], require global synchronization. One of the most popular of such methods, the Conjugate Gradient (CG) method, computes global inner product at each iteration [8], [9]. The burden of this synchronization cost is increasing in modern computing environments due to two reasons: 1) as the number of parallel processes rapidly increases, the cost of global synchronization does too; 2) new environments are being considered for computationally expensive tasks, e.g. distributed (drones, power grid) and heterogeneous (accelerators) computing. Due to these factors, there is a critical need for asynchronous algorithms that can operate without the need for synchronization at every iteration and are able to handle the increase of data errors introduced by the increased number of failure points and unreliabilities.

The contributions of this paper are four-fold:

1) We introduce the s-step Approximate Conjugate Directions (s-ACD) method, which is a novel asynchronous Krylov-like linear system solver that achieves scaling with respect to the condition number that is comparable with CG on the tested 2D Poisson problem.
2) We introduce and investigate a demonstrative scenario that results in data errors by introducing unreliabilities into the calculations.
3) We develop resiliency measures that are used in s-ACD to detect corruption and could be used in other iterative methods.
4) We provide a comparative study using numerical experiments of the newly introduced developments.

In Section II, we begin by providing a background of iterative and asynchronous methods. Additionally, we briefly discuss *Skywing* [10], the collaborative autonomy framework that provides the agent-based approach that our implementation utilizes. Following this, Section III describes the s-ACD method for the solution of linear systems. Section IV discusses how the corruption of calculations in an unreliable environment are modeled and what situations the resulting corruption type and failure model might apply to. Then, Section V introduces methods that can be used for adding resiliency to iterative solvers, which results in the Resilient s-ACD method. Section VI provides a variety of numerical experiments developed to test the properties of the various methods to demonstrate their efficacy. Final concluding remarks are presented in Section VII.

This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344 and was supported by the LLNL-LDRD Program under Project No. 21-FS-007 and 22-ERD-045. The work of Agnieszka Międlar was supported by the National Science Foundation (NSF) under Grant DMS-2144181 and DMS-2324958. LLNL-CONF-849356.

II. Background

First, let us consider the Krylov subspace methods, a class of iterative methods where an initial guess of the solution to $A\mathbf{x} = \mathbf{b}$ is updated by iteratively building up a Krylov subspace span$\{\mathbf{b}, A\mathbf{b}, A^2\mathbf{b}, \ldots\}$. For symmetric positive definite matrices (SPD), the CG method, a particular Krylov solver, constructs a series of direction vectors $\mathbf{p}^\kappa$ that are A-conjugate to each other, as well as residual vectors $\mathbf{r}^\kappa$ that span the same Krylov subspace for iteration κ [8], [9]. Asymptotically, this method achieves convergence to a given tolerance in $\mathcal{O}(\sqrt{\operatorname{cond}(A)})$ iterations for a problem with condition number $\operatorname{cond}(A)$, making it the solver of choice for SPD matrices. However, global communication is needed to ensure the orthogonality necessary for the method to be robust.

To reduce the cost of global communication, methods such as the communication-avoiding s-step algorithms [11], [12] and communication hiding pipeline methods [13], [14] have been proposed in the synchronous case [15]. To address the issue of unreliable computing environments, some fault-tolerant or resilient CG methods are also available [16], [17], [18]. However, both of these classes of methods still require a high level of global synchronization for orthogonality to be preserved. In sufficiently distributed environments, these costs may become too restrictive, leading to the need of methods that do not require global synchronization and exact orthogonality.

For the solution of linear systems, chaotic or asynchronous methods [19], [20], [21] such as asynchronous Jacobi [22], [23], [24] have been developed to provide asynchronicity to already existing solvers. Although resiliency has been added to asynchronous Jacobi [25] to make it more fault-tolerant, the number of iterations scales proportional to the condition number, driving the need for more powerful asynchronous linear solvers.

A. Skywing

Edge computing, in which many small devices exist and work together in an unstructured setting, is a rapidly growing field in computing. Edge computing applications pose a unique set of challenges:

1) Both the physical and cyber environments are highly unreliable, as devices are placed in uncontrolled locations, e.g. homes or along power lines. As such, they can readily and unexpectedly break, get unplugged, or become compromised by cyberattacks.
2) The collection of participating devices is often quite heterogeneous, with a range of vendors and device capabilities.
3) The computational workflows are frequently streaming workflows that continually monitor and respond to some needs, rather than being a single computational task that terminates upon completion.

While traditional parallel computing paradigms, such as HPC or database computing, each have some of these challenges in common, the combination is unique to edge computing.

This paper details a new method in the *collaborative autonomy* paradigm, a class of methods in which multiple computational units work independently of each other but towards a common goal. Through adapting to unreliability present in the environment, these methods can provide reliable computing in unreliable environments.

Existing software platforms like Apache Hadoop [26] and Apache Spark [27] are designed for large-scale, “big data” computing work, but they largely implement leader-follower patterns and perform computing in batches. These approaches, while effective in controlled cluster environments, lack the resilience necessary to withstand common faults in edge computing applications such as hardware faults and, increasingly, cyber intrusions. Other parallel computing frameworks, such as OpenMP and MPI, do not necessarily rely on leader-follower paradigms, but are more naturally designed for well-controlled environments and terminating computational tasks.

Skywing is a software platform developed at Lawrence Livermore National Lab, which follows a publication/subscription paradigm. This allows any agent involved in the computation to subscribe or publish to a stream of data, and any data on a stream an agent is subscribed to is considered agnostic. Because of the unstructured nature, this enables increased flexibility, particularly for consensus based methods. Skywing aims to provide *method composition* to enable a modular approach, allowing users to utilize appropriate levels of resiliency for each module. The source code of Skywing is available on GitHub [10].

III. s-ACD

A. Problem Statement

Consider solving the linear system

$$A\mathbf{x} = \mathbf{b} \tag{1}$$

for $\mathbf{x} \in \mathbb{R}^m$, where $A \in \mathbb{R}^{m\times m}$ and $\mathbf{b} \in \mathbb{R}^m$. Assume the linear system is distributed across N agents according to a non-overlapping partition. Denote $A_i \in \mathbb{R}^{m_i\times m}$, $m_i < m$, as the block of rows of matrix A that are stored on agent i, $i = 1, \ldots, N$. Then

$$A = [A_1^T \cdots A_N^T]^T. \tag{2}$$

Given a SPD matrix A, two vectors $\mathbf{u}, \mathbf{v} \in \mathbb{R}^m$ are A-conjugate if and only if

$$\langle \mathbf{u},\ \mathbf{v}\rangle_A := \langle \mathbf{u},\ A\mathbf{v}\rangle = \mathbf{u}^T A\mathbf{v} = 0. \tag{3}$$

This paper establishes an asynchronous iterative method for solving $A\mathbf{x} = \mathbf{b}$, where agent i computes successive approximations to the solution vector $\mathbf{x}$, denoted $\mathbf{x}^0$, $\mathbf{x}^1$, etc…

B. Conjugate Directions Algorithm

Due to the high communication costs of edge computing environments, the classical Conjugate Gradient (CG) method cannot be directly used due to the need for significant synchronization when computing orthogonal direction vectors. However, we can utilize a variant called the Conjugate Directions

(CD) method by relaxing the global orthogonality constraints. The CD method, introduced by Hestenes and Stiefel in [9], is a generalization of the classical CG method. It solves the problem iteratively by computing a sequence of conjugate direction vectors. CG defines the new search direction based on a residual vector and the previously computed search directions, while the CD uses only the previous search directions. In this section, a short introduction to the CD method is given. For more details, see Hestenes and Stiefel [9].

Denote a vector $\mathbf{z} \in \mathbb{R}^m$ at iteration κ as $\mathbf{z}^\kappa$. Let $\mathbf{x}^0$ be an initial guess to the solution, then set the initial residual $\mathbf{r}^0 = \mathbf{b} - A\mathbf{x}^0 \in \mathbb{R}^m$ and select an arbitrary initial direction $\mathbf{p}^0 \in \mathbb{R}^m$. At each iteration $\kappa = 0, 1, \ldots$, the new solution approximation and the residual are computed as

$$\alpha^\kappa = \frac{\langle \mathbf{p}^\kappa,\ \mathbf{r}^\kappa \rangle}{\langle \mathbf{p}^\kappa,\ A\mathbf{p}^\kappa \rangle}, \tag{4}$$

$$\mathbf{x}^{\kappa+1} = \mathbf{x}^\kappa + \alpha^\kappa \mathbf{p}^\kappa, \tag{5}$$

$$\mathbf{r}^{\kappa+1} = \mathbf{r}^\kappa - \alpha^\kappa A\mathbf{p}^\kappa. \tag{6}$$

A new direction vector $\mathbf{p}^{\kappa+1}$ is chosen such that

$$\left\langle \mathbf{p}^{\kappa+1},\ \mathbf{p}^\iota \right\rangle_A = 0, \quad \iota = 0, \ldots, \kappa. \tag{7}$$

In the special case of the Conjugate Gradient (CG) method, we initialize the first direction vector as $\mathbf{p}^0 = \mathbf{r}^0$ and compute the subsequent direction vectors using a three-term recurrence relation, i.e.,

$$\beta^\kappa = -\frac{\|\mathbf{r}^{\kappa+1}\|_2}{\|\mathbf{r}^\kappa\|_2} = \frac{\langle \mathbf{r}^{\kappa+1},\ \mathbf{p}^\kappa \rangle_A}{\langle \mathbf{p}^\kappa,\ \mathbf{p}^\kappa \rangle_A}, \tag{8}$$

$$\mathbf{p}^{\kappa+1} = \mathbf{r}^{\kappa+1} - \beta^\kappa \mathbf{p}^\kappa. \tag{9}$$

The second formulation for β^κ in equation (8) represents the coefficient used to orthogonalize the new residual vector $\mathbf{r}^{\kappa+1}$ against the prior direction vector $\mathbf{p}^\kappa$ using Gram-Schmidt orthogonalization with the A-norm. In other words, $\mathbf{p}^{\kappa+1}$ is computed by A-orthogonalizing the new residual vector $\mathbf{r}^{\kappa+1}$ against the prior direction vector $\mathbf{p}^\kappa$. Our method combines the Conjugate Direction (CD) method globally while allowing each device to perform Conjugate Gradient (CG) steps locally. This approach achieves improved scaling compared to asynchronous Jacobi (for which some convergence is presented in [23]) without requiring the synchronization at each iteration as CG does.

C. Asynchronous s-Approximate Conjugate Directions (s-ACD)

Within the framework of the Conjugate Directions (CD) method, our objective is to design a fully asynchronous method. First, we introduce the following notation. Let $\mathbf{z}^{\psi(i,j,\kappa)} \in \mathbb{R}^m$ denote the local copy of the vector $\mathbf{z}$ from agent j received by node i at iteration κ. Let $\mathbf{z}_i \in \mathbb{R}^{m_i}$ denote the subvector of $\mathbf{z}$ corresponding to the block of elements that agent i is approximating. Each agent has access to its local portion A_i of the matrix A, the full right-hand side vector $\mathbf{b}$, and maintains a set of local variables: a local residual vector $\mathbf{r}^\kappa \in \mathbb{R}^m$, a local solution vector $\mathbf{x}^\kappa \in \mathbb{R}^m$, and a local direction vector $\mathbf{p}^\kappa \in \mathbb{R}^m$ for each iteration κ. In this context, $\kappa = 1, 2, \ldots$ represents the local iteration count of agent i. It is important to emphasize that the iteration count may vary between agents due to the asynchronous nature. Therefore, the agents may be at different stages of the iterative process at any given time.

Each agent will initialize its local vectors as follows for $\kappa = 0$:

$$\mathbf{x}^0 = \mathbf{0}, \tag{10}$$

$$\mathbf{r}^0 = \mathbf{b}, \tag{11}$$

$$\mathbf{p}^0 = \mathbf{b}. \tag{12}$$

Then, each agent will asynchronously advance from local iteration κ to $\kappa + 1$ using the following steps:

1) Compute the local matrix-vector product $\mathbf{w}^\kappa := A_i^T \mathbf{p}_i^\kappa$, where $\mathbf{w}^\kappa \in \mathbb{R}^m$ and $\mathbf{p}_i^\kappa \in \mathbb{R}^m$ is the subvector of $\mathbf{p}^\kappa$ corresponding to the block of elements that agent i is responsible for.
2) Asynchronously send the vector $\mathbf{w}^\kappa$ from step 1 and the vector $\mathbf{p}_i^\kappa$ to the other agents.
3) Receive available updates from other agents
$$\left\{ \mathbf{w}^{\psi(i,j,\kappa)},\ \mathbf{p}_j^{\psi(i,j,\kappa)} \right\}_{j \in \mathcal{U}_i^\kappa},$$
where $\mathcal{U}_i^\kappa$ is the set of updates, i.e. $j \in \mathcal{U}_i^\kappa$ if and only if agent i during its local iteration κ received an update from agent j.

Note that for the restart mechanism introduced later, $\mathbf{r}^\kappa$ and $\mathbf{x}^\kappa$ are also sent and received during these communications. Note that the non-blocking communication allows agents to send and receive information in an asynchronous fashion, which enables parallelism while avoiding the need for synchronization at every iteration.

Once the updates have been received, each agent i will assemble the *asynchronous direction vector* $\widetilde{\mathbf{p}}^\kappa \in \mathbb{R}^m$ blockwise according to the partition:

$$\widetilde{\mathbf{p}}^\kappa = \begin{cases} \mathbf{p}_i^\kappa, & j = i; \\ \mathbf{p}_j^{\psi(i,j,\kappa)}, & j \in \mathcal{U}_i^\kappa; \\ \mathbf{0}_j, & \text{otherwise}, \end{cases}$$

where $\mathbf{p}_j^{\psi(i,j,\kappa)}$ represents the partial local direction vector agent i received from agent j at iteration κ. Since the matrix A is SPD,

$$A\mathbf{z} = A^T\mathbf{z} = \sum_{j=1}^{N} A_j{}^T \mathbf{z}_j \text{ for } \mathbf{z} \in \mathbb{R}^m.$$

Thus, the exact A matrix-vector product of the asynchronous direction vector, denoted $\widetilde{\mathbf{w}}^\kappa := A\widetilde{\mathbf{p}}^\kappa$, can be computed using only the received and local partial matrix-vector products:

$$\begin{aligned} \widetilde{\mathbf{w}}^\kappa := A\widetilde{\mathbf{p}}^\kappa &= A_i^T \mathbf{p}_i^\kappa + \sum_{j \in \mathcal{U}_i^\kappa} A_j{}^T \mathbf{p}_j^{\psi(i,j,\kappa)}, \\ &= \mathbf{w}^\kappa + \sum_{j \in \mathcal{U}_i^\kappa} \mathbf{w}^{\psi(i,j,\kappa)}. \end{aligned}$$

We use the asynchronous direction vector $\widetilde{\mathbf{w}}$ to construct the *s-conjugate direction vector*, denoted $\mathbf{d}^\kappa$. It is essential that $\mathbf{d}^\kappa$ is A-conjugate to the s prior s-conjugate direction vectors $\mathbf{d}^{\kappa-s-1}, \dots, \mathbf{d}^{\kappa-1}$. To achieve this, we can employ a method such as Gram-Schmidt orthogonalization. In order to ensure conjugacy with prior direction vectors, additional storage of the prior s conjugate direction vectors, $\left\{\mathbf{d}^{\kappa-\ell}\right\}_{\ell=1}^{s}$, and their A-products, $\left\{\mathbf{v}^{\kappa-\ell}\right\}_{\ell=1}^{s}$, is necessary. These vectors are defined recursively, with $\mathbf{d}^0 = \widetilde{\mathbf{p}}^0$, $\mathbf{v}^0 = \widetilde{\mathbf{w}}^0$, and for $\kappa > 0$,

$$\begin{aligned} \mathbf{d}^\kappa &= \widetilde{\mathbf{p}}^\kappa - \sum_{\ell=1}^{\min(s,\kappa)} \mathrm{GS}_A\big(\widetilde{\mathbf{p}}^\kappa, \mathbf{d}^{\kappa-\ell}\big)\mathbf{d}^{\kappa-\ell}, \qquad (13)\\ \mathbf{v}^\kappa &= A\mathbf{d}^\kappa = \widetilde{\mathbf{w}}^\kappa - \sum_{\ell=1}^{\min(s,\kappa)} \mathrm{GS}_A\big(\widetilde{\mathbf{p}}^\kappa, \mathbf{d}^{\kappa-\ell}\big)\mathbf{v}^{\kappa-\ell}, \end{aligned}$$

where $\mathrm{GS}_A(\widetilde{\mathbf{p}}^\kappa, \mathbf{d}^{\kappa-\ell})$ is the magnitude of the projection of the vector $\widetilde{\mathbf{p}}^\kappa$ onto the vector $\mathbf{d}^{\kappa-\ell}$ under the A-inner product, i.e.,

$$\begin{aligned} \mathrm{GS}_A\big(\widetilde{\mathbf{p}}^\kappa, \mathbf{d}^{\kappa-\ell}\big) &:= \frac{\left\langle \widetilde{\mathbf{p}}^\kappa,\ \mathbf{d}^{\kappa-\ell}\right\rangle_A}{\left\langle \mathbf{d}^{\kappa-\ell},\ \mathbf{d}^{\kappa-\ell}\right\rangle_A},\\ &= \frac{\left\langle \widetilde{\mathbf{p}}^\kappa,\ \mathbf{v}^{\kappa-\ell}\right\rangle}{\left\langle \mathbf{d}^{\kappa-\ell},\ \mathbf{v}^{\kappa-\ell}\right\rangle}. \end{aligned}$$

Note that the exact matrix-vector product $\mathbf{v}^\kappa = A\mathbf{d}^\kappa$ is ensured due to the definition of $\widetilde{\mathbf{w}}^\kappa := A\widetilde{\mathbf{p}}^\kappa$.

In the following theorem, we prove that $\mathbf{d}^\kappa$ is A-conjugate to the prior s conjugate direction vectors $\left\{\mathbf{d}^{\kappa-\ell-1}\right\}_{\ell=1}^{s}$.

Theorem 1. *Let $\mathbf{d}^\kappa, \mathbf{v}^\kappa$ be defined as in* (13). *Then for $\ell = 1, \dots, \min(s,\kappa)$,*

$$\left\langle \mathbf{d}^\kappa,\ \mathbf{d}^{\kappa-\ell}\right\rangle_A = 0.$$

Proof. We proceed by induction on the iteration number κ. For $\kappa = 0$, the statement holds trivially. Suppose that the statement holds true for $\kappa = 0, \dots, \iota - 1$. We now show the statement holds true for $\kappa = \iota$.

By the definition of $\mathbf{d}^\kappa$, for $1 \le \ell \le \min(s,\kappa)$

$$\begin{aligned} &\left\langle \mathbf{d}^\kappa,\ \mathbf{d}^{\kappa-\ell}\right\rangle_A\\ &= \left\langle \widetilde{\mathbf{p}}^\kappa - \sum_{\nu=1}^{\min(s,\kappa)} \mathrm{GS}_A\big(\widetilde{\mathbf{p}}^\kappa, \mathbf{d}^{\kappa-\nu}\big)\mathbf{d}^{\kappa-\nu},\ \mathbf{d}^{\kappa-\ell} \right\rangle\\ &= \left\langle \widetilde{\mathbf{p}}^\kappa,\ \mathbf{d}^{\kappa-\ell}\right\rangle_A -\\ &\sum_{\nu=1}^{\min(s,\kappa)} \mathrm{GS}_A\big(\widetilde{\mathbf{p}}^\kappa, \mathbf{d}^{\kappa-j}\big)\left\langle \mathbf{d}^{\kappa-\nu},\ \mathbf{d}^{\kappa-\ell}\right\rangle_A. \end{aligned}$$

By the induction hypothesis, $\left\langle \mathbf{d}^{\kappa-\nu},\ \mathbf{d}^{\kappa-\ell}\right\rangle_A = 0$ for all $\nu = 1, \dots, \min(s,\kappa)$ such that $\nu \neq \ell$. Hence,

$$\begin{aligned} &\left\langle \mathbf{d}^\kappa,\ \mathbf{d}^{\kappa-\ell}\right\rangle\\ &= \left\langle \widetilde{\mathbf{p}}^\kappa,\ \mathbf{d}^{\kappa-\ell}\right\rangle_A - \mathrm{GS}_A\big(\widetilde{\mathbf{p}}^\kappa, \mathbf{d}^{\kappa-\ell}\big)\left\langle \mathbf{d}^{\kappa-\ell},\ \mathbf{d}^{\kappa-\ell}\right\rangle_A,\\ &= \left\langle \widetilde{\mathbf{p}}^\kappa,\ \mathbf{d}^{\kappa-\ell}\right\rangle_A - \frac{\left\langle \widetilde{\mathbf{p}}^\kappa,\ \mathbf{d}^{\kappa-\ell}\right\rangle_A}{\left\langle \mathbf{d}^{\kappa-\ell},\ \mathbf{d}^{\kappa-\ell}\right\rangle_A}\left\langle \mathbf{d}^{\kappa-\ell},\ \mathbf{d}^{\kappa-\ell}\right\rangle_A,\\ &= 0. \end{aligned}$$

Thus at iteration κ, we have that $\left\langle \mathbf{d}^\kappa,\ \mathbf{d}^{\kappa-\ell}\right\rangle_A = 0$ for $\ell = 1, \dots, \min(s,\kappa)$. □

Using this definition of $\mathbf{d}^\kappa$, we can proceed in a manner similar to the Conjugate Directions (CD) method. Define the step size

$$\alpha^\kappa := \frac{\langle \mathbf{r}^\kappa,\ \mathbf{d}^\kappa\rangle}{\langle \mathbf{d}^\kappa,\ \mathbf{v}^\kappa\rangle}. \qquad (14)$$

Using the step size α^κ, the approximate solution and residual vectors are updated

$$\mathbf{x}^{\kappa+1} := \mathbf{x}^\kappa + \alpha^\kappa \mathbf{d}^\kappa, \qquad (15)$$

$$\mathbf{r}^{\kappa+1} := \mathbf{r}^\kappa - \alpha^\kappa \mathbf{v}^\kappa. \qquad (16)$$

Finally, the next local direction vector is computed by enforcing the new residual $\mathbf{r}^{\kappa+1}$ to be s-conjugate with the s-conjugate direction vectors $\mathbf{d}^{\kappa-\ell}$, $0 \le \ell \le \min(s,\kappa) - 1$,

$$\mathbf{p}^{\kappa+1} := \mathbf{r}^{\kappa+1} - \sum_{\ell=0}^{\min(s,\kappa)-1} \mathrm{GS}_A\big(\mathbf{r}^{\kappa+1}, \mathbf{d}^{\kappa-\ell}\big)\mathbf{d}^{\kappa-\ell}. \qquad (17)$$

Restarting: Due to the asynchronous nature of the s-ACD algorithm, it is possible that the direction vectors, and consequently the approximate solution vectors, differ between agents at each local iteration. To address the potential stagnation that can result from such a scenario, we incorporate an asynchronous restarting procedure. By introducing these asynchronous restarts, we provide an opportunity for the agents to realign their progress, mitigate the effects of asynchronicity, and make collective advancements towards the true solution. The frequency of the restarts can be adjusted based on the specific requirements and characteristics of the problem being solved. As mentioned earlier, during the s-ACD communication stage, each agent will send its local solution vector $\mathbf{x}^\kappa$ and local residual vector $\mathbf{r}^\kappa$. This exchange allows each agent to have an updated understanding of the current state of the (global) computation, enabling more efficient choices of direction vectors for the subsequent iterations.

The algorithm is restarted periodically after detecting stagnation in the residual norm. The detection of stagnation and following restart is purely a local decision and calculation. The restarting will be performed if a specified number of iterations have passed since the last restart and the residual norm has decreased less than a prescribed tolerance. This involves resetting the necessary variables, such as solution vectors, residual vectors, and direction vectors, to a common starting point. By doing so, the agents can restart from a more unified state and resume the algorithm to overcome the convergence stagnation. When a restart is deemed necessary, the local approximation to the asynchronous residual vector $\widetilde{\mathbf{r}}^\kappa$ is constructed by averaging the most recent updates $\left\{\mathbf{r}^{\psi(i,j,\kappa)}\right\}$ received from each neighbor. If no updates have been received from agent j, then set $\mathbf{r}^{\psi(i,j,0)} := \mathbf{b}$, i.e.,

$$\widetilde{\mathbf{r}}^\kappa = \frac{1}{N}\sum_{j=1}^{N}\mathbf{r}^{\psi(i,j,\kappa)},$$

where $\mathbf{r}^{\psi(i,i,\kappa)} = \mathbf{r}^\kappa$. Then, local approximation to the asynchronous solution vector $\widetilde{\mathbf{x}}^\kappa$ is computed by averaging the most recently received solution vectors $\left\{\mathbf{x}^{\psi(i,j,\kappa)}\right\}$. If no updates have been received from an agent j, then set $\mathbf{x}^{\psi(i,j,0)} = \mathbf{0}$, i.e.,

$$\widetilde{\mathbf{x}}^\kappa = \frac{1}{N}\sum_{j=1}^{N}\mathbf{x}^{\psi(i,j,\kappa)}, \tag{18}$$

where $\mathbf{x}^{\psi(i,i,\kappa)} = \mathbf{x}^\kappa$. Note that

$$\begin{aligned}\mathbf{b} - A\widetilde{\mathbf{x}}^\kappa &= \mathbf{b} - \frac{1}{N}\sum_{j=1}^{N}A\mathbf{x}^{\psi(i,j,\kappa)},\\ &= \frac{1}{N}\sum_{j=1}^{N}\Big(\mathbf{b} - A\mathbf{x}^{\psi(i,j,\kappa)}\Big),\\ &= \frac{1}{N}\sum_{j=1}^{N}\mathbf{r}^{\psi(i,j,\kappa)},\\ &= \widetilde{\mathbf{r}}^\kappa.\end{aligned}$$

Thus, the restarting procedure maintains the accuracy of the residual. Additionally, we found empirically that explicitly recomputing the local partial residual as

$$\widetilde{\mathbf{r}}_i^\kappa = \mathbf{b}_i - A_i\widetilde{\mathbf{x}}^\kappa$$

generally improves convergence and enables convergence for some non-symmetric matrices A. Modifications to (13) and (17) are required to account for the possibility that the s prior s-conjugate direction vectors may no longer be consistent after a restart. To address this issue, we introduce the set $\mathcal{S}$, which represents the subset of "active" s-conjugate direction vectors. After a restart, this set is reset to $\mathcal{S} = \emptyset$. After each iteration, we update $\mathcal{S}$ by taking the union of the set with the newly computed direction vector $\mathbf{d}^\kappa$, i.e., $\mathcal{S} = \mathcal{S} \cup \{\mathbf{d}^\kappa\}$. Only the vectors within the set $\mathcal{S}$ can be used in the s-step orthogonalization process. Thus, (13) and (17) need to be modified accordingly, i.e.,

$$\mathbf{d}^\kappa = \widetilde{\mathbf{p}}^\kappa - \sum_{\ell=1}^{\min(s,|\mathcal{S}|)}\mathrm{GS}_A\big(\widetilde{\mathbf{p}}^\kappa, \mathbf{d}^{\kappa-\ell}\big)\mathbf{d}^{\kappa-\ell}, \tag{19}$$

$$\mathbf{v}^\kappa = A\mathbf{d}^\kappa = \widetilde{\mathbf{w}}^\kappa - \sum_{\ell=1}^{\min(s,|\mathcal{S}|)}\mathrm{GS}_A\big(\widetilde{\mathbf{p}}^\kappa, \mathbf{d}^{\kappa-\ell}\big)\mathbf{v}^{\kappa-\ell},$$

and

$$\mathbf{p}^{\kappa+1} := \mathbf{r}^{\kappa+1} - \sum_{\ell=0}^{\min(s,|\mathcal{S}|-1)}\mathrm{GS}_A\big(\mathbf{r}^{\kappa+1}, \mathbf{d}^{\kappa-\ell}\big)\mathbf{d}^{\kappa-\ell}. \tag{20}$$

To complete the restarting procedure, all the agents set their local vectors accordingly: $\mathbf{x}^\kappa = \widetilde{\mathbf{x}}^\kappa$, $\mathbf{p}^\kappa = \widetilde{\mathbf{r}}^\kappa$, and $\mathbf{r}^\kappa = \widetilde{\mathbf{r}}^\kappa$.

IV. Data Errors and Corruption Modeling

As increased parallelism and new environments are considered, the likelihood of errors increases and so too does the costs associated with data errors. Practical Krylov methods introduce restarts to handle errors introduced through finite precision calculations. However, the restarts alone are not enough when larger or more discrete data errors happen, the methods can lose the underlying subspace and orthogonality properties that they rely on. Thus, additional resiliency measures must be considered in environments where such large disruptions are expected. Even the s-ACD method above, which has the self-correcting restart mechanism, is still susceptible to errors introduced through numerous pathways including malicious injection, disconnection of agents, corruption introduced into the signal, delays in communication, agents entering a failed state, bit-errors introduced locally, etc. We focus on data corruption where the original data being communicated at a single iteration is replaced by other values.

One important note is that we only corrupt one vector at a time. Because the $\mathbf{x}$ and $\mathbf{r}$ vectors are only used during the restart, to accurately model the errors, we must force a restart after a corruption occurs, otherwise corruptions in $\mathbf{x}$ and $\mathbf{r}$ may be masked. To understand this, imagine we corrupt a transmission of vector $\mathbf{x}$ at iteration ι, and we do not force a restart. The receiving agent receives this corrupted $\mathbf{x}$ at iteration κ, stores it, but it does not use it in the calculation because a restart does not happen. However, at iteration $\kappa' > \kappa$ when a restart occurs, the transmitted vector $\mathbf{x}$ from iteration κ' is stored (overwriting the previous corrupted vector with an uncorrupted vector) and is used during the restart. Thus, the corrupted $\mathbf{x}$ that was stored at iteration κ was overwritten and never used, leading to the corruption being masked.

The failure model we consider is that of *one-off* corruption, meaning that at some point in time, one or more agents all have corruption applied to one of the vectors transmitted during that iteration. This failure model has been chosen for multiple reasons:

- such corruption clearly partitions time into a "before" and "after" corruption portions, where the "before" portion should be identical to the uncorrupted case,
- one can easily visually identify where the corruption occurs,
- it is simple to implement,
- it forms the basis for other forms of corruption and can relatively easily be generalized to the other forms.

V. Resilient s-ACD

While the s-ACD method has the self-correcting restart mechanism that allows it to be resilient to the presence of non-orthogonal directions introduced by the asynchronous approach (and somewhat resilient to other data errors), additional resiliency measures would be able to decrease the impact of other data errors. In this section, we introduce resiliency in

Algorithm 1 s-Approximate Asynchronous Conjugate Directions.

```
for node $i \leftarrow 1$ to $N$ do
  INPUT: global vector $\mathbf{b}$, local portion $A_i$ of the $A$ matrix
  OUTPUT: Each node $i$ has a local approximation $\mathbf{x}^\kappa$ to the solution vector $\mathbf{x}$
  for $j \leftarrow 1$ to $N, j \neq i$ do
    initialize $\mathbf{x}_j = \mathbf{0}$, $\mathbf{r}_j = \mathbf{b}_j, \mathbf{p}_j = \mathbf{b}_j$
  end for
  for $\kappa \leftarrow 0$ to $t_{\mathtt{max}}$ do
    $\mathbf{w}^\kappa \leftarrow A_i^T \mathbf{p}^\kappa$
    Send $\mathbf{w}^\kappa$, $\mathbf{p}_i^\kappa$, $\mathbf{x}^\kappa$, $\mathbf{r}^\kappa$
    $\left\{\mathbf{w}^{\psi(i,j,\kappa)}, \mathbf{p}_j^{\psi(i,j,\kappa)}, \mathbf{x}^{\psi(i,j,\kappa)}, \mathbf{r}^{\psi(i,j,\kappa)}\right\}_{j \in \mathcal{U}_i^\kappa} \leftarrow$ ReceiveAsync
    Set $\mathcal{U}_i^\kappa :=$ set of node indices from which updates were received
    $\widetilde{\mathbf{p}}_i^\kappa = \mathbf{p}_i^\kappa$
    $\widetilde{\mathbf{w}}^\kappa = \mathbf{w}^\kappa$
    for $j \in \mathcal{U}_i^\kappa$ do
      $\widetilde{\mathbf{p}}_j^\kappa = \mathbf{p}_j^{\psi(i,j,\kappa)}$
      $\widetilde{\mathbf{w}}^\kappa = \widetilde{\mathbf{w}}^\kappa + \mathbf{w}^{\psi(i,j,\kappa)}$
      $\mathbf{x}^{\psi(i,j,\ell)} = \mathbf{x}^{\psi(i,j,\kappa)}$
      $\mathbf{x}^{\psi(i,j,\ell)} = \mathbf{r}^{\psi(i,j,\kappa)}$
    end for
    $\mathbf{d}^\kappa = \widetilde{\mathbf{p}}^\kappa - \sum_{\nu=1}^{\min(s,|\mathcal{S}|)} \mathrm{GS}_A(\widetilde{\mathbf{p}}^\kappa, \mathbf{d}^{\kappa-\nu})\mathbf{d}^{\kappa-\nu}$
    $\mathbf{v}^\kappa = \widetilde{\mathbf{w}}^\kappa - \sum_{\nu=1}^{\min(s,|\mathcal{S}|)} \mathrm{GS}_A(\widetilde{\mathbf{p}}^\kappa, \mathbf{d}^{\kappa-\nu})\mathbf{v}^{\kappa-\nu}$
    $\alpha^\kappa = \langle \mathbf{r}^\kappa,\ \mathbf{d}^\kappa \rangle / \langle \mathbf{d}^\kappa,\ \mathbf{v}^\kappa \rangle$
    $\mathbf{x}^{\kappa+1} = \mathbf{x}^\kappa + \alpha^\kappa \mathbf{d}^\kappa$
    $\mathbf{r}^{\kappa+1} = \mathbf{r}^\kappa - \alpha^\kappa \mathbf{v}^\kappa$

    $$\mathbf{p}^{\kappa+1} = \mathbf{r}_i^{\kappa+1} - \sum_{\nu=0}^{\min(s,|\mathcal{S}|-1)} \mathrm{GS}_A(\mathbf{r}^{\kappa+1}, \mathbf{d}^{\kappa-\nu})\mathbf{d}^{\kappa-\nu} \tag{21}$$

    if $\|\mathbf{r}^{\kappa+1}\| / \|\mathbf{b}\| < \epsilon$ then

      return $\mathbf{x}^{\kappa+1}$
    end if
    if ShouldRestart($\mathbf{r}^{\kappa+1}$, $\kappa$) then
      $\mathbf{x}^\kappa = \frac{1}{N}\left(\mathbf{x}^\kappa + \sum_{j=0,j\neq i}^{N} \mathbf{x}^{\psi(i,j,\ell)}\right)$
      $\mathbf{r}^\kappa = \frac{1}{N}\left(\mathbf{r}^\kappa + \sum_{j=0,j\neq i}^{N} \mathbf{x}^{\psi(i,j,\ell)}\right)$
      $\mathbf{r}_i^\kappa = \mathbf{b}_i - A_i \mathbf{x}^\kappa$
      $\mathbf{p}^\kappa = \mathbf{r}^\kappa$
      $\mathcal{S} = \emptyset$
    end if
  end for
end for
```

two stages: the detection stage and the correction stage. The benefit of this approach is to separate the tasks of identifying deviations from "normal" behavior and the ability to correct said behavior.

A. Detection Stage

To detect data errors, we need to be able to identify when the method is in a state that is not "normal." In CG, this can be done through the orthogonality conditions or monotonically decreasing quantities — which if violated indicate that something is not as expected. However, in order to achieve asynchronicity, s-ACD loses the orthogonality conditions. Instead, we can develop different detection schemes leveraging knowledge from CG.

1) Checksum: The checksum method is based off on idea of checksums, i.e., calculating a quantity locally, transmitting it with the information, and checking that the received quantity, when recalculated locally, is consistent. One simple way of doing this is using the inner-product of two vectors. The downside of this method is that it relies on a trustworthy sender (the sender can adjust both the checksum and sent vectors accordingly) and requires additional communication. However, it comes with a number of pros, e.g., it requires only a small amount of local computation (perhaps some that is being performed anyway), provides per-agent detection, puts constraints on the possible malicious vectors that can be used, and is cheap and easy to implement. In particular, we use $\mathbf{p}^T\mathbf{w}$, where only the local portions of both vectors are used (as only the local portion of $\mathbf{p}$ is sent and available to check with). This is done by calculating the checksum before an agent sends its vectors (Alg. 2), and comparing the received value against the recalculated value at the arrival (Alg. 3).

Algorithm 2 Checksum calculation before sending.

```
$\gamma^\kappa \leftarrow \mathbf{w}_i^{\kappa T} \mathbf{p}_i^\kappa$
Send $\mathbf{w}^\kappa$, $\mathbf{p}_i^\kappa$, $\mathbf{x}^\kappa$, $\mathbf{r}^\kappa$, $\gamma^\kappa$
```

Algorithm 3 Checksum calculation after receiving.

```
for $j \in \mathcal{U}_k^\kappa$ do
  if $\gamma^\kappa == \mathbf{w}^{\psi(i,j,\kappa)^T} \mathbf{p}_j^{\psi(i,j,\kappa)}$ then
    $\widetilde{\mathbf{p}}_j^\kappa = \mathbf{p}_j^{\psi(i,j,\kappa)}$
    $\widetilde{\mathbf{w}}^\kappa = \widetilde{\mathbf{w}}^\kappa + \mathbf{w}^{\psi(i,j,\kappa)}$
    $\mathbf{x}^{\psi(i,j,\ell)} = \mathbf{x}^{\psi(i,j,\kappa)}$
    $\mathbf{x}^{\psi(i,j,\ell)} = \mathbf{r}^{\psi(i,j,\kappa)}$
  else
    Mark update $\kappa$ from agent $j$ as corrupted
  end if
end for
```

2) General: As mentioned previously, one way of detecting corruption is to detect when the result from a calculation is different from what it should be. One can use "metrics" (also called *indicator variables*), which are simple scalars that change over time, and see when they change in unexpected ways. This allows us to adapt to different convergence speeds and parts of the convergence without relying too heavily on tunable parameters. While we lose precise orthogonality conditions and monotonically decreasing quantities in s-ACD, we do still have some relations that are roughly predictable. For example, as iterations progress, $\langle \mathbf{d}^\kappa,\ \mathbf{v}^\kappa\rangle$, $\langle \mathbf{p}^\kappa,\ \mathbf{p}^\kappa\rangle_A$, and $\langle \mathbf{r}^\kappa,\ \mathbf{r}^\kappa\rangle$ all tend to decrease. Thus, we can monitor these values and determine when they increase between successive iterations more than expected.

Because there is significant variation of the metrics over the course of the solve, we should not look directly at the successive difference of a timeseries metric ξ between iterations. Instead, we apply a smoothing step, take the difference between the smoothed values, and compare that against a smoothed version of the difference of smoothed values. When the ratio of these quantities gets above a specified value (which tends to be quite robust), we mark this iteration as corrupted.

To perform the smoothing we use a running average with a window size σ of 15 iterations, which allows us to perform these calculations online. If we let ξ be a $\mathbb{R}^\kappa$ timeseries with ξ^i being the value at point i in time, then we define the smoothed timeseries as

$$\mathrm{smooth}(\xi, \sigma, i) = \frac{\sum\limits_{j=\max(0,i-\sigma)}^{i} \xi^j}{\min(i, \sigma)}.$$

We define the relative successive difference to be

$$\mathrm{diff}(\xi, i) = \frac{\xi^{i+1} - \xi^i}{|\xi^i|}.$$

We consider a timeseries ξ to be corrupted at time i if $\mathrm{smooth}(\mathrm{diff}(\mathrm{smooth}(\xi, size, i), i), size, i) > \epsilon$ for some tolerance $\epsilon > 0$.

In particular, we track the timeseries defined by $\langle \mathbf{v}^\kappa,\ \mathbf{d}^\kappa\rangle$ and $\langle \mathbf{r}^\kappa,\ \mathbf{r}^\kappa\rangle$. The biggest drawbacks of this method are that it does not provide per-agent detection and introduces additional computational steps. However, it is easily generalizable to other methods, requires only local computation, doesn't rely on a trustworthy sender, and the computational complexity can be mitigated by updating the differences and smoothed timeseries at each time step rather than recalculating the entire timeseries.

3) Algorithm-Based: The final class of detection methods that we will discuss are the algorithm-based metrics. These rely on knowing specific analytical relations within the calculations, such as the orthogonality conditions in CG. Although we do not have the orthogonality conditions, we do know that, $A\mathbf{x} = \mathbf{b}$ and $\mathbf{r} = \mathbf{b} - A\mathbf{x}$. There are many solution approximations and associated residuals that can be calculated, all of which should be similar to each other. Thus, if one of these vectors differs significantly from the others (or what is expected via explicit calculation of the residual), this indicates that a corruption is likely to have occurred. We compare the incoming solution and residual vectors from other agents against the updated value of the currently considered solution and residual, as well as the most recent solution and residual that have been checked by the detection mechanisms and identified as uncorrupted.

Due to the many comparisons and matrix-vector products involved, this is a computationally expensive check. However, it doesn't require any additional communication and provides per agent detection. Furthermore, the adaptive properties of the general metrics can be explored, although they are not currently used in our implementation (Alg 4).

Algorithm 4 Algorithm-based check for agent i, which compares the proposed update when applied to the incoming solution and residual vectors from agent j, with baseline updated solution and residual vectors.

```
for j=1, ..., N do
  $\mathcal{X}_j := \mathbf{x}^{\psi(i,j,\kappa)} + \alpha^\kappa \mathbf{d}^\kappa$
  $\mathcal{R}^{exp} := \mathbf{b}_i - A_i \mathcal{X}_j$
  $\mathcal{R}^{iter} := \mathbf{r}^{\psi(i,j,\kappa)} + \alpha^\kappa \mathbf{d}^\kappa$
  $\mathbf{x}^S$ := the last $\mathbf{x}^{\psi(i,j,\iota)}$ vector considered to be uncorrupted
  $\mathbf{r}^S$ := the last $\mathbf{x}^{\psi(i,j,\iota)}$ vector considered to be uncorrupted
  for $(x, r) \in ((\mathbf{x}^\kappa, \mathbf{r}^\kappa), (\mathbf{x}^S, \mathbf{r}^S))$ do
    $\mathfrak{X}_j := x + \alpha^\kappa \mathbf{d}^\kappa$
    $\mathfrak{R}^{exp} := \mathbf{b}_i - A_i \mathfrak{X}_j$
    $\mathfrak{R}^{iter} := r - \alpha^\kappa \mathbf{v}^\kappa$
    if $(\frac{||\mathfrak{X}_j||-||\mathcal{X}_j||}{min(||\mathfrak{X}_j||,||\mathcal{X}_j||)} > \epsilon_1)$ or $(\frac{||\mathfrak{R}^{exp}||-||\mathcal{R}^{exp}||}{min(||\mathfrak{R}^{exp}||,||\mathcal{R}^{exp}||)} > \epsilon_2)$ or $(\frac{||\mathfrak{R}^{iter}||-||\mathcal{R}^{iter}||}{min(||\mathfrak{R}^{iter}||,||\mathcal{R}^{iter}||)} > \epsilon_3)$ then
      Agent $i$ considers agent $j$'s communication at iteration $\iota$ as corrupted.
    end if
  end for
end for
```

B. Correction Phase

Once a transmission has been identified to contain a data error, a correction must be performed. Under traditional methods, this might require restarting the entire computation [28], however, we are able to utilize a more nuanced approach which reduces the amount of redundant calculations. We introduce a simple rejection approach, which performs well for the class of investigated data errors. The simplest form of correction is to ignore the updates associated with an iteration that has been flagged as corrupted. If a specific agent has been identified as the source of the corruption, it is possible to ignore the updates from that agent only.

VI. Numerical Experiments

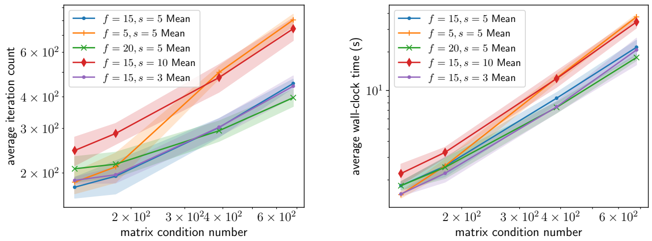
To demonstrate the performance of the newly proposed s-ACD and resiliency methods, a number of numerical experiments are conducted. These experiments are performed on a MacBook Pro (2019) with a 2.4GHz 8-Core Intel Core i9 CPU, and 64GB of 2667 MHz DDR4 Memory. Unless otherwise stated, experiments are run with four agents. When a 2D Poisson problem is used, it has homogeneous Dirichlet boundary conditions and is discretized with first order central finite differences with a right-hand side $g(x, y) = \sin(\pi x)\sin(\pi y)$ for a point at location (x, y). When a random SPD matrix is used, it has a condition number of 50, with a right-hand side defined by a vector of all ones.

Fig. 1 displays a variety of restarting frequencies f and s-step sizes s when using s-ACD over five runs, where the mean of the runs is plotted in a solid line and the 95% confidence interval displayed in the corresponding shaded region. We can see that having a large s-step size s relative to restart size f, such as the cases of $f = 15, s = 10$ and $f = 5, s = 5$ results in both a higher iteration count and a slower convergence. This is likely due to when the s-step size and restart sizes are similar, the number of full s sized s-step updates performed is small. There was not a significant difference in the other tested combinations. For the following tests, $f = 15$ and $s = 5$.

Fig. 2 demonstrates the scaling of the s-ACD method against the scaling of the asynchronous Jacobi and serial CG methods when changing the number of rows (and hence the condition number) of a 2D Poisson matrix with five runs, with the means plotted with solid lines and the 95% confidence interval plotted in the shaded region. We can see that our s-ACD method achieves better asymptotic scaling than the asynchronous Jacobi method, although not as good as serial CG, especially for larger condition numbers. The scaling achieved on systems with condition numbers in the range of 10^2 to 10^3 is comparable with CG, with a significant improvement in the absolute number of iterations compared to asynchronous Jacobi. The development of convergence theory could be used to better understand the results seen, and asynchronous preconditioning can improve the convergence further.

A 100×100 random SPD problem is used for Fig. 3, where different vectors are corrupted during communication, and the resulting l^2-norms are plotted for each agent, demonstrating the impact of these data errors on the metrics. The metrics are very noisy, due to the loss of orthogonality and independent nature of each agent. We see spikes around each restart, as the local residual and solution vectors are changed, potentially significantly, compared to the previous iteration. We observe that in all cases, the convergence slows down after the corruption at one second, while in the $\mathbf{x}, \mathbf{p}, \mathbf{r}$ cases, there is a significant spike in the observed metrics. This is because corrupting the $\mathbf{x}, \mathbf{r}, \mathbf{p}$ vectors (directly or indirectly) permanently destabilizes the subspace and has immediate consequences, while the $\mathbf{w}$ vector is recalculated at each iteration from the $\mathbf{p}$ vector.

The varying steps of the "generic" correction scheme are demonstrated in Fig. 4, which is a random SPD problem with a data error occurring after one second, separating out the global post-processed metrics from the metrics visible to each agent (Fig. 4a). We see that the global post-processed metric is very smooth, ignoring the spike at each restart, indicating that the overall behavior of the agents approximates is similar to the behavior of CG. We observe that the local metrics do correlate strongly with the trend of the global post-processed metrics, indicating that they can be used as a proxy for the overall convergence. While in synchronous CG, we would expect these metrics to be monotonically decreasing, the asynchronous algorithm removes these guarantees. Thus, the procedure of smoothing and successive differences must be used and through this adaptive method is able to detect when the corruption happens via local computations. It is clear that after these procedures (Fig. 4e) the aberration can be easily detected.



(a) Comparing by iteration count.

(b) Comparing by time.

Fig. 1: Comparing the scaling of different restarting frequencies f and s-step sizes s for s-ACD on a 2D Poisson problem discretized with finite differences with four agents and five runs proceeding until a tolerance of 1e-5 is reached. The shaded region represent a 95% confidence interval.

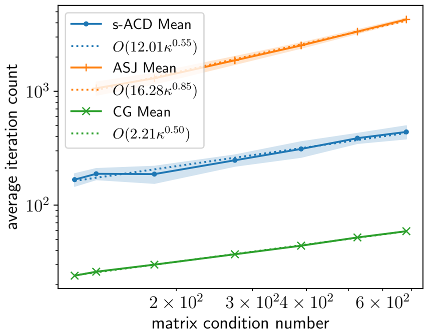


Fig. 2: Scaling of s-ACD vs asynchronous Jacobi (ASJ) and serial CG method on a 2D Poisson problem discretized with finite differences with four agents and five runs proceeding until a tolerance of 1e-5 is reached. The shaded region represents the 95% confidence interval.

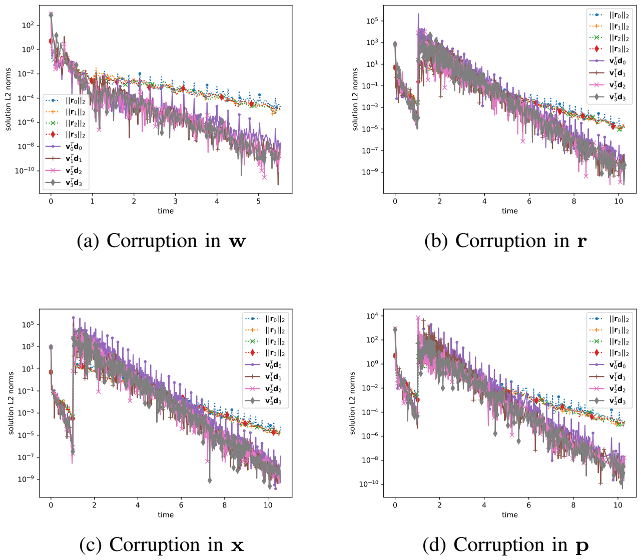
Finally, Fig. 5 shows the residual of a 100×100 random SPD problem for four agents for the s-ACD method with and without the resiliency measures, for 30 runs with the mean of runs plotted as the solid line, while the dotted lines correspond to individual runs and the shaded region to the 95% confidence interval. By enabling all three sets of resiliency measure discussed above, the data errors are successfully detected and corrected. We can see that adding the resiliency measures annihilates the impact of the corruption, leading to four times faster convergence than without resiliency measures.



(a) Corruption in $\mathbf{w}$

(b) Corruption in $\mathbf{r}$

(c) Corruption in $\mathbf{x}$

(d) Corruption in $\mathbf{p}$

Fig. 3: Demonstrating the impact of errors introduced into different vectors of s-ACD after one second into all agents, where the metric of each agent is displayed. The problem considered is a 100×100 random SPD problem with condition number 50.

VII. Conclusion

We have seen that due to the increased parallelism and new computational paradigms, asynchronous and resilient methods should be developed. In this paper, we have developed the s-ACD method that combines the CD method globally with the CG method locally. This provides scaling with respect to the condition number comparable with CG on the tested 2D Poisson problem, while ensuring complete asynchronicity, as global orthogonalization is no longer required, as well as some resiliency. Furthermore, we developed three detection techniques: a "generic" detection scheme, a "checksum" detection scheme, and an algorithm-based detection scheme. These methods were applied to s-ACD, creating the resilient s-ACD method. Numerical experiments were performed to demonstrate that this resilient s-ACD method is able to handle the introduction of data errors into the communication pattern, resulting in a significant decrease of iterations compared to the uncorrupted case. Future improvements include developing theory for the s-ACD method and resilient variation, adding more elaborate correction methods such as rollback, as well as developing asynchronous preconditioners to allow the considered methods to scale to larger problems.

***Abstract*—Measuring instruments are increasingly defined by complex software while using simple hardware sensors. For such systems, software conformity between certified prototypes and devices in the field is usually demonstrated using version numbers and hashes over executable code. Legal requirements for regulated instruments could equally be satisfied if prototype and device in the field display identical functional behavior even if hashes differ. Such functional identification can give instrument manufacturers room for software patches and bugfixes without the need for recertification. Based on the L^* algorithm, which is used to learn the language which deterministic finite automata accept, a risk-based method is proposed that realizes automatic functional identification of software to a certain extent, thereby enabling quality control of regularly updated measuring instruments without the need for frequent manual inspections. Risk assessment may be used to identify critical state transitions in monitored devices, which can be used to trigger recertifications if needed.**

I. Introduction

MODERN communication infrastructure and the ubiquitous availability of significant computation power even in small devices like smart watches and smart sensors allow software developers to remotely and regularly fix bugs identified during use of an IT component in the field. The same mechanism can also be used to deliver upgraded software with new features to remote devices, enabling IT equipment manufacturers to sell devices based on long-living hardware which can be upgraded to customers' needs through software updates. However, this development also comes at a certain cost: Remote update capabilities have proven to introduce unexpected or unintended errors into otherwise stable systems [1]. Therefore, approaches to cover this gap (without forcing potential users of updated software to validate the complete source code of a device) have received significant attention in recent years [2], [3]. Such approaches enable users of IT equipment to monitor a device's behavior for potential anomalies without having to check each individual update, thus providing a high-level approach to identify software by means of its functionality rather than by means of its bit pattern.

Monitoring and identifying a device's functional behaviour becomes especially important if requirements on these devices are mandated by legal regulations, typically involving recertification of the entire system in case of modifications. One industry sector affected by such regulations is Legal Metrology covering all measurements conducted in the European Union for commercial or official use. These regulated instruments include, e.g., taximeters for taxi fare calculation, gas meters for measuring gas consumption and length measuring instruments to determine the dimensions of sold goods. Any such instrument put on the common EU market has to be subjected to a conformity assessment procedure according to Annex II of the Measuring Instruments Directive 2014/32/EU (MID) [4]. One conformity assessment body performing this task is Germany's national metrology institute Physikalisch-Technische Bundesanstalt (PTB).

During conformity assessment, manufacturers have to demonstrate that their instrument fulfills the essential requirements given in Annex I of the MID. During use, market surveillance authorities across the EU monitor devices and their usage to detect potential non-compliance. As an example, essential requirement 8.3 states that, ”Software that is critical for metrological characteristics shall be identified as such and shall be secured. Software identification shall be easily provided by the measuring instrument. Evidence of an intervention shall be available for a reasonable period of time.“ [4]. Not only does this entail the identifiability of software in general, but also the possibility to detect changes to said software and make them evident to all parties involved. Typically, both identifiability and detection of changes are achieved by using cryptographic hashes over the executable code to identify specific versions of the software and to detect unwanted modifications [5]. However, such an approach quickly may put serious strain on conformity assessment bodies and market surveillance authorities alike. For example, even a recompilation of otherwise unchanged source code my result in a different hash due to the inclusion of compile time stamps etc. Therefore, solutions that automatically evaluate software modifications and link them to a potential risk of non-compliance are needed.

To this end, a novel risk-focused method for remotely monitoring software in devices subject to legal control is proposed here. It is envisioned that the method will be used by market surveillance authorities and inspectors to automatically check certified devices in the field for potential non-compliant behavior. If a device is deemed to be in violation of legal requirements after a software modification, the manufacturer would then be requested to resubmit the modified software for a complete conformity assessment procedure. The main contributions of the paper are the following: The proposed method

IEEE Catalog Number: CFP2385N-ART ©2023, PTI

constitutes a first step towards automatic remote quality control of devices subject to legal control. It enables automatic selection of risk scenarios based on remotely obtained behavioral data and thus also realizes functional identification of software to a certain extent.

The remainder of the paper is structured as follows: Section II provides some background on modelling and learning algorithms and presents the current state of the art in quality control for software as well as the risk assessment method currently used in Legal Metrology in the European Union. In Section III, the concept of modelling certain types of measuring instruments as deterministic finite automata (DFA) is investigated. The section also outlines which preconditions need to be fulfilled to justify such an approach. Afterwards, Section IV describes a novel risk-focused method of monitoring evolving software in measuring instruments based on the Active Continuous Quality Control (ACQC) approach from [2]. The method is then experimentally tested and evaluated in Section V. Finally, Section VI summarizes the paper and provides suggestions regarding further work.

II. Background and Related Work

Certain types of algorithms can be described as finite automata. The corresponding models and how to learn the behavior of such algorithms, which is of particular interest during monitoring of potentially modified software, are described in Section II-A. The methods proposed by Neubauer, Windmüller and Steffen together with Howar and Bauer [2], [3], which apply active automata learning to quality control for evolving systems, are briefly described in Sections II-B and II-C before recapitulating the previously published method of risk assessment for measuring instruments in Legal Metrology in Section II-D.

A. Active Automata learning

Simple state machines steered by input symbols from a finite alphabet that trigger internal state changes can be used to describe the behavior of certain types of algorithms such as used in controllers for elevators, household appliances, simple digital watches etc. [6]. From a mathematical point of view, these state machines, also referred to as DFAs, are defined as a 5-tuple $(Q, \Sigma, \delta, q_0, K)$ [6] where:

1) Q is a finite nonempty set of states.
2) Σ is a finite input alphabet.
3) $\delta : Q \times \Sigma \rightarrow Q$ is the transition function. (1)
4) $q_0 \in Q$ is the initial state.
5) $K \subset Q$ is the subset of accept states.

To indicate whether an arbitraty input sequence has successfully been processed, DFAs may contain accept states K which then trigger an *accept* message if such a state is reached. Otherwise, the output would be a *reject* message. It should be noted that the set K may also be empty, implying that the DFA does not contain any accept states triggering an *accept* message. In practice, the output of an algorithm is usually more complex than such binary feedback, requiring the existence of an output symbol from a finite output alphabet Γ. Such more general state machines are referred to as Mealy automata, which can be characterized as a 6-tuple $(Q, \Sigma, \Gamma, \delta, \gamma, q_0)$ [7] where:

1) Q is a finite nonempty set of states.
2) Σ is a finite input alphabet.
3) Γ is a finite output alphabet.
4) $\delta : Q \times \Sigma \rightarrow Q$ is the transition function. (2)
5) $\gamma : Q \times \Sigma \rightarrow \Gamma$ is the output function.
6) $q_0 \in Q$ is the initial state.

In addition to the transition function δ, describing state changes depending on the input symbol, these also possess an output function γ that associates an output symbol with each state change. Such Mealy automata were originally conceived to represent arbitrary logic circuits and can even mimic complex IT systems at a certain abstraction level [2]. For additional details, see Section II-B. To infer a DFA without having to know the exact implementation, the L^* algorithm was developed by Dana Angluin in 1987 [8]. The algorithm was later extended to the L^*_M algorithm to learn properties of the more general Mealy machines as well. Given that software changes in measuring instruments may have unknown effects and the instrument itself thus takes on the characteristics of a system with unknown behavior after an update, the basics of the L^* shall be briefly summarized here. See the original publication by Dana Angluin [8] for additional details of the L^* algorithm and the paper by Shahbaz and Groz [9] for an extended discussion including the L^*_M extension:

The aim of the L^* algorithm is to determine the properties of an unknown DFA by means of so-called membership and equivalence queries. To this end, the L^* learner communicates with a teacher T. The teacher abstracts the system under test (SUT), so that generic queries may be used by the learner to determine the SUT's internal DFA. If $L(A)$ is the set of strings a SUT A accepts, i.e., its language, and $Aut\,(A)$ is the set of all finite state machines with input alphabet Σ then the two types of generic queries used by the learner can be defined as follows:

- Membership queries $Q_M : \Sigma^* \rightarrow \{0,1\}$ where the learner asks the teacher to test the SUT with a given string x from the free monoid Σ^* that contains all words over Σ. If $x \in L(A)$ the response of the teacher is 1, otherwise 0.
- Equivalence queries $Q_E : Aut\,(\Sigma) \rightarrow \Sigma^* \cup \{\text{true}\}$ where the learner L^* asks the teacher T to perform an equivalence test between the current learned automaton representation $A' \in Aut(\Sigma)$ and the SUT A, resulting either in a counterexample $c \in \Sigma^*$ or confirmation of the equivalence.

Internally, the L^* algorithm operates on a so-called observation table that stores results of the queries in a systematic fashion. To this end, the learner continually performs membership queries until it has constructed an initial model A'. Subsequently, it issues an equivalence query to the teacher, which either confirms correspondence between A' and A or responds with a counterexample $c \in \Sigma^*$ that fulfills either $c \in L(A) \wedge c \notin L(A')$ or $c \notin L(A) \wedge c \in L(A')$. The algorithm finishes if the obtained data is sufficient to generate a system with the same algorithmic behavior as the SUT A. To illustrate the outcome of the L^* algorithm, an exemplary DFA is described in Section III together with a resulting transition function δ in tabular form in Table I.

B. Active Continuous Quality Control (ACQC)

In [2] Windmüller, Neubauer, Steffen, Howar and Bauer presented a novel approach for ensuring compliance of evolving complex applications through active automata learning technology. Their goal is to supervise and control modifications of applications during their entire life cycle. This is realized by establishing a consistent level for comparison via adaptive behavioral abstraction. Abstraction is achieved by means of a user-centric communication alphabet, where elements of the alphabet may correspond to entire (complex) use cases. One advantage of the method lies in its capability to identify bugs by simple examination of so-called ”difference views“ between consecutive models. The authors observe that software testing in general is not tailored to keep up with current, continuously evolving component-based software systems since repeatedly updating test suites for such systems is time-consuming and expensive. In [2] incremental active automata learning technology (also referred to as test-based modeling) is employed to address this issue.

To this end, daily system builds with an integrated fully automatic testing process are used, where the testing process is controlled by incremental active automata learning. The proposed approach aims to address the following main problems:

- ”Stable abstraction“: Downward compatibility is assumed, meaning users of the system should not change the way they interact with the system. Nevertheless, the source code etc. may change, but such modifications should not be apparent to the user. Therefore, the chosen abstraction mechanism is oriented on the level of use cases to facilitate comparisons between different software versions. Subsequently, the user-centric communication alphabet reflects distinct activities as part of the use cases.
- ”Bridging implementation“: A mechanism of the common abstraction level must ensure that any test is supported by a correct (version-dependent) implementation of an adapter for the symbols of the alphabet.
- ”Maximal reuse“: The central aspect of ACQC is based on the L^*_M learning algorithm for model inference. Based on selected counterexamples, the algorithm infers models from executed tests, see Section II-A. One drawback of the approach is the computationally expensive tests needed for the active learning process.

The authors observe that hypothesis models for new software releases are derived at the same level of detailedness as for the previous software release, which constitutes the main advantage of ACQC over similar approaches. Since identification of counterexamples is inherently ineffective, the derived system description will improve over time. Obviously, a precise initial model is needed to enable model-based testing. According to Windmüller, Neubauer, Steffen, Howar and Bauer, derivation of such models from source code is impractical for systems of a certain size. Indeed, any form of use-case-level modelling is difficult for such systems. Instead, active automata learning is used to extract models from live systems. The learned models then serve as the basis for regression tests. This approach will be reused in the method to be investigated here, see Section IV.

In [2] the proposed continuous quality control approach was validated by applying it to the Online Conference Service used for submitting and reviewing publications at Springer Verlag as an example with specific use cases as input symbols. Correspondingly, each input symbol represents processes like paper submission, reviewer selection or review submission. With such a high-level representation, a reasonably stable abstraction (as required above) was realized. The authors found that the chosen high-level modelling of input and output alphabets as abstraction of different use cases is well suited as a quality management facility for evolving IT systems. Not only is their method able to detect bugs, it also verifies if functional behavior of a system remains unchanged from one release to the next.

It should be noted, however, that the model learned by the L^*_M algorithm does not directly provide a link between the known set of states Q and the derived transition function δ. Instead, most L^* and L^*_M implementations assign input symbol sequences to the states they lead to. If the binary input 0 leads from a transition from the default empty state $\{\}$ to a state A, that state will be represented by the input sequence 0. If another input symbol 0 then leads to a transition from A to B, whereas the alternate input symbol 1 leads from A to C, B would be represented as 00 and C as 01. From a theoretical point of view, this corresponds to building the equivalence classes of the automata congruence relation for all states. It follows that an outside examiner can match the learned transition function δ against a known reference, but it is not guaranteed that the mapping between known states Q and learned states Q' is correct. This observation will be revisited again and illustrated by a more detailed example in Section V.

C. Risk-Based Testing via Active Continuous Quality Control

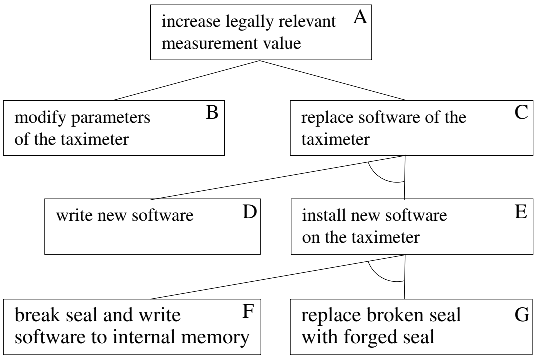
In [3] Neubauer, Windmüller and Steffen extended their approach to active automata learning and testing by adding a risk prioritization component. In this context, risk assessment is used to produce alphabet models which help to control the ACQC process to increase coverage of risk scenarios. The authors explain, that today’s complex IT systems usually consist of a combination of application servers with webinterfaces and third-party services. Due to the resulting heterogeneous structure, the subsequent system behavior becomes increasingly difficult to predict. During updates in particular, the mix of modified functionality and upgraded third-party components may have unintended effects. Their aim, therefore, was to continually perform automatic quality checks while using risk assessment to reduce the manual labor involved in regression testing.

In this regard, platform migrations are of particular interest since user experience may drastically change, even though the underlying functionality was not intended to be modified. Of course, potential risks resulting either from a platform change or from modified functionality cannot be automatically inferred. Therefore, the authors amended the original ACQC approach from [2] by enabling risk analysts to identify critical system aspects and prioritize them for error detection during the automatic model inference and checking steps. However, the paper [3] does not specify how risk levels are formally determined. Since risk analysts are typically not involved in software development itself, it becomes necessary to provide them with an abstraction layer that can be included in the original ACQC approach without performance loss. To this end, Neubauer, Windmüller and Steffen used the already abstract alphabet symbols from [2], which model different use cases of the SUT (see Section II-B).

The authors of [3] acknowledge that there are also model-driven approaches to risk-based testing such as the one described by Lund, Solhaug and Ketil Stølen in [10]. The so-called CORAS methodology offers the possibility to perform risk assessment using well-defined software models based on UML and the Unified Process (UP). However, CORAS and similar approaches only address the modelling aspect for risk assessment and are unable to monitor and perform comparisons between subsequent models of SUTs. Neubauer, Windmüller und Steffen also observe that it is unrealistic to assume that the internal number of states of a system will not change during its lifecycle. They therefore propose to continually repeat the learning process. This will be mirrored in the approach presented here, see Section IV.

D. Software Risk Assessment in Legal Metrology

One mandatory element of conformity assessment for measuring instruments consists of carrying out and evaluating a risk assessment for the instrument or type pattern to be assessed. In [11] Esche, Grasso Toro and Thiel described a method for software risk analysis particularly tailored for the software of such systems. The method is based on ISO 27005 [12] and ISO 18045 [13] and makes use of so-called assets, e.g., software, measurement data and parameters, and matching security properties, i.e., integrity, authenticity and availability, derived from the essential requirements from Annex I of the MID. These assets include the software, parameters and data of the instrument, but also the indication of the result, accompanying inscriptions and stored data. Within the frame of this paper, only the data during processing shall be considered. For such data, the MID requires integrity, authenticity and availability, i.e., it must be ensured that data cannot be modified or deleted without detection and that they are traceable to a known source. In short, any inadmissible influence on the processed data must be detectable.



increase legally relevant measurement value A
modify parameters of the taximeter B
replace software of the taximeter C
write new software D
install new software on the taximeter E
break seal and write software to internal memory F
replace broken seal with forged seal G

Fig. 1. Graphical representation of an attack tree that illustrates necessary steps to manipulate the calculated fare of a taximeter during processing [14]. Child nodes must be read as OR-connected, unless they are connected by an arc, which represents an AND-connection [11].

The first step of a risk assessment then consists of formulating certain threats that constitute an invalidation of any security property for the assets. For example, such a formal threat might read, ”An attacker manages to invalidate integrity or authenticity of measurement data during processing.“ Given the known properties of the instrument, the assessor then identifies potential attack vectors which encompass practical technical steps to be implemented to realize the threat. Since such attacks tend to be made up of several steps which may even be shared between different threats, Esche, Grasso Toro and Thiel introduced the concept of Attack Probability Trees (AtPT) in [11]. An AtPT can be used to divide complex attacks into smaller subgoals by means of a tree representation, see Figure 1 for an example addressing attacks on the calculated fare of a taximeter. The AtPT method may be seen as an example of fault tree analysis (FTA) with an added layer that links the method to the vulnerability analysis from ISO 18045 enabling users of AtPTs to rank threats by means of a formalized and well-defined risk assessment. In the Figure, node A, which corrsponds to the threat of manipulating the measurement value, is divided into nodes B and C which represent the alternatives of either manipulating the measurement parameters or replacing the software of the instrument. These two child nodes may be split into further subtrees themselves. Once the tree has been established, all leaf nodes are assigned scores for required time, needed expertise, knowledge of the system, window of opportunity for an attacker and necessary equipment in accordance with the corresponding guidelines from ISO 18045 [13]. Finally these scores are propagated up the tree as prescribed by the rules from [11] to calculate probability of occurrence score and impact score of the original threat represented by the root node. The product of both, rounded to the next integer number, then becomes the (ideally) reproducible, numerical representation of the risk associated with the threat.

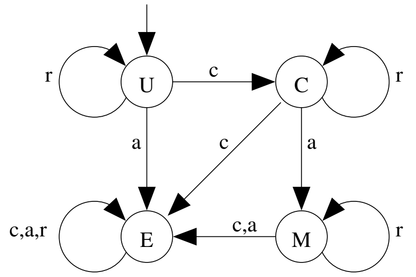


Fig. 2. DFA representing the different states of a heat meter and the state transitions. The heat meter states are: U for an unconfigured device, C for a configured yet inactive device, M for a measuring device and E for a an error state. The input alphabet consists of the symbol c for a configuration dataset, a for an activation signal and r for a request to retrieve measurement data from the device.

III. Modelling Measuring Systems as Deterministic Finite Automata

In principle, finding mathematical representations, i.e., functional identifications, even for simple measuring instruments is a complex task since various physical influences need to be taken into account and must be reflected in a corresponding uncertainty budget [15]. Automatic detection of unwanted behavior of complete instruments thus quickly becomes unfeasible. Nevertheless, many commonly used instruments, e.g., heat meters, typically contain internal state machines which ensure that the instrument behaves differently during installation/configuration than during permanent use. Among other qualities, heat meters have to guarantee that the installation point (either on supply side or return side of a heat generating device) can only be set during configuration and that the state cannot be reached again without physically tampering with the device. From this example, it should be clear that state machines within such instruments share many properties with DFAs and can thus be used to provide a simple form of high-level functional identification.

In the simple heat meter example, $Q = \{U, C, M, E\}$ would consist of the states U for an unconfigured device, C for a configured yet inactive device, M for a currently measuring device accumulating the consumed energy into a register and E for a device in an error state. A simple input alphabet would consist of three symbols $\Sigma = \{c, a, r\}$ where c represents a configuration datagram, a is the activation signal and r is a request to read measurement data from the device. For illustration purposes, a graphical representation of the complete DFA is given in Figure 2. It should be noted that the depicted DFA is only a simplistic exemplary representation of the possible software states of a heat meter. A real device will likely contain more states and more possible transitions. Also, the shown DFA only addresses the software aspects of the meter. For instance, if the permanent error state E is reached, recovery might still be possible via a hardware reset which is beyond the representation capabilities of the selected model. The corresponding transition function δ, which maps a current state to the next state given a specific input symbol, is shown in Table I. There exist some approaches to model both, the measuring function and the DFA of measuring instruments, resulting in a so-called digital twin describing an instruments behavior under arbitrary conditions. However, these are not suitable to monitor and evaluate frequent software changes. As stated in Section I, mechanisms are needed that can automatically identify and evaluate software modifications. It should be clear from the above-mentioned example for heat meters, that some measuring instruments contain state machines that control the interpretation of sensor data to produce the measured quantity value.

TABLE I

	E	E	E	E

While certain measuring instruments include internal DFAs controlled by external input [5], such instruments usually also produce variable output data - namely the measurement result - either in a digital or visual representation. Therefore, such systems fulfill the criteria of the more general Mealy automata. Nevertheless, as illustrated by the heat meter example above, many measuring instruments already contain simple DFAs enabling the use of the original L^* algorithm without having to define additional output alphabets and resorting to the correspondingly more complex L^*_M algorithm for Mealy automata. This approach also mirrors the fact that evaluation of software security aspects in measuring instruments and evaluation of the measurement functionality are usually two separate tasks during conformity assessment of such devices. Section IV will revisit this aspect when elaborating on a possible quality control strategy for measuring instruments in the field.

IV. Risk-Based Continuous Quality Control for Measuring Systems

In [3], the authors used risk assessment to prioritize the input alphabet for the L^*_M algorithm applied to a Mealy machine to ensure quick detection of potential implementation or migration errors in evolving IT systems. In the scenario where software is updated in measuring instruments subject to legal control, a little more flexibility might be possible given that mere bugfixes, which do not affect the functionality of the instrument, should be covered by the original conformity assessment certificate without the need to revise the certificate. To achieve this, the focus shall not be put on the choice of the input alphabet but rather on the state transitions δ discovered by executing the L^* algorithm for a new or unknown system. A graphical representation of the automatic quality control method proposed here may be found in Figure 3.

As discussed in Section II-D, performing and evaluating a software risk assessment has become an integral part of conformity assessment for most measuring instruments in the EU. During such an assessment, the risks assigned to individual threats or their subgoals can be used to derive a list of critical state transitions that the evaluator deems to be in violation or facilitate violation of the essential requirements from the MID, see top-left corner of Figure 3. If necessary, the numerical risk scores for individual threats described in Section II-D could be used to rank new state transitions according to their risk level. In the heat meter example from Section III, one such critical transition would be reverting from measurement state M back to the configuration state C, potentially leading to modified measurement parameters while a device is in use. The conformity assessment procedure could also be used to perform an initial execution of the L^* algorithm in a known environment. The initially discovered transition function δ and the known remaining elements of the DFA shall together be referred to as the model M_{old}. Continuous repeated learning of the DFA (right-hand side of Figure 3) will produce potentially modified models M_{new} which can be compared against the previously learned and accepted model taking into account the identified list of critical state transitions. As long as no critical transition is identified, the learning loop could be repeated indefinitely to ensure that the system still operates within certified functional limits. The updated model representation also allows human evaluators to graphically identify the recent software changes and determine their potential effect. Of course, model comparison only allows inspection of the internal DFAs of measuring instruments, neglecting to address the measurement function itself. However, this approach is also used in many conformity assessment bodies in the EU where software examination (focussed on the IT security of examined prototypes) and metrological examination of the measurement functionality itself (addressing measurement uncertainty, reproducibility etc.) are two separate tasks usually conducted by two separate examiners. Therefore, it appears justifiable to monitor changes to the protection and security measures, e.g., the order of transitions within internal DFAs, separately from the measurement function itself.

If a critical modification is detected (if-then-statement in the lower right corner of Figure 3), a manual intervention is needed. In order to revert to a certified state, conformity assessment for such a modified instrument must be repeated. If problems are identified with the modified instrument during reassessment, potential corrective actions regarding improper use of non-conformant measuring instruments may be required. The workflow of the procedure will be illustrated by a detailed example in Section V. Depending on the complexity of the automaton, learning its representation can be computationally expensive. Since measuring instruments usually possess rather simple DFAs and devices like taximeters are usually inactive for longer periods on a daily basis, applying the L^* algorithm to such instruments still appears feasible.

It should be noted that neither L^* nor L^*_M work in actual black-box scenarios. Instead, they require the existence of a teacher T who has full access to the SUT and can answer membership and equivalence queries accordingly, see Section II-A. To this end, it is envisioned that such a teacher T might be developed by the instrument manufacturer and evaluated during initial conformity assessment. Subsequently, the teacher T could then act as a test interface for market surveillance and inspectors, enabling them to continually monitor individual device in the field remotely until the need for manual intervention arises.

V. Exemplary Evaluation

To illustrate the usage of the proposed risk-based ACQC workflow for measuring instruments, a real-world exemplary instrument will be examined in detail in Section V-A, followed by an investigation into different types of new state transitions in Section V-B and a discussion regarding discovery of unknown states in Section V-C. An analysis of the example that also identifies open issues of the approach will be provided in Section V-D.

A. Taximeter as a complex DFA

A taximeter (as defined in Annex IX of the MID [4]) is a ”device [that] measures duration, calculates distance on the basis of a signal delivered by the distance signal generator. Additionally, it calculates and displays the fare to be paid for a trip on the basis of the calculated distance and/or the measured duration of the trip.“ Therefore, the sensor is not part of this type of measuring instrument and it solely performs processing operations on the received digital distance data. This makes

TABLE II
TRANSITION FUNCTION δ FOR THE TAXIMETER EXAMPLE IN FIG 4. STATE F REPRESENTS A FREE VEHICLE WITH NO PASSENGER, O AN OCCUPIED VEHICLE AND M AN ONGOING MEASUREMENT. Fig. 4. DFA representing the different states of a taximeter and the state transitions. The taximeter states are F for a free vehicle with no passenger, O for an occupied vehicle, M for an ongoing measurement, I for retrieval of fiscal data and U for a software update. The input alphabet consists of the symbol s to start a measurement, e to exit a state, i to initialize fiscal review and u for a software update package. In the original model of the DFA shown here, the instrument will always return to the default state F after completing a software update in state U.

taximeters especially suitable as a test case for the proposed method, see Section III.

Since taxis have frequently changing customers, they usually possess DFAs that mirror the process of a customer entering and leaving a vehicle as well as the starting and stopping of the measurement itself. Subsequently, said DFAs contain a state F that represents a free vehicle, whereas the DFA enters the state O to signal that the taxi is now occupied. This could either be triggered through a button on the device or by means of a seat contact. For the sake of a simple example, it shall be assumed that the price per travelled kilometer is fixed. It should be noted, however, that some EU member states have complex tariff structures that take current time, number of passengers etc. into account. If the occupied vehicle starts travelling, the internal DFA then enters the measuring state M. To leave the state, the customer must first pay the price, after which the driver pushes the corresponding button to exit the measurement state. In addition, most taximeters also possess an option to retrieve fiscal data, such as the overall total of calculated fares and the complete travelled distance. Both are needed to perform tax audits for taxi companies. The corresponding fiscal inspection state I can be entered if no measurement is running and it should not be possible to start a measurement from this state. Finally, some taximeters possess a functionality to perform software updates. This functionality shall be represented by a state U. A use case oriented input alphatbet would then consist of the symbol s to start a measurement or transition from the free state F to the occupied state O. The symbol e correspondingly signals the exiting of the current state and return to the default free state F. Input symbols i for fiscal inspection and u for a software update indicate the command to either perform an inspection or trigger a remote update. The corresponding graphical representation of the complete DFA may be found in Figure 4. The corresponding transition function δ, which maps a current state to the next state given a specific input symbol, is shown in Table II. As indicated in Section II-D, all measuring instruments must be subjected to a risk assessment as part of the necessary conformity assessment procedure before putting such instruments on the common European market. Figure 1 shows the attack probability tree as one outcome of the risk assessment procedure for a taximeter's software. When comparing the attack probability tree with the example described above, it should become clear that child node B (modification of a taximeter's parameters) cannot be linked to the transition function δ in Table II since there is no corresponding state that enables parameter changes. Child node C (replacing the software of a taximeter), however, could be enabled by inadmissible transitions to and from the update state U. In fact, node E (installing new software) addresses specifically the functionality behind the update state. In this context, one should keep in mind that breaking and replacing of the seal (represented by child nodes F and G) do not necessarily have to address physical hardware seals. So-called electronic seals realized as protected logbooks are equally common in Legal Metrology [5]. Subsequently, all additional transitions to and from the update state U (represented by the detected state su in Table III) would be classified as critical during conformity assessment since such transitions could interfere with normal processing of updates and damage the continuous audit trail of logged software modifications.

TABLE III
TRANSITION FUNCTION δ OBTAINED BY L^* ALGORITHM FOR THE ORIGINAL TAXIMETER EXAMPLE FROM FIGURE 4. STATES ARE GIVEN IN THE REPRESENTATION OBTAINED BY THE ALGORITHM, E.G., ssu, TOGETHER WITH THEIR CLEARTEXT REPRESENTATION, E.G., M.

	ss/O	sss	s	ss	si
	sss/M	sss	s	sss	sss
	si/I	si	s	su	si
	su/U	su	s	su	su

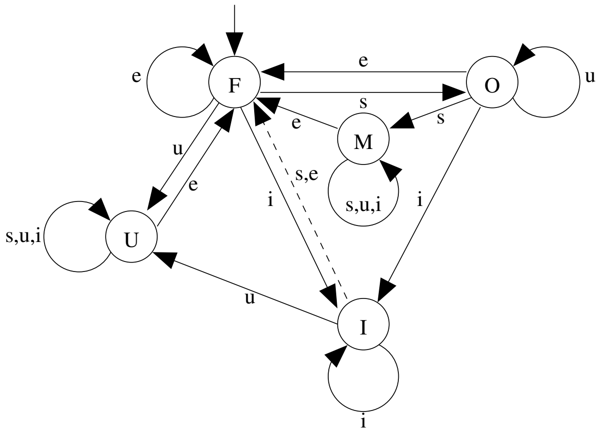

Fig. 5. DFA representing the different states of a taximeter and the state transitions after addition of an non-critical state change from fiscal inspection I to the free state F (dashed arrow). While originally only the input symbol e for exiting triggered that change, symbol s now has the same effect. In the orignal example, symbol s had no effect on the automaton when in state I.

As explained in Section II-B the L^* algorithm produces a transition function δ that references the internal states of the examined DFA by their corresponding input sequences. To improve readability of the example, the first column of Table III contains both the cleartext representation of the states as well as their representations obtained by the learning algorithm, which correspond to the symbol sequences needed to transition to a certain state. Since s is the first symbol tested by thevused algorithm, it denotes the default state F also with that symbol. Consequently, all other state representations start with that symbol, too. Section V-C will address how representation variations may affect the interpretation of the algorithm output and how this effect can be mitigated.

B. Non-critical and critical state changes

To test the proposed automatic detection method, the DFA of the taximeter shall now be modified by adding another transition from state I for fiscal inspection to the free state F triggered by the input symbol s (originally only triggered by symbol e), see Figure 5. Although this transition no longer matches the original assignment linked to that input symbol, it does not constitute a critical modification from the point of view of conformity assessment. Following the learning cycle proposed in Figure 3, the L^* algorithm is applied to the modified DFA resulting in a new version of the transition function δ, see Table IV. As can be seen from the table, the state representation obtained by the L^* algorithm remains the same, e.g., state M is still represented by the input symbol sequence sss. The only difference between the original transition function (see Table III) and the updated version in Table IV may be found in the row for transitions from state si/I, where the input symbol s now triggers a return to state s/F. Since an added transition to this state was deemed uncritical during conformity assessment, monitoring of the system can be continued without the need for human intervention.

	su/U	su	s	su	su

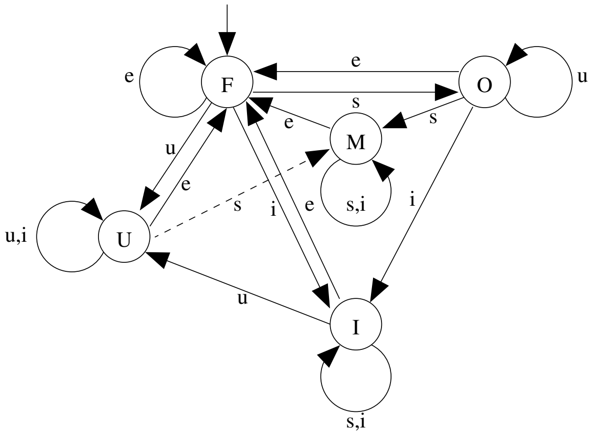

Fig. 6. DFA representing the different states of a taximeter and the state transitions after addition of a critical state change directly from the update state U to the measurement M (dashed arrow) if the input symbol s is received.

As a second test case, the original taximeter DFA shall now be modified by adding a state change between update state U and measurement state M, see Figure 6. Such a transition was deemed critical during initial assessment of the measuring instrument and should trigger an automatic response. The corresponding function δ learned after application of the L^* algorithm to the modified example is given in Table V. Again, the linking between cleartext names of the states and the representations found by the algorithm appears to be unchanged. However, as can be seen from Table V, the transition function δ now also reflects the intended additional transition from the

TABLE V

update state U (represented by the symbol sequence su in the table) to the measurement state M (represented by the symbol sequence sss). Since any additional transition to and from the update state was classified as critical during the original risk assessment (see Section V-A), the algorithm now issues a warning that triggers a repetition of the conformity assessment procedure to check whether the modified instrument still complies with legal regulations. As part of the repeated assessment, the risk analysis would also be performed and evaluated again. During this step, the classification of critical state changes might have a different outcome because of additional information not available during original assessment. If the modified software were deemed acceptable, the proposed quality assurance algorithm would be supplied with a new list of critical state changes and the L^* algorithm would be started again. If not, manual withdrawal of all affected taximeters in the field would become necessary.

C. Necessary discovery of state correspondences

As indicated in Sections II-B and V-A, the state representations by their corresponding input symbol sequences within the transition function δ obtained by the L^* algorithm depend on the order in which states are discovered. To illustrate this fact, a modified version of the original taximeter DFA shall be used, where the state transition from free state F to the fiscal inspection state I has been removed, see Figure 7. The corresponding state transitions identified by the L^* algorithm may be found in Table VI. Due to the different order of state discovery, the fiscal inspection state I is now no longer referenced as si but rather as ssi in the table. Since such an assignment of a different label could potentially affect more than one state, it becomes necessary to add a matching step to the comparison step between consecutive learned models $M_{\text{old}}, M_{\text{new}}$ included in the proposed workflow in Figure 3. For the sake of simplicity, the matching step shall consist of checking all possible assignments between cleartext representations of DFA states and corresponding symbolic state representations from Table II. The one assignment that minimizes the number of new or modified state transitions compared to the original DFA shall then be assumed to be correct and the identified transitions shall be evaluated against the list of critical state changes from the risk assessment. If there is more than one assignment that minimizes the number of new or modified state transitions, the state assignment is no longer unambiguous and the modification will be assumed to be critical by default. This approach will only fail under two conditions: If the overall number of discovered states does not match the original DFA or if sufficiently many state changes have been implemented by the manufacturer so that the learned transition function matches the original one, even if the underlying functionality is different. Both cases will be revisited in Section V-D.

D. Analysis of the Example

When comparing the transition functions obtained by the L^* algorithm for the non-critical and critical modifications of the taximeter DFA (see Tables IV and V respectively), it can be seen that the proposed risk-based quality control approach can effectively identify and deal with both types of modifications. Manual intervention as the result of a detected assumed critical change will likely be able to assess the actual impact of the modifications and ensure compliance of all serial devices in the field. The monitoring approach might fail, however, if several state transitions are modified or added iteratively so that they are only examined individually by the L^* algorithm. Even if the combination of modifications or additions produces effects that are in violation of legal requirements, the current implementation would not be able to detect these effects. However, this scenario is implicitly already covered by today's practice of performing periodic reverifications of measuring instruments in use. As outlined in Section IV, the manufacturer of the measuring instrument would need to implement a teacher in the form of a test interface for the proposed approach to work. Of course, it cannot be guaranteed that such an interface actually interacts with the internal DFA of the measuring instrument. Instead, a dummy DFA could be implemented to hide software modifications from the automatic quality checker. During the above-mentioned reverifications, however, it would be possible to also practically check whether the implemented teacher T

correctly abstracts the measuring instrument's DFA for the external Learner L^*, thereby mitigating such a threat. As illustrated in the example in Section V-C, reproducibility of the L^* algorithm's output depends on the context-based interpretation of learned state labels. The proposed brute-force matching algorithm to identify correspondences between cleartext state representations and learned state identifiers has several shortcomings which shall be addressed here:

- While a brute-force approach, matching all DFA states against all possible representations, is guaranteed to find one or more optimal matches, the approach might become computationally complex if large DFAs are monitored. Breadth-first search algorithms should be able to provide quicker solutions without missing any transition modifications.
- As discussed in Section V-C, the number of discovered states does not necessarily have to match the number of states in the original DFA, even after application of the DFA minimization algorithm. In such a case, the currently investigated approach would always classify the modification as critical, even if a state has been removed that is not legally regulated.
- It is theoretically possible to implement sufficiently many state changes simultaneously that cannot be detected because the learned transition function δ contains the same number of states and matching state transitions as the original transition function.

It should be noted again that the current approach only focuses on simple state transitions within DFAs while the behavior of more complex instruments than heat meters or taximeters will likely be better characterized by the more general Mealy automata, see Section III. Using Mealy automata would enable checking of input and ouput behavior of such systems, thus ensuring a wider range of useful application scenarios. Investigation into an approach using the adapted L^*_M algorithm will, therefore, form the basis for further work. Similarly, machine learning algorithms such as the one described by Yan, Tang, Luo, Fu, and Zhang in [16] are already able to perform anomaly detection for complex IT systems. Due to the similarities between such systems and measuring instruments, similar approaches might also be able to model and monitor the software of measuring instruments to some extent, while potentially bridging the gap between automata models and mathematical models for measurements themselves. Once more elaborate quality control approaches for software in measuring instruments are available and have proven their reliability, it might be possible to replace mandatory periodic reverifications with risk-based reverifications based on the detected behavior of individual devices. If proven useful, such quality control approaches could be added as an acceptable solution for dealing with software modifications in the currently established technical interpretation of the MID, namely the WELMEC 7.2 Software Guide [5]. Such an acceptable solution could facilitate the uptake of the method and harmonize the approach across the EU if needed.

VI. Summary

In this paper, a new risk-based quality control approach for measuring instruments in legal metrology was proposed as a high-level attempt to realize functional identification for software of such systems. The approach is based on work published in [2] as well as [3] and uses the L^* algorithm to monitor changes in the DFAs of measuring instruments in the field. To this end, the outcome of the mandatory risk assessment procedure for regulated measuring instruments is used to identify critical state transitions to be checked if software changes occur. Based on an example for a DFA in a taximeter, the approach was evaluated regarding the detection of non-critical and critical state changes, even in light of varying conditions like modified state representations. To mitigate potential effects of varying state representations, a brute-force matching algorithm was added to the proposed method that can effectively reduce the number of falsely identified critical state transitions. This proof of concept has shown that automatic quality control of measuring instruments is indeed possible if the SUT fulfills certain preconditions, such as a clear separation between measurement function and internal DFA. Manual intervention in case of doubt and periodic reverifications are still necessary to cover all eventualities. While the method requires instrument manufacturers to implement a test interface in their devices, they would benefit from the possiblity of issuing bugfixes to their software without having to go through conformity assessment by default. Similarly, conformity assessment bodies would have to check said interfaces initially, but would benefit when updates are deemed to be in line with the originally certified instrument functionality, thus avoiding repetition of software examinations. Finally, market surveillance authorities and inspectors in Legal Metrology could use the data provided by the L^* algorithm to assess modifications in devices in the field to a certain extent without the need to be on site. It is envisioned that the approach would work in any industry sector where software systems are used whose compliance with specific requirements must be checked by external authorities in the field. Further work will focus on validating the current approach with additional, more realistic practical test cases (also outside legal metrology) and optimizing the matching algorithm between learned and known state representations. Extending the approach from DFAs to more general Mealy automata will hopefully pave the way towards an actual functional identication mechanism for software in measuring instruments since it would also encompass the output language of devices in the field rather than simply monitor state transitions.

***Abstract*—For economics and sociological research, lists of industries and their branches are widely used in research to categorize data and get an overview on different types of industries. However, many different taxonomies and ordering schema exist, due to different research focus but also due to different national scenarios and interests. In this paper, we will focus without loss of generality on regional data from Germany. Manual annotation of textual data is time-consuming and tedious, naturally giving rise to our initial research question, also highly inspired by questions from computational social sciences: How can we automatically categorize textual data, e.g. job advertisements or business profiles, by industrial sectors? We will present an approach towards classification using a pre-trained domain-adapted Transformer model. We find that domain-adapted models generalize better and outperform state of the art non domain-adapted Transformer models on Out-Of-Distribution data. Additionally, we open source two novel data-sets mapping textual data to WZ2008 sections and divisions, enabling further research.**

I. Introduction

FOR economics and sociological research, lists of industries and their branches are widely used in research to categorize data and get an overview on different types of industries. However, many different taxonomies and ordering schema exist, due to different research focus but also due to different national scenarios and interests.

The manual annotation of a diverse set of textual data may not only require an equally diverse set of human experts, but also homogeneity in the ruling of annotation with respect to the underlying taxonomies thereof. Additionally, the process of manual annotation can be time consuming and cumbersome, requiring constant calibration of the annotators ruling. Naturally, one may desire a method to automatically annotate a diverse set of textual data. In this paper, we will focus without loss of generality on annotating German textual data with their respective WZ2008 key (a multi-class classification problem) and provide further details in Section III.

The applications of automated industrial sector recognition are many and varied:

- The categorization of companies. Here, the most important question is on which data a classification should operate. In this paper we will focus on textual data, but other data (e.g. economic data) are also available and could help to improve automated methods.
- The categorization of advertisements, e.g. job advertisements or training advertisements. However, the main question here is whether we want to classify the job position (e.g. a miner under “Mining and Quarrying”) or the occupation being recruited. Obviously the two approaches are not interchangeable.
- However, we can also apply this to other textual data: Which industries are mentioned in political speeches or in newspapers? Approaches to literature are even more challenging.

Very limited work has been carried out in this field as we will discuss in the next section. According to our knowledge, no work on German texts has been carried out. Data on companies is usually collected and sold by commercial providers like statista.

This paper is divided into eight sections. The first section provides an introduction and gives a brief overview of the background of the research question, the second section presents related work. Section three presents the data and an overview about existing resources. In section four, we will introduce the methods used to answer the research question. The fifth section is dedicated to experimental results and the evaluation of these methods. In section six, we discuss our findings and give a detailed interpretation of the results. After we briefly discuss possible bias in the penultimate section, our conclusions and outlook onto further research are drawn in the final section.

The contributions of this paper include the following:

(i) We fine-tune and compare an openly available domain-adapted BERT model with a standard BERT model. We find that the domain-adapted model shows an increased ability to generalize over the vanilla model on Out-Of-Distribution data.

(ii) We evaluate the models on two novel data-sets, one mapping Wikipedia paragraphs to WZ2008 keys, the other mapping job ads to WZ2008 keys. Both data-sets are open sourced for further research [1].

(iii) We discuss shortcomings of our approach and gain insight on how to improve the current methods. We conjecture that a more diverse mixture of training data will drastically improve a domain-adapted models ability to generalize.

II. Related Work

Very little work has been done in this area. There are several applications for the given research question: For example, Pejic et al. state the need to analyse Industry 4.0 skills, but do not present a generic categorization approach, but rather pre-select job advertisements according to their needs [2]. Chaisricharoen et al. noted the importance of industrial sectors for legal categories. However, their work is limited to industry-standard keywords [3]. For the generic categorization of English texts, some work has been done by McCallum [4] and Kibriya et al. [5]. However, the data and industrial sectors are mainly for marketing purposes and cannot be used in economic and sociological research. Several other works rely on these data-sets, see for example [6], [7], which underlines the general need for publicly available training and evaluation data.

Text mining on labor market data is a widely considered topic. For an automated analysis of labor-market related texts, the situation in German-speaking countries like Germany, Austria and Switzerland is not much different to English-speaking countries: “Catalogs play a valuable role in providing a standardized language for the activities that people perform in the labor market” [8]. However, while these catalogs are widely used for creating and computing statical values, for managing labor market and educational needs or for recommending trainings and jobs, there is no single ground truth. According to Rodrigues et al., one reason for this could be the fact that labor market concepts are modeled by multiple disciplines, each with a different perspective on the labor market [9]. For German texts, in particular job advertisements, Gnehm et al.[10] introduced transfer learning and domain adaptation approaches with jobBERT-de and jobGBERT. This model was also used for the detection of skill requirements in German job advertisements [11], [12].

For regional data, especially in German-speaking countries, industrial sectors are widely used as a basis for economic and labour market research, see for example [13], [14], [15], they are particularly important for future skills and qualifications [16]. Although classification is a key issue for industrial sectors, see [17], little research has been carried out using computational methods. Examples are mainly limited to regional industries [18] or agriculture and green economy [19].

To our knowledge, no work has been done on German texts. Company data are usually collected and sold by commercial providers such as statista. There is also an online guide from the Federal Office of Economic Affairs and Export Control (BAFA) (“Merkblatt Kurzanleitung Wirtschaftszweigklassifikation”[1]), but this is only a short version of the data available from the Federal Statistical Office. Therefore, we will now discuss the available data.

III. Data

As discussed above, several classifications of industrial sectors exist. In our case, we rely on the official German statistics using WZ08. We will describe this taxonomy in the first subsection. However, also a rich variety of possible applications exists. Thus, in the next subsection we will describe several textual data for training and evaluation.

A. Classification of industrial sectors

The so-called “Klassifikation der Wirtschaftszweige” (Classification of branches of industry, short: WZ) is used in Germany, in particular for official statistics by the “Statistische Bundesamt” (Federal Statistical Office), to classify economic activities of employers. The most recent version is WZ 2008, making WZ 2003 and 1993 deprecated. It is compatible to the European “Nomenclature statistique des activités économiques dans la Communauté européenne” (NACE) Rev. 2, but adds more detailed data. For more details we refer to [20]. All data is available in English and German at https://www.destatis.de/DE/Methoden/Klassifikationen/Gueter-Wirtschaftsklassifikationen/Downloads/klassifikation-wz-2008-englisch.html. In this text, for the description of examples we usually rely on the official English translation, while the work itself is carried out on German data.

Similar to NACE, WZ 2008 provides several hierarchical levels. A first level describes 21 sections (letters A-U), a second divisions, a third groups, a fourth classes. In contrast to NACE, WZ 2008 adds subgroups as fifth level, which is, however, only added to particular classes. See Figure 1 for an illustration of a particular hierarchy in sector C. Thus, with examples we find the following hierarchical elements:

- Sections (21), A-U, e.g., “B MINING AND QUARRYING”
- Divisions (88), 01-99, e.g., “05 Mining of coal and lignite”
- Groups (272), 01.1-99.0, e.g., “05.1 Mining of hard coal”
- Classes (615), 01.11-99.00, e.g., “05.10 Mining of hard coal”
- Sub-classes (839), 01.11.0-99.00.0, e.g., “05.10.0 Mining of hard coal”

While sectors are very broad and specific, for example A (Agriculture, Forestry and Fishing) and B (Mining and Quarrying), others are not clearly defined at this level, for example S (Other Service Activities). On the other hand, classes and groups often do not differ and the naming of divisions and groups usually does not provide much more information (e.g. 77 “Rental and leasing activities” towards 77.1 “Renting and leasing of motor vehicles”). In addition, a company might well belong to two or even more industrial sectors, e.g. to several manufacturing divisions. However, the official guidelines recommend to label the most dominant sector. Thus, while the taxonomy of industrial sectors is well-defined by WZ08, we rely on external data to train and evaluate our approaches. In addition, we need to discuss on

which level, e.g. sectors or divisions, the categorization can be carried out.

B. *Training and evaluation data*

1) Official Data: The German Federal Statistical Office (see above) provides a list with 33,945 keywords or descriptive texts of up to 30 words, hence subsequently called snippets, covering all classes in WZ08[2], see Figure 2 for an illustration. It clearly separates between different industries, for example for barrel-locks (“Zylinderschloss”) we find entries for retail (47.52.1), whole sale (46.74.1), trade agency (46.15.4) and production (25.72.0). However, this underlines the complexity of this data-set containing not only single keywords but also activities and often even more information, e.g. technical information (“Zylinderschleifereien für Kraftwagen von 3,5 t und weniger”). Thus, we will carefully evaluate how and in which cases we can use this data for training.

The data-set is very imbalanced, as approx. 44% of all snippets map onto a single WZ08-group, namely G 46 Wholesale (excluding trade in motor vehicles) (“Großhandel (ohne Handel mit Kraftfahrzeugen)”). Similarly, about 66% of snippets map onto one of five out of the overall 40 groups.

2) Wikipedia: Covering free text descriptions, we collected and manually annotated 1122 entries of German Wikipedia by industrial sector, division and group. This list contains companies (e.g. “Vereinigte Margarine-Werke Nürnberg”), brands (“Whiskas”), concepts (“Tabak”, “Flachglas”) and activities or tools (“Weben”, “Hammer”, “Werkzeug”). Thus, this data highlights how broad industrial sectors are and the questions remains what really characterises them. However, having a cross section of these entities at hand might result in better accuracy.

As a first example, consider 10.9 “Manufacture of prepared animal feeds”: here the entries refer to pet food (“food”), but also to brands such as Whiskas. Other industries are even more fuzzy, such as 61.1 “Wired telecommunications activities”: Here we collected mainly technical entries (e.g. network connection, mobile phone network), as there are no entries for industries with such a limited focus in the German Wikipedia.

Similarly to the WZ08 snippets, the wikipedia data-set is imbalanced, but towards a different section, namely “C” Manufacturing Industry, containing WZ08-groups like mechanical engineering and so on. About 41 % of the text descriptions belong to this section, please refer to Figure III-B3 for more details.

3) Job Advertisement: As a third data collection, we have 635 manually annotated job advertisements. Here, it is crucial to differentiate, whether the job itself or the company ought to be categorized, as the data may contain information about both domains. This is especially challenging, as the information for and requirements about the position in question may lead to a misclassification in case the inference model cannot distinguish between company-specific or job-specific information. For the annotation process, we decided to categorize companies or businesses, because in most cases job advertisements contain a section with information on them. We excluded advertisements without this profile. In addition, we excluded all advertisements from temporary-employment agencies, because they allow no conclusion about the real company searching for the particular job profile.

We collected data from the BA’s official job search, “Jobsuche”, which also classifies advertisements by industry, see figure 3. The adverts provide a free text field describing the job and the requirements, see Figure 4 (left). There is also information about the employee, although not all the information seems to be mandatory, see Figure 4 (centre, right). Some companies add extensive promotional texts and descriptions of their profile.

The data-set is also quite imbalanced, although towards completely different sections than the other two data-sets. The most represented section is “C” (Manufacturing Industry) with about 20%, followed by “M” (Provision of freelance, scientific and technical Services) with about 12%.

We make all data-sets openly available at [1].

[2] See https://www.destatis.de/DE/Methoden/Klassifikationen/Gueter-Wirtschaftsklassifikationen/Downloads/klassifikation-wz-2008-3100100089004-aktuell.pdf.

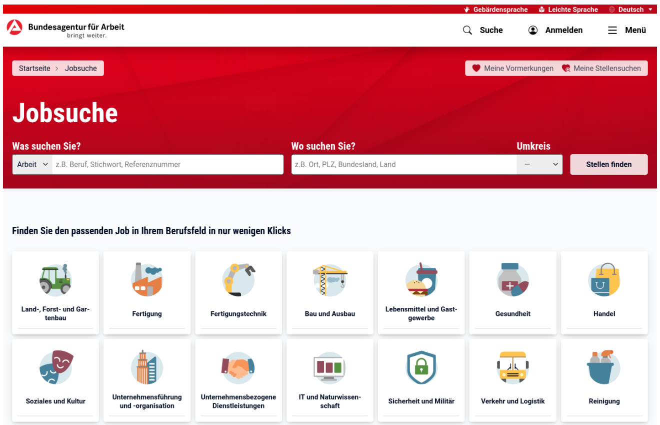

Fig. 3. The landing page of BA "Jobsuche" with job advertisements sorted by industrial sectors (bottom).

C. Manual curation

In this section, we present some information about the manual curation of the data and how we created a gold standard to evaluate the methods presented in this paper. The process was carried out by five domain experts.

During the annotation of various job advertisements from the data-set of the Federal Employment Agency, it was found that certain occupations could not be clearly assigned to one economic sector, but belonged to several industries. Thus, uniqueness was disproved. Furthermore, it can be concluded that occupations can be assigned individually to the economic sectors depending on the job description in the job advertisement and are dependent on this description. Thus, depending on the description, the industry or the frequency of economic categories changes.

The same challenges apply to Wikipedia data: Similar to companies, skills and tools may belong to different industries, leading to either ambiguity in the assignments or missing data. Therefore, we decided to annotate the data only up to the group level, choosing the most typical representations and avoiding generic lemmas.

In the near future, we will provide a more detailed qualitative evaluation of the annotation process, such as the interannotator agreement.

IV. Method

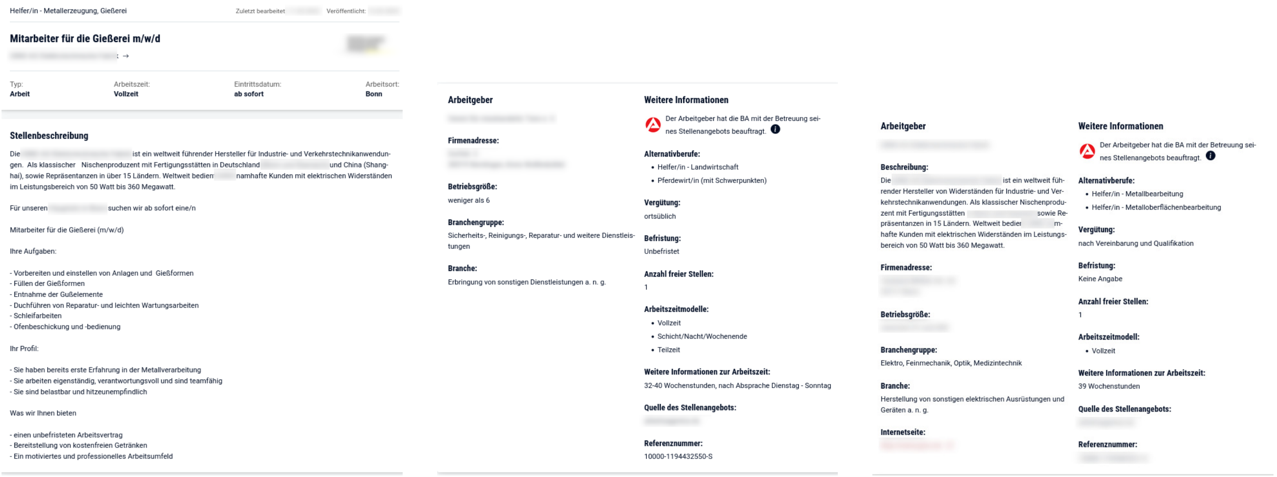
A. Preprocessing

The training subset contains data from the 10 most frequent sections. Only classes with more than 100 samples were selected. To reiterate on the issue of imbalanced data, about 44% of the data points of the training data-set map onto one class (G 46 Wholesale). As we didn't want to introduce an intrinsic bias of our classifier towards one class, we had to re-balance the data-set s.t. the samples constitute a uniform distribution over the WZ08-groups. Naturally, one may consider the threshold for samples per class to be the sample size for the lowest represented class (minority class). This approach might work, but limits the effective usage of a large portion of the training data for classes, which are over-represented (majority class). We chose to set a sample threshold of 4000, under-sample the majority classes, i.e. draw from the pool of samples for the respective class without replacement, and over-sample, i.e. sample with replacement from the respective samples, for the minority-classes to arrive at precisely 4000 samples for each of the classes. To optimize the diversity of the data of the minority classes, we made sure that all of the samples originally contained within the subset were present in the over-sampled data-set. This allowed for a balanced training data-set, trading in loss of generalization of the model on minority classes for a gain of generalization on the majority classes. In practice, we observed that for our training data-set the over- and under-sampling yielded very minor performance improvements on the evaluation data-sets.

B. Model Architecture

We used the `spacy` Python framework for Natural Language Processing (NLP) to fine-tune pre-trained transformer models to the task of text classification. Since it's great influx in popularity following the original publication by authors at Google [21], the transformer has arrived as a commonly used Neural Network Architecture. It has become the de-facto-standard for applications in NLP, given it's highly preferable ability to work on sequential data in parallel, making use of today's large amount of available compute resources as well as enabling the processing of even larger data-sets. The breakthrough included the introduction of a so called "Self-Attention-Layer", a Neural Network component (Figure 6) able to introduce the importance of the relationship between words within a sequence into an embedding used for subsequent processing. Each "Attention-Head" within the Self-Attention-Layer learns to attend to different semantic relationships during training, allowing for enough capacity to find crucial structural and semantic information in the data. We used the encoder part of the transformer to create sequence embeddings, which were then fed into a fully connected block, followed by classification head. This allowed us to fine-tune the pre-trained models on the variable length snippets. We fine-tuned two transformer models `bert-base-german-cased` and `agne/jobBERT-de`, evaluating them respectively on the evaluation data-sets described in Section (III-B). The base BERT (Bidirectional Encoder Representations from Transformers) model is a transformer based model trained by authors at Deepset, available at [22] and was pre-trained on German Wikipedia dumps, OpenLegalData dumps and news articles. The jobBERT-de model [23] is based on the previously mentioned base BERT model and adapted to the domain of job advertisements through continued in-domain pre-training on approx. 4 million German-speaking job advertisements from Switzerland from the years of 1990 to 2020.

We trained our models on a V100 GPU for approximately one hour each. We make the training configurations as well



Helfer/in - Metallerzeugung, Gießerei Zuletzt bearbeitet [redacted] Veröffentlicht: [redacted]

Mitarbeiter für die Gießerei m/w/d

[redacted] →

[redacted]

Typ:	Arbeitszeit:	Eintrittsdatum:	Arbeitsort:
Arbeit	**Vollzeit**	**ab sofort**	**Bonn**

Stellenbeschreibung

Die [redacted] ist ein weltweit führender Hersteller für Industrie- und Verkehrstechnikanwendungen. Als klassischer Nischenproduzent mit Fertigungsstätten in Deutschland [redacted] und China (Shanghai), sowie Repräsentanzen in über 15 Ländern. Weltweit bedien[redacted] namhafte Kunden mit elektrischen Widerständen im Leistungsbereich von 50 Watt bis 360 Megawatt.

Für unseren [redacted] suchen wir ab sofort eine/n

Mitarbeiter für die Gießerei (m/w/d)

Ihre Aufgaben:

- Vorbereiten und einstellen von Anlagen und Gießformen
- Füllen der Gießformen
- Entnahme der Gußelemente
- Duchführen von Reparatur- und leichten Wartungsarbeiten
- Schleifarbeiten
- Ofenbeschickung und -bedienung

Ihr Profil:

- Sie haben bereits erste Erfahrung in der Metallverarbeitung
- Sie arbeiten eigenständig, verantwortungsvoll und sind teamfähig
- Sie sind belastbar und hitzeunempfindlich

Was wir Ihnen bieten

- einen unbefristeten Arbeitsvertrag
- Bereitstellung von kostenfreien Getränken
- Ein motiviertes und professionelles Arbeitsumfeld

V. Evaluation

In the following we present the performance of the two fine-tuned models, for simplicity we will address them by the name of the pre-trained transformer model they are based on, `bert-base-german-cased` (BERT) and `agne/jobBERT-de` (jobBERT). We evaluated both models on three different data-sets. For each pre-trained model, we fine-tuned two classifiers, one to classify Sections and one to classify Divisions. As portrayed in Figure 1, a Sector may contain multiple Divisions. Naturally, the task to classify Divisions is harder, as there are more classes to be classified than in sector-classification.

A. Sections

TABLE I

Precision	0.62	0.66	0.29	0.43	0.94	0.87
Recall	0.72	0.71	0.25	0.23	0.97	0.90
Top 5 Accuracy	0.92	**0.95**	0.58	**0.72**	0.99	**0.99**

We can see from Table I, that the BERT model has generally demonstrated a higher capability to capture information from the training set (Snippets) and archives better results on the Snippets evaluation data-set, which comes from the same data distribution as the training set. The domain-adapted jobBERT model although, demonstrates it's ability to generalize better across data distributions, as we can see that the metrics for the non-training data distributions (i) Wikipedia and (ii) Job-postings are increased in comparison to the vanilla BERT model.

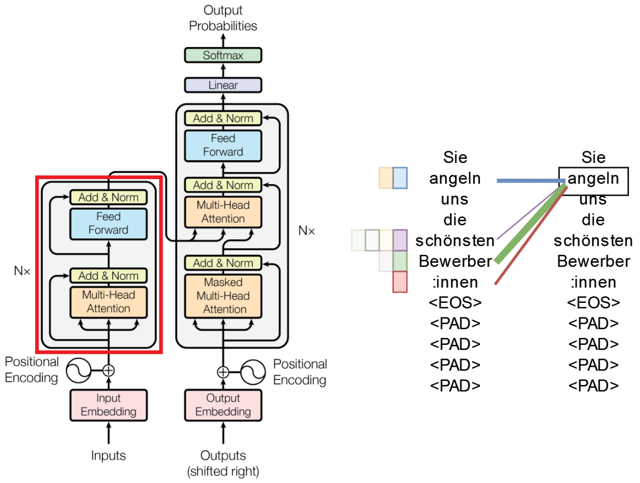

Fig. 6. *Left*: Encoder- (red box) and Decoder-components of the Transformer architecture presented in [21]. For our experiments, the encoder part of the architecture was used.
Right: The Self-Attention mechanism. Different attention-heads (here indicated by different colors) attend to different words in the sequence. Note, that for clarity only the attention for the word "angeln" is displayed. This example highlights the importance of context-sensitive methods. The word "angeln" (fishing) can have multiple meanings in different contexts.

B. Divisions

Our experiments for the classification task on divisions, which partition the sections into subsections, is in contrast to our findings for the section-classification, as we see in Table II that the difference in the predictive capability on the training set data distribution for both classifiers is very similar. The advantages of the domain-adapted jobBERT model on the Job-postings data-set is marginal and on the Wikipedia data-set, the BERT model even outperforms the jobBERT model in terms of the macro-Precision metric. Nonetheless, the jobBERT model still achieves higher top 5 accuracy on the non-training data distributed evaluation data-sets.

TABLE II
(MACRO-) F_1-SCORE, PRECISION, RECALL AND TOP-5-ACCURACY FOR CLASSIFIERS TRAINED FROM BERT (a) AND JOBBERT (b) TO CLASSIFY DIVISIONS (40 CLASSES).

Data-set	Wikipedia		Job-postings		Snippets	
Model	(a)	(b)	(a)	(b)	(a)	(b)
F_1	0.46	0.43	0.11	0.13	0.86	0.86
Precision	0.70	0.51	0.17	0.16	0.87	0.87
Recall	0.45	0.46	0.13	0.14	0.86	0.87
Top 5 Accuracy	0.80	**0.85**	0.41	**0.51**	0.98	**0.98**

VI. Discussion

With our experiments, which we presented in the previous section, we provided empirical evidence, that the domain-adapted transformer model jobBERT generalizes better on non-training data distributions whereas the vanilla BERT model outperforms jobBERT on the training data distribution for a text classification task. We think that the results presented in Table I are comparatively more representative, as the lowered granularity increased the overall training data size. The precision of these results may be improved further by collecting a more diverse data-set, containing more samples from the under-represented minority classes. In our experiments, we counteracted the imbalance of the data-set with oversampling but although this method was mainly introduced to avoid an intrinsic bias of the model and still be able to use most of the training data for the majority classes, it cannot improve predictive capability on the minority classes. If anything, it even lowers the predictive capability for minority classes as our model is prone to over-fitting. An additional concern is, that since the number of tokens the BERT models can process is limited to 512 tokens, some of the valuable information contained in the latter parts of a job-posting or Wikipedia article might be lost, as the underlying `spacy` textcat-model may truncate the input to fit its maximal token length. An approach would be to split the input sequence into sub-sequences that individually conform to the token length constraints of the model, then feed the sub-sequences to the model individually, obtaining multiple classifications from one partitioned sequence. This approach would then introduce the obvious problem, that the model cannot include potentially crucial context across sub-sequences. Another approach would be to make use of a summarization-model or repeated prompting of a Large Language Model (LLM), in order to condense or extract important information. Simple tests, which we've conducted using state of the art LLMs have shown that this approach yields underwhelming summarization or data-extraction performance for our data. However, using more powerful models or different prompting techniques like Chain-Of-Thought [24] or Tree-Of-Thought [25], one might be able to improve upon the simple pre-processing used in this work.

Most importantly though, we would like to bring attention to the dominant problem we are faced with in classifying sectors, namely the problem of mixed domains. As already outlined in the latter parts of subsection III-B, job-postings might contain information on the job itself (e.g. mechanic) *and* the company searching for said talent (e.g. an agricultural firm looking for a mechanic). It is challenging to make the context sensitive distinction between both pieces of information. Staying in the domain of job-postings, text-segmentation could be used to first partition the text into sections (e.g. Address of company, Job description, Requirements etc.), then feeding the segmented text into a subsequent network.

A point of discussion should also be the plausibility of the choice of granularity for the classification, meaning whether it is plausible to attempt to differentiate between Divisions, as for some cases the distinction of inter-section Divisions is challenging even for a human expert. It is for this reason we decided to include the Top-N Accuracy metric into our analysis. We show that even with a straight forward approach like fine-tuning domain-adapted transformer models, we are able to reach 85% Top-5 Accuracy on non-training data distributions (Wikipedia data-set, Table II), i.e. data from a distribution the model has never seen before and hence has had no chance of adapting to. To this end, our findings should be interpreted as a proof of concept, as we have demonstrated that with simple data-sets and straight forward methods we are able to generalize across different data distributions. Naturally, more work is to be done, as we currently lack big annotated data-sets from different data-distributions (one may consider Twitter data, YouTube descriptions, reddit posts etc.) in order to train a model on a balanced mixture data-set.

VII. Bias

We would like to touch on the topic of bias, which is in part introduced by the fine-tuned models themselves a priori. It is likely, that BERT has seen some collection of job-postings, for which the data distribution is unknown. Similarly, the domain-adapted jobBERT was pre-trained on a corpus of job-postings, for which we also don't know the data-distribution. Additionally, it is crucial to mention, that the job-postings on which jobBERT was pre-trained on are of Swiss origin which introduces additional bias. It remains a topic of discussion, whether a corpus of Swiss job-advertisements suffices as a pre-training data-set, if one is trying to fine-tune for classification onto German industrial sectors. As for the evaluation data-sets, the Wikipedia data-set and the Job-postings data-set may have introduced human bias of unknown form. As outlined in subsection (III-C) we will supplement the open sourced datasets provided at [1] with a detailed qualitative evaluation of the annotation process, such as the inter-annotator agreement.

VIII. Conclusion and Outlook

In this paper, we presented our novel approach to classifying general textual data onto German industry sectors using pre-trained transformer models. In the second sections, we introduced the WZ08, a taxonomy of the German industrial sectors, and subsequently discussed the imbalance of both the training- and evaluation-data. We sourced two novel data-sets (a) Wikipedia articles and (b) Job-postings mapping to WZ08 Divisions, to be included in our analysis and discussed the respective details in section III. In the evaluation, we showed that in spite of the difficult challenge of mixed domains and the imbalance of the data available, the domain-adapted transformer model jobBERT was able to generalize better across different data distributions than the regular BERT model in a text classification task. This hints that even with simple methods like fine-tuning a domain-adapted transformer model, one is able to generalize relatively well across unknown data-distributions given a good mixture of data-sets.

Our initial research question was whether one can automatically categorize textual data, such as job ads or company profiles, by industry. We presented and discussed several approaches and showed that this categorization is possible. However, its quality depends on both training and evaluation data. Thus, it also depends on the application and the research question.

All approaches failed for job advertisements. Here we need to redefine a precise research question and in particular provide more feasible information about what data is available (e.g. which metadata could help to improve the quality) and what the expected result should be.

However, our approach provides a reasonable recall of Wikipedia data. Thus, it could help to recommend and provide suggestions for manual curation and annotation on similar textual data. Further research and quality control could help to improve the model. While the presented approach works and provides meaningful results, it is far from being ready for productive use, but shows the significant impact of research in this area.

The initial research question was difficult not only because of the diversity of data and expected outcomes, but also because of the interdisciplinary nature of the research. The social sciences and the example use cases for labor market research have a different perspective on industrial sectors than, for example, economics. Thus, understanding the correct classification depends not only on the research questions, but also on the perspective of different scientific domains. It is very unlikely that a single generic solution could be developed to cover all these different needs. However, more interdisciplinary exchange could help to clarify and guide computer science research in this area.

Acknowledgments

We would like to thank our colleagues Katharina Bär, Nicolai Bör, Lisa Fournier and Jan-Philipp Schroer for helping us out with data annotation.

***Abstract*—The process of open innovation based on advanced materials involves the collaborative sharing of knowledge, ideas, and resources among different organisations, such as academic institutions, businesses, and government agencies. It is suggested that Business Process Modelling and Notations (BPMN) and Elementary Multiperspective Material Ontology (EMMO) be closely integrated to accelerate the development of new materials and technologies and address complex material challenges. In this paper, we examine the integration of EMMO and BPMN through an initial investigation to streamline workflows, enhance communication, and improve the understanding of materials knowledge. We propose a four-step approach to integrate both ontologies, which involves ontology alignment, mapping, integration, and validation. Our approach supports faster and more cost-effective research and development processes, leading to more effective and innovative solutions.**

I. Introduction

DIGITALISATION efforts in the engineering and materials development domains are today introducing new methods for digital collaboration and open innovation, like the one proposed in VIPCOAT[1]: Development projects implementing digitalisation approaches offer a multi-sided platform to create a collaborative environment to connect modellers (software owners, academia), and translators [1], manufacturers, governmental bodies and society to initiate and implement innovation projects (see Fig.1). To assist industrial end-users in making optimal decisions about materials and process design and manufacturing based on predictive modelling, it is increasingly necessary to examine innovation through a quadruple helix approach, which addresses the need for a *Digital Single Market strategy for Open Innovation 2.0* [2].

In parallel, an enormous amount of materials, manufacturing and processing data are currently generated by high throughput experiments and computations, possessing a significant challenge in terms of data integration, sharing and interoperability. A common ontology lays the foundation for solving these issues, enabling semantic interoperability of models, experiments, software and data, which is vital for using rational development design principles and testing and manufacturing of materials in general.

The aim of this work is to contribute to the current efforts by the European Materials Modelling Council EMMC on establishing common standards for materials modelling through the Elementary Multiperspective Material Ontology (EMMO), e.g.: [3]. The basic idea is to merge Business Decision Support Systems, implemented in terms of the BPMN and DMN standards, with materials modelling workflows by using ontologies as a glue between these hitherto distinct worlds.

Given that a product or a material system is defined by a combination of its physical, chemical and other technical properties, as well as other business-related aspects, such as cost, environmental footprint, and other relevant information to the organisation and the society at large. Therefore, it is essential for companies to gather data on the properties of the materials used in their products and vice versa. For instance, the physical and chemical properties of a protective coating can have a significant impact on production time, resource utilisation, manufacturing cost, sustainability, and toxicity.

[1] https://ms.hereon.de/vipcoat/

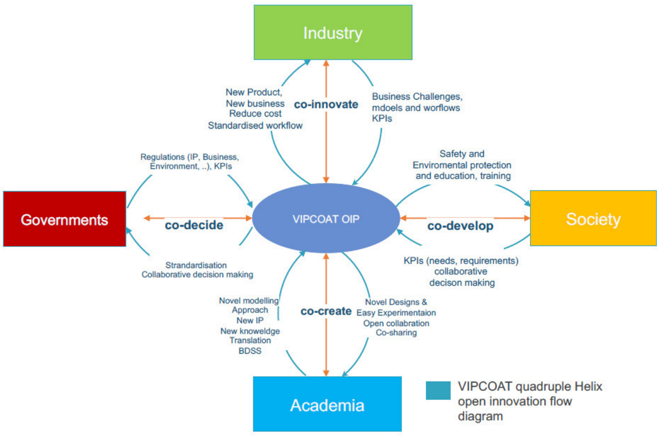

Fig. 1: Four Helix Virtual Open Innovation Framework: Industry, Society, Academia, and Governments

Hence, comprehending the properties of materials is critical to streamlining the manufacturing process, identifying appropriate machinery and equipment, and estimating relevant business indicators for informed decision-making [4]. This integration is particularly important in the context of Open Innovation, where companies collaborate to develop new products and services [5].

BPMN is a crucial tool for Open Innovation processes [6]. BPMN enables organisations to visually depict their business processes and workflows in a standardised format, which fosters more effective communication and collaboration with external stakeholders such as customers, suppliers, and partners. The standardised representation of business processes using BPMN allows for the identification of inefficiencies, redundancies, and bottlenecks in the workflow, leading to streamlined operations and increased efficiency [7]. Moreover, the use of BPMN provides a common language for discussing business processes, making it easier to share ideas and identify opportunities for improvement [5]. As a result, the ontology facilitates collaboration, accelerates innovation, and promotes the sharing of knowledge and best practices between organisations.

Elementary Multiperspective Material Ontology (EMMO), [8], is a comprehensive and versatile ontology for materials science that aims to provide a common language for describing materials and their properties. EMMO was developed by a group of European researchers as a part of the European Materials Modelling Council (EMMC)[2], which recognised the need for a unified approach to materials modelling and interoperability. EMMO is designed to be applicable to all levels of granularity, from atoms and molecules to macroscale materials, and it covers all aspects of materials science, including properties, structures, processes, and applications. EMMO is based on a multiperspective approach, which means it considers different perspectives and scales when describing materials. It provides a hierarchical structure that allows for the description of complex systems and a comprehensive set of classes and relationships for describing materials properties, including chemical composition, crystal structure, thermodynamic and mechanical properties, and more. EMMO is also designed to be extensible. Thus, it can be customised to meet the specific needs of different domains and applications. One of the key strengths of EMMO is its potential to promote interoperability between different materials modelling approaches and software tools. By providing a common language for describing materials and their properties, EMMO can facilitate the integration of models and data from different sources and the development of open standards and interfaces for materials modelling. This, in turn, can accelerate the development of new materials and improve the efficiency of materials design and testing.

In order to bridge the gap between the material science and business domains, this manuscript proposes the use of ontologies to establish a common understanding of the terminology and concepts used in both fields. The integration of the Business Process Model and Notation (BPMN) and the European Materials and Modelling Ontology (EMMO) can facilitate communication and collaboration among stakeholders, ultimately leading to the development of new materials and products. The integration of ontologies can lead to faster and more cost-effective research and development and the creation of innovative solutions to address complex material challenges. The paper aims to answer the research question of *how BPMN can be connected with EMMO* or vice versa, and proposes a concrete approach for integrating ontologies, consisting of conceptual alignments, concept mapping, concept integration, and validation. The proposed approach is applied to a preliminary analysis of integrating BPMN into EMMO. Section II provides an overview of the ontologies, extension mechanisms, and related works, while Section III describes the process of developing the integrated ontology. To know: III-A proposes processes alignment, III-B explains the concept and relationships mapping, III-C yields the integration of the concepts, and finally, III-D formally validates this integration using Incoherence Solving techniques. The paper concludes in Section IV with suggestions for future research areas.

II. Background

This section introduces BPMN and EMMO ontologies, reminds the different ontology extension mechanisms at our disposal, and presents the main related works.

A. BPMN

BPMN stands for Business Process Model and Notation [9]. It is a graphical representation for specifying business processes in a standardised way. BPMN was created by the Business Process Management Initiative (BPMI) and is now maintained by the Object Management Group (OMG)[3].

The primary purpose of BPMN is to provide a standardised notation that is readily understandable by all business stakeholders, including technical and non-technical users. This

[2] https://emmc.eu/

[3] https://www.omg.org/

notation enables clear communication and collaboration between business and technical teams when modelling and analysing processes and supports the execution of processes in a technology-agnostic manner.

BPMN provides a set of graphical elements, such as process, task, gateways, and events, that can be used to model various types of business processes. The notation also supports the modelling of more complex process flows, such as parallel and sequential execution, exception handling, and compensation.

BPMN is a widely adopted standard that helps organisations model, analyse, and improve their business processes, leading to increased efficiency and effectiveness.

B. EMMO

The Elementary Multiperspective Material Ontology (EMMO) is an ontology that provides a standardised and structured representation of the domain of materials science and engineering [10]. An ontology is a type of knowledge representation that defines a common vocabulary and formal model for describing concepts and relationships in a specific domain.

EMMO provides a comprehensive, hierarchical, and interlinked view of the concepts, classes, and relationships that are commonly used in materials science and engineering. It covers a wide range of topics, including material properties, processing techniques, and the relationships between materials and their components. EMMO aims to provide a shared understanding of the concepts and terms used in the field, making it easier for researchers, engineers, and data scientists to collaborate and exchange information.

EMMO is designed to be used as a resource for a variety of applications, including knowledge management, semantic search, and data integration in materials science and engineering. It can also help to integrate diverse data sources and support interdisciplinary research by providing a common vocabulary and conceptual framework. In this paper, we use the EMMO version 1.0.0.bata4 from github. [4]

C. Ontology extension mechanism

According to [11], the integration of two models (metamodels [12] or ontologies [13]) requires resolving three types of heterogeneity: *syntactic*, *semantic* and *structural*. For our integration, only the semantic and structural heterogeneity have been addressed. Indeed, the syntactic heterogeneity aims at analysing the difference between the serialisations of metamodel and, as explained by [14], addresses technical heterogeneity like hardware platforms and operating systems, or access methods, or it addresses the interface heterogeneity like the one which exists if different components are accessible through different access languages [15], [16]. Hence, it is not relevant in the case of this ontological integration.

Structural heterogeneity exists when the same metamodel concepts are modelled differently by each metamodel primitive. This structural heterogeneity has been addressed together with the analysis of the conceptual mapping and the definition of the integration rules. Finally, the semantic heterogeneity represents differences in the meaning of the considered metamodel's elements and must be addressed through elements mapping and integration rules. Regarding the mappings, three situations are possible: no mapping, a mapping of type 1:1, and a mapping of a type n:m (n concepts from one metamodel are mapped with m concepts from the other).

After analysing the heterogeneities, ontology extension mechanisms are applied. Ontology extension mechanisms refer to the ways in which an existing ontology can be expanded or modified to better suit the needs of a particular application or domain. There are several methods that can be used for ontology extension, including:

- Inheritance (generalisation): Inheritance is a refinement, detailing. Generalisation lifts things up. It is an additional level of abstraction. This is a common method of ontology extension in which a new class is defined that inherits properties and characteristics from an existing class. This allows new classes to be defined while reusing existing definitions and knowledge (e.g., in [17], inheritance relationships to extend OWL-S)
- Restriction (specialisation): This is a method of ontology extension in which the definition of an existing class is restricted to exclude certain individuals or objects. This can be used to refine a class's definition to better match a particular application's requirements.
- Extension (by adding axioms): This is a method of ontology extension in which new axioms or statements and rules are added to the ontology to provide additional information or, *a priory*, knowledge.
- Modules and Libraries: This is a method of ontology extension in which ontologies can be packaged as modules or libraries and can be imported or reused in other ontologies.

Each of these methods has its own strengths and limitations, and the appropriate method for a particular extension depends on the application's requirements and the design of the ontology being extended on a case-by-case basis.

D. Related Works

In [18], the proposed approach aims to integrate material modelling with business data and models to develop a Business Decision Support System (BDSS) [6] that assists in the complex decision-making process of selecting and designing polymer-matrix composites. This system combines materials modelling, business tools, and databases into a single workflow, providing a comprehensive solution supporting decision-making. In [7], the authors suggest utilising the BPMN and DMN[5] standards [19] to bridge the gap between business processes, materials science, and engineering workflows in the context of composite material modelling, which can potentially open up new horizons for industrial engineering applications. By using these standards ([20], [19]), it is possible to establish

[4] https://github.com/emmo-repo/EMMO

[5] https://www.omg.org/dmn/

a connection between the diverse domains and provide a more integrated approach to the modelling process, which could lead to improved efficiency and effectiveness in engineering applications.

In line with the previous approach, [21] extends the analysis by incorporating technical key performance indicators (KPIs) and financial KPIs, such as part costs, calculated using cost modelling applications. By including financial KPIs in the analysis, a more comprehensive understanding of the overall performance can be achieved, which can assist in the decision-making process related to product design and development. In [22], the authors discuss the development of an ontology called OSMO, which is an extension of the MODA workflow metadata standard [23], [24] used in European materials modelling projects. OSMO was created as part of the VIMMP project[6] and is connected to the larger effort of ontology engineering by the European Materials Modelling Council, with EMMO as its core. The article explains the purpose, design choices, implementation, and applications of OSMO [22], including its connections to other domain ontologies in computational engineering.

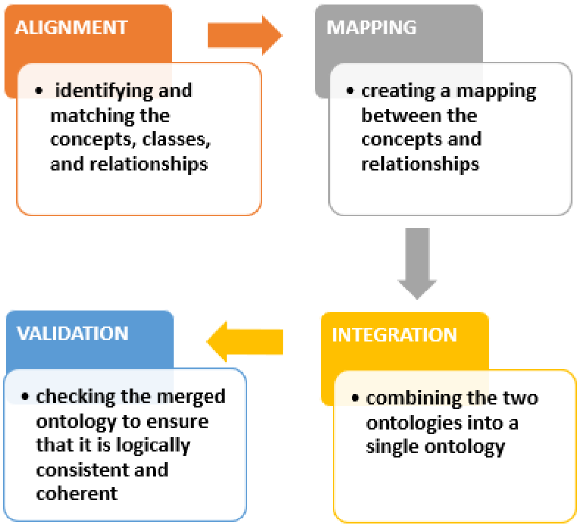
III. Integrating EMMO with BPMN

Merging two ontologies involves the integration of two separate ontologies into a single ontology that reflects the combined knowledge represented by both ontologies [25], [26]. To incorporate BPMN into EMMO, we propose a method, illustrated in Figure 2, that includes the following four steps:

- **Alignment**: This involves identifying and matching the concepts, classes, and relationships in the two ontologies that correspond to each other. This step requires a careful examination of the structure, content, and meaning of the concepts and relationships in both ontologies.
- **Mapping**: This involves creating a mapping between the concepts and relationships in the two ontologies based on the results of the alignment step. This mapping defines how the concepts and relationships in the two ontologies correspond to each other.
- **Integration**: This involves combining the two ontologies into a single ontology, using the mapping as a guide. The resulting merged ontology should reflect the combined knowledge represented by both original ontologies.
- **Validation by Incoherence Solving**: This involves checking the merged ontology to ensure that it is logically consistent and coherent and that it correctly represents the combined knowledge from both original ontologies.

A. Alignment

Conceptual alignment is the process of identifying and establishing the syntactic and structural correspondences between concepts or entities from two or more different sources or domains, should it be at the definition or at the association with other concepts level. To achieve this alignment, we listed all BPMN concepts, including their definition and association, and then we looked for correspondence with the EMMO concepts.



ALIGNMENT
• identifying and matching the concepts, classes, and relationships
MAPPING
• creating a mapping between the concepts and relationships
VALIDATION
• checking the merged ontology to ensure that it is logically consistent and coherent
INTEGRATION
• combining the two ontologies into a single ontology

Fig. 2: Four steps of the method used to integrate BPMN into EMMO: Alignment, Mapping, Integration and Validation

After a deep review of all BPMN concepts, we observed that eight concepts from BPMN may be aligned with nine concepts from EMMO. This alignment is possible based on analysing the concepts' names and definitions (syntactic alignment) and their associations with the other concepts (structural alignment).

1) Process vs. IntentionalProcess: The definition of **Process** from BPMN is *a Process describes a sequence or flow of Activities in an organisation with the objective of carrying out work*, although in EMMO, the **Process** is defined by *A whole that is identified according to criteria based on its temporal evolution that is satisfied throughout its time extension* and the **IntentionalProcess** extends the definition with *occurring with the active participation of an agent that drives the process according to a specific objective (intention)*. Both the **Process** and the **IntentionalProcess** are respectively part of and subClass of Process, and are associated with the **Participant**.

2) Participant (BPMN) vs. Participant (EMMO): In BPMN, a **Participant** *represents a specific PartnerEntity (e.g., a company) and/or a more general PartnerRole (e.g., a buyer, seller, or manufacturer) that are Participants in a Collaboration. A Participant is often responsible for the execution of the Process enclosed in a Pool* although in EMMO, this is *an object which is a holistic spatial part of a process. If plays an active role in the process, this is an Agent*. Both are linked to the concept of BPMN and EMMO's **Process**.

3) Activity vs. Elaboration: BPMN defines the **Activity** as a *work that is performed within a Business Process. An Activity can be atomic or non-atomic (compound)*. From the side of EMMO, an Elaboration is *the process in which an agent works with some entities according to some operative*

[6] Virtual Materials Market Place – https://cordis.europa.eu/project/id/760907

rules. Elaboration is a subClass of IntentionalProcess, and Activity is a component of Process (although not represented in BPMN metamodel from [20]). Both also have subClasses ElementaryWork, Computation, Workflow for Activity and, similarly, CallActivity, Task, SubProcess for Elaboration.

4) Task vs. ElementaryWork: The definition of **Task** in BPMN is *an atomic Activity within a Process flow. A Task is used when the work in the Process cannot be broken down to a finer level of detail. Generally, an end-user and/or applications are used to perform the Task when it is executed*. In EMMO, a **ElementyraWork** is *an elaboration that has no elaboration proper parts, according to a specific type*, which means that an ElementaryWork does not break down into smaller pieces of work. **Task** and **ElementaryWork** are respectively subClasses of **Activity** and **Elaboration**.

5) ThrowEvent vs. Status: Throwing events, following BPMN, *are triggers for catching events and are triggered by the process*, which result in **ThrowEvent** and **Status**, following EMMO, consists in *an object which is a holistic temporal part of a process*. Both concepts have no similar association with other modelling concepts.

6) InteractionNode vs. SubProcess and Stage: The alignment between both concepts from both metamodels is more arduous to establish but is real. In BPMN, the **InteractionNode** is *a type of flow object that represents a point in a process where participants interact with each other to exchange information or perform some action*, and in EMMO, the **SubProcess** is *a process which is a holistic spatial part of a process*, and the **Stage** is *a process which is a holistic temporal part of a process*. The semantic analysis of these three definitions does not make it possible to establish an indisputable alignment between the concepts. However, the analysis of associations clearly shows the similarities. Indeed, the InteractionNode is a subClass of Activity and FlowElementaryContainer, and is composed of Artifact and similarly, (1) the SubProcess has SubProcess and is SubClass of Process and (2), the stage has Stage and is SubClass of Process.

7) SequenceFlow and WorkFlow: According to BPMN, the **SequenceFlow** *is used to show the order of Flow Elements in a Process or a Choreography. Each Sequence Flow has only one source and only one target*. For EMMO, the **Workflow** is *an elaboration that has at least two elaborations as proper parts.* At the association level, the SequenceFlow is a subClass of FlowElement (abstract superclass for all elements that can appear in a Process flow), and the WorkFlow is a SubClass of Elaboration.

8) ItemAwareElement and EncodeData: The **ItemAwareElement** in BPMN refers to *several elements that are subject to store or convey items during process execution* and the **EncodedData** are in EMMO *causal object whose properties variation are encoded by an agent and that can be decoded by another agent according to a specific rule.* The ItemAwareElement concept has type DataObject, DataSTore, DataInput and DataOutput, which are type of information, and the EncodedData is a subClass of Data and has subClass Information.

B. Mapping

In order to integrate BPMN concepts and relationships within EMMO, it is necessary to analyse and select the best ontology extension mechanism (detailed in Section II-C) for each conceptual mapping achieved in Section III-A: Inheritance, Restriction, Extension, or Modules and Libraries – knowing that the last method is inappropriate to the purpose of our work.

1) IntentionalProcess: The analyse of the definitions provided in Section III-A1 demonstrates that both metamodels define the IntentionalProcess/Process based on the same arguments, to know: that a process is structured following a sequence of activities and that it aims to reach an objective. BPMN's semantics is richer than EMMO's semantics in that it associates the process to an organisation. Therefore, the preferred extension mechanism is the restriction (EMMO restricts BPMN conceptual semantics).

2) Participant: EMMO's definition of Participant is more generic than the definition of BPMN, which considers that the participant is a human, or an organisation, that is often responsible for the execution of a process. This is more specific than EMMO's point of view, which considers that an object demonstrating a holistic spacial part of the process is a participant. Accordingly, the extension mechanism that fits this alignment is inheritance. First, the BPMN's participant inherits the characteristics of EMMO's participant, and second, the EMMO's participant is extended with two possible statements: the participant is either a human or an organisation.

3) Elaboration: EMMO's definition of Elaboration is semantically a bit different than BPMN's definition of Activity. On one side, BPMN explains that the Activity may be atomic or compound, and on the other side, EMMO stresses the importance of the Elaboration to work following some operative rules. As a result, the most appropriate extension mechanism is inheritance, and the EMMO Elaboration is extended with a composition link from/to the EMMO Elaboration concept.

4) ElementaryWork: Task and ElementaryWork have the same semantics, and both refer to the smallest and indivisible piece of work composing a process. The definition of the Task from BPMN (Section III-A4) is semantically richer in that it stresses the importance of being within a traffic flow and being performed by an end-user or an application. In this case, the ontology extension mechanism used is the extension (BPMN extends EMMO conceptual semantic).

5) Status: The definition of Status in EMMO highlights that this concept stands for an object that reflects a temporal part of a process, whereas BPMN defines ThrowEvent as a trigger for catching events by the process. Although not explicitly embedded in the definition, the Status associated with a process often triggers other events in practice. Therefore, we consider that this Status may be a type of trigger and, by extension, a ThrowEvent. Therefore, the mapping between both concepts is achieved using the restriction mechanism given that EMMO restricts ThrowEvent to Status.

6) SubProcess and Stage: Both concepts represent part of the process (spacial or temporal), such as the InteractionNode from BPMN, which is described as a point in a process. The semantic heterogeneity between both BPMN and EMMO meanings is that the first specialises the finality of the concept to a place (or moment) where participants get together to achieve something or to exchange information. The description of the InteractionNode is consequently semantically more expressive, although both SubProcess and Stage refer to a spacial or a temporal dimension. As a result, the extension mechanism is the restriction since both EMMO's concepts restrict BPMN one. This situation is quite similar to the case of the IntentionalProcess, but because two concepts of EMMO are mapped to one concept of BPMN, it is not necessary to extend the concepts with a dedicated extension mechanism.

7) WorkFlow: Analysing the definitions of the WorkFlow and of the SequenceFlow, we conclude that the equivalence between both concepts is thin and limited. Both concepts are direct or indirect elements of the process that are associated with at least two flowing elements. The SequenceFlow adds a supplementary characteristic which is the existing sequence between the happening of the flowing elements. The extension mechanism preferred is, by the way, the restriction as WorkFlow restricts the SequenceFlow meaning.

8) EncodedData: The ItemAwareElement concept in BPMN represents an abstract concept that may be specialised in many types like DataObject, DataStore, DataInput and DataOutput although the EncodedData concept is well defined and refers to properties variation of an object. This definition restricts by the way the definition of the ItemAwareElement and, as a consequence, the restriction extension mechanism is the one naturally designated.

C. Integration

In the approach used in this work, all concepts from BPMN without EMMO equivalence have been introduced in the integrated EMMO ontology. The main concepts are: Gateway, Events, Artifact, InteractionNode, FlowElementContainer, FlowElement, MessageFlow, DataAssociation, DataOutputAssociation, DataInputAssociation, DataObject, DataOutput, DataInput, CallableElement. Further explanations of those concepts are available in BPMN 2.0 specifications [9].

The integration of BPMN concepts with EMMO equivalence is achieved based on the mapping performed in Section III-B and taking in hand the resolution of potential associations–related issues. This analyses, for each concept is the following:

1) IntentionalProcess: The BPMN process being semantically richer than the IntentionalProcess, we may consider that the IntentionalProcess is a subClass of the BPMN Process concept, which is represented as a **type of** relation in UML. In the integrated ontology, the IntentionalProcess is preserved. Concerning the relationships, two associations which did not exist for the EMMO concept have been added in the integrated version. It consists of (1) the IntentionalProcess **is linked to** Collaboration and (2) the IntentionalProcess **is composed of** Artefact.

2) Participant: EMMO's definition of Participant being more generic, we have maintained the EMMO's Participant concept in the integrated ontology, and we have extended it with an attribute inherited from BPMN, to know: *the Participant is an individual or an organisation that is often responsible for the execution of the Process*. Regarding the relationships, two associations which did not exist for the EMMO concept have been added in the integrated version: (1) the Participant **composes** the Collaboration (2) the Participant is a **type of** InteractionNode.

3) Elaboration: Given the small heterogeneity's existing between Elaboration and Activity and the decision to consider the inheritance extension mechanism, we have maintained the EMMO's Participant concept in the integrated ontology, and we have extended it with a composition link, as explained in Section III-B3, such as an Elaboration **composes** an Elaboration. In parallel, three additional Activity related associations from BPMN have also been included in EMMO Elaboration: (1) an Elaboration **is composed of** DataInputAssociation, (2) an Elaboration **is composed of** DataOutputAssociation, and (3) an Elaboration is a **type of** FlowNode.

4) ElementaryWork: Alike the IntentionalProcess, the ElementaryWork is less rich than the Task semantic from BPMN, and for the same reason, the extension mechanism elected during the mapping step was the extension mechanism. Accordingly, we keep the ElementaryWork in EMMO extended ontology. Concerning the associated relationships, we complete the existing ones with (1) the ElementaryWork is a **type of** InteractioNode, and (2) the ElementaryWork **has type** various kinds of tasks (i.e., ScriptTask, ServiceTask, BusinessRuleTask, ManualTask, SendTask, ReceiveTask and UserTask)

5) Status: EMMOS's definition of Status restricts BPMN's definition of ThrowEvent to a state of a temporal part of a process, and as a result, that a Status is a **type of** ThrowEvent. Accordingly, the Status process is preserved in the EMMO ontology. Concerning the relationships, four associations which previously did not exist in EMMO have been added in the integrated version. It consists of (1) Status is a **type of** Event, (2, 3 and 4) Status **has type** EndEvent, ImplicitThrowEvent and IntermediateThrowEvent.

6) SubProcess and Stage: SubProcess and Stage's definitions, as reviewed in Section III-B6, restrict the definition of InteractionNode. They are both preserved in the EMMO ontology. Moreover, to express that these concepts may correspond to points where participants get together to achieve something or to exchange information, new associations are defined between them and the participants.

7) WorkFlow: Provided the tight analogy between Wokflow from the EMMO ontology and the SequenceFlow from BPMN, our strategy was to use the restriction extension mechanism and, consequently, to preserve the concept of WorkFlow in the integrated ontology. Two associations are needed to complete the ontology integration with some workflow–related semantics coming from BPMN: (1) the WorkFlow **is source**

of and **targets** FlowNode and (2) the WorkFlow is a **type of** FlowElement.

8) EncodedData: EncodedData from EMMO has a precise meaning compared to ItemAwareElement from BPMN, which has more for the purpose of specifying a collection of data. On the opposite, the ItemAwareElement may be of various types described in [20]: DataObject, DataStore, DataOutput and DataInput. Hence, EncodedData will remain in the integrated ontology. Finally, one additional association must be integrated: EncodedData **is source** and **is target** of DataAssociation.

D. Validation by Incoherence Solving

In general, validating a single ontology involves checking whether the ontology adheres to certain principles and standards [27]. Here are the type of validations that can be encountered and applied: syntax validation (*Does the ontology follows the correct syntax and format of the ontology language?*), consistency validation (*Is the ontology internally consistent?*), completeness validation (*Does the ontology covers all the necessary concepts and relationships in the domain?*), coherence validation (*Is the ontology coherent with other ontologies and standards in the same domain?*), usability validation (*Is the ontology easy to use and understand?*), but also the validation of specific ontology criterion such as the accuracy, coverage, scalability, and maintainability.

In the case of the validation of the integration of one ontology with another (BMPN with EMMO), we may assume that the above validation types have been achieved during the design of each specific ontology and that the item left to be validated is merging part itself, to know: Checking for inconsistencies between the ontologies. In general, this can be achieved by using a reasoner that checks for logical consistency (e.g., Pellet [28]), such as whether there are unsatisfiable classes or cycles in the hierarchy.

In the integration of BPMN within EMMO (Figure 3), we illustrate the validation by discussing one type of incoherency manually discovered in the integrated ontology. This incoherence is a cycle in the hierarchy that has been introduced between in the concept of **ElementaryWork** from EMMO and **InteractionNode** from BPMN. Solving this incoherency, in this case, requires a deeper analysis of both source ontologies. Therefore, by analysing EMMO and BPMN, it can be argued that an **ElementaryWork** can be considered a type of **InteractionNode** because an elementary work is a basic process that involves the transformation of materials, energy, or information, often through the application of energy such as heat or mechanical work. This transformation typically involves some kind of interaction between two or more entities, such as a chemical, an electrical or even a nuclear reaction or a physical change in state. Moreover, an **InteractionNode** is a node representing any type of interaction between two or more entities in a business process model. This can include tasks, events, and gateways, which are used to model different types of interactions. Therefore, it can be argued that an elementary work, which represents a basic process that transforms materials, energy, or information, can also be considered an **InteractionNode** because it involves an interaction between two or more entities, even if it is a more fundamental type of interaction compared to other types of nodes. Hence, both **ElementaryWork** and **InteractionNode** represent different types of nodes in a business process model, but an **ElementaryWork** can be seen as a more fundamental type of interaction that involves the transformation of materials, energy, or information, making it a type of **InteractionNode** in a broader sense. As a consequence, the decision was made during the Validation by Incoherence Solving step to keep the link "ElementaryWork is a type of InteractionNode" in the integrated model while removing the link "InteractionNode is a type of ElementaryWork".

IV. Conclusions and future works

This paper enhances the process of open innovation within the materials industry [2]. To achieve this goal, we propose an approach never achieved before that involves integrating two ontologies to unify the innovation process with the processing of materials. Specifically, we utilise the BPMN ontology to support the open innovation process and the EMMO ontology to describe the materials. By merging these two ontologies, we can create a more comprehensive framework that can facilitate collaboration and innovation in the materials industry. This integration aims to streamline the workflow, improve communication, and enhance the understanding of materials, leading to more effective and innovative solutions.

Our proposed approach consists of four key steps: Alignment, Mapping, Integration, and Validation by Incoherence Solving. While alignment and mapping are relatively straightforward, the integration step requires more careful consideration. For instance, we have observed that when the extension mechanism takes the form of a restriction, the BPMN concept is not taken into account. On the other hand, when the extension mechanism is an inheritance, the EMMO concept is extended with the attributes inherited from BPMN. So far, we have not yet encountered a case where the extension mechanism involves a type extension by adding new axioms.

This paper presents a significant step towards achieving open innovation in the materials industry. The ontological integration of BPMN with EMMO can bring about transformative changes to the field by enabling faster and more cost-effective research and development processes and creating innovative material solutions to address complex challenges. Our approach also has the potential to improve communication and streamline workflows, which can lead to greater efficiency and productivity. Moreover, the integration of these two ontologies can enhance the understanding of materials and provide a more detailed description of materials in the innovation process. As a result, organisations can gain a competitive advantage by leveraging this approach and advancing the materials industry with novel and impactful solutions. Overall, our proposed approach has the potential to revolutionise the field of materials science and accelerate progress towards open innovation.

As future works, much must be done to improve ontology and

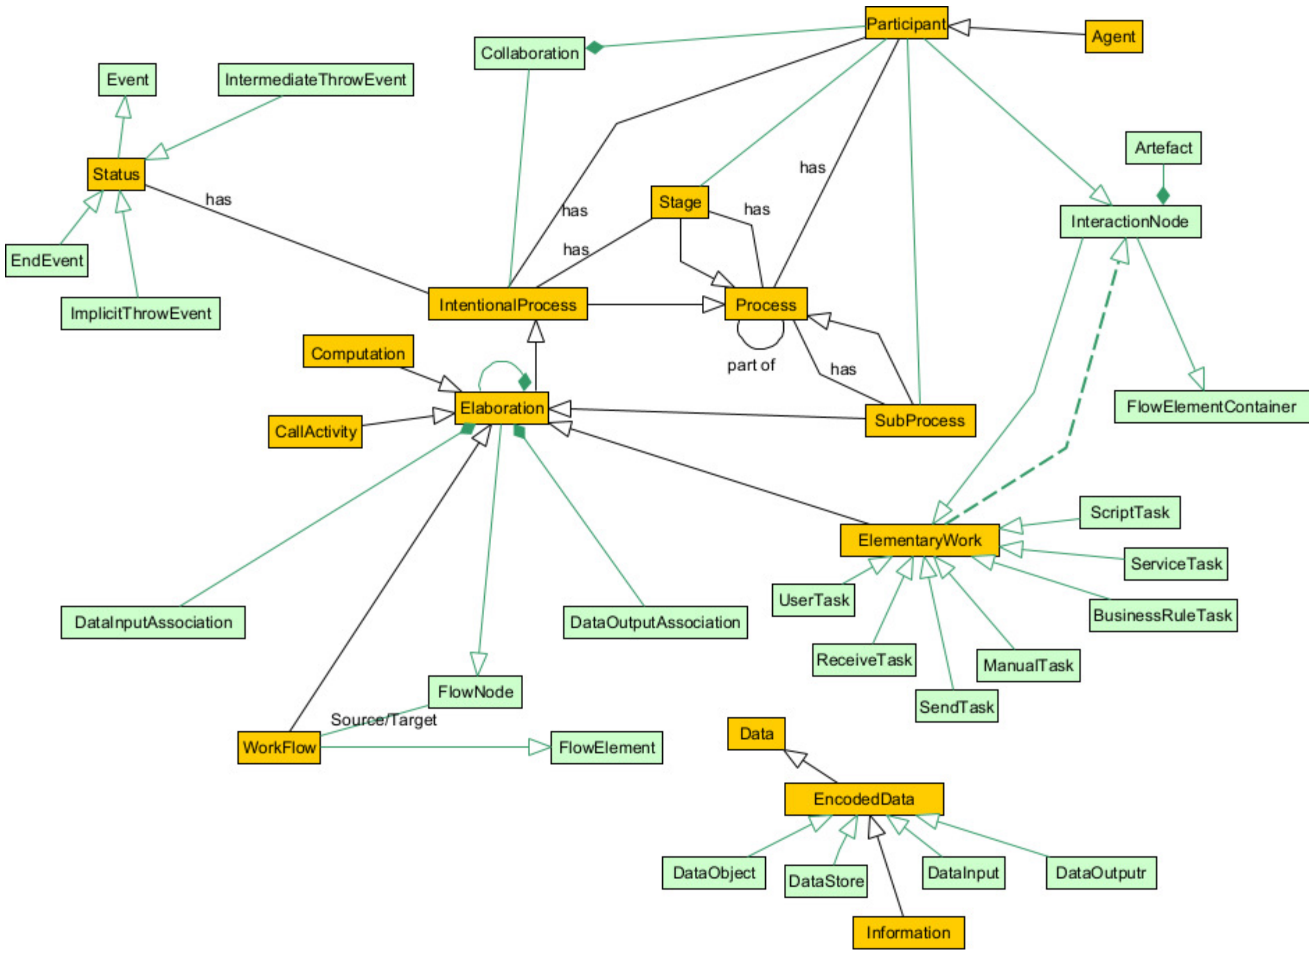


Fig. 3: Integrated BPMN's concepts within EMMO ontology. On this schema, the concepts from EMMO ontology are represented in orange and the concepts from BPMN are in green.

its application in real-world scenarios. Our first priority is to enhance the integration of the two ontologies by potentially considering other concepts that have not yet been integrated. By doing so, we aim to create a more robust and complete ontology that can capture all relevant aspects of the domain. Secondly, we must conduct further analysis to identify potential incoherencies in the integrated ontology. While we have already identified one example of a cyclic association between the ElementaryWork and the InteractionNode, additional review and analysis are necessary to ensure that no remaining incoherencies exist. Thirdly, we plan to validate the ontology by applying it to a real case and observing to what extent it is possible to consider all the dimensions of the real scenario with the integrated ontology. This will allow us to assess the advantages of using the integrated ontology in practice and identify any areas for further improvement. Finally, we aim to deploy the ontology in a software tool like *Protégé* [29] to facilitate its manipulation and representation. This will enable other researchers and practitioners to use the ontology easily and effectively in their own work. Overall, our goal is to create a more comprehensive, coherent, and useful ontology that can help researchers and practitioners better understand and navigate the complex domain. We hope our ongoing efforts will lead to further advancements in the field and contribute to developing more effective tools and applications.

***Abstract*—Metaprogramming, the practice of writing programs that manipulate other programs at compile-time, continues to impact software development; enabling new approaches to optimisation, static analysis, and reflection. Nevertheless, a significant challenge associated with advanced metaprogramming techniques, including the *constexpr* functionality introduced to C++ in 2011, is an increase in compilation times. This paper presents ClangOz, a novel Clang-based research compiler that addresses this issue by evaluating relevant constant expressions in parallel, thereby reducing compilation time.**

ClangOz includes a set of compiler intrinsics that allows developers to parallelise their own code and take full advantage of recent constexpr language support. By utilising parallel evaluation, ClangOz significantly reduces the compile time for metaprogramming-intensive codebases, enhancing developer productivity and iterative software development processes.

Benchmark results demonstrate the performance advantage of ClangOz over traditional compilers, including a decrease in compilation times across all benchmarks; and parallel efficiency of up to 95% in one case. The evaluation of constant expressions in parallel unlocks substantial speedups, enabling developers to leverage advanced metaprogramming techniques without sacrificing compilation efficiency.

We highlight the opportunities afforded by the constexpr functionality and emphasise the importance of compiler support for efficient metaprogramming. By introducing ClangOz, a compiler tailored for parallel evaluation of relevant constant expressions, developers can utilise modern metaprogramming while minimising compilation times parametrically.

I. Introduction

COMPILE time metaprogramming in C++ has been of interest since the discovery that C++ templates were Turing complete [1]. Exploration of compile time metaprogramming has resulted in the addition of constant expressions to the language; a concept proposed in 2003 [2]; and added in C++11 with the inclusion of the *constexpr* specifier. A constant expression is an expression which would remain constant at runtime and could thus be evaluated at compile time. The *constexpr* specifier allows functions and variable declarations to assert that they can be evaluated at compile time. With the addition of this specifier, compile time programming has become more approachable, with a syntax almost identical to runtime code.

Since the addition of constant expressions to C++, the standard library specification has begun to incorporate support for both compile time and runtime execution for its functionality. With the increasing *constexpr* support, larger program segments can now be evaluated at compile time. However, as more components are evaluated at compile time, so too do compilation times increase. Adding parallelism to a program can help increase performance when used correctly. Yet parallelism is currently only available in runtime contexts; there is no existing concept of C++ compile time parallelism.

In this article we introduce ClangOz [3], an experimental Clang [4] compiler which adds support for the parallel execution of for-loops at compile time. ClangOz seeks to give users control of parallelism through compiler intrinsics. The intrinsics are a set of functions built into the compiler, which may be utilised to convey information about the algorithm being *constexpr* parallelised to ClangOz. A higher level application programming interface (API) is also provided which builds upon the *execution policy* overloads of existing standard C++ runtime library functions such as *std::for_each*, to allow easier access to *constexpr* parallelism.

A survey of related and relevant literature is presented in Section II. Section III covers the ClangOz compiler, discussing its architecture; parallel constant expression evaluation; and intrinsics library, along with a concise implementation example of *std::for_each*. Before concluding in Section V, Section IV reports on experiments, with benchmarks implemented using the novel compile time parallelism feature, and considers performance and scaling in comparison with serial counterparts.

II. Background

Parallelism within compilers is not new, and much research has been undertaken, aiming to speed up different phases of the compiler. For example, investigation on the parallelisation of parsing [5], assembling [6], semantic analysis [7], lexical analysis [8] and code generation [9] compiler phases have been conducted. Despite this, most modern compilers avoid the additional complexity of adding parallelism for performance. The research presented in this paper differs from the prior art as it pertains to a smaller segment of the compiler; a subsection of the semantic analysis process. Nevertheless, it does adds an overhead for compiler developers; even if it is smaller in scope. This work is also distinct in placing the parallelism into the users' hands through an API, making the parallelism explicitly programmable.

The landscape of C++ compile time programming has continued to expand in recent years. In the 2020 iteration of the language (C++20 [10]) dynamic memory allocation and deallocation at compile time was added [11]. This allowed the creation of variable size containers at compile time. C++20 also introduced a feature called *Concepts* [12], allowing a user to constrain template instantiation according to composable boolean predicates. Concepts allow for increased user defined type-safety within code bases, while improving error messages. Further proposals are pending, with the most interesting possible additions being metaclasses [13] and reflection [14]. The former allows users to define a compile time function that manipulates how a class's definition is generated; for example to make member functions of a class public by default. The latter allows deeper compile time introspection of types; for instance, to check the names of class members.

Additions like these to the language specification have allowed for projects that were previously impossible. The processing of regular expressions at compile time [15], static reflection through a library rather than the language [16], big-integer computation [17] and compile time functional composition [18] are prominent examples. Such projects require a sizable amount of computation at compile time, and would benefit from acceleration by *constexpr* parallelisation.

Providing language features to allow processing at compile time is not unique to C++. Lisp [19], D [20], Rust [21], Julia [22], Elixir [23] and Circle [24] all give various compile time facilities. Lisp was the first language with Turing-complete compile time functionality; Lisp provides this feature in the form of macros which, unlike C-style macros, can perform computation as well as text substitution. The D programming language has many similarities to C++. Its compile time features are based upon it, with the intent to simplify them. The D language allows compile time programming using constructs similar to C++ templates and constant expressions, though it extends these concepts with the introduction of eponymous and nested templates. In contrast: Rust, Julia and Elixir make use of Lisp-style macros that manipulate the AST for their compile time metaprogramming. Rust and Julia also support compile time computation through constant expressions that share similarities with C++. The Circle language is interesting as it builds on-top of C++17, adding a host of new data-driven metaprogramming features including range operators and pack generators. The concepts introduced in this paper could in turn be extended to such programming languages, having similar compile time capabilities, albeit in a different guise when the capabilities are macro based.

The evaluation of constant expressions at compile time has parallels in the field of partial evaluation [25], where programs are specialised dynamically at runtime or statically at compile time to achieve better performance. Partial evaluation of programs can lead to optimisations including constant folding; code simplification; strength reduction; and control flow optimisation. All such optimisations are possible through the explicit utilisation of *constexpr* within C++ to specialise code; and we recognise that the comparison of partial evaluation and C++'s compile time features has been made before [26]. Research into partial evaluation and its applications have been ongoing for many years; and recently applied to the field of High-Performance Computing with the aim of increasing performance in a myriad of ways. For example, using static partial evaluation to optimise memory access patterns on the GPU [27]; creating domain specific languages utilising partial evaluation to facilitate high-performance libraries for accelerators [28]; and in the development of compilers and interpreters for dynamic languages that utilise partial evaluation to speculatively optimise code [29]. In a similar vein to the work in this paper for compile time evaluation, some research on parallel evaluation of partial evaluation has also been conducted. Some examples are the parallelisation of a partial evaluator utilised in the specialisation of mutually recursive procedures [30]; distributed parallelisation of partial evaluators within programming languages [31]; and parallelisation of partial evaluations within evolutionary algorithms [32].

III. Compile Time Parallelism

The ClangOz[1] compiler builds on Clang by adding parallelisation support to *for* loops in specific *constexpr* contexts. This is performed using an API of four intrinsic functions[2], used to communicate to the compiler how a loop should be parallelised. The intrinsic calls are placed within the function body containing each targeted loop; and assist with loop dependency analysis [33].

When the following constraints have been met within a *constexpr* function, ClangOz will use these intrinsics to gather the information required to partition the loop body across multiple CPU threads. There are two constraints that have to be met by a *for* loop to be *constexpr* parallelised. First, it must be within a *constexpr* function; and adjacent to the appropriate parallelisation intrinsics. Second, the enclosing function must include our new C++ execution policy class [34] within its parameter list; and be invoked with the corresponding object as an argument. An execution policy parameter allows an algorithm designer to overload a function's behaviour based on the

[1] The compiler has no connection to Mozart and the Oz language.

[2] These are not *Clang* intrinsics per se; though they perform a similar role.

type of each distinct policy. For example, a *std::for_each* function may be passed a *std::execution::parallel_policy* which indicates that the *std::for_each* should select an overload that has a parallelised implementation. In the case of ClangOz a new *constexpr_parallel_policy* was added to ClangOz's C++ standard library (a modified version of Clang's implementation of the C++ standard library: libc++) which is used to indicate that a function should be *constexpr* parallelised if possible.

These constraints define a minimal C++ API that *constexpr* functions must meet to undergo the parallelisation process. The constraints were added as a way to limit the scope at which ClangOz would try to apply its parallelisation process.

There are some limitations of the ClangOz compiler worth noting. First, there is no support for nested parallelism; only the outer loop of a loop nest is parallelisable. Second, only a single loop is parallelisable within each function. Thirdly, only container argument types owning *contiguous* data are supported; and container objects must utilise a pointer-based iterator. An example usage of a *constexpr* parallel *std::for_each* from ClangOz's modified libc++ can be found in Listing 1. *execution::ce_par* is a simple, 1-byte, pre-constructed *constexpr_parallel_policy* object. Passing this policy into the *std::for_each* indicates to use a parallel implementation of the function; if one exists. The 4th argument, a C++ lambda function, is then executed in parallel on the elements of the *std::array*.

Listing 1 ClangOz's modified libc++ supports a new *ce_par* policy parameter, allowing users to avoid compiler intrinsics.

```
constexpr auto f() {
  std::array<int, 4> arr {};
  std::for_each(execution::ce_par,
                arr.begin(), arr.end(),
                [](int &i) { i++; });
  return arr;
}
```

The parallelisation process takes place within Clang's constant expression evaluator. The constant expression evaluation executes within the frontend, usually during the semantic analysis process; either when generating the abstract syntax tree (AST), or during later code generation.

The constant expression evaluator attempts constant folding on expressions stored in AST nodes; collapsing them into a value or values at compile time by processing the expression. The values are calculated and stored using Clang's *APValue* class. This class holds constant data of arbitrary bit-widths for several C++ value types; including *float*, *integer* and arrays.

Manipulation of *APValue* objects is pivotal to the parallelisation process, and in particular those that are *LValue*s. Generally, *LValue*s are locators for objects. An *LValue* can contain either the path from a complete object to its subobject; or a memory address offset. These are important as the majority of the parallelised standard C++ library algorithms use *iterators*: an idiomatic abstraction over the traversal strategy of each container. The parallelisation process manipulates and gathers information from these iterators; with pointers a common form.

Clang's *CallStackFrame* and *EvalInfo* classes are also integral. The former acts as a call stack for the constant expression evaluator; maintaining information for the current call stack frame, and tracking the arguments passed to the frame and the temporaries that reside within it. Alongside, a pointer to the preceding frame in the stack is also stored, to facilitate backwards traversal. The *EvalInfo* class maintains information about the expression being evaluated, including the *CallStackFrame*. These classes maintain most of the evaluator's state during evaluation.

Two Clang AST components that are useful for the parallelisation process are the *Expr* and *Decl* family of classes. The former maintains information about types of expressions; for example *CallExpr* maintains information about function invocations. The latter, tracks declarations or definitions of different language constructs; for example information on each function definition is stored within a *FunctionDecl*.

A. The Parallelisation Process

The parallelisation process consists of four phases (See Fig. 1). The first phase is *verification*, confirming that the two constraints have been satisfied. These constraints are checked whenever a *for* loop is encountered within a *constexpr* context.

TABLE I
THE CLANGOZ INTRINSIC FUNCTIONS

Intrinsic Function Code	Function and Parameters Synopsis

`template <class T, class U>`
`constexpr void`
`__BeginEndIteratorPair(`
`  T& Begin,`
`  U& End`
`)`
	Indicates the range of a *for* loop, allowing the partitioning process to split work across multiple threads. The *__BeginEndIteratorPair* or *__PartitionUsingIndex* intrinsic are required and the minimum necessary for parallelisation.
	• **Begin**, **End**: Indicates the beginning and end of the loops range.
	• **Type requirements**: *T* and *U* must be a one member iterator where the member is a pointer or a pointer.

`template <class T, class U>`
`constexpr void`
`__PartitionUsingIndex(`
`  T LHS,`
`  U RHS,`
`  RelationalType RelTy`
`)`
	Indicates the range of a *for* loop, allowing the partitioning process to split work across multiple threads. The *__BeginEndIteratorPair* or *__PartitionUsingIndex* intrinsic are required and the minimum necessary for parallelisation.
	• **LHS**, **RHS**: Indicates the beginning and end of the loops range.
	• **RelTy**: Indicates the relational operator used within the loop's condition e.g. >, <, !=, <=, >=.
	• **Type requirements**: *T* and *U* must be a numeric type, such as an integer.

`template <class T>`
`constexpr void`
`__IteratorLoopStep(`
`  T& StartIter,`
`  OperatorType OpTy,`
`  const T& BoundIter`
`)`
	States *StartIter* is bound to the loops step. Thread clones will initially be offset by invoking operator based mutation the same number of steps taken by the thread partitions loop at its start point. The operator used for mutation is indicated by *OpTy*.
	• **StartIter**: Indicates the variable that will be offset.
	• **OpTy**: Indicates the prefix or postfix operator (e.g. ++) used for mutation.
	• **BoundIter**: Indicates the boundary of *StartIter* if one exists, preventing offsetting past the boundary.
	• **Type requirements**: *T* must be a one member iterator where the member is a pointer or a pointer.

`template <class T>`
`constexpr void`
`__ReduceVariable(`
`  T Var,`
`  ReductionType RedTy,`
`  OperatorType OpTy`
`)`
	Indicates that a container or value should be reduced when the launched threads are joined. Three types of reduction are supported *PartitionedOrderedAssign*, *OrderedAssign* or *Accumulate*.
	• **Var**: Notates the variable that should be reduced on thread completion.
	• **RedTy**: Indicates the reduction method to be used by the compiler.
	• **OpTy**: States the operator, if any, used to mutate the variable in the reduction step.
	• **Type requirements**: *T* must be a vector or array iterator or numeric value.

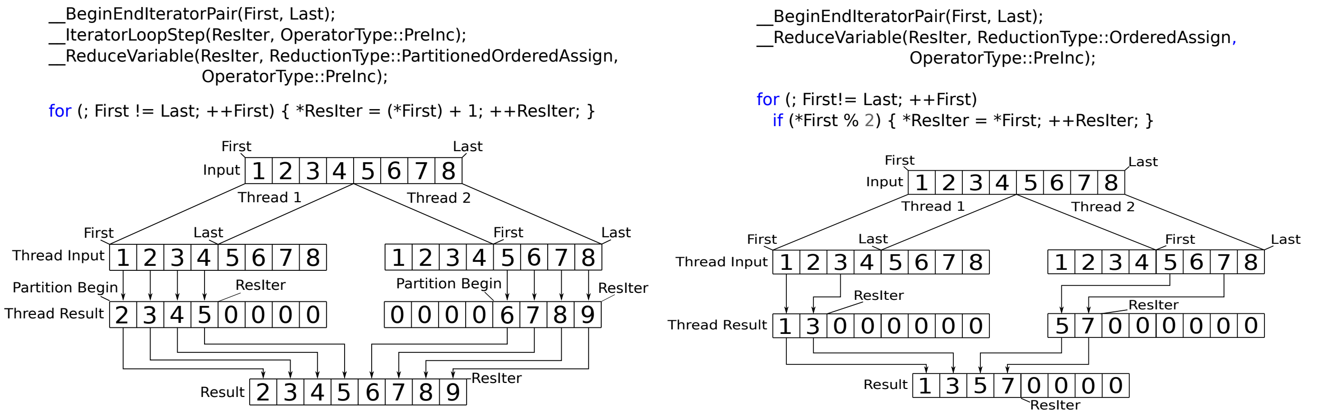
The first step checks the enclosing context is a function, before iterating over the function's parameters to detect if the function takes a *constexpr_parallel_policy* as an argument. As nested parallelism is not supported, the second check makes sure that no other *constexpr* parallel tasks are in flight.

The second phase is *preparation*, where the intrinsics are processed; local data is prepared for each thread; and the loop space is partitioned. This phase involves creating a clone of the *EvalInfo* object per thread, as well as each of the *CallStackFrame*s it contains. The *APValue*s that reside in each *CallStackFrame* are also cloned; representing both dynamically and statically allocated data.

After the data has been cloned the partitioning process begins, using static loop partitioning to divide the work across multiple threads. If the data cannot be divided evenly across threads which are maintained by a single thread pool; any excess work is given to the final thread. This partitioning process is part of the *LoopIntrinsicGatherer* class, an addition to ClangOz that implements the functionality for handling the intrinsics, cloning data and reducing data. The partitioning is reliant on the *__BeginEndIteratorPair* or *__PartitionUsingIndex* intrinsic being used by the creator of the function to specify the loop bounds. These and other intrinsics are discussed further in Section III-B.

The intrinsics are discovered prior to the partitioning process by traversing the function body containing the loop, statement by statement, checking the name of each function called against the list of intrinsic names. This is done by making the *LoopIntrinsicGatherer* a child of *Clang*'s *ConstStmtVisitor* which recursively visits a *Stmt*, breaking it into its constituent *Stmt* types. Each *Stmt* in the body of the *FunctionDecl* is then iterated over, and passed to the recursive visitor, which then searches for *CallExpr* nodes to verify and process.

Each thread has copies of the variables defining the loop



```
__BeginEndIteratorPair(First, Last);
__IteratorLoopStep(ResIter, OperatorType::PreInc);
__ReduceVariable(ResIter, ReductionType::PartitionedOrderedAssign,
                 OperatorType::PreInc);

for (; First != Last; ++First) { *ResIter = (*First) + 1; ++ResIter; }
```

```
__BeginEndIteratorPair(First, Last);
__ReduceVariable(ResIter, ReductionType::OrderedAssign,
                 OperatorType::PreInc);

for (; First!= Last; ++First)
  if (*First % 2) { *ResIter = *First; ++ResIter; }
```

Fig. 2. Example PartitionedOrderedAssign (Left) and OrderedAssign (Right) Reduction With Two Threads

bounds; provided in the initialisation, condition and iteration statements. Dividing the workload across threads requires offsetting the underlying *APValue*s of these variables; and in particular those found in the loop's condition statement, which help to define its range. In the case of the standard library algorithms, the loop conditions are equality checks; for example, comparing the start and end pointers from a container to check that they are not equal. It is possible to offset the pointer's *APValue* to point to the start and end of the loop partition for each thread, effectively segmenting the loop.

To calculate the appropriate size of each partition, and the amount required to offset the loop's start and end by, the size of the iteration space must be calculated. This distance can then be divided by the number of partitions provisioned. For loop bounds defined by integer values, this is straightforward. With pointers, the size of the container's element type is required; and memory addresses to a contiguous container are traversed using an offset based on the size of the element type. Calculating the distance requires utilising this size to convert from a memory address to an integral number representing the loop's range. This can then be used to calculate the offset for each partition, and then each pointer can be offset by the appropriate amount. Only containers of contiguous data are supported, as partitioning non-contiguous data involving arbitrary memory locations is non-trivial, and time intensive.

After the work has been distributed, the third phase begins: the *execution* phase. Tasks, encapsulated as C++ function objects (often lambda functions), are launched asynchronously, and then a *wait* for completion is issued. The parallelised task contains the *constexpr* evaluation of the body of the loop. The initialisation and destruction steps in the loop's evaluation are executed sequentially, and occur once on loop entry and exit. The task itself does not deviate from the original sequential algorithm.

The final phase after thread completion is *consolidation*. This phase focuses on synchronising thread data back into the main process's *CallStackFrame* and *EvalInfo*, allowing sequential evaluation to continue. This is done in two steps, the first copies the cloned data back into its original location. The second step involves an optional reduction, and is controlled by the *__ReduceVariable* intrinsic discussed in Section III-B. Data that is marked for reduction by *__ReduceVariable* skips the first step.

Data which has been cloned, is split into two components before being copied back. The second component is specific to array data, the first is for everything else. A primary thread is selected to copy data for the non-array component, which is dependent on an *EvalStmtResult* object returned by each parallel task. This *EvalStmtResult* is a Clang enumerator that contains different evaluation result flags for statements. Each returned *EvalStmtResult* is checked: if all return successfully, then the final thread is selected as the primary thread. As the whole loop range was iterated across, the newest values should be contained within the final partition space. In other cases, where threads complete early, perhaps due to encountering *return* or *break* statements, the first thread that signalled early completion is selected. This ensures that values in later partitions are ignored, as they would not be processed when executing the loop sequentially.

The re-synchronisation of arrays is done by determining which elements have been written to by each thread and then copying these elements from the respective clone, to the original. This does not factor in alteration of the same array element by multiple threads.

Applying reductions can be thought of as a special case of the first step which can be requested by a user through the *__ReduceVariable* intrinsic when a more complex data synchronisation method is required. There are several different types of reduction possible, and these are discussed in Section III-B.

B. The Intrinsic Functions

The compiler intrinsics are used as standard C++ functions, to communicate to the compiler how a loop is to be parallelised. They are implemented as functions rather than Clang intrinsics as it simplified modifications to the parallelisation process. This use of an API of intrinsics has much in common

```
template <class _ExecutionPolicy, class _ForwardIterator, class _Function>
constexpr __enable_if_constexpr_par_execution_policy_t<_ExecutionPolicy, void>
for_each(_ExecutionPolicy&& __exec, _ForwardIterator __first,
         _ForwardIterator __last, _Function __f)
{
    __BeginEndIteratorPair(__first, __last);
    __ReduceVariable(__first, PartitionedOrderedAssign, PreInc);

    for (; __first != __last; ++__first)
        __f(*__first);
}
```

Fig. 3. *Constexpr* parallelised libc++ *std::for_each* implementation

with OpenMP [35] and other directive-based programming paradigms.

The intrinsics required to describe the parallelisation of a loop should be placed prior to the loop within a function that meets the aforementioned constraints. There are four different intrinsic functions used for parallelisation, with descriptions listed in Table I. The intrinsics have no body and are no-ops at runtime with a trivial overhead at compile time. They are defined as function templates so that they can be used with a variety of different types. The name of the intrinsics are prefixed with double underscores to avoid conflicts with user-defined functions. The parameters of each intrinsic allow users to pass important information to the compiler.

__BeginEndIteratorPair and *__PartitionUsingIndex* indicate to partition iterations of the loop across multiple threads based on the loop bounds indicated by their arguments. The former was designed with the use of C++ standard library containers and algorithms in mind, which make use of *begin* and *end* iterators to mark the range of loops. The latter was designed with numeric loop conditions in mind and takes an extra parameter indicating the relational operator used within the loop's condition clause.

__IteratorLoopStep indicates that a pointer based index is bound to the loop's step. Clones of the index are offset by the number of loop steps taken by the loop in the thread partition at its start point. The offset is calculated by mutating the index by the number of loop steps taken by the C++ operator indicated by the *OpTy* argument. This keeps the bound value synchronised with the loop across all threads, and is used for indices not used within *__BeginEndIteratorPair*.

The intrinsic *__ReduceVariable* helps to denote how a container or value should be reduced when the launched threads are joined. Three reduction types are supported: *PartitionedOrderedAssign*, *OrderedAssign* and *Accumulate*. *Accumulate* is used in conjunction with an accumulator variable, ensuring that the local result from each thread is combined using the specified operator to obtain a final value. *PartitionedOrderedAssign* is intended for use with containers, and its operation is illustrated in Fig. 2. This reduction assigns elements to the original container in order, where each element is taken from the starting offset in each thread partition, to its final offset on thread completion. This allows appropriate collapse of data as threads are working on local copies of data rather than shared data. *OrderedAssign* (also Fig. 2) is similar to *PartitionedOrderedAssign*, although it is used with containers that have not been modified in lock step with the loop. *OrderedAssign* assigns elements to the original container in order, where each element is taken from the initial offset of each cloned container to its final offset within its partition.

C. An Example Constexpr Parallel Function

Within ClangOz's libc++ library, 30 of the functions contained inside the Algorithms and Numerics libraries have been *constexpr* parallelised. In Fig. 3 a *std::for_each* is shown as an example of how a function can be *constexpr* parallelised. The function takes an execution policy as its first parameter which will be verified by the compiler before it attempts parallelisation. In this example there is also an alias for an *std::enable_if* check, which ensures the correct execution policy is used in conjunction with this variation of *std::for_each*. Alternatively, the compiler will select a more apt function if one exists, or issue an error message.

Once the policy has been verified, each of the intrinsics is processed; and in this example there are only two. The first, *__BeginEndIteratorPair* defines the loop's range which the parallelisation process uses to partition the loop across multiple threads. In this case the range is delimited by the arguments *__first* and *__last*. The second intrinsic *__ReduceVariable* states that a *PartitionedOrderedAssign* should be performed on the data pointed to by the argument *__first*. *OperatorType::PreInc* indicates which operator to use when traversing the data, allowing the compiler to correctly reduce the data.

IV. Parallelism Benchmarking

Three *constexpr* programs based on existing benchmarks were created to test the performance of the *constexpr* parallelism implementation. The original benchmarks were modified to utilise function templates from ClangOz's C++ standard library supporting *constexpr* parallel execution. Benchmark selection was also mindful that certain language features are not available at compile time; for example assembly instructions or *goto* statements.

The *Blackscholes* benchmark is taken from The Princeton Application Repository for Shared-Memory Computers (PARSEC) [36]. The PARSEC suite contains several multi-threaded programs that explore different workloads on shared memory

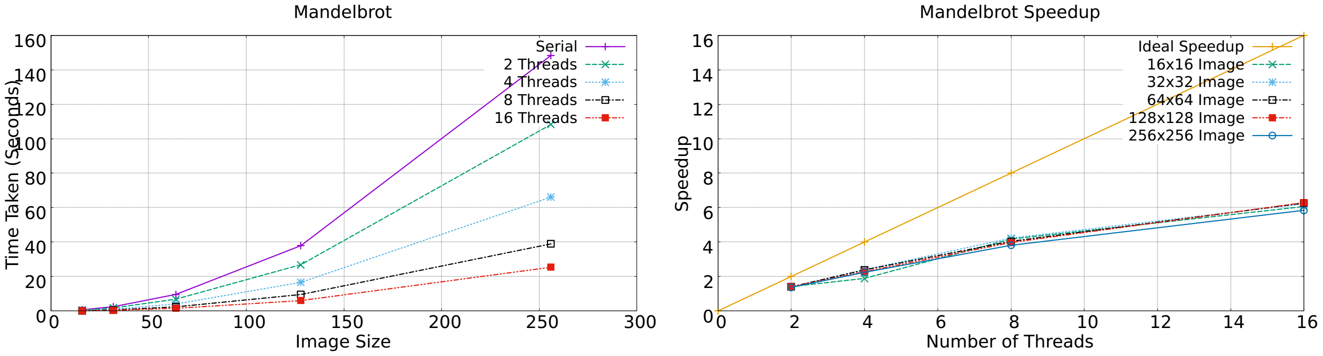


Fig. 4. Compilation Time and Speedup for the Mandelbrot Benchmark

architectures. *Blackscholes* processes financial data using a partial differential equation.

The *N-Body Problem* and *Mandelbrot* benchmarks are based on solutions provided to The Computer Language Benchmarks Game [37]. These are originally micro-benchmarks with the goal of testing performance of different programming languages as opposed to directly testing parallel performance.

All benchmarks are parallelised using static partitioning. The partition sizes are selected by the compiler based on the number of threads made available and the size of a loop's range. The parallelised loop regions are indicated by an invocation of a *std::for_each*, which has been adapted to support *constexpr* parallelisation. The *std::for_each* invokes a function on each piece of data, in this case each thread will be given a set of data to invoke the function on individually.

The performance data gathered for each benchmark is displayed using two types of graph. The first is a line graph comparing serial and parallelised execution times (during compilation). Each of the plots in these graphs is calculated by averaging six separate runs of each benchmark and data size configuration. The second type of graph displays *parallel speedup*; comparing times when using different numbers of threads against the ideal speedup on different problem sizes for the benchmark. The ideal speedup is a one to one match for the number of threads used. A cumulative speedup graph is also provided, including speedups for all of the benchmarks.

A. Timing Compile Time Performance

Performance of the *constexpr* paralleliser is measured by comparing the speed of the parallelised constant expression evaluator against the original serial implementation on each of the benchmarks. The benchmarks are tested with different numbers of threads using an Intel Core i9-12900K CPU, containing eight performance cores, and with support for 16 hardware threads via hyper-threading. The benchmarks were run under the WSL2 virtual machine on Windows 11; and executed using two, four, eight and sixteen threads.

Time is measured from the beginning of a parallel region to its end, rather than timing the length of the entire program; this is to allow us to focus on the regions of interest. The same location is measured for the serial execution. Three timing intrinsics were implemented to allow measurement of the phase within the ClangOz compiler.

It is worth noting that the same compiler is used for both the parallel and serial tests, as the intrinsics are needed for timing alongside a modified standard library implementation. This has a minor impact on the measurements for both implementations as the time measurement functionality requires checking the intrinsics' names, every time a function is considered for parallel execution. To determine if the parallel code path should be executed within the compiler, the verification phase discussed in Section III-A must be processed, which also adds an extra performance cost when evaluating the original serial implementation.

B. Mandelbrot

The Mandelbrot benchmark consists of three main areas of computation that are executed in parallel using *std::for_each*. Two initialisation steps populate a 2D array of complex values (a class containing two 64-bit floats) per pixel. Subsequently, the main Mandelbrot computation uses the naïve escape time algorithm. This algorithm loops over each complex value and performs a repeating calculation until an escape condition is met (limited to a maximum of 128 iterations). The final value generated after the escape condition has been met is the colour of the pixel which is assigned to an array of integers representing the final image.

The graphs in Fig. 4 show that the increase in data size gradually progresses towards higher polynomial growth as the number of threads diminish. With more threads, the increase in data size has less impact on compilation time. Breaking the computation into two separate parallel regions, requiring two thread group launches, has had minimal impact on this benchmark. The speedup graph shows that across all image sizes the performance improvement is similar.

C. Blackscholes

Blackscholes has two areas of computation which are parallelised, requiring two separate calls to *std::for_each*. The first is the main computation which computes the Black-Scholes equation; the second verifies the results from the

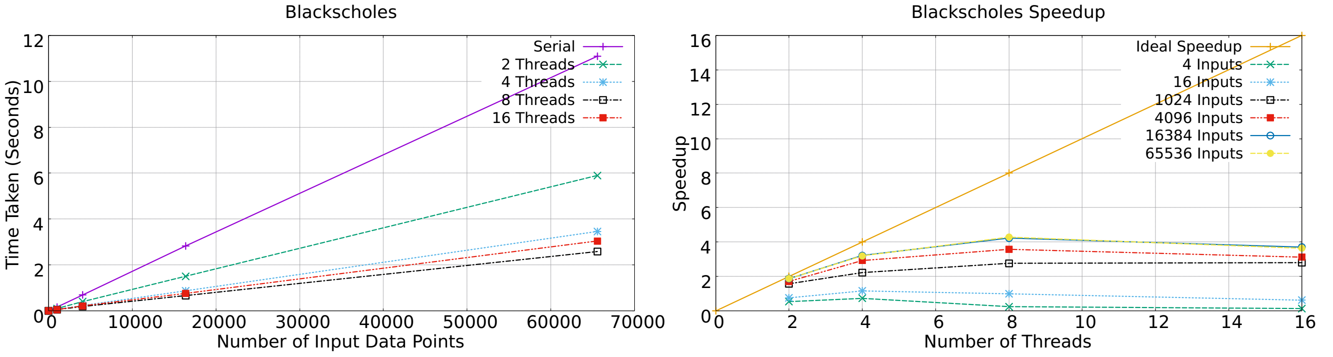

Fig. 5. Compilation Time and Speedup for the Blackscholes Benchmark

first computation. The main data that requires cloning in this benchmark is a 1D array containing a structure for each input that owns 9 literal values.

The Blackscholes data in Fig. 5 shows promising performance increases when utilising both two and four threads. The speedup graph indicates that the highest speedup occurs when larger input sets are used. Smaller data sets still yield an increase but plateau or fall slightly at four threads. The poor performance of the 4 and 16 sized data sets can be accounted for by the increased cost of preparing and launching threads outweighing the work required to process these tiny data sets.

D. N-Body

The N-Body benchmark has two parallel regions: the advance of the particle system; and the position and velocity update. This means with more iterations of the system more launches of threads occur. To allow a range of body numbers, the number of iterations is restricted to 32; while still avoiding compilation limits. The main data cloned within the benchmark are the bodies; structures containing seven 64-bit floats stored contiguously within an array. The number of bodies is the parameter that is varied within this benchmark.

The graphs in Fig. 6 show that increasing the number of threads again outperforms the serial implementation, however using two threads is the closest to the ideal speedup achieved within this benchmark, with larger body numbers also aligned with better performance. This is likely due to the cost of cloning having an adverse impact on smaller workloads. As with the Blackscholes benchmark, there is no improvement in speedup as the number of cores is increased from eight to sixteen (which utilises hyper-threading).

E. Benchmark Comparison

The speedup graph in Fig. 7 compares the most time consuming variations of each benchmark against each other and indicates which benchmarks achieved the best performance after parallelisation. The N-Body benchmark is the best performer reaching the closest to the ideal speedup across all of the benchmarks. This is due to the trivial size and simplicity of the data that requires cloning. Until eight threads, the Mandelbrot benchmark is the furthest from the ideal speedup; possibly according to the number of parallel regions, compared to the other benchmarks. Two of the parallel regions execute relatively small computations, to fill small arrays of data, while cloning a significant amount within the context of each parallel function call. The possibility of multiple thread launches causing cloning to have a negative impact is highlighted by Blackscholes performing better than Mandelbrot despite having a similar amount of data to clone per parallel region, but less parallel regions overall. With sixteen threads, hyperthreading should allow two threads to run efficiently on each of the eight performance cores, but only the Mandelbrot benchmark shows a reduction in execution time at the largest thread count.

The results indicate that the parallelisation of *for* loops during compile time evaluation can lead to notable speedups when a large portion of the program conforms reasonably to a loop. However, the cost of cloning and partitioning data comes with significant costs. It is plausible that performance could be increased by removing the need for cloning in cases where it should not be required. For example, containers like *std::array* which have no conflicting data accesses across threads should not require cloning. This could yield a performance increase in most of these benchmarks as the main input data is generally contained in an array. Data that is not required for the execution of the parallel *constexpr* function could also be elided from the cloning process, which could have a large impact on benchmarks that contain a significant amount of data unrelated to the parallel invocation. A simple form of workload balancing may also yield reasonable results in certain circumstances where the majority of the work is not perfectly divisible by the number of threads in use. Whilst this is not seen in the performance analysis within the paper, there is likely an opportunity for improvement over the current implementation that could allow a performance increase.

V. Conclusion

As the C++ standard has evolved, additional compile time language features have been added, extending the reach of compile time metaprogramming. As C++'s compile time repertoire and its use has expanded, the problem of increasing

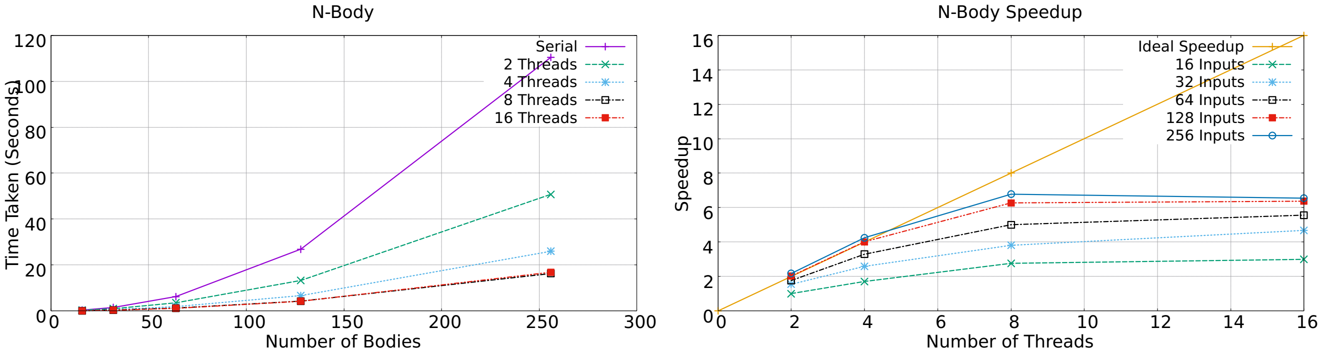

Fig. 6. Compilation Time and Speedup for the N-Body Benchmark

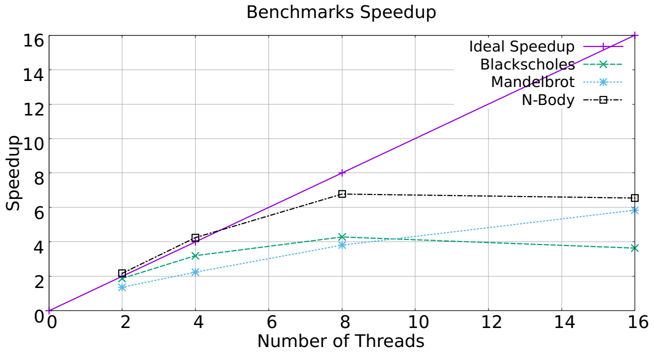

Fig. 7. Speedup Graph Comparison of all Benchmarks Compilation Time

compilation times becomes prominent, leading to adverse effects on programmer work flow. This opens up the question of how to alleviate the issue. In the project introduced here, the option of acceleration through multi-threaded data-parallelism, within the compiler is investigated. ClangOz, an extended Clang compiler for C++ is introduced that can parallelise *for* loops at compile time; including with reduction/accumulation. Therein, intrinsic functions allow users to explicitly relay information to the compiler about the loop being parallelised. This firstly allows users the flexibility to implement their own low-level compile time parallel algorithms, while understanding the intrinsics' semantics. Together, the compiler and intrinsics create a framework for accelerating constant expression evaluation.

This low-level functionality has then been utilised to provide a *high-level API*, which builds on recent C++ standard library support for parallelism to implement 30 *constexpr* parallel function templates. These functions are based on existing function template signatures within the C++ standard library, and differ only by a single argument; the policy parameter, providing access to parallelism through C++ overloading. Three compile time benchmarks were implemented that utilise a *constexpr* parallel *std::for_each* from this extended library. Through testing of these benchmarks it was shown that the ClangOz framework can have large performance benefits; with up to 95% parallel efficiency on one benchmark, and above 50% on average. These benchmarks also show that the complexity of the framework can be hidden within a library; removing users from the onus of understanding low-level intrinsics, while maintaining high performance. Benchmark results nevertheless indicate that there is still room for improvement.

The current parallelisation process has some areas that could be addressed to improve performance. One issue stems from the fact that the data copying process required when forking and joining threads can be expensive. This leads to significant startup costs, meaning that multiple sequential parallel regions for trivial amounts of computation are slower than if done sequentially. Large data dependencies can also have an impact on how much of a performance increase you will get from the parallelisation process. Optimising or removing the need for the cloning process would likely improve performance. Another issue is the lack of work load balancing in the implementation, which necessitates that users must choose their thread partitioning carefully. When data is indivisible by the thread count this can have a performance penalty as one thread will keep the others waiting as it deals with the excess data. A solution would be implementing a work load balancing algorithm within the compiler. These adjustments to the compiler could improve the parallelisation algorithm's overall performance.

***Abstract*—The article concerns the well-known RIONA algorithm. We focus on the explainability property of this algorithm. The theoretical results, formulated and proved in the paper, show the relationships of the RIONA classifiers to both instance- and rule-based classifiers. In particular, we show the equivalence (relative to the classification) of the RIONA algorithm with the rule-based algorithm generating all consistent and maximally general rules from the neighbourhood of the test case.**

I. Introduction

IN THE paper, we focus on the learning algorithm for supervised learning [1], [2], [3]. Specifically, we focus on the well-known RIONA algorithm [4], [5], [6]. This algorithm combines two widely-used empirical approaches: rule induction and instance-based learning [7], [8], [9], [10]. Both these approaches use reasoning schemes comprehensible to a human. It is essential since, Explainable AI [11], [12], [13] is becoming more and more useful in real-life applications. The classifying system should provide for the given test object not only decision but also its user-understandable explanation. In the paper, we present theoretical results of considered algorithm that allow to meet these requirement.

A few concepts form the framework of the RIONA algorithm. First, instead of inducing an excessive number of decision rules in advance to use them during testing, it induces decision rules relevant only for the test example. This is a strategy of so-called lazy learning [14]. Second, only rules from the neighbourhood of the given test example are considered. Third, it automatically groups numerical and symbolic values of attributes by using more general than commonly-used conditions. Fourth, RIONA computes optimal size for the neighbourhoods of objects.

The properties of RIONA algorithm are worth studying as it was reported in the literature as one of the most accurate classification methods in many experimental comparisons done by various researchers (the most commonly used RIONA implementation is a classifier in the WEKA platform named RseslibKnn [15]), to name a few: Facebook content recognition [16, Chapter 1] (RIONA was the best one of 21 tested algorithms), environmental sound recognition [17] (best of 9 algorithms), metabolic pathway prediction of plant enzymes [18] (2nd of 47 algorithms), acoustic-based environment monitoring [19] (2nd of 8 algorithms), context awareness of a service robot [20] (2nd of 8 algorithms), student performance prediction [21] (5th of 47 algorithms).

The novelty of the paper is in theoretical results creating the basis for explainability of classifications returned by classifiers. The results concern the relationships of the classifiers generated by the RIONA algorithm to classifiers obtained by applying instance-based as well as rule-based approaches. In particular, it occurs that RIONA classifiers are equivalent (relative to the classification property) to classifiers produced by the rule-based algorithm based on all consistent and maximally general rules generated from the neighbourhood of the test case. Such rules are easily interpretable by humans.

The paper relates to the PhD thesis [6].

II. Basic notions

$|X|$ denotes cardinality (size) of the set X set. If $\mathbf{A}$ and $\mathbf{B}$ are algorithms then the equality $\mathbf{A}(v) = \mathbf{B}(w)$ means that the values returned by $\mathbf{A}$ on input v and by $\mathbf{B}$ on input w are the same.

By $\mathbf{X}$ we denote a set of objects, called the domain of learning and by $Atr = A \cup \{d\}$ a finite set of attributes atr, where $atr : \mathbf{X} \longrightarrow V_{atr}$. V_{atr} is called the value set of atr. Attributes from A are called *conditional attributes* and the attribute $d \notin A$ is called the *decision*. V_d is called the decision set. We assume for simplicity of notation that $V_d = \{1, \ldots, n_d\}$. Any object $x \in \mathbf{X}$ is represented relative to its signature $Inf_{A(x)}$, i.e. a set of pairs $(a, a(x))$ for each $a \in A$. We use the symbols A_{sym} and A_{num} for denoting the sets of symbolic and numerical attributes, respectively. If $a \in A_{sym}$ then V_a is a finite set. If $a \in A_{num}$ then without loss of generality, we assume that V_a is equal to an interval (l_a, u_a), where $l_a, u_a \in \mathbb{R}$ (possibly not all of the values from the interval are used).

A *decision system* is a triplet $(\mathbf{X}, A, d)$ if $\mathbf{X}$ is the set of objects, A is a set of attributes, and d is a decision function. A *pseudometric decision system* is a 4-tuple $(\mathbf{X}, A, d, \{\varrho_a\}_{a \in A})$ if $(\mathbf{X}, A, d)$ is a decision system and for any attribute $a \in A$, ϱ_a is a pseudometric on the respective value set V_a, i.e. for any $a \in A$, (V_a, ϱ_a) is a pseudometric space [22].

In the sequel by $\mathbb{D}$ is denoted a given (pseudometric) decision system of the above form.

In the paper we study a combination of two methods (learning algorithms) inducing a *classifier* from a given subdecision system $(trnSet, A, d)$, where $trnSet \subseteq \mathbf{X}$ and attributes from $A \cup \{d\}$ are restricted to $trnSet$, which for any $x \in \mathbf{X}$ computes the decision $\hat{d}(x)$ in such a way that $\hat{d}$ is *close* to d [2]. It should be noted that in practical experiments, the normalized Euclidean metric was used for numerical attributes, and the SVDM [23] pseudometric for symbolic attributes. If $a \in A_{num}$, the normalisation is obtained by using $a^{\max}$ and $a^{\min}$, which denote the maximal and the minimal values for an attribute a among training examples $trnSet$.

A. Rule-based methods

The induction of rule sets is one of the fundamental Machine Learning (ML) techniques (see e.g. [7]). Its significance stems from the fact that a human may easily comprehend knowledge representation in the form of rules. Decision rules specify the appropriate course of action in a given circumstance. Decision rules frequently have the form 'if φ then ψ', where φ denotes the premise of the rule and ψ denotes its consequence; ψ is a formula defined by the decision attribute d.

Decision rules are generated using rule induction algorithms from a training set. The premises of the rules are represented by a conjunction of *elementary conditions* and the consequences are describing the particular decision. Each elementary condition describes a collection of the attribute's values. Roughly speaking, it has the form $a \in V$, where $V \subseteq V_a$, and a is an attribute. We first determine how such sets V of values can be expressed in a formal language. Next, we define the semantics (meaning) of specified expressions from this language in the powerset of the attribute value set V_a. For simplicity of notation we do not distinguish between symbols denoting values (or intervals) and values (or intervals) themselves.

Definition II.1. *Let $\mathbb{D}$ be a (pseudometric) decision system. For symbolic attributes $a \in A_{sym}$, the* description of any elementary set *has one of the following forms:*

$$\emptyset \tag{1}$$

$$\{v\}, \text{ where } v \in V_a, \tag{2}$$

$$V_a, \tag{3}$$

$$B(c,r), \text{ when } \mathbb{D} \text{ is pseudometric decision system and where } c \in V_a,\ r \in \mathbb{R}, r \geq 0. \tag{4}$$

The description of elementary set *for the decision attribute d is of the form $\{v\}$, for $v \in V_d$.*

For numerical attributes $a \in A_{num}$, the description of elementary set *has one of the following forms:*

$$\emptyset \tag{5}$$

$$[b,e], (b,e], [b,e), (b,e), \text{ where } b,\ e \in \mathbb{R} \text{ are such that the corresponding interval between points } b \text{ and } e \text{ is included in } V_a. \tag{6}$$

The semantics $||des||_{\mathbb{D}} \subseteq V_a$ of any description des of the elementary set for attribute $a \in A \cup \{d\}$ is defined as follows:

$$\begin{aligned} ||\emptyset||_{\mathbb{D}} = \emptyset, \quad ||\{v\}||_{\mathbb{D}} = \{v\}, \quad ||V_a||_{\mathbb{D}} = V_a, \\ ||[b,e]||_{\mathbb{D}} = [b,e], ||(b,e]||_{\mathbb{D}} = (b,e], \\ ||[b,e)||_{\mathbb{D}} = [b,e), ||(b,e)||_{\mathbb{D}} = (b,e), \\ ||B(c,r)||_{\mathbb{D}} = \{w \in V_a : w \in B(c,r)\} \\ = \{w \in V_a : \varrho_a(c,w) \leq r\} \text{ (called the ball set).} \end{aligned}$$

Now, the elementary conditions expressed in a language and their semantics can be defined.

Definition II.2. *Let $\mathbb{D}$ be a (pseudometric) decision system.*

Any expression $a \in V$, where $a \in A$ and V is a description of elementary set for attribute a is called an elementary condition. *The semantics of $a \in V$ is defined by $[[a \in V]]_{\mathbb{D}} = \{x \in \mathbf{X} : a(x) \in ||V||_{\mathbb{D}}\}$.*

$[[a \in V]]_{\mathbb{D}}$ may be restricted to subsets of $\mathbf{X}$, e.g. $[[a \in V]]_{trnSet} = [[a \in V]]_{\mathbb{D}} \cap trnSet$.

An example (case) x satisfies the elementary condition $a \in V$(or, in short, $(a \in V)(x)$ is satisfied) if $x \in [[a \in V]]_{\mathbb{D}}$.

The set $||V||_{\mathbb{D}} \subseteq V_a$ for a given elementary condition $a \in V$ is equal to

- $\{v\}$ for some $v \in V_d$ for the decision attribute d (see set description 2 and its semantics),
- a proper interval for the numerical attribute (see set description 6 and its semantics), and
- $\{v\}$ for some $v \in V_a$, V_a or a ball set for the symbolic attribute a (see set descriptions 2, 3, 4, respectively and their semantics).

A given object x satisfies the elementary condition $a \in V$ if the value of a on x, i.e. $a(x)$ is in the set defined in $\mathbb{D}$ by V, i.e. $a(x) \in ||V||_{\mathbb{D}}$. Instead of $a \in \{v\}$ we write $a = v$ and instead of *trivial* elementary condition $a \in V_a$ (always true, i.e. the set of objects satisfying this condition is equal to the set $\mathbf{X}$) we write $a = *$.

Now, we introduce concepts related to syntax and semantics of decision rules.

Definition II.3. *Let $\mathbb{D}$ be a (pseudometric) decision system. A* decision rule *is an expression of the form*

$$if\ t_1 \wedge t_2 \wedge \ldots \wedge t_m\ then\ d = v,$$

where $m = |A|$, t_i is an elementary condition for an attribute a_i for $i = 1, 2..., m$, and $v \in V_d$.

The semantics of the premise $t_1 \wedge t_2 \wedge \ldots \wedge t_m$ of the rule r (in $\mathbb{D}$) is defined by

$$[[t_1 \wedge t_2 \wedge \ldots \wedge t_m]]_{\mathbb{D}} = [[t_1]]_{\mathbb{D}} \cap [[t_2]]_{\mathbb{D}} \ldots [[t_m]]_{\mathbb{D}}$$

If $x \in [[t_1 \wedge t_2 \wedge \ldots \wedge t_m]]_{\mathbb{D}}$ then we say that

- *the premise of the rule r is satisfied by example x (or x satisfies this premise),*
- *example x* matches *the rule r,*
- *r* covers *x.*

One can treat a single rule as a classifier assigning examples covered by that rule to the decision class from the rule's consequence. Ideally, we could search for rules $if\ \varphi\ then\ d = v$ such that $[[\varphi]]_{\mathbb{D}} \subseteq [[d = v]]_{\mathbb{D}}$. However, the restriction of this inclusion to $trnSet$, i.e. $[[\varphi]]_{trnSet} \subseteq [[d = v]]_{trnSet}$ is available only. Rules satisfying this last condition (for $trnSet$) are induced from $trnSet$ and an hypothesis on extension of the truth of this inclusion on $\mathbf{X}$ is made. Moreover, rules covering as many as possible examples are generated.

In description of decision rules, trivial conditions are usually omitted [1]. The typical conditions are equations $a = v$ in case of symbolic attributes and inclusions into intervals in case of numerical attributes, e.g.:

$$if\ a_2 = 3 \wedge a_4 \in [2, 5] \wedge a_7 = 3\ then\ d = 2.$$

In this paper we use for symbolic attributes more general conditions, i.e. $a \in V$ (see Definition II.2), making it possible to extend singleton sets to the ball sets. If the data set under consideration has some numerical attributes, then by applying discretisation the relevant intervals can be constructed. By applying discretisation to a given decision system a new one is obtained with new attributes being characteristic functions of induced intervals including objects from $trnSet$ labeled by the same decision (see e.g. [24]).

By $t_i(r)$, where r is a given decision rule we denote the i-th condition t_i from Definition II.3. We write $t_a(r)$ instead of $t_i(r)$ if the condition t_i from Definition II.3 concerns the attribute a.

We define three kinds of decision rules by distinguishing elementary conditions (used in Definition II.3) occurring in them. In consequence, we obtain three sets of decision rules.

Definition II.4. *Let $\mathbb{D}$ be a decision system.*

The set $SimRules$ of simple rules *is the set of all rules from Definition II.3 with the elementary conditions of the form $a = v$ for $v \in V_a$ and $a = *$ only.*

The set $CombRules$ of combined rules *is the set of all rules from Definition II.3 with elementary conditions for symbolic attributes of the form as in $SimRules$ and for numerical attributes of the form $a \in I$ (where I is a proper interval description) only.*

Definition II.5. *Let $\mathbb{D}$ be a pseudometric decision system such that for any symbolic attribute $a \in A_{sym}$ there is a distinguished specific value $c_a \in V_a$.*

The set $GenRules\left(\{(\varrho_a, c_a)\}_{a \in A_{sym}}\right)$ (or simply $GenRules$ whenever pairs (ϱ_a, c_a) are clear from the context or irrelevant due to generality) of general rules *is the set of all rules from Definition II.3 where set descriptions in elementary conditions in the premises of the rules are*

(i) *as in the definition of $CombRules$ for numerical attributes and*
(ii) *of specific form of 4, i.e. $B(c, r)$, where $c = c_a$, $r = \varrho_a(c_a, v)$, $v \in V_a$ for symbolic attributes $a \in A_{sym}$.*

More details on *general rules* presented in Section III-A will help the reader to better understand our definition.

Definition II.6. *A rule if ϕ then $d = v$ is* consistent *with a set of objects $X \subseteq \mathbf{X}$ (or* consistent *if X is clear from the context) if $d(x) = v$ for any object $x \in X$ matching this rule.*

If the rule if ϕ then $d = v$ is not consistent than it is called inconsistent.

Typically, in the above definition $trnSet$ is used as X. Any rule if ϕ then $d = v$ consistent with $trnSet$ classifies correctly all the training examples covered by that rule i.e. $[[\phi]]_{trnSet} \subseteq [[d = v]]_{trnSet}$.

For further considerations the concept of maximality of rule will be useful.

Definition II.7. *Let $\mathbb{D}$ be a (pseudometric) decision system and let $a \in A$, and let V_1, V_2 be elementary conditions for a. The condition $a \in V_2$ is* more general than *(or is* implied by*) $a \in V_1$, in symbols $a \in V_1 \Rightarrow a \in V_2$ if $||V_1||_{\mathbb{D}} \subseteq ||V_2||_{\mathbb{D}}$.*

For any two rules r_1, r_2 (over $\mathbb{D}$) with the same consequence $d = v$, we say that a rule r_2 is more general than *(or is* implied by*), in symbols $r_1 \Rightarrow r_2$ if $t_i(r_1) \Rightarrow t_i(r_2)$ for $i = 1, \ldots, m$ and $m = |A|$.*

A consistent rule r with a training set $trnSet$ is maximally general *(relative to $trnSet$ and a given set of rules $Rules$) if there is no rule in $Rules$ more general than r which is different from r and consistent with $trnSet$.*

Definition II.8. *Let $\mathbb{D}$ be a (pseudometric) decision system and let $Rules$ be a given set of admissible rules. The* set of maximally general rules *(relative to $trnSet$) $MaxRules(Rules, trnSet)$ is equal to the set of all maximally general rules $r \in Rules$ consistent with $trnSet$.*

We use the following sets of rules: $SimRules$, $CombRules$, $GenRules$ from Definitions II.4 and II.5 as $Rules$ (see Definition II.8). We write $MaxRules$ instead of $MaxRules(Rules, trnSet)$, if from the context $Rules$ and $trnSet$ are known. Hence, $MaxRules$ may denote: $MaxRules(SimRules, trnSet)$, $MaxRules(CombRules,trnSet)$, or $MaxRules(GenRules,trnSet)$.

Computing from $trnSet$ the set of all consistent and maximally general matching at least one case from $trnSet$ is important for some learning algorithms.

In the case of $MaxRules(SimRules, trnSet)$, a consistent rule is maximally general relative to $trnSet$ if it becomes inconsistent (relative to $trnSet$) after substitution of the trivial condition instead of a non-trivial one. Hence, consistent rules from $MaxRules(SimRules, trnSet)$ can be characterised as the rules with minimal length (measured by the number of non-trivial conditions in predecessors). Hence, in the considered case, the problem is to generate the complete set of consistent and minimal decision rules (see e.g. [25]). One can observe that searching for the set of minimal rules can be motivated by the minimum description length principle (MDL) (see e.g. [26]). However, the computational time complexity of

[1] In fact, in the description of rules only non-trivial conditions are used. We use trivial conditions only to make the notation simpler.

algorithms generating $MaxRules(SimRules, trnSet)$ is not feasible when the number of training objects or attributes are large. In fact, the size of the $MaxRules$ set can be exponential relative to $|trnSet|$ (see e.g. [27]). Hence, efficient heuristics are often used to overcome this drawback, especially when not necessarily complete sets of minimal rules are required (see e.g. [28]). There are also other approaches inducing a set of rules fully covering cases from $trnSet$ (see e.g. [29]). Here, we focus on the complete $MaxRules$ set.

In the case of $MaxRules(CombRules, trnSet)$, additionally we deal with numerical attributes. From $trnSet$ maximally general intervals of reals are induced. Searching for maximally general rules for numerical attributes is closely related to the problem of discretisation. A partition of reals in discretisation is consistent if each interval covers only objects with the same decision (see e.g. [24], [27]).

The discretisation problem is a complex task. For example, searching for a consistent partition with the minimal number of cuts is NP-hard (see e.g. [24]). In Subsection III-A we show how to overcome this drawback using lazy learning and focusing on a local part of $\mathbf{X}$ instead of on the whole universe. This is illustrated by the lazy rule induction algorithm Algorithm 3 or Algorithm 4.

In the case of $MaxRules(GenRules, trnSet)$, the additional search is performed for the relevant grouping of values for symbolic attributes into a partition of value sets of symbolic attributes. One can define a partition over an attribute a as any function $P_a : V_a \to \{1, \ldots, m_a\}$. It should be noted that the problem of searching for a consistent family of partitions with the minimal $\sum_{a \in A} |P_a(V_a)|$ is NP-hard (see e.g. [30]). We show in the paper how to overcome this drawback by limiting the number of possible groupings of values of any attribute (from 2^n to n^2, where n is the number of values for an attribute) and by using the lazy rule induction (see Section III-A).

The induced sets of rules from $trnSet$ are used to classify objects. First, for any test object tst there are selected all rules from the set matching this object. Next, the set of matched rules is checked. If all rules matched by tst have the same decision then this decision is assigned to tst else it should be resolved conflict between matching rules voting for different decisions (see e.g. [31]). Typically, it is selected the decision with the highest value of a selected measure used for conflict resolution. We use the commonly used measure for conflict resolution.

Definition II.9. *Let us assume that $\mathbb{D}$ – (pseudometric) decision system, $trnSet$ – training set $trnSet$, tst – test example (case), and $MaxRules$ – set of maximally general rules are given. By $supportSet(r) \subseteq trnSet$, where $r \in MaxRules$ we denote the set of all objects from $trnSet$ matching r, and by $MatchR(tst, v) \subseteq MaxRules$ (where $v \in \{1, \ldots, n_d\}$, i.e. v is a decision of d on some object from $trnSet$) the set of rules from $MaxRules$ with decision v matching the test object tst. Now, we define*

$$Strength(tst, v) = \left| \bigcup_{r \in MatchR(tst,v)} supportSet(r) \right|. \quad (7)$$

From definition it follows that by computing $Strength(tst, v)$ it is counted the number of objects from $trnSet$ covered by some maximally general rule from $MaxRules$ (i) with the decision v and (ii) covering the test example tst.

On the basis of $MaxRules$ and the defined conflict resolution strategy using $Strength$ we define the classifier assigning to a given test object tst the most frequent decision of such training examples from $trnSet$ which are covered by matched by tst rules from $MaxRules$, i.e.:

$$decision_{MaxRules}(tst) = \arg\max_{v \in V_d} Strength(tst, v). \quad (8)$$

As it was observed, the drawback of the presented approach comes from the high computational complexity of $MaxRules$ generation.

B. Lazy rule learning for symbolic attributes

The *lazy learning* (or *memory based learning*) algorithms do not require construction of sets of decision rules before classification of new objects.

kNN is the well known example of such algorithms (see Algorithm 1). For these algorithms, first for any test object tst it is defined its neighbourhood $N(tst, trnSet, k, \varrho) \subseteq trnSet$ (N, for short) with k the most similar to tst (relative to a given distance function ϱ) training examples (where k is a parameter). If more than one example has the same distance from tst as the one already added to the N under construction then all of them are added to $N(tst, trnSet, k, \varrho)$. Then the set $N(tst, trnSet, k, \varrho)$ may contain more than k examples[2].

An interesting example of lazy rule-based algorithm for $SimRules$ is presented in [32]. For a new tst it generates only the relevant for it decision rules and next tst is classified as before on the basis of such rules. The value of Eqn. 7 is computed for any tst object without computing the whole set $MaxRule$.

For given two objects tst, trn, we first define *simple local decision rule*, in symbols $s\text{-}rule(tst, trn)$. The relationship of the set of such rules with $SimRules$ will be presented in the following proposition.

Definition II.10. *Let $\mathbb{D}$ be a decision system, $trn \in trnSet$ and let tst be a test object. A* simple local decision rule *(for short* s-rule*) $s\text{-}rule(tst, trn)$ is the decision rule of the form* if $\bigwedge_{a \in A} t_a$ then $d = d(trn)$, *where conditions t_a for each symbolic attribute a are as follows*

$$t_a = \begin{cases} a = a(trn) & \text{if } a(tst) = a(trn) \\ a = * & \text{if } a(tst) \neq a(trn). \end{cases}$$

[2] This assumption is used in RIONA. Hence, we also adopt it for the kNN algorithm in the paper.

Algorithm 1: kNN(tst, $trnSet$, k, ϱ)

```
Input: a test example $tst$, training set $trnSet$, positive
       integer $k$, pseudometric $\varrho$
Output: predicted decision for $tst$
begin
    $neighbourSet = N(tst, trnSet, k, \varrho)$
    foreach decision $v \in V_d$ do
        $supportSet(v) = \emptyset$
    end
    foreach $trn \in neighbourSet$ do
        $v = d(trn)$
        $supportSet(v) = supportSet(v) \cup \{trn\}$
    end
    return $\arg\max_{v \in V_d} |supportSet(v)|$
end
```

Algorithm 2: isCons(r, $verifySet$)

```
Input: a rule $r$ : if $\alpha$ then $d = v$,
       set of examples $verifySet$
Output: true if rule $r$ is consistent with $verifySet$, false
otherwise
for all $trn \in verifySet$ do
    if $d(trn) \neq v$ and $trn$ satisfies $\alpha$ then
        return $false$
    end if
end for
return $true$
```

Observe that both objects trn and tst are matching the rule $s\text{-}rule(tst, trn)$ which is maximally specific (the number of trivial conditions is minimal; or inversely, the number of non-trivial conditions is maximal). The following crucial relation between s-rule and maximally general consistent rules from $SimRules$ holds:

Theorem II.1. *[32][3] If $trn \in trnSet$ and tst is a test object than the rule $s\text{-}rule(tst, trn)$ is consistent with $trnSet$ if and only if $MaxRules(SimRules, trnSet)$ contains a rule covering both objects tst and trn.*

Hence, for any test object tst, decision $v \in V_d$ and $MaxRules(SimRules, trnSet)$ set the value $Strength(tst, v)$ from Eqn. 7 is equal to the number of $trn \in trnSet$ having decision $d(trn) = v$ and for which the rule $s\text{-}rule(tst, trn)$ is consistent with $trnSet$. The *simple lazy rule induction algorithm for symbolic attributes* (LAZY) presented in Algorithm 3 realises this idea.

$isCons(r, verifySet)$ in Algorithm 3 verifies if r is consistent with a $verifySet$. For a given object tst and any $trn \in trnSet$, the rule $s\text{-}rule(tst, trn)$ is constructed by

Algorithm 3: LAZY(tst, $trnSet$)

```
Input: test example $tst$, training set $trnSet$
for all decision $v \in V_d$ do
    $supportSet(v) = \emptyset$
end for
for all $trn \in trnSet$ do
    $v = d(trn)$
    if $isCons(s\text{-}rule(tst, trn), trnSet)$ then
        $supportSet(v) = supportSet(v) \cup \{trn\}$
    end if
end for
return $\arg\max_{v \in V_d} |supportSet(v)|$
```

Algorithm 3. Next, Algorithm 3 is testing the consistency of the rule $s\text{-}rule(tst, trn)$ with the set $trnSet \setminus \{trn\}$, i.e. if all the training examples matching the left-hand side of $s\text{-}rule(tst, trn)$ have identical decision with trn. If the result of testing is positive than trn is added to the support set with the relevant decision. Finally, Algorithm 3 predicts the decision with the support set of the highest cardinality. From Theorem II.1 we obtain:

Corollary II.2. *The following equality holds: $LAZY(tst, trnSet) = decision_{MaxRules}(tst)$, where $trnSet$ is a training set, tst is a test object, and $decision_{MaxRules}(tst)$ is the classifier from Eqn. 8 with $MaxRules = MaxRules(SimRules, trnSet)$.*

From the above considerations it follows that LAZY takes into account only these decision rules that can be involved in the classification of a given test object.

III. RIONA DESCRIPTION

A. Extension and generalisation of lazy rule learning

We introduce an extension and generalization of the LAZY algorithm (see Algorithm 3) that was discussed in Subsection II-B. This novel algorithm permits the use of numerical attributes as well as more general conditions for symbolic attributes.

In Subsections III-A1, III-A2 we present a generalisation of rules introduced before.

For a given test object tst, training object $trn \in trnSet$ and pseudomietric decision system $\mathbb{D}$ with pseudometrics ϱ_a for $a \in A_{sym}$, in addition to simple local decision rule (in short s-rule) (see Subsection II-B) denoted by $s\text{-}rule(tst, trn)$, we consider two new types of local rules: *combined local decision rule* (in short c-rule) and *generalised local decision rule* (in short g-rule) denoted by $c\text{-}rule(tst, trn)$, $g\text{-}rule\left(tst, trn, \{\varrho_a\}_{a \in A_{sym}}\right)$ (or simply $g\text{-}rule\,(tst, trn)$), respectively. In this way we obtain sets composed out of simple rules, combined rules and general rules, denoted by $SimRules$ (see Subsection II-A), $CombRules$, $GenRules$, respectively. We already demonstrated (see Subsection II-B) an important relation between any s-rule and the set of maximally general consistent rules

[3] The formulation of this proposition in [32] was different. However, in the case of $SimRules$ it is equivalent to the original proposition and makes it possible in a more direct way present the relationship between local rules as well as $MaxRules$ and algorithms based on these two types of rules.

$MaxRules(SimRules, trnSet)$. Here, we show analogous important relations between any c-rule or g-rule and sets of maximally general rules $MaxRules(CombRules, trnSet)$, $MaxRules(GenRules, trnSet)$ corresponding to sets of rules $CombRules$ and $GenRules$, respectively.

1) Extension of lazy rule learning for numerical attributes: In this section we assume that $\mathbb{D}$ is a given decision system and $trnSet \subseteq \mathbf{X}$.

Now, we extend the definition of the local decision rule to the case of symbolic and numerical attributes.

Definition III.1. *Let tst be a test object and $trn \in trnSet$. By t_a for $a \in A_{sym}$ we denote a condition as in Definition II.10 and $min_a = min(a(tst), a(trn))$, $max_a = max(a(tst), a(trn))$ for $a \in A_{num}$ We define the* combined local decision rule *(for short* c-rule*) if $\bigwedge_{a \in A} T_a$ then $d = d(trn)$, denoted by $c\text{-}rule(tst, trn)$, where conditions T_a for $a \in A$ are as follows*

$$T_a = \begin{cases} a \in [min_a, max_a] & \text{if } a \in A_{num} \\ t_a & \text{if } a \in A_{sym}. \end{cases}$$

Let us note that conditions for numerical attributes contain intervals with endpoints determined by attribute values of objects tst and trn.

The relationship of the set $MaxRules(CombRules, trnSet)$ and $c\text{-}rule(tst, trn)$ is analogous to the relation between $MaxRules(SimRules, trnSet)$ and $s\text{-}rule(tst, trn)$ as the following lemma states.

Lemma III.1. *Any rule $r \in MaxRules(CombRules, trnSet)$ covering the given test object tst and training object trn is implied by the rule $c\text{-}rule(tst, trn)$.*

Proof. From $r \in MaxRules(CombRules, trnSet)$ we have, in particular that r is consistent with $trnSet$. Hence, the postcondition of r is $d = d(trn)$, i.e. the decision of r is the same as $c\text{-}rule(tst, trn)$.

Since r covers tst and trn, $t_a(r)(trn)$ and $t_a(r)(tst)$ are satisfied for each $a \in A$, i.e. $trn \in [[t_a(r)]]_{\mathbb{D}}$ and $tst \in [[t_a(r)]]_{\mathbb{D}}$.

It is enough to show that for any $a \in A$ the implication $t_a(c\text{-}rule(tst, trn)) \Rightarrow t_a(r)$ holds, i.e. $V_a(c\text{-}rule(tst, trn)) \subseteq V_a(r)$, where for any rule r' if $t_a(r')$ is of the form $a \in V$ then $V_a(r')$ is defined as $V_a(r') = ||V||_{\mathbb{D}}$.

Let us first assume that $a \in A_{sym}$. If $t_a(r)$ is of the form $a \in V_a$, then the implication obviously holds (trivial condition is implied by any condition, because for any elementary condition $a \in V$ for attribute a, $||V||_{\mathbb{D}} \subseteq ||V_a||_{\mathbb{D}}$. If $t_a(r)$ is for some $v \in V_a$ of the form $a = v$ (i.e. $a \in \{v\}$) then $v = a(trn) = a(tst)$. The last equalities hold because we already concluded that $t_a(r)(trn)$ and $t_a(r)(tst)$ are both satisfied. Hence, we have $trn \in [[a = v]]_{\mathbb{D}}$ and $tst \in [[a = v]]_{\mathbb{D}}$, i.e. $a(trn) \in \{v\}$ and $a(tst) \in \{v\}$. It means that in the considered case the equality $t_a(r) = t_a(c\text{-}rule(tst, trn))$ holds (see Definition III.1 and Definition II.10).

If $a \in A_{num}$ is numerical then $t_a(r)$ is of the form $a \in I$, where I is the description of interval corresponding to the numerical attribute a of rule r. Because $t_a(r)(trn)$ and $t_a(r)(tst)$ are both satisfied then $a(trn) \in ||I||_{\mathbb{D}}$ and $a(tst) \in ||I||_{\mathbb{D}}$. Thus $\{a(trn), a(tst)\} \subseteq ||I||_{\mathbb{D}}$. Hence, all points between $a(trn)$ and $a(tst)$ are also in $||I||_{\mathbb{D}}$. In consequence, $[min_a, max_a] \subseteq ||I||_{\mathbb{D}}$, where $min_a = min(a(tst), a(trn))$, $max_a = max(a(tst), a(trn))$ what ends the proof of inclusion $V_a(c\text{-}rule(tst, trn)) \subseteq V_a(r)$ (see Definition III.1). □

Theorem III.2. *The rule $c\text{-}rule(tst, trn)$ for the test object tst and the training object trn is consistent with the training set $trnSet$ if and only if there exists a rule $r \in MaxRules(CombRules, trnSet)$ covering objects tst and trn.*

Proof. We start from a proof of the following fact: if $c\text{-}rule(tst, trn)$ is consistent with $trnSet$ then it can be extended to a rule from $MaxRules(CombRules, trnSet)$. Such a rule can be constructed inductively. From assumption we have that $r_0 = c\text{-}rule(tst, trn) \in CombRules$ is consistent with $trnSet$. In the induction step to define each next rule r_i, for $i = 1, 2, \ldots, m$, where $m = |A|$, we assume that r_{i-1} is consistent with $trnSet$ and conditions $t_j(r_{i-1})$ for all $j = 1, 2, \ldots, i-1$ are maximally general, i.e. if we replace any condition t_j with a more general t (i.e. $t_j \Rightarrow t$) preserving consistency, then $t_j = t$.

$t_i(r_i)$, in i-th induction step, is defined as the maximal generalisation of $t_i(r_{i-1}) = \ldots = t_i(r_0) = t_i(c\text{-}rule(tst, trn))$ preserving consistency with $trnSet$. All others conditions and the decision of the rule are not changed, i.e. $t_j(r_i) = t_j(r_{i-1})$ for $j \neq i$; $d(r_i) = d(r_{i-1})$. Hene, in i-th induction step we simply maximally generalise condition for attribute a_i.

If $a_i \in A_{sym}$ and $t_i(r_{i-1})$ is the trivial condition, then we put $r_i = r_{i-1}$. If $t_i(r_{i-1})$ is non-trivial, it is substituted by $a \in V_a$ if the consistency of the rule is preserved; otherwise, we put $r_i = r_{i-1}$.

If $a_i \in A_{num}$ then $t_i(r_{i-1})$ is of the form $a_i \in [min, max]$. Let us denote by $rule_i(r, t)$ the result of replacement in r of i-th condition by a condition t. Now, we define a set of values of attribute a by $a(Inc) = \{a(trn) : trn \in Inc\}$, where $Inc = \{trn \in trnSet : d(trn) \neq d(r_0) \wedge rule_i(r_{i-1}, a_i = *)$ covers $trn\}$, i.e. Inc contains objects which may violate the consistency of the rule under the maximal possible extension of the condition $t_i(r_{i-1})$. From the inductive assumption, r_{i-1} is consistent with Inc because $Inc \subseteq trnSet$. Hence, $a(Inc) \cap [min, max] = \emptyset$. Now we define $newmax = min\{v \in a(Inc) : v > max\}$. This minimum exists because Inc and also $a(Inc)$ are finite sets. If the set $\{v \in a(Inc) : v > max\}$ is empty we take $newmax = u_{a_i}$ (i.e. maximal possible extension of the right end of the interval). Analogously, we define $newmin = max\{v \in a(Inc) : v < min\}$. If $\{v \in a(Inc) : v < min\}$ is empty we put $newmin = l_{a_i}$ (i.e. maximal possible extension of the left end of the interval). Finally, we define $t_i(r_i)$ by $a \in (newmin, newmax)$. From the definition, r_i is consistent with $trnSet$ and is also maximal because other ends of the interval $(newmin, newmax)$ even if extended by one point to a closed interval will cause inconsistency (in case $newmin = l_{a_i}$ this end of the interval cannot be extended; analogously in case $newmax = u_{a_i}$).

It is easy to prove that all other conditions $t_j(r_i)$ for $j < i$ remain still maximal. To prove this, let us assume that for some $j < i$ $t_j(r_i)$ could be extended to t with preserving consistency, i.e. $rule_j(r_i, t)$ is consistent. We also have $rule_j(r_{i-1}, t) \Rightarrow rule_j(r_i, t)$. Therefore $rule_j(r_{i-1}, t)$ is consistent with $trnSet$. From the inductive assumption t is identical with $t_j(r_{i-1})$. Because $t_j(r_{i-1})$ is the same as $t_j(r_i)$ for $(j < i)$, then t is the same as $t_j(r_i)$. It means that $t_j(r_i)$ is maximally general.

Our inductive reasoning leads to a conclusion that the last rule r_m is consistent with $trnSet$ and maximally general.

We have $c\text{-}rule(tst, trn) \Rightarrow r$ for any rule $r \in MaxRules(CombRules, trnSet)$ covering objects tst and trn (see Lemma III.1). Hence, inconsistency of $c\text{-}rule(tst, trn)$ implies inconsistency of all rules $r \in MaxRules(CombRules, trnSet)$ covering tst and trn. □

2) Generalisation of lazy rule learning for symbolic attributes:
In the section by $\mathbb{D}$ we denote a given pseudometric decision system and $trnSet \subseteq \mathbf{X}$ is a given training set.

In the previous Definitions II.10 and III.1, the trivial condition $a \in V_a$ for a symbolic attribute a is introduced. This condition represents the specific grouping of all possible values of an attribute and is satisfied by any object. However, a proper subset of V_a may be more relevant for the classification. Grouping of values can be obtained by applying a given pseudometric ρ_a for a. Here, now we formulate the following generalisation of Definition III.1, related to a grouping of values for symbolic attributes:

Definition III.2. *Let tst be a test object, $trn \in trnSet$, and $min_a = min(a(tst), a(trn))$, $max_a = max(a(tst), a(trn))$ for $a \in A_{num}$. We also use the following notation: (i) $r_a = \varrho_a(a(tst), a(trn))$ for radius, (ii) $B(c, R)$ for closed pseudometric ball of radius R centred at point c defined by the pseudometric ϱ_a. Now, we define the* generalised local decision rule *(for short* g-rule*) if $\bigwedge_{a\in A} t_a$ then $d = d(trn)$, denoted by g-rule $\left(tst, trn, \{\varrho_a\}_{a\in A_{sym}}\right)$ or simply g-rule (tst, trn) (if parameters $\{\varrho_a\}_{a\in A_{sym}}$ are clear from the context or irrelevant due to generality of considerations), where:*

$$t_a = \begin{cases} a \in [min_a, max_a] & \text{if } a \text{ is numerical} \\ a \in B\left(a(tst), r_a\right) & \text{if } a \text{ is symbolic.} \end{cases}$$

Now, we prove that an analogous relationship of the set $MaxRules(GenRules, trnSet)$ and $g\text{-}rule\,(tst, trn)$ (g-rule) to the relation between $MaxRules(SimRules, trnSet)$ and $s\text{-}rule(tst, trn)$ holds.

Lemma III.3. *Let tst be any test object and $trn \in trnSet$. Let GenRules be defined by parameters ϱ_a (from given pseudometric decision system) and $c_a = a(tst)$ for $a \in A_{sym}$ (see Definition II.5), i.e. $GenRules = GenRules\left(\{(\varrho_a, a(tst))\}_{a\in A_{sym}}\right)$. Then g-rule $\left(tst, trn, \{\varrho_a\}_{a\in A_{sym}}\right) \Rightarrow r$ for any $r \in MaxRules(GenRules, trnSet)$ covering objects tst and trn.*

Proof. The proof is an extension of proof of Lemma III.1. For numerical attributes, the proof is the same as before. For symbolic attributes, it is enough to change the part of the proof of Lemma III.1 by the following one. Let $a \in A_{sym}$. Then $t_a(r)$ is of the form $a \in B(a(tst), R_a)$, where $R_a = \varrho_a(a(tst), v)$, for some $v \in V_a$. Hence, $R_a \geq \varrho_a(a(tst), a(trn))$ because $t_a(r)(trn)$ is satisfied. So, we obtain $B\left(a(tst), r_a\right) \subseteq B(a(tst), R_a)$, where $r_a = \varrho_a(a(tst), a(trn))$. Hence, we have $t_a(g\text{-}rule\,(tst, trn)) \Rightarrow t_a(r)$. □

Theorem III.4. *Under the assumptions of Lemma III.3, the rule g-rule $\left(tst, trn, \{\varrho_a\}_{a\in A_{sym}}\right)$ is consistent with $trnSet$ if and only if there exists a rule $r \in MaxRules(GenRules, trnSet)$ such that r covers tst and trn.*

Proof. The proof can be obtained by a modification of the proof of Theorem III.2.

It is enough to modify the inductive step of the proof of Theorem III.2 for $a_i \in A_{sym}$ as follows. If $a_i \in A_{sym}$ then $t_i(r_{i-1})$ is of the form $a \in B(a(tst), r_a)$, where $r_a = \varrho_a(a(tst), v)$, for some $v \in V_a$. Now, let us consider possible extensions of $a \in B(a(tst), r_a)$ by $a \in B(a(tst), R_a)$, where $R_a = \varrho_a(a(tst), w)$, for some $w \in V_a$ and $R_a \geq r_a$ preserving consistency (with $trnSet$) of the rule. In the finite set of such possible extensions (due to the fact that V_a is finite) we select the one with the maximal value of R_a. The selected extension is maximally general.

If $a_i \in A_{num}$ then we extend the formula as in Theorem III.2.

One can conclude that the last rule r_m is consistent with $trnSet$ and maximally general by performing analogous reasoning as in Theorem III.2.

Also, in analogous way as in Theorem III.2 with the use of Lemma III.3, we obtain that the following implication holds: if $g\text{-}rule\,(tst, trn)$ is inconsistent with $trnSet$, then in $MaxRules(GenRules, trnSet)$ there is no rule covering tst and trn. □

Let us note that the set $MaxRules(GenRules, trnSet)$ is defined for the given values c_a for $a \in A_{sym}$ (in the testing procedure we assume $c_a = a(tst)$). The idea behind construction of $MaxRules(SimRules, trnSet)$ was to compute all maximally general rules in advance for the later use in the classification process. In order to construct $MaxRules(GenRules, trnSet)$, this should be done for all possible combinations of all possible values for all symbolic attributes. It would increase the number of generated rules by the factor no more than b^k, where b is the maximal cardinality of $|V_a|$ for $a \in A_{sym}$ and k is the number of symbolic attributes.

From Theorem III.4 it follows that it is sufficient to generate g-rules for all training examples and then check their consistency with $trnSet$ (instead of computing the support sets for rules from $MaxRules(GenRules, trnSet)$ covering a new test case). The lazy Rule Induction Algorithm (RIA) realises this idea.

```
Algorithm 4: RIA($tst$, $trnSet$, $\{\varrho_a\}_{a\in A_{sym}}$)
Input: test example $tst$, training set $trnSet$, family of
       pseudometrics for symbolic attributes
       $\{\varrho_a\}_{a\in A_{sym}}$
Output: predicted decision for $tst$
1  begin
2      foreach decision $v \in V_d$ do
3          $supportSet(v) = \emptyset$
4      end
5      foreach $trn \in trnSet$ do
6          $v = d(trn)$
7          if $isCons\left(g\text{-}rule\left(tst, trn, \{\varrho_a\}_{a\in A_{sym}}\right), trnSet\right)$ then
8              $supportSet(v) = supportSet(v) \cup \{trn\}$
9          end
10     end
11     return $\arg\max_{v\in V_d} |supportSet(v)|$
12 end
```

$isCons(r, verifySet)$ is defined in Algorithm 2 (see Subsection II-B). The RIA (see Algorithm 4) and LAZY (see Algorithm 3) algorithms differ only in line 7, namely in Algorithm 3 the rule $s\text{-}rule(tst, trn)$ is used and in Algorithm 4 this is the rule $g\text{-}rule\left(tst, trn, \{\varrho_a\}_{a\in A_{sym}}\right)$.

RIA computes the measure $Strength$ for $MaxRules = MaxRules(GenRules, trnSet)$ what directly follows from Theorem III.4. Hence, the results of RIA are equivalent to the results of the algorithm based on calculating $MaxRules$ with $Strength$ as a strategy for conflict resolution. In this way, we obtain the corollary analogous to Corollary II.2 (see Subsection II-B).

Corollary III.5. *For any test object tst, and the classifier* $decision_{MaxRules}(tst)$ *(see Eqn. 8), where*

$$MaxRules = MaxRules(GenRules, trnSet)$$

and

$$GenRules = GenRules\left(\{(\varrho_a, a(tst))\}_{a\in A_{sym}}\right),$$

we have

$$RIA(tst, trnSet, \{\varrho_a\}_{a\in A_{sym}}) = decision_{MaxRules}(tst).$$

B. Combining instance-based learning and rule methods – RIONA

In this section, we additionally assume that Agr is an aggregation function defined as sum of individual metrics.

Let us recall that RIONA is based on a combination of instance-based learning and rule-based methods. The primary observation used in the development of RIONA concerns the property of the widely used kNN method. kNN has quite good performance, usually for small values of k. Hence, one may expect that that only training examples close to a given test case are important in the process of inducing (inferring) the final decision. The intuition supporting this claim is that the training examples which are far from a given test object are less relevant for classification than the closer ones. Contrary to this, in the case of rule-based methods, in general, all training examples are used in the process of rule generation. Hence, instead of considering all training examples in constructing the support set in the case of rule-based approach, like in the RIA algorithm, one can bound it to a certain neighbourhood of a test example. In the case of RIONA algorithm, the classification of a given test case is based on training objects from a neighbourhood of this example.

Our approach to inducing of decision for a given test case is basing on a combination of instance-based learning and lazy rule learning (see Section III-A). The core idea concerns the strategy for conflict resolution based on $Strength$ measure (see Eqn. 7) slightly modified by bounding it to the neighbourhood of the test case:

$$LocStrength(tst, v, k, \varrho) = \\ = \left| \bigcup_{r\in MatchR(tst,v)} locSuppSet(r) \right|, \tag{9}$$

where most notation is as in Eqn. 7; additionally $\varrho = Agr(\{\varrho_a\}_{a\in A})$ is the aggregated pseudometric and k is the number indicating the size of the neighbourhood, and $locSuppSet(r) = supportSet(r) \cap N(tst, trnSet, k, \varrho)$. One can observe that the change from $supportSet(r)$ to $locSuppSet(r)$ causes that only those examples covered by the rules matched by a test object that are in a specified neighbourhood of the test example are considered. The predicted decision based on $LocStrength$ is analogous to the previous one (see Eqn. 8):

$$decLoc_{MaxRules}(tst, k, \varrho) = \\ \arg\max_{v\in V_d} LocStrength(tst, v, k, \varrho). \tag{10}$$

Let us note that the size k of the neighbourhood is optimised in the learning phase (see [5]) while in the classification process, we assume that number k for the neighbourhood $N(tst, k)$ is set to this optimal value.

The above measures can be calculated for a given $MaxRules$ by bounding the support sets of the rules from $MaxRules$ covering a test example to the specified neighbourhood of a given test example. Hence, the algorithm based on maximally general rules with $LocStrength$ can be used here.

It is worthwhile mentioning that $LocStrength$ can also be calculated using the lazy rule learning methodology. This can be done analogously to computing by RIA the measure $Strength$ (see Corollary III.5). For this purpose we modified Algorithm 4 as follows (i) in line 5 of the algorithm, only examples $trn \in N(tst, k)$ should be considered, (ii) it is not necessary to consider all the examples from the training set to check the consistency of the $g\text{-}rule\left(tst, trn, \{\varrho_a\}_{a \in A_{sym}}\right)$ (see line 7 of Algorithm 4). This follows from the next proposition.

Proposition III.6. *Suppose that ϱ_a (for $a \in A_{num}$) in a given pseudometric decision system are defined as normalised Euclean metric, $\varrho = Agr(\{\varrho_a\}_{a \in A})$ and Agr is defined either by sum of metrics or weighted sum of metrics. If $trn' \in trnSet$ satisfies g-rule $\left(tst, trn, \{\varrho_a\}_{a \in A_{sym}}\right)$, then $\varrho(tst, trn') \leq \varrho(tst, trn)$.*

Proof. If trn' satisfies $g\text{-}rule\left(tst, trn, \{\varrho_a\}_{a \in A_{sym}}\right)$, then we have (see Definition III.2 of g-rule):

- for any $a \in A_{sym}$ we have $a(trn') \in B\left(a(tst), r_a\right)$, where $r_a = \varrho_a(a(tst), a(trn))$. Hence, from definition of the closed ball it follows that $\varrho_a(a(tst), a(trn')) \leq \varrho_a(a(tst), a(trn))$.
- for any $a \in A_{num}$ we have $a(trn') \in [min_a, max_a]$, where $min_a = min(a(tst), a(trn))$, $max_a = max(a(tst), a(trn))$. Hence $|a(tst) - a(trn')| \leq |a(tst) - a(trn)|$. Thus, using definiton of metric for numerical attributes (normalised Euclidean metric) we have $\varrho_a(a(tst), a(trn')) = \frac{|a(tst) - a(trn')|}{a^{\max} - a^{\min}} \leq \frac{|a(tst) - a(trn)|}{a^{\max} - a^{\min}} = \varrho_a(a(tst), a(trn))$.

Hence, for any $a \in A$ we have $\varrho_a(a(tst), a(trn')) \leq \varrho_a(a(tst), a(trn))$. In consequence, we obtain the following inequality between the global distances[4] for Agr defined by sum of metrics $\varrho(tst, trn') = \sum_{a \in A} \varrho_a(a(tst), a(trn')) \leq \sum_{a \in A} \varrho_a(a(tst), a(trn)) = \varrho(tst, trn)$.

One can observe that we have the same result also for aggregation function defined by weighted sum of metrics. This is because adding weights for each attribute preserves the above inequality.

□

From the above considerations it follows that the examples distanced from tst more than the training example trn cannot cause inconsistency of $g\text{-}rule\left(tst, trn, \{\varrho_a\}_{a \in A_{sym}}\right)$. Hence, one can use $N(tst, trnSet, k, \varrho)$ instead of $trnSet$ in line 7 of Algorithm 4.

The description of classification algorithm RIONA is presented in Algorithm 5. Later on we prove that Algorithm 5 computes $LocStrength$ (see Theorem IV.2). Algorithm 5 returns the most common class corresponding to decisions on the training examples covered by the rules satisfied by tst and belonging to the specified neighbourhood. One should note that all pseudometrics in the argument of Algorithm 5 are given (used for computation of the final pseudometric). However, in g-rule only pseudometrics for symbolic attributes are used (see Definition III.2 and note after it).

Algorithm 5: RIONA-classify(tst,$trnSet$,k,$\{\varrho_a\}_{a \in A}$)

```
Input: test example $tst$, training set $trnSet$, positive
       integer $k$, family of pseudometrics for attributes
       $\{\varrho_a\}_{a \in A}$
Output: predicted decision for $tst$
1  begin
2      $\varrho = Agr(\{\varrho_a\}_{a \in A})$
3      $nSet = N(tst, trnSet, k, \varrho)$
4      foreach decision $v \in V_d$ do
5          $supportSet(v) = \emptyset$
6      end
7      foreach $trn \in nSet$ do
8          $v = d(trn)$
9          if
             $isCons\left(g\text{-}rule\left(tst, trn, \{\varrho_a\}_{a \in A_{sym}}\right), nSet\right)$
           then
10             $supportSet(v) = supportSet(v) \cup \{trn\}$
11         end
12     end
13     return $\arg\max_{v \in V_d} |supportSet(v)|$
14 end
```

For every decision value, RIONA computes the support set restricted to the neighbourhood $N(tst, k)$ rather than the whole support set of the maximally general rules covering tst (as in the case of RIA algorithm). This is done as follows. For any $trn \in trnSet$ from $N(tst, k)$ RIONA constructs the rule $g\text{-}rule\left(tst, trn, \{\varrho_a\}_{a \in A_{sym}}\right)$ based on trn and tst. Next, RIONA is testing whether g-rule is consistent with the examples from the neighbourhood $N(tst, k)$. If g-rule is consistent with $N(tst, k)$ then the support set of the decision $d(trn)$ is extended by trn. Finally, RIONA returns the decision value with the support set of the highest cardinality.

IV. Relationships of RIONA to other approaches

A specific combination of kNN approach and lazy rule induction allowed us to develop the algorithm RIONA. One can observe that only the line 9 of RIONA, where is examined the consistency of the rule determined by the training and testing example, differs from Algorithm 1 (kNN).

The relationships between RIONA, RIA and kNN for $k = 1$ are as follows.

Proposition IV.1. *Let us assume that* 1NN *is the nearest neighbour algorithm for $k = 1$ with a distance defined by pseudometric $\varrho = Agr(\{\varrho_a\}_{a \in A})$. Then for any test object tst we have*

$$RIONA(tst, trnSet, k, \{\varrho_a\}_{a \in A}) =$$
$$\begin{cases} RIA(tst, trnSet, \{\varrho_a\}_{a \in A_{sym}}) & for\ k \geq |trnSet| \\ 1NN(tst, trnSet, \varrho)\ for\ k = 1, |N(tst, trnSet, k, \varrho)| = 1. \end{cases}$$

[4] We assume that pseudometrics used for grouping symbolic attributes are the same as the pseudometrics composing the aggregated pseudometric used for measuring distance between examples. The analogous assumption is used for numerical attributes: real values are grouped using interval contained in the ball $B(a(tst), \varrho_a(a(tst), a(trn)))$ determined by the Euclidean metric. The same Euclidean metric (however normalised) is used for components of the final pseudometric.

Proof. If $k \geq |trnSet|$ then the $neighbourSet = trnSet$, where $neighbourSet$ is defined in the RIONA algorithm (see Algorithm 5). Hence, RIONA works exactly as the RIA algorithm (see Algorithm 4).

If $k = 1$ and $|N(tst, trnSet, 1, \varrho)| = 1$[5] then the $neighbourSet$ in the RIONA algorithm is a singleton set and consistency checking can be omitted. Hence, RIONA works exactly as 1NN (see Algorithm 1). □

RIONA behaves like the RIA algorithm for the maximal neighborhood (and from the Corollary III.5 as the algorithm based on the maximally general rules with the $Strength$ strategy for conflict resolution). By taking a neighbourhood based on the one nearest training example, the nearest neighbour algorithm is obtained. RIONA is positioned between the rule-based classifier based on the maximally general rules and the nearest neighbour classifier. If a small neighborhood is chosen then it acts more like a kNN classifier and if a large neighbourhood is chosen it works more like a rule-based classifier based on inducing maximally general rules. Selection of a neighbourhood that is not the maximal may be interpreted as taking more specific rules instead of maximally general rules consistent with the training examples.

Below, we present more properties of RIONA.

Theorem IV.2. *The following equality holds:*
$RIONA(tst, trnSet, k, \{\varrho_a\}_{a\in A}) =$
$decLoc_{MaxRules}(tst, k, \varrho)$,
where

(i) *tst is any test object,*
(ii) $decLoc_{MaxRules}(tst, k, \varrho)$ *is the output of classifier from Eqn. 10 with*
- $MaxRules = MaxRules(GenRules, trnSet)$,
- $GenRules = GenRules\left(\{(\varrho_a, a(tst))\}_{a\in A_{sym}}\right)$,
- $\varrho = Agr(\{\varrho_a\}_{a\in A})$.

Proof. We have $RIA(tst, trnSet, \{\varrho_a\}_{a\in A_{sym}})$ $= decision_{MaxRules}(tst)$ (see Corollary III.5). This is based on the following fact: RIA computes measure $Strength$ for $MaxRules = MaxRules(GenRules, trnSet)$, i.e. for each $v \in V_d$ $supportSet(v)$ (in line 11 of Algorithm 4) $=$ $Strength(v)$ (see Theorem III.4). RIONA works only on training examples from $N(tst, trnSet, k, \varrho)$ and examples consistent with $N(tst, trnSet, k, \varrho)$ are also consistent with the whole training set, $trnSet$ (see Proposition III.6). In computing of the measure $LocStrength(tst, v, k, \varrho)$ are used only training examples from the neighbourhood $N(tst, trnSet, k, \varrho)$. Hence, $supportSet(v)$ (see line 13 of Algorithm 5) $=$ $LocStrength(tst, v, k, \varrho)$ for any $v \in V_d$. From this the equation of the theorem follows. □

Theorem IV.3. *The following equality holds:*
$RIONA(tst, trnSet, k, \{\varrho_a\}_{a\in A}) =$
$decLoc_{MaxRules}(tst, k, \varrho)$,
where

(i) *tst is any test object,*
(ii) $decLoc_{MaxRules}(tst, k, \varrho)$ *is the output of classifier from Eqn. 10 with*
- $MaxRules =$ $MaxRules(GenRules, N(tst, trnSet, k, \varrho))$,
- $GenRules = GenRules\left(\{(\varrho_a, a(tst))\}_{a\in A_{sym}}\right)$,
- $\varrho = Agr(\{\varrho_a\}_{a\in A})$.

Proof. The following equality holds (see Theorem IV.2):
$RIONA(tst, N(tst, trnSet, k, \varrho), k, f) =$
$decLoc_{MaxRules}(tst, k, \varrho)$,
where $trnSet$ is substituted by a new training set $N(tst, trnSet, k, \varrho))$,
and
$f = \{\varrho_a\}_{a\in A}$,
$MaxRules = MaxRules(GenRules, N(tst, trnSet, k, \varrho))$.
We also have
$RIONA(tst, N(tst, trnSet, k, \varrho), k, f) =$
$RIONA(tst, trnSet, k, f)$
what ends the proof. □

From the last two theorems the following interesting corollary follows.

Corollary IV.4. *Let us assume that there are given* $\{\varrho_a\}_{a\in A}$, $\varrho = Agr(\{\varrho_a\}_{a\in A})$, $trnSet$,
$MaxRules = MaxRules(GenRules, trnSet)$,
$MaxLocalRules =$
$MaxRules(GenRules, N(tst, trnSet, k, \varrho))$,
where $GenRules = GenRules\left(\{(\varrho_a, a(tst))\}_{a\in A_{sym}}\right)$.
Then the outputs returned by the following classifiers are the same for any tst *object:*

1. $RIONA(tst, trnSet, k, \{\varrho_a\}_{a\in A})$,
2. $decLoc_{MaxRules}(tst, k, \varrho)$,
3. $decLoc_{MaxLocalRules}(tst, k, \varrho)$,
4. $decision_{MaxLocalRules}(tst)$ *with a new training set* $trnSet' = N(tst, trnSet, k, \varrho)$.

Proof. From Theorems IV.2 and IV.3 it follows the equivalence of the first three classifiers. To obtain the equivalence of the third and fourth classifiers let us observe that
$trnSet' = N(tst, trnSet, k, \varrho) =$
$N(tst, N(tst, trnSet, k, \varrho), k, \varrho) = N(tst, trnSet', k, \varrho)$.
We also have $supportSet(r) \subseteq trnSet'$. Hence, from the previous equation we obtain $supportSet(r) \subseteq N(tst, trnSet', k, \varrho)$. Then $locSuppSet(r) =$ $supportSet(r) \cap N(tst, trnSet', k, \varrho) = supportSet(r)$. Now one can see that Eqn. 9 becomes Eqn. 7, what implies that Eqn. 10 becomes Eqn. 8. □

Summarising, the conclusions are the following: (i) RIONA calculates the $LocalStrength$ measure (see Eqn. 9). (ii) The $LocStrength$ measure is the $Strength$ measure with $N(tst, k)$ as the local training set (fourth algorithm). (iii) The algorithm presented in Eqn. 8 after substitution of a

[5] This assumption can't be omitted. If $|N| > 1$ then it may happen (even for consistent training set) that N has (equally distanced from test example) two cases with different decisions leading to inconsistency.

new training set $trnSet' = N(tst, trnSet, k, \varrho)$ instead of $trnSet$ becomes the fourth algorithm. (iv) One can consider the RIONA algorithm as an algorithm for computing all maximally general, consistent rules locally and using (locally) $Strength$ for conflict resolution.

In Table I and Table II is presented comparison of these algorithms (the third algorithm is omitted because it is very similar to the fourth).

Table I
A GENERAL COMPARISON OF THREE ALGORITHMS FROM COROLLARY IV.4: ALGORITHM (1) RIONA, ALGORITHM (2) BASED ON THE MEASURE $LocStrength$ AND ALGORITHM (4) BASED ON THE MEASURE $Strength$ COUNTED LOCALLY.

RIONA	algorithm (2) based on the measure $LocStrength$	algorithm (4) based on the measure $Strength$ counted locally
counting rules		
no need to count rules explicitly	counts $MaxRules$ globally once at the beginning	counts $MaxRules$ locally for each test case
counting support		
counts support using lazy local rules	counts support locally	counts support locally

Table II
A COMPARISON SCHEME OF THREE ALGORITHMS FROM COROLLARY IV.4: ALGORITHM (1) RIONA, ALGORITHM (2) BASED ON THE MEASURE $LocStrength$ AND ALGORITHM (4) BASED ON THE MEASURE $Strength$ COUNTED LOCALLY.

RIONA	algorithm (2) based on the measure $LocStrength$	algorithm (4) based on the measure $Strength$ counted locally
Global input: $trnSet$, $k \in \mathbb{N}$		
1.	count $MaxRules$ for $trnSet$	
Input: test case tst		
2. $nSet = N(tst, k)$		
3.	$RuleBase = MaxRules$	count (locally) $MaxRules(nSet)$ $RuleBase = MaxRules(nSet)$
4.	consider rules from $RuleBase$ with premise satisfied by tst	
5. for each decision d		
6. consider $trn \in nSet$ with decision d	consider rules from step 4 with decision d	
7. count the number of trn from step 6 forming consistent rules with tst	count the number of $trn \in nSet$ supporting rules from step 6	
8. choose the decision with the maximal count (maximally supported)		

A. RIONA and rules

Some important properties of instance-based classifiers and rule-based classifiers are inherited by the RIONA algorithm. Even though rule-based classifiers produce less accurate classifications, there are several features of them that users prefer over instance-based classifiers. The ability for a human, non-computer science professional, to interpret rules is one of these crucial features. He or she can check to see if the information found in such rules is non-trivial, accurate, and revealing brand-new features of the considered case. A rule includes an explanation for making the specific decision that is simple enough for a human to comprehend.

Here, we assume that the RIONA algorithm's parameter k is fixed (potentially learnt [5]). Let's now concentrate on algorithm (4) from Sect. III. Because the local complete set of consistent and maximally general decision rules must be computed for each test case tst, the direct computation of $MaxLocalRules$ may initially appear to be highly expensive and impractical. However, if we assume that the size of N is k, then the size of the local training sample is much smaller than the size of the entire training sample being reduced from $n = |trnSet|$ to k. As a result, the total cost of computing $MaxRules$ (globally or locally) is decreased from $O(2^n)$ to $O(m \cdot 2^k)$, where m is the number of test cases. We don't just present this strategy from a theoretical standpoint only. When a classifier's decision needs to be explained, this kind of method might be useful. In this way, the RIONA algorithm shares characteristics with rule algorithms and quick lazy learning algorithms, i.e. its parameters can be converted into rules.

Additionally, algorithm (4) might be extended to construct all rules globally once at the beginning, analogously to algorithm (2) from Corollary IV.4, except that the rules would be based on the local neighborhood only. Such rules would mimic the RIONA algorithm's behavior. The use of such a strategy has several benefits. First, a set of rules could be immediately provided to explain the predicted decision on a particular test object. Second, the usefulness of the knowledge acquired might be tested against all potential rules generated at the beginning.

The approach for construction of these rules is analogous as in algorithm 4 from Corollary IV.4. One could just construct $MaxRules$ locally for each training case and use each training example as a test example. It could be seen as a computation of specific local reducts i.e. reducts constructed during generation of maximally general rules for a given object (see e.g. [33], [34], [35], [32]). Usually, in construction of local reducts one should be aware to keep discernibility for objects with various decisions. Only objects with different decisions and at a distance of no more than determined by k would be required to be discernible in this case.

V. CONCLUSION

The presented findings indicate some important relationships of classifiers generated by the RIONA learning algorithm with instance- and rule-based classifiers. For example, it is proved the relative to classification equivalence of the RIONA algorithm to the algorithm generating all consistent and maximally general rules from a training set including the close training cases to a given test case. As a result, the classification by RIONA classifier can be performed by a relatively small set of rules that are simple for a person to comprehend. It might be applied in circumstances where it's crucial to provide an explanation for the decision that was reached by classifier. Finally, it is worthwhile to mention that the RIONA algorithm, based on hybridization of instance- and rule-based techniques, has the following properties (i) it is efficient as well as effective from the point of view of classification, (ii) it can be used as a high quality tool in the process of explanation of the predicted decisions.

***Abstract*—Accurate estimation of absolute distance and height of objects in open area conditions is a significant challenge. In this paper, we address these problems and we propose a novel approach that combines classical computer vision algorithms with modern neural network-based solutions. Our method integrates object detection, monocular depth estimation, and homography-based mapping to achieve precise and efficient estimations of absolute height and distance. The solution is implemented on the edge device, which enables real-time data processing using both visual and thermography data sources. Experimental evaluation on a height estimation dataset prepared by us demonstrates an accuracy of 97.06% and validates the effectiveness of our approach.**

I. Introduction

ACCURATE estimation of spatial positions and parameters of objects, such as their localization on a bird's-eye view map, absolute distance, and absolute height, is an important computer vision task with wide practical implications. In this paper, we propose a novel solution for absolute distance and height estimation that combines homography-based mapping algorithms with state-of-the-art deep learning techniques. Our approach harnesses the strengths of both classical and modern solutions to achieve highly accurate and efficient estimations under various conditions.

The proposed method integrates several key components to provide a comprehensive solution for absolute height estimation. Firstly, we capture video frames from visual and thermography cameras and input them into an object detector, specifically the YOLOv5 model [1]. This model enables robust identification and localization of objects in the monocular view. To estimate the relative depth information, we utilize a transformer-based monocular depth estimation model called DPT Levit 224 [2], [3]. This model learns to infer depth information from a single image, allowing us to determine the relative distances between objects in the scene. Additionally, we incorporate homography-based mapping techniques to establish correspondences between points in different images or views. By leveraging homography projection, we can accurately map objects from the video frame plane to the bird's-eye view 2D map, enabling easy estimation of their distance from the camera. The final stage of our approach involves polynomial regression-based estimations to compute the absolute distance and height of objects.

The proposed solution is implemented on the Arabox III-A edge device, which is based on the Jetson Nano board and offers real-time data processing capabilities. Arabox is specifically designed for fully anonymous data acquisition and is commonly used in the Digital Out-of-Home (DOOH) advertising industry.

In our experimental evaluation, we demonstrate the effectiveness of our approach and its evaluation on the prepared by us absolute height estimation dataset. The obtained results show accuracy equal to 97.06% in real-time performance, emphasizing the usefulness of our solution in a wide range of applications requiring precise absolute distance and height estimation.

The rest of this paper is organized as follows: Section 2 II provides a detailed overview of related works, including object detection, homography-based mapping, monocular depth estimation, and absolute height estimation techniques. Section 3 III presents a comprehensive description of the architecture of our solution, along with information about the necessary configuration and calibration process. Section 4 IV presents the experimental results, which are divided into indoor and outdoor experiments, accompanied by a description of the dataset used and the methodology employed. Finally, section 5 V discusses the implications of our findings and identifies potential areas for future improvement.

II. Related works

In this chapter, we provide an overview of the existing research and advancements in the field of computer vision, with a special focus on object detection, homography-based mapping, monocular depth estimation, and absolute height estimation techniques.

A. Object detection

The task of object detection is widely used in computer vision and has a wide range of applications [4]–[6]. Currently, the best object detectors are based on convolutional neural networks (CNN). The initial success of CNN-based object detectors came with two-stage detectors like the region-based convolutional neural network (R-CNN) proposed by Girshick et al. [7] which has shown remarkable performance. This led to further advancements such as Fast R-CNN [8] and Faster R-CNN [9] - improved two-stage detectors, faster and with better accuracy. Another approach that gained popularity are one-stage detectors, exemplified by groundbreaking architectures like You Only Look Once (YOLO) [10] and Single-Shot Detector (SSD) [11]. They are faster, part of them can even work in real-time on edge devices, and currently have comparable accuracy to two-stage detectors [12].

The leading one-stage detection architecture YOLO has undergone significant improvements over time. Namely, its improved versions YOLOv2 [13] and YOLOv3 [14] introduced deeper convolutional backends, residual skip connections, residual blocks, and upsampling, resulting in one of the fastest object detection techniques while maintaining respectable accuracy. Bochkovskiy et al. presented YOLOv4 [15], which brought further enhancements to the training process, including data augmentation methods like CutMix, regularization techniques such as DropBlock, and architectural changes like the CSPDarknet53 backend network and path aggregation network with spatial attention blocks.

More recently, Jocher et al. presented YOLOv5 [1], which refreshed the YOLO architecture and improved its performance. The YOLO-based architecture remains a state-of-the-art object detector, with subsequent versions continually being developed and published under different names.

These advancements in object detection have significantly improved the accuracy and speed of detecting objects in various applications.

B. Homography-based mapping

Homography-based mapping is a widely used technique in computer vision that establishes correspondences between points in different images or views. It relies on the concept of a homography, which is a projective transformation that maps points from one plane to another. This mapping has numerous applications, including image stitching, augmented reality, camera calibration, and object tracking.

Works by Hartley and Zisserman [16], as well as by Cyganek and Siebert [17] provide a comprehensive overview of homography estimation algorithms. Additionally, the work of Szeliski [18] presents techniques for the robust estimation of homographies in the presence of outliers and noise. These studies serve as foundational knowledge for our use of homography-based mapping in height estimation.

C. Monocular Depth Estimation

Monocular depth estimation aims to recover depth information from a single image. This task is challenging due to the inherent ambiguity in monocular vision. Nevertheless, it plays a crucial role in various applications such as 3D reconstruction, scene understanding, and autonomous navigation.

Over the years, significant progress has been made in monocular depth estimation techniques. Early approaches were focused on hand-crafted features, superpixelation, and traditional computer vision algorithms [19]–[21]. However, with advancements in deep learning, convolutional neural networks have emerged as powerful tools for monocular depth estimation.

One notable work in this field is the pioneering study by Eigen et al. [22] where they introduced a CNN-based approach for monocular depth prediction. This work paved the way for subsequent research in deep learning-based depth estimation. Another significant contribution is the work of Laina et al. [23], who proposed a faster and lighter solution by training a fully convolutional residual network based on ResNet-50 [24]. They replaced the fully connected layers with up-convolutional blocks and modified the loss function.

Subsequently, the development of CNN-based solutions accelerated, leading to the creation of numerous works addressing this area. A few noteworthy contributions deserving special attention are listed below. Lee et al. [25] proposed a solution based on the relative depths between objects in the image. Ranftl et al. [26] presented a tool for mixing multiple datasets during monocular depth estimation training, even when their annotations were incompatible. This tool has facilitated future advancements in this field. Additionally, Ranftl et al. [2] proposed a dense vision transformer-based depth estimation architecture with a transformer backbone. Their architecture produces more fine-grained and globally coherent predictions compared to fully-convolutional architectures.

D. Absolute height estimation

Absolute height estimation is an intriguing computer vision task, but less popular than those mentioned above. To address this problem, various approaches based on image depth estimation [27], convolutional neural networks [27]–[29], and convolutional-deconvolutional deep neural networks (CDNNs) [30] have been proposed.

A notable work in this domain is the study conducted by Yin et al. [27], where they developed a four-stage estimator based on multiple CNN networks operating on a single-depth image. Their approach achieved impressive accuracy in height estimation, reaching as high as 99.1%. It is worth mentioning that their solution was limited to a controlled laboratory environment, where measurements were conducted on individuals positioned approximately 2 meters away from the camera. Despite this limitation, the achieved result is truly remarkable.

The field of absolute height estimation is relatively specialized, and fewer studies have been conducted compared to

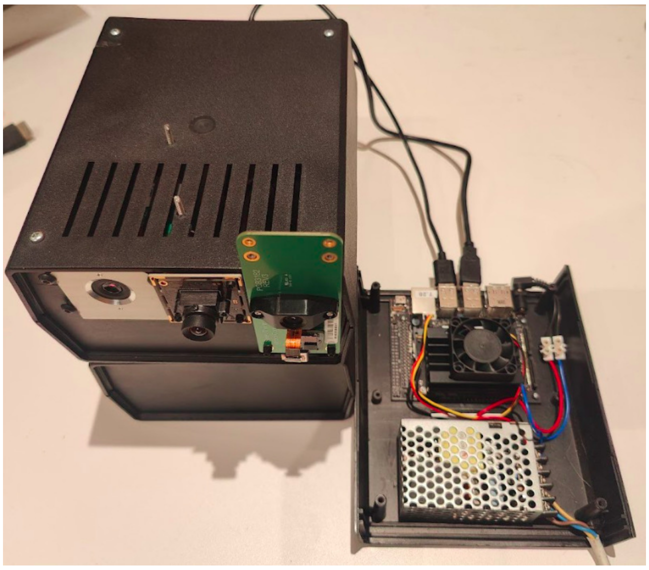

Figure 1: Arabox device - version with normal and termovision cameras and Jetson Nano board.

other computer vision tasks. Therefore, we believe that it is an interesting area for further research and development.

III. System Architecture

In this chapter, we present the architecture of our method for estimating the absolute height and distance of objects, which is implemented on an edge device called Arabox III-A, developed by MyLED [31]. Our approach for height estimation relies on two sources of data: a video signal and a thermal image signal. The system flow consists of integrating object detection using the YOLOv5 neural network, monocular depth estimation transformer, homography-based mapping, and polynomial regression-based estimations. We provide a detailed explanation of our method in section III-B.

A. Arabox device

Arabox, shown in Figure 1, is a device developed for fully anonymous data acquisition in the retail industry. It can be used in both stationary stores (including those operating in the omnichannel model) and the outdoor advertising industry (particularly in digitized form, known as DOOH). The device's key component is an embedded system that includes a GPU, such as the Jetson Nano, which is responsible for encrypting and processing data from the connected cameras. Arabox also includes a carrier board, power supply, fans, and a special case. Arabox has many use cases, but below we will focus on its height estimation functionality.

B. Height estimation pipeline

The main contribution of our paper is the absolute height estimation pipeline presented in Figure 2. It utilizes two data sources: a video signal and a thermal image signal. Both signals are initially processed by the YOLOv5 object detector before being fed into separate flows. In the first flow, we project the video signal onto a bird's-eye view using homography-based mapping. This enables us to estimate the spatial position of objects, as well as their distance from the camera and height (based on initial configuration, polynomial regressions, and the height of bounding boxes estimated by YOLOv5). We perform the same process for the thermal image signal, but with a different homography matrix.

The second flow is only performed for the video signal and is based on DPT Levit 224 monocular depth estimation model. This network estimates the relative depth of the image, and its output is combined with YOLOv5 detections to calculate the average depth value for the detected bounding boxes. Using a polynomial regression model from the device configuration and the relative depths of the detected objects, we can estimate their absolute distance from the camera, as well as their absolute height, in the same way as in the first flow. Finally, we average the results from all three flows to estimate the final height of the objects. More details on each of the pipeline steps are provided in the following subsections.

1) YOLOv5 detections: This part of our pipeline comprises two YOLOv5 models, which have been trained on two datasets that we prepared - one based on visual and the other on thermal images. These datasets contain approximately 20,000 annotated photos captured in urban environments. The YOLOv5 models output class of an object (such as human, car, or bus), its anchor location represented by two coordinates, and the height and width of the bounding box. All expressed in local coordinates associated with an image plane. This information is then used in the subsequent steps of our system, i.e. in the homography-based mapping and monocular depth estimation.

2) Homography-based mapping: The goal of this step is to project the location of the detected object from a 3D photo to a 2D "map" presented from a bird's-eye view. This projection enables us to estimate the distance and height of the object in the next step. To accomplish this, we first calculate the homography matrix for a given location during the device calibration process III-C. Subsequently, we use this matrix to transform the YOLOv5 detections and project them onto a 2D plane. By knowing their positions on the 2D plane and the scale of the plane saved during the configuration process, we can accurately estimate their distance from the camera, as well as their height, using polynomial regression.

3) Monocular depth estimation: In this step, we utilize the monocular depth estimation neural network called DPT Levit 224 [2], [3]. Given an input image, the network returns a map of relative depth estimates, where lower pixel values correspond to objects that are further from the camera. To improve the accuracy of our estimations, we first crop the image to remove any visible sidewall or casing fragments before passing it to the neural network.

The DPT Levit 224 model we use was trained using a publicly available tool for mixing monocular depth estimation datasets [26]. By using this pre-trained model, we can estimate the relative depth of objects in the scene with high accuracy, even in cases where the objects are partially occluded or have

complex geometries.

4) Objects' absolute distance estimation: The estimation of object distance from the camera is performed using two methods, depending on the results of the previous step. If we estimate the distance based on the spatial position of the object obtained through homography-based mapping, the calculation is straightforward. We simply multiply the object's distance from the camera (expressed in pixels) by the scale factor included in the device configuration III-C.

On the other hand, if we estimate distance using monocular depth estimation, the process is more complex. In this case, we first calculate the average depth value for each bounding box returned by YOLOv5, and then substitute these values into a polynomial regression formula contained in the device configuration. This formula expresses the relationship between depth values and distance at a given location, enabling us to estimate absolute distance accurately. Details on how to calculate the coefficients of said polynomials are contained in the configuration section III-C.

5) Objects' absolute height estimation: After we have obtained the absolute distance of the object from the camera, we can estimate its height. However, for the estimate to be accurate, we need to calibrate the device to a specific location beforehand and calculate the coefficients of the 3rd-order polynomial accurately. This polynomial regression formula is used to determine the relationship between the distance of the object from the camera and the ratio of its height in pixels to the height in the real world. The process of calibration and calculating these coefficients is further explained in the configuration section III-C.

Once we have the coefficients and the distance value, we substitute them into the polynomial formula to obtain a height ratio. We then multiply this ratio by the height of the object in pixels obtained from the YOLOv5 detector. This calculation allows us to obtain an accurate estimate of the absolute height of the object.

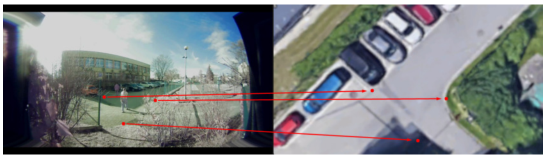

Figure 3: A photo showing the process of calculating the homography matrix. The person responsible for the configurations marks the points on the image from the camera and the corresponding 2D map.

C. Configuration and calibration process

To ensure the proper functioning of the methods described, it is necessary to configure and calibrate the system. The most important parameters that we need to configure for each location where the device is to be used are: homography matrices, coefficients of the third-order polynomials used in the polynomial regression of distance and height, and the scale factor of pixels to meters.

Homography matrices are calibrated for a specific location using a simple script that requires marking several points on the original image and the 2D image, as shown in Figure 3. If the points are marked accurately, the script will return a homography matrix that allows for the projection of objects' locations from the camera's perspective onto a bird's-eye view. A separate matrix should be calculated for each camera (i.e. visual and thermal), since their parameters are different.

The polynomial regression is employed to determine the relationship between the distance of an object from the camera and the ratio of its height in pixels to its height in the real world. To compute the third-order polynomial coefficients used

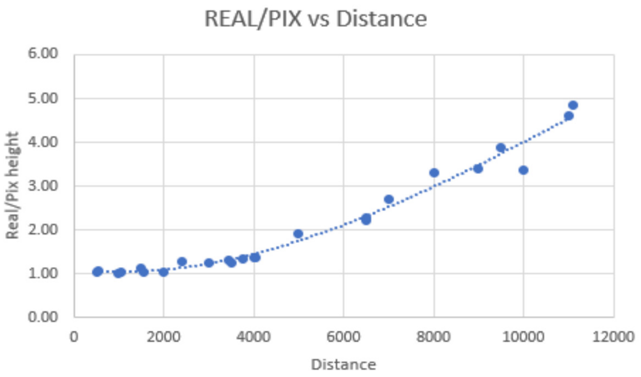

Figure 4: Regression curve calculated in the calibration phase for mapping the height of objects in pixels to the height of objects in meters.

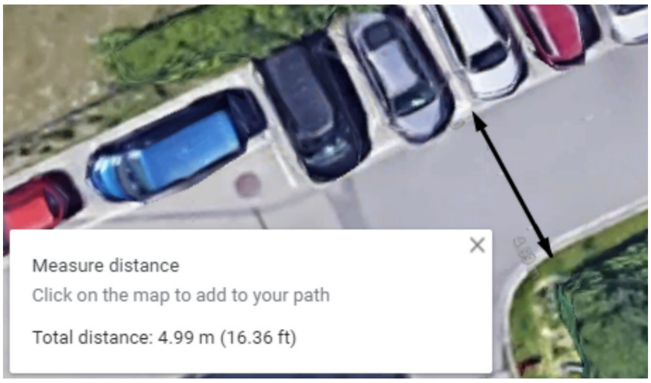


Measure distance

Click on the map to add to your path

Total distance: 4.99 m (16.36 ft)

Figure 5: An example of distance measurement for device calibration using Google Maps.

for this regression, the following steps are proposed: Firstly, several YOLOv5 detections of a person with a known height should be made at different distances from the camera, and the height returned by YOLOv5 in pixels should be recorded. Next, a plot similar to the one shown in Figure 4 should be created, and a third-order polynomial regression should be computed on it. The obtained coefficients should then be saved in the device configuration. The height estimation module will then multiply the distance of the object from the camera by these coefficients and then by the height of the YOLOv5 prediction. This will provide an estimate of the height of the given object. A similar process should also be performed for the monocular depth estimation module and its depth-to-distance regression.

The final parameter needed to calibrate the device to a specific location is the scale that determines how many centimeters in the real world correspond to one pixel on the 2D map. This parameter can be easily calculated by measuring the distance between two characteristic objects on a Google Maps and then checking how many pixels on our 2D map they correspond to, as shown in Figure 5. Once all the parameters have been calibrated and configured, the device is ready for use in estimating the absolute height and distance of objects for chosen location. In the future we want to improve and automate the configuration process.

IV. Experimental part

To validate the effectiveness of our method, we conducted an experiment using a small dataset comprising videos of 11 individuals with known heights. The videos were captured in two distinct locations: one in an open environment and the other inside the building. By utilizing this dataset, we evaluated the performance of our system following the methodology outlined in section IV-B and achieved an estimation accuracy of 97.06%.

The experiment aimed to assess the system's ability to accurately estimate the height of individuals in different environmental conditions and validate the effectiveness of our proposed approach. In the following sections, we will discuss the details of the gathered dataset, our methodology and we will present the results obtained from our evaluation.

A. Dataset

The dataset comprises 10 recordings, each featuring a different individual with a known height. The recordings were captured using two types of cameras: a regular vision camera (model ELP-USB500W05G-FD100) and a thermal imaging camera (model SEEK Thermal MS202SP Micro Core).

The dataset includes videos from two distinct locations: indoors, specifically in an office space, with a total of three recordings, and outdoors, in a parking lot, with a total of seven recordings. The individuals participating in the recordings had heights ranging from 160cm to 185cm. While the dataset may not be extensive, we believe it provides sufficient variety to validate and confirm the effectiveness of our absolute growth estimation method. Sample frames from videos used in our dataset are presented in Figure 6.

B. Methodology

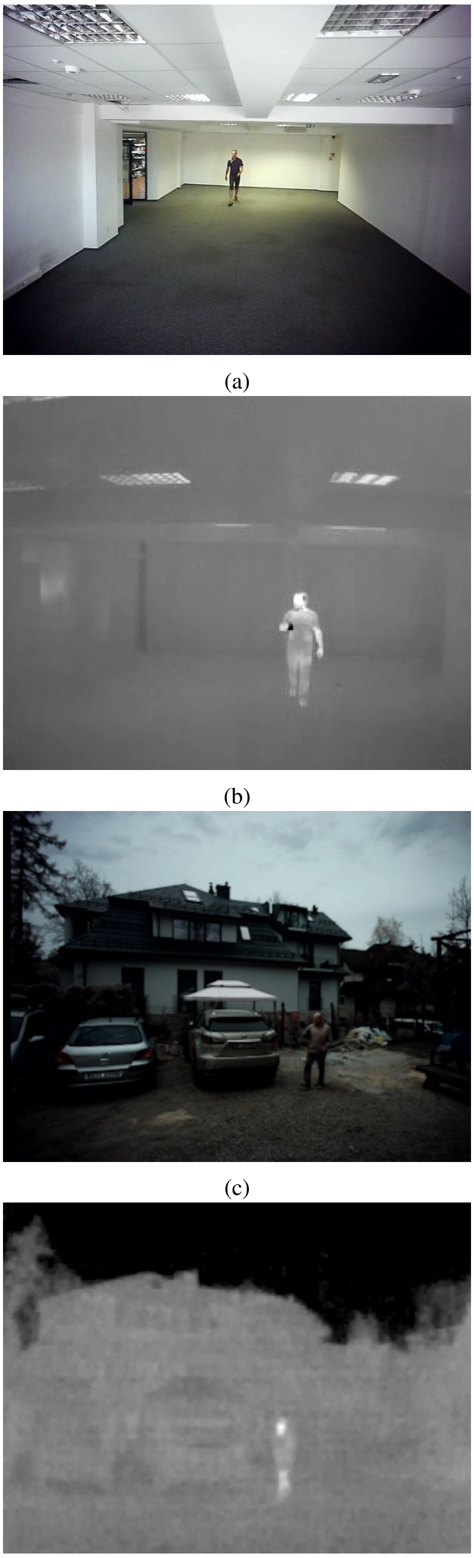
To validate the performance of our method for estimating the absolute height of individuals, we employed the following methodology.

For each video in our dataset, our model conducted height estimations on every frame in which the YOLOv5 detection model detected a person. The estimated heights were stored in a temporary table, and the measurements were averaged at the end of the video, using the Formula 1. Where, h_a represents the averaged height measurement result, h_i represents the result from a single frame, and N is the number of frames in which the person was measured.

$$h_a = \frac{\sum\limits_{i=1}^{N} h_i}{N} \tag{1}$$

These estimates were then compared against the known actual heights of the individuals (h_e) to calculate the percentage errors using Formula 2.

$$\delta = |\frac{h_a - h_e}{h_e}| * 100\% \tag{2}$$



(a)

(b)

(c)

(d)

Figure 6: Sample images from the dataset

To provide a comprehensive evaluation, we stored all the results, as well as results from every module of our system in Table I and Table II, respectively. These tables serve as a consolidated record of the estimated heights, actual heights, and corresponding absolute errors for each video. Additionally, they contain the estimated heights from each component of the pipeline, namely results from the homography-based mapping using the vision data (HBM vision), homography-based mapping using the thermal data (HBM thermo), monocular depth estimation (MDE), and the fusion module. The fusion module results are calculated as presented in formula 3.

$$Fusion = \frac{\frac{HBE_{vision}+HBE_{thermovision}}{2}+MDE}{2} \tag{3}$$

As can be observed, the fusion formula is not a simple arithmetic average, as the module based on monocular depth estimation carries the greatest weight. This is because the homography-based mapping modules provide similar information, whereas the monocular depth estimation module offers distinct and additional insights. By utilizing this methodology, we can quantitatively assess the accuracy and reliability of our height estimation method across the entire dataset. The percentage error values obtained will allow us to analyze the performance of our system and identify areas for improvement.

In the subsequent sections, we will present the detailed results obtained from our evaluation and discuss the implications of these findings for the effectiveness of our proposed method.

C. Results

The results of our experiments are presented in three separate tables. Table I displays the measurements conducted indoors for three individuals, while Table II showcases the measurements carried out in an open area for eight individuals. Finally, Table III provides a weighted average summary of the results obtained from all experiments.

The average accuracy achieved in each experiment is as follows: 97.73% for Experiment 1, 96.77% for Experiment 2, with an overall weighted average accuracy of 97.06%. These accuracy percentages represent the degree of agreement between the estimated heights and the actual heights of the individuals. A more detailed description of the experiments and their results is provided below.

1) Experiment 1 - indoor area: In the first experiment conducted indoors, specifically in an office space; we recorded the heights of three individuals ranging from 173 cm to 186 cm; the maximum distance from the camera in which they could walk was around 12 meters. The system performed around 370 measurements for each person and then averaged them to obtain the final results presented in Table I. The average accuracy of the absolute height estimations obtained in this experiment was 97.73%. The best-performing module is based on homography mapping with a signal from the video camera with an error of only 1.14%. On the other hand, the worst-performing module is also homography-based mapping, but with a signal from the thermal camera - with a percentage

Table I: Indoor experiment results

	HBM vision	HBM thermo	MDE	Fusion	Ground Truth	Number of frames
Person 1	185cm	180cm	188cm	185cm	186cm	346
Error 1	0.54%	3.23%	1.08%	0.54%	-	346
Person 2	179cm	167cm	170cm	172cm	178cm	350
Error 2	0.56%	6.18%	4.49%	3.37%	-	350
Person 3	177cm	167cm	164cm	168cm	173cm	412
Error 3	2.31%	3.47%	5.20%	2.89%	-	412
Avg. Error	1.14%	4.29%	3.59%	2.27%	-	-

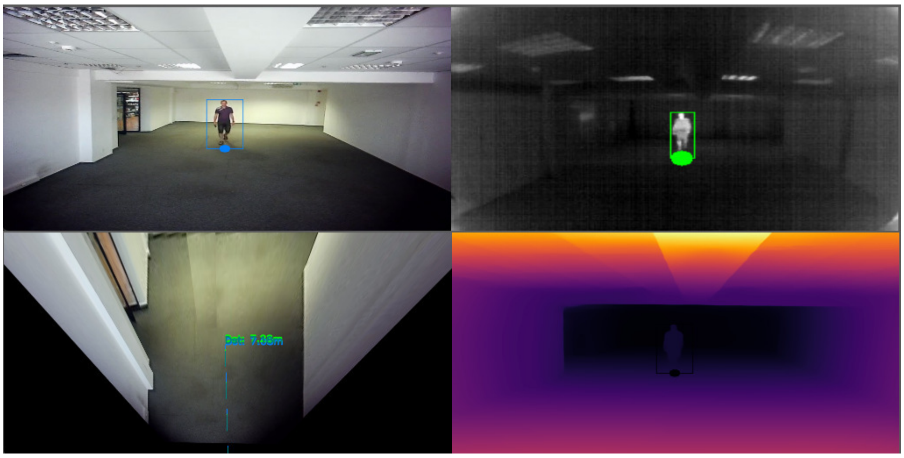


Figure 7: Visualization of the described method: Upper left - detection on a video signal, upper right - detection on a thermal image, bottom left - projection of a person's detections into bird's eye view, bottom right - monocular depth estimation output

error equal to 4.29%. A sample visualization of our method's work on data from the indoor experiment was presented in Figure 7.

2) Experiment 2 - outdoor area: In the second experiment, we conducted measurements in an open area, specifically a small parking lot. Seven individuals with heights ranging from 160 cm to 185 cm participated in this experiment; the maximum distance from the camera in which they could walk was around 20 meters. For each person, a varying number of measurements, ranging from 865 to 1968, were conducted and averaged. Final results are presented in Table II. The average accuracy of the estimations obtained in the second experiment was 96.77%. The best-performing module in this experiment was the monocular depth estimation model, with an average percentage error equal to 3.03%, whereas the worst-performing method was once again thermovision homography mapping with an error equal to 4.39%.

3) Results summary: Summarizing the results of the aforementioned experiments, we achieved a weighted average accuracy of 97.06%. Among the different modules used, the height estimation module based on homography projecting yielded the highest accuracy of 97.35%. The other modules, namely the monocular depth estimation module and homography-based mapping working on thermal imaging, achieved slightly lower accuracies of 95.89% and 95.64%, respectively.

Looking for reasons for such results, the lower accuracy of the model working on thermal imaging data can be attributed to the less accurate detections of the YOLOv5 on the thermal images. The thermal images dataset, on which the YOLOv5 model was trained, was smaller than the traditional dataset, which can correspond to weaker results. Notably, the detections from the thermal-based model were often 10-15% higher in the vertical axis, which was not observed in normal data.

Regarding monocular depth estimation, certain challenges were encountered due to the background conditions. For instance, if a person passed in front of a car, the model believed that person to be closer than if they were at the same distance but there was no car in the background. Despite this limitation, the results achieved in this experiment were considered very good, taking into account the difficulty of the scenery.

Experiment no. 2 presented slightly weaker results due to the more complex scene and higher maximal distance in which individuals could walk. Particularly, beyond 15 meters, the system encountered significant challenges in accurately estimating the distances and therefore absolute heights.

Moving forward, we aim to expand our dataset and conduct experiments in a larger number of testing locations with a more diverse group of individuals. This will further validate and enhance the proposed method. Additionally, we will focus on improving other aspects of our method, which will be discussed in detail in the following section.

V. Conclusion and future works

Presented in this paper a method for absolute distance and height estimation that incorporates a combination of visual and

thermal imaging data, and which employs advanced technologies such as object detection, homography-based mapping, and monocular depth estimation, constitutes a significant scientific contribution to the field of spacial position estimation in real conditions.

With an accuracy of 97.06%, our method demonstrates promising results, making it suitable for applications on edge devices. However, we acknowledge that there is room for improvements. In our future endeavors, we aim to enhance the accuracy of our method and streamline the configuration and calibration processes.

Moving on to future works, one of our primary objectives is to expand our dataset by incorporating additional locations and involving a more diverse range of participants. This expansion would provide valuable insights into the performance of different modules of our height estimation method and their effectiveness in various environmental conditions. By evaluating our method on a more diverse dataset, we can identify areas for improvement and optimize its performance accordingly.

Another improvement of the proposed method will be streamlining the configuration and calibration process. At the moment, it takes an experienced operator about 30 minutes to configure the device for a new location. We would like to streamline this process and automate it further, especially the part related to the calculation of the polynomial regression coefficients of the distance and height estimation modules.

Additionally, we plan to extend our method with new modules. These could include methods such as monocular depth estimation based on thermal imaging, a human pose estimation [32] module, and the utilization of the object segmentation [33] methods for obtaining more accurate data for calculating the average depth of objects with monocular depth estimation module. By incorporating these new modules, we aim to enhance the capabilities and versatility of our method in estimating absolute distance and height.

In conclusion, our article shows that the accurate estimation of absolute distance and height from the monocular view is possible with high accuracy by using a hybrid solution based on object detection, homography-based mapping, and monocular depth estimation. Furthermore, we recognize the potential for further development and propose future improvements in this task.

The reception of holidays in social networks: A case study on Twitter

E-Mail: hakius@wiedenest.de

***Abstract*—This study aims to push the boundaries of research in practical theology by applying methods from computational social science to identify the reception of holidays in online social networks in German tweets. Can we identify how people talk about holidays and especially Christian holidays on Twitter? As a subquestion, we try to find relevant information for interreligious topics, especially between Christians and Jews: Can we see how Christian holidays are related to or embedded in their Jewish counterparts? Is there an awareness of the Jewish roots of certain Christian holidays? While there is a growing awareness of these issues, there are still a number of unanswered questions. In addition to analysing and discussing these questions, we will also discuss methodological issues. First, we will discuss how computational methods fit in with common research in practical theology. Secondly, we will discuss the challenges of working with digital data beyond quantitative and qualitative research.**

I. Introduction

MUCH research in practical theology is devoted to religious practices and their interaction with society. It tends to take an empirical approach similar to that of the social sciences. Digital methods and the analysis of digital texts and communications are emerging themes. There is an ongoing theological and cultural discussion about the connection between Jewish and Christian holidays, and we want to find out how they are perceived in online social networks.

The research of this project tries to identify the reception of holidays in online social networks in German tweets and to evaluate the lack of awareness of the relationship between Christianity and Judaism in the context of a post-Christian society in German-speaking countries. While not our primary concern, we will also present a discussion on tweets with anti-Semitic content[1]. Our main research questions are

- Can we identify how people talk about holidays and especially Christian holidays on Twitter? (RQ1)
- If we find relevant information: Can we see how Christian holidays are related to or embedded in their Jewish counterparts? Is there an awareness of the Jewish roots of certain Christian holidays? (RQ2)

We will provide an overview of related work, leading to a careful reflection on the methodological background of the computer science methods used. While these methods – using an API, searching, clustering, analysis – are not new, they are not directly related to traditional empirical methods. We reflect on the validity of the chosen mix of methods – combining qualitative and quantitative research – and evaluate our methodological approach. We also provide a brief introduction to the religious and theological background of the material studied.

This paper is divided into five sections. The first section provides an introduction, the second a brief overview of related work. The third section describes the methodological background, the data, the pipeline and the matching approaches. The fourth section is devoted to the analysis of the results. This includes a religious-historical and theological pre-location of the festivals studied and a discussion of the relevance of these results for Christian churches. Conclusions and implications are drawn in the final section.

II. Related Work

The proposed approach aims to analyse social networks, in this case Twitter, to gain insights into religious phenomena [5], [6]. The analysis of online social networks is an emerging trend in research within the last decade [7]. For a general overview of Twitter data analysis, see [6], [8]. The applications and research questions are numerous, it has been used for health analysis [9], IoT [10], politics, recommender systems or emergency situations [11]. In addition to technical issues, ethical issues are also discussed [12].

First, we consider social network analysis of Twitter data in theological and religious research. This is more or less a niche topic, see [13], [14], [14]. Research questions focus on how religious leaders use social media [15], uncovering hidden church populations [16] or the relationship between sentiment of tweets and church growth [17]. In addition to metadata such as geographic data, word frequencies are widely used [18]. Secondly, clustering approaches are widely used to organise data [19], [20]. This is either related to identifying topics [22] or grouping similar tweets, for example using word similarities [21]. However, there is no one-size-fits-all solution and the choice of the best technology also depends on the data being processed, e.g. hashtags [22].

Thirdly, while we focus on German tweets, the technologies used are largely identical to other languages [23]. Basic statistical information can be extracted [24], other researchers focus on hashtag and word frequencies [25].

In summary, we can rely on many existing solutions, and especially the focus on German tweets does not remain a technical challenge. However, for interdisciplinary research,

[1] For further details on hate speech, racism and anti-Semitism we refer to [1], [2], [3], [4]. Especially hate-speech detection is under constant research. However, in this work we will only collect evidence for further research.

especially for religious and theological research, there are several methodological issues that have received more attention in recent years: While the analysis of online social networks is based on methods from computer and data science, which lead to quantitative data, the research usually also includes a qualitative analysis of these data [26]. While the use of qualitative analysis was widely perceived as inappropriate [27], the situation has changed [28], [29]. Salvatore and Bianchi propose a mixed methods approach, while Dongo et al. summarise that “the differences in terms of accuracy and efficiency of both extraction methods [give] relevance to much more problems related to this area to pursue true transparency and legitimacy of information on the Web.” As this issue is particularly important for religious and theological research, which often focuses on qualitative research, we will also focus on a critical interdisciplinary reflection of a mixed-methods approach

III. Method

While there are numerous features that can be used to analyse Twitter data, such as network measures, finding related information, text measures, word frequency patterns, sentiment analysis and local information, our approach mainly aims at answering the question “what people say when they tweet about holidays”, similar to the approach of Vidal et al. [30]. We propose a mostly generic analysis workflow, which we present in the first subsection. We then describe the clustering approach and the data generated and analysed.

With the digital methods presented here, we have created a text corpus focusing on aspects of two Jewish-Christian festivals. The available quantitative data will be analysed in terms of content and interpreted with available qualitative methods (especially the concordant search function) and with methods of qualitative social research, and only on the side we consider the findings of corpus linguistics [31].

In general, tweets were retrieved using Python and the Tweepy library, which accesses the Twitter API itself. This allows us to search for Twitter users, tweets and collect data. We also used spaCy and sklearn.

In order to preserve the anonymity of the Twitter users, we provide a paraphrasing translation of the German tweets into English. For an in-depth discussion of these and other ethical issues, we refer to [32].

A. Analysis Workflow

The analysis workflow consists of four steps: querying Twitter (using Twitter API v2), data processing, data storage and data analysis, see Figure 1. Querying Twitter is done using predefined queries, and data processing consists of two simple tasks: Extraction and handling of metadata, e.g. tweet ids, datetime, retweets and likes, and a basic NLP approach to extract hashtags.

Due to the relatively small number of tweets, we used a SQLite database to store the tweets for further analysis. We used a clustering approach based on hashtags, which is described in the next subsection.

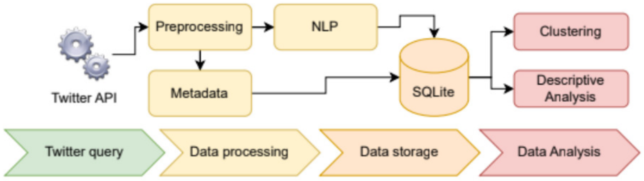

Figure 1. The proposed workflow queries the Twitter API and uses basic NLP techniques to extract hashtags and stores all data and metadata in a SQLite database. Data analysis is performed using descriptive analysis and clustering approaches.

B. Clustering

To cluster tweets by hashtags, we rely on K-means as a classic hard clustering approach. Similarity was computed as semantic relatedness according to GermaNet [33], similar methods exist for other data and languages [34]. However, for some small datasets no meaningful clustering of the data can be obtained. For all other datasets, we worked with different values of K that gave the best performance in distinguishing four different clusters of interest:

- Church related tweets.
- Pandemic related tweets.
- Tweets related to holidays.
- Tweets related to holidays and travel in general.

For two datasets, we will describe more details on these steps in the next section.

As mentioned above, we were not able to apply clustering to all datasets. Therefore, we will now briefly present the data retrieved from Twitter.

C. Data

In order to query Twitter for the four different holidays, we prepared special queries. As there are hardly any differences in the naming, spelling and usage of these holidays in German, these queries are quite simple, see Table I.

In summary, we used population data have retrieved around 65,000 unique German tweets about different holidays. As we can see, Easter is by far the most present, while Shavuot receives very little attention. The overlap between Jewish and Christian holidays is also comparatively small.

We now move on to a more detailed analysis.

IV. Evaluation

For the analysis, the results for the individual feasts are discussed and then the texts in which the Jewish and Christian feasts are mentioned together are specifically discussed. In the qualitative textual analysis, the quantitative clustering (see Section II B) was further differentiated. The new clustering is based on a content categorization of individual tweets, especially in the festival months and the month before and after. Here, the method of conversation analysis [35], [36] and hermeneutic principles were applied.

This also depends on knowledge of Christianity and Judaism, especially basic knowledge of the Hebrew language and

Table I
DIFFERENT DATASETS USED FOR THE ANALYSIS AND THEIR SIZE.

Dataset	Query	Years	Tweets
Easter	“Ostern”	2018-2022	32,081
Pentecost	“Pfingsten”	2018-2022	22,254
Passah	“Passah” or “Pessach”	2018-2022	11,035
Shavuot	“Schawuot”	2018-2022	510
Pentacost / Schavuot	“Schawuot” and “Pfingsten”	2018-2022	92
Easter / Passah	“Ostern” and (“Passah” or “Pessach”)	2018-2022	817

knowledge of Jewish customs, mores and traditions. Therefore, a brief historical and theological context of the festivals is given first. Two research questions guided the study: (1) How do people talk about Christian holidays on Twitter; (2) How are Christian holidays related to or embedded in their Jewish counterparts? Is there an awareness of the Jewish roots of certain Christian holidays?

We also took a look at the other hashtags that appeared for each holiday (e.g. Easter 2018 hashtag). Here, randomly selected years were analyzed to identify peculiarities or patterns. In the next step, the results were summarized and theses, further hypotheses and questions were derived.

Finally, we reflected on the validity of the chosen mix of methods and evaluated our methodological approach. We articulate findings for further research, for Christian and Jewish communities, and provide suggestions for social actors seeking to prevent anti-Semitism.

A. Religious-historical and theological pre-location of the studied festivals

The two Christian feasts under consideration here, Easter and Pentecost, were originally Jewish feasts that were confirmed by Jesus Christ and his disciples on the one hand (aspects of continuity) and given new meanings on the other (aspects of discontinuity).

What Christians celebrate today at Easter is the resurrection of Jesus from the dead on the “first day of the week”, as mentioned by the evangelists (Bible: Mark 16:2, 9; Luke 24:1; John 20:1), after having been crucified according to Roman law (Good Friday).

According to Jewish reckoning, the first day of the week is the first day of creation. These events occurred exactly at the time of the Jewish festival of Passover, which most scholars believe took place in April 33 CE [37]. The Jewish festival of Passover commemorates the Exodus from Egypt: the journey from slavery to freedom.

As part of the Jewish festival of Passover (15th-21st of Nissan), the counting of the Omer (16th of Nissan, Reschith) begins, which lasts until the day after the seventh Shabbat, the 50th day, and ends with the festival of Shavuot. Other names for Shavuot include Pentecost (πεντηκοστὴ ἡμέρα, “fiftieth day”), Feast of Weeks, Feast of Harvest, Mattan Torah (Hebrew, “Gift of the Law”) in commemoration of the gift of the 10 Commandments and the Mosaic Law. Since the Jewish feast of Pentecost is a pilgrimage, the city of Jerusalem was traditionally filled with pilgrims. The disciples were in Jerusalem at Jesus’ command, awaiting “power from on high” (Luke 24:49), and on this feast of the commandments they now received the additional gift of the Holy Spirit. Apart from very different receptions in the past and present, believing Christians of the Eastern and Western Churches (Orthodox, Catholics, Protestants in churches and free churches) have always held to the bodily and historical evidence of the resurrection of Jesus, which followed the crucifixion. Since the Enlightenment, however, historical-critical theology has contributed to the secularization of churches and Western societies by subjectivizing, relativizing, and psychologizing the resurrection event. As a result, the theological and spiritual meaning of this great event was lost in many churches and thus in society.

Similarly, the Feast of Pentecost has been celebrated by Christians for over 2000 years, and Christians remember and ask again for the outpouring of God’s Spirit.

However, since the 4th century with the Constantinian turn, the Christian festivals were deliberately decoupled historically, theologically and also calendrically by imperial and episcopal legislative decisions of the emperor. The reasons for this were clearly anti-Semitic. The result was that Christians lost the Jewish references to the feasts until today, although since the Shoah a new awareness of the Jewish roots of the Christian faith has slowly emerged [38], [39], [40]. How deep is the understanding of these festivals and the connections between them – and how is this expressed in communication – is what we want to find out.

B. Easter

Figure 2 shows the total number of tweets related to “Easter” between 2018 and 2022. We see a clear increase of tweets with the start of the pandemic measures Easter 2020. An analysis of tweets shows an increased need for communication for several reasons. First, due to organizational issues. New information on restrictions for events, the contact restrictions, the date postponements and date changes, new information about alternative online offers (links) in terms of replacement events. We also see behavioral issues. Uncertainties and questions regarding travel behavior and celebration options and religious customs. In addition, we find emotional expressions of approval and disapproval, understanding and lack of understanding of policy restrictions (rules, measures, and punishments), fears and anger regarding pandemic relaxations or further restrictions, empathy for those affected by the lockdown of other religious communities

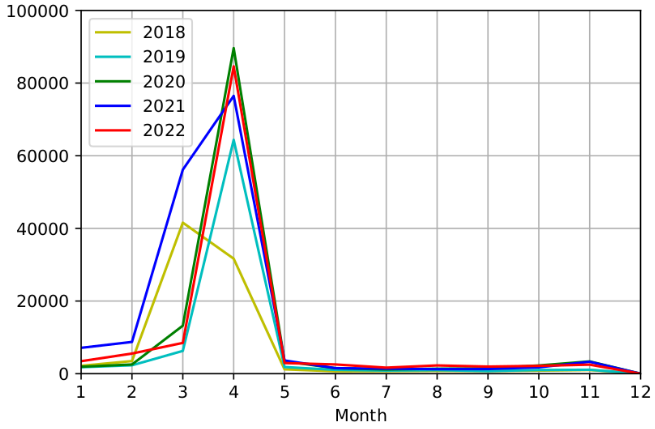

Figure 2. Total number of tweets related to “Easter” between 2018 and 2022. The peak clearly relates to the date of Easter in that year.

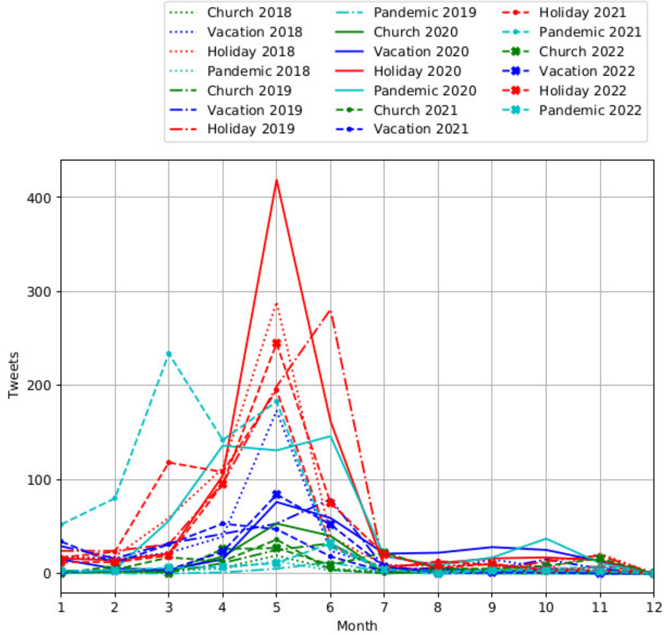

Figure 3. Total number of tweets related to “Easter” and showing the four clusters of interest during five years: Church, Vacation, Holiday, Pandemic. between 2018 and 2022. Interestingly, these topics are not aligned with the actual date of Easter in one particular year.

(e.g., Muslims Ramadan, Jews Passover). There is also an increased need for community and closeness in the phase of lockdowns, expressed through wishes, greetings, words of blessing, expressions of friendship (“I miss you ...”). However, we also see an increased interest in understanding theological and historical background of Easter celebration – often also interest (questions – answers) in context or comparison to other Christian celebrations or Jewish backgrounds. The increasing digitalization and the increased interest in Easter also in print media (e.g. newspapers) coincides with the above observations. An example is the analysis of the DWDS (Digital Dictionary of the German Language), which evaluates the text corpus of German-language newspapers. In 2020, the word course curve of the lexeme “Ostern” (Easter) showed a frequency of 20.69 per 1 million tokens[2] . We can provide some examples for explanatory, understanding, reflective tweets:

> 2018-04: ‘My thesis is that more people do not feel they belong to any religion, however, they believe in a higher power. This starts with the fact that many don’t even know the history behind Christmas, Easter, and Pentecost.’
>
> 2022-04: ‘so resurrection (Easter) is that after the crucifixion (Good Friday), then a few weeks later he goes again (Ascension) and still a little later the Holy Spirit comes (Pentecost).’

Other tweets are distant, derogatory (negative) or even faith-denying:

> 2019-04: ‘Easter is over ¿ soon comes Pentecost.... Religious people (Christians now using the example) really have something to celebrate all year round.... (We #atheists / #agnostics, on the other hand, look for substitute events to look forward to - they’re still not #substitutegods, are they?)’
>
> 2021-04:‘14 days after Ramadan: the numbers are finally receding. But then comes Pentecost with mass baptisms and singing in the free churches. We have already had experience with Easter and Christmas. Religion as a superspreader. Now we finally know what it (religion) is really good for.’

However, we also find examples for politicization of terms and language used in faiths:

> 2021-04: ‘50 days. This is also the period between Easter and Pentecost. The decisive MPC at the beginning of March could have been the resurrection and the day today could have been the outpouring of the Holy Spirit, the realization that it can work if you listen to science.’
>
> 2022-04: ‘@Karl_Lauterbach @haintz_markus Also happy Easter #LauterbachRuecktritt ! Now only the Holy Spirit has to enlighten them on Pentecost and convince them to resign’

As discussed above, several tweets are also concerning the explanation of culture change or showing incomprehension:

> 2019-04: ‘On the other hand, I would also like to see those who say that on Easter, Christmas and Ascension Day as well as Pentecost should be worked. If we limit the privileges of the churches, then we also limit our privileges that result from the church.’
>
> 2022-04:‘Why don’t Jews and Muslims just move their holidays to Easter, Pentecost, etc.? Wouldn’t that be the easiest solution?’

[2] See https://www.dwds.de/r/plot/?view=1&corpus=zeitungenxl&norm=date\%2Bclass&smooth=spline&genres=0&grand=1&slice=1&prune=0&window=3&wbase=0&logavg=0&logscale=0&xrange=1946\%3A2022&q1=Ostern.

> 2022-04: ‘The holidays already make no sense because no one knows what is actually the reason for the holiday. What percentage of the population can say what happened on Corpus Christi, Pentecost? And the main holidays are also just Santa Claus and Easter Bunny.’

So there is basically explanatory talk about the festivals, but there is also negative and derisive talk, especially because the church and faith itself are no longer perceived as credible. In addition, there is always the interreligious aspect, not only towards Judaism, but also towards Muslim festivals. But there are also secular and rejectionist tendencies, such as the shifting of festivals.

In Figure 3 we show the results of the cluster analysis described in the previous section. The events around Corona strongly influence the communication at Easter and dominate 2020 and 2021, which is not surprising since the Corona-related changes (restrictions) at the festivals were massive. However, we also see a religious consciousness that still dominates Easter. In the first year of the pandemic, 2020, Easter is the dominant factor, with only a small increase in attention to the church. According to the tweets, a marginalization of the church can be observed before 2020, while from 2020 onwards, the festivals enjoy a high level of attention, but the church as an institution does not correlate with this. As with Pentecost, the holiday plays a very large role in 2018, while it plays a rather subordinate role in 2019 (even before the pandemic).

C. *Pentecost*

As discussed above, we analyze tweets related to a particular holiday by year and month. For a first overview of the total number of tweets per month, we refer to Figure 4. This clearly shows that the tweets are related to the date of Pentecost, underlining that there is little background noise in the data.

The K-means clustering approach was performed on $K = 7$ clusters, see Figure 6 for a PCA plot of these clusters. We will present some more details on some of the clusters obtained. In Figure 7 we show a word cloud for cluster 7, which is mostly related to holidays. However, we still see “Corona” as a central theme, while other words refer to traffic jams, traffic and holiday destinations. This underlines that some topics can be identified quite well. Other topics are more difficult: In Figure 8 we show the word cloud for a cluster related to “Church”. However, there are also other topics in this cluster: the pandemic and holidays. Therefore, a closer look at the tweets themselves was necessary to identify the underlying topic, and clustering could not be used without supervision.

For a more detailed analysis, we group tweets with hashtags into different categories related to church, vacation, holidays and pandemic, see figure 5 for details. Clearly, the number of tweets is still related to the date of Pentecost. However, few tweets use hashtags and are therefore available for categorization. While holidays are important in 2018 and 2022, the pandemic is the most prominent topic in 2020 and 2021. This again shows that the data is not too noisy. What is striking, however, is that the term is usually not mentioned in connection with churches or religious issues.

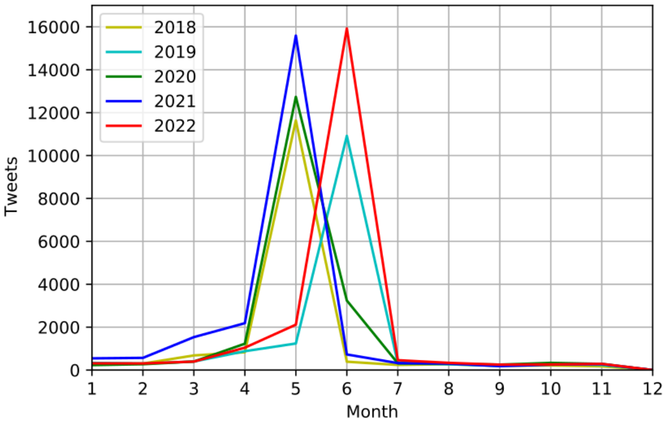

Figure 4. Total number of tweets related to “Pentecost” between 2018 and 2022.

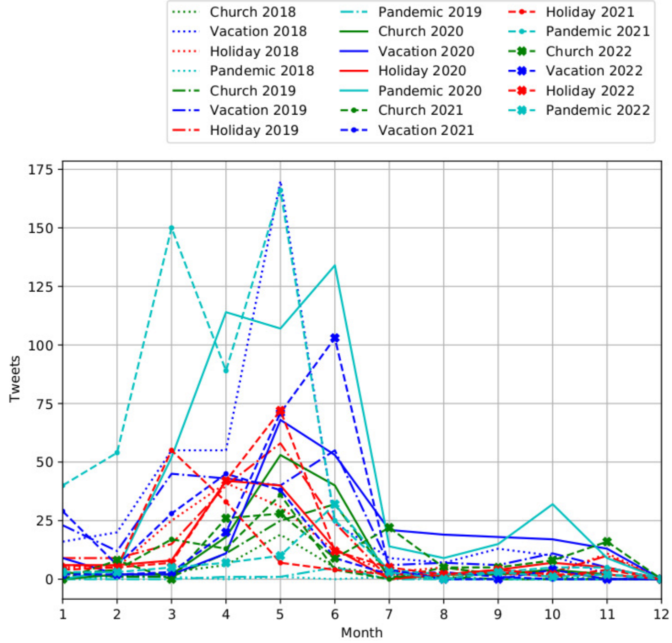

Figure 5. Total number of tweets related to “Pentecost” and showing the four clusters of interest during five years: Church, Vacation, Holiday, Pandemic. between 2018 and 2022.

There are a number of important observations. Pandemic topics dominate around the time of the Pentecost holidays in 2020 and 2021, which is understandable since the restrictions strongly influenced or limited holiday behavior. Tweets mentioning churches spike in 2020 - the first pandemic year with lockdowns and massive restrictions on worship. However, given the number of church restrictions during this time, the curve is rather flat, which may indicate the writers’ comparatively low interest in church. There is an increasing interest in holidays over the study period. Can we infer an increased awareness of the religious significance of these holidays? In some tweets there seems to be a basic understanding that

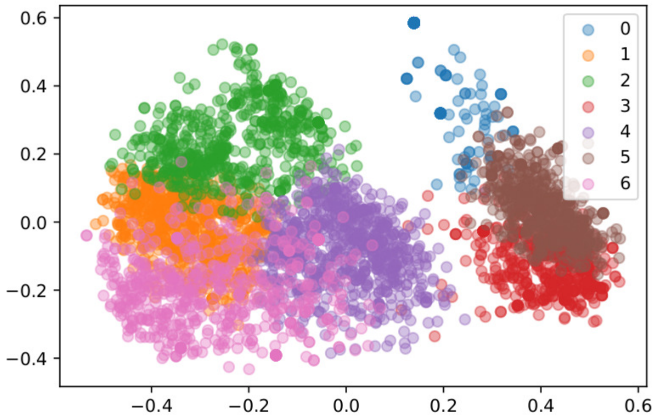

Figure 6. PCA plot of K-means clustering for tweets related to "Pentecost" with $K = 7$.

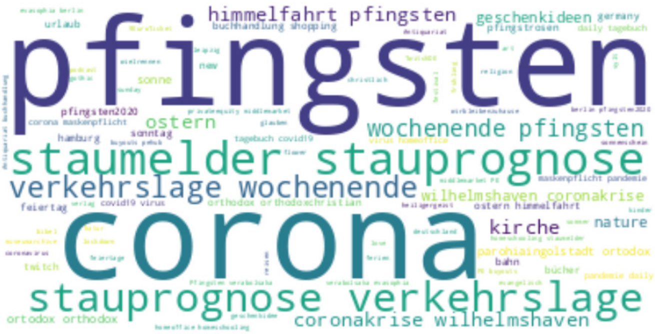

Figure 7. Wordcloud for Cluster 7, mostly related to vacation.

Pentecost has something to do with the "Spirit", even if the hit rate for "Holy Spirit" is almost zero:

> 2022-06 'I still don't know what is celebrated on Pentecost, Ascension Day and Corpus Christi. Something about a holy spirit or something? I do not know.'

However, the comments, explanations and questions about the content are rather low in 2018 and 2019. Similar to our previous analysis we find several negative tweets:

> 2021-05: 'Question at the Pentecost Walk: "Are Christians celebrating on Pentecost that they invented something as 'Spirit-rich' as the Church?" — "No, they celebrate that God's Spirit is still there. In spite of this church.'

As with Easter, it is striking that the Spirit is spoken of primarily as a metaphor in a political and social context. Spirit stands as a symbol for "having the right insights, making the right decisions, doing the right things. These metaphors are used almost exclusively in the negative sense, meaning the absence of spirit. Criticism of people or parties, organizations or groups is usually made with a sarcastic undertone and is emotionally charged.

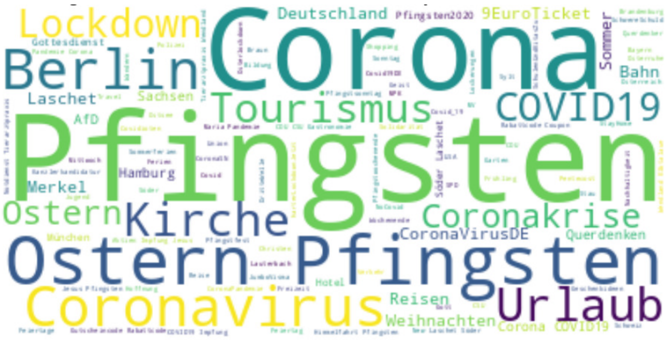

Figure 8. Wordcloud for Cluster 2, related to church but also covering different topics like the pandemic and vacation.

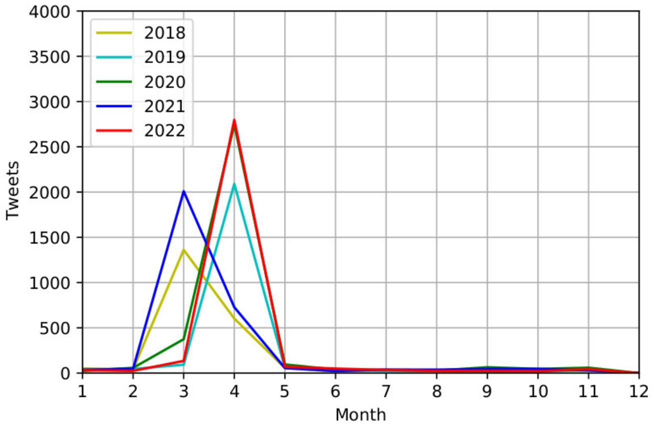

Figure 9. Total number of tweets related to "Passah" between 2018 and 2022.

D. Passah

For a first overview of the total number of tweets per month, we refer to Figure 9. Again, this shows that the tweets are related to the date of Passah, underlining that there is little background noise in the data. We find a significant higher number of tweets related to Passah compared to Shavuot, which underlines the importance of this festival compared with other Jewish festivals within the German-speaking part of Twitter. The total number of almost 3,000 German Tweets is high – compared to the Jewish population in German-speaking countries (about 0,1%).

However, a more detailed cluster analysis, was not possible. A detailed analysis of tweets showed that they are mostly connected to religious topics. For example, 69 tweets were connected to Ramadan. Having both festivals at the same time is a challenge for Jews, as the Ramadan period is known for unrest, especially in Israel and Jerusalem. Corresponding comments and prayers for peace/wishes for political unrest, e.g. on the Temple Mount. In addition, wishes for a happy holiday are the most common, but Easter and Ramadan are often mentioned as well. Another block is information about events and tweets that actively deal with customs, e.g. 'Are you allowed to drink beer on Passover or do you have to dispose

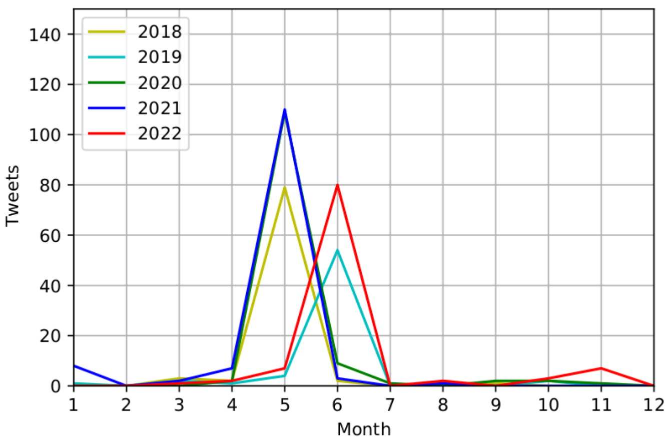

Figure 10. Total number of tweets related to “Shavuot” between 2018 and 2022.

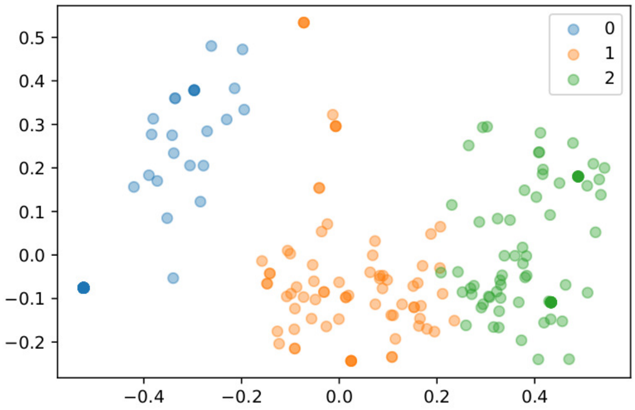

Figure 11. PCA plot of K-means clustering for tweets related to “Shavuot” with $K = 3$.

of it beforehand’ (2022-02 12/10).

E. Shavuot

For a first overview of the total number of tweets per month, we refer to Figure 10. Again, this shows that the tweets are related to the date of Shavuot, underlining that there is little background noise in the data. Since the pandemic, there have been significantly more mentions of the festival. All of the tweets are highly religiously charged and almost all of the terms have a reference to spiritual, religious themes related to the festival. This clearly anchors Shawuot as a spiritual festival for individuals.

However, a more detailed cluster analysis was not possible. In Figure 11 we show a PCA plot for K-means clustering for tweets related to “Shavuot” with $K = 3$. It is almost impossible to distinguish between the predefined topics and it shows again that clustering cannot be used without supervision. It also shows that this approach is difficult to apply to small datasets.

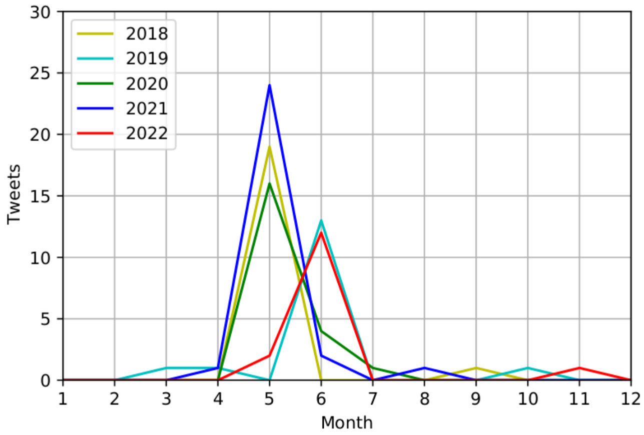

Figure 12. Total number of tweets related to “Pentacost / Schavuot” between 2018 and 2022.

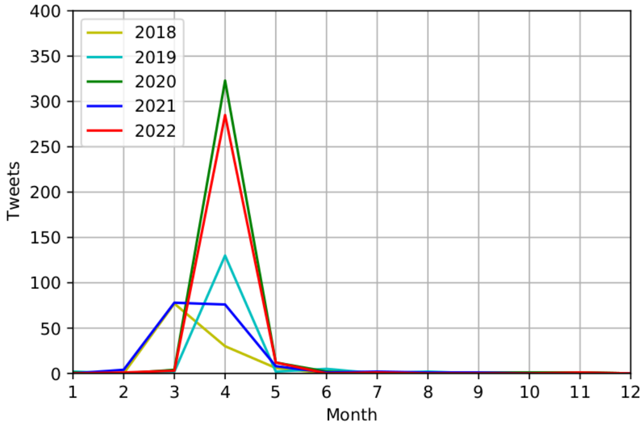

Figure 13. Total number of tweets related to “Easter / Passah” between 2018 and 2022.

While tweets referring to Passah showed that they are mostly connected to religious topics, for Shavuot we find much more information on events, links to webpages and several tweets explaining cultural issues. For example:

> 2022-06 77: ‘On Shavuot, Jews celebrate receiving the Torah at Mount Sinai. This is the most important event in Jewish history, but the holiday is rather unknown. And what is it about the cheesecake?’

F. Connection to Jewish holidays

In Figure 12 we show the total number of tweets related to “Pentacost / Schavuot” between 2018 and 2022.

In 2018, 2019, and 2022, the Christian and Jewish holidays of Pentecost/Shavuot fell on the same calendar days. However, the influence on the dates is not obvious. What is evident, however, is a significant increase in 2018, 2020 and 2021, when both are referenced.

In Figure 13 we show the total number of tweets related to “Easter / Passah” between 2018 and 2022. Again, we see

Table II
SUMMARY OF PARTICULAR TOPICS IDENTIFIED WITHIN DIFFERENT HOLIDAYS. ALTHOUGH ALL TOPICS WERE FOUND, SOME WERE MORE IMPORTANT THAN OTHERS. THESE ARE MARKED WITH AN "X".

#	Topic	Easter	Pentecost	Passah	Shavuot	Pentacost / Schavuot	Easter / Passah
1	Explanatory	X	X	X	X	X	X
2	Faith-based					X	X
3	Distance	X	X				
4	Critics	X	X				
5	Metaphorical/ political use	X	X	X	X		
6	Incomprehension	X	X	X	X	X	X
7	Hate speech						
8	Pandemic	X	X	X	X	X	X

an increasing interest in the combination of both festivals in 2020 and 2022.

Comparing these results to our previous analysis clearly shows that there are less references to Jewish Holidays, and very little references to them and the corresponding Christian Holidays.

In spite of all this, we can take two questions as an interim conclusion for further discussion: First, it seems that the Corona period made people more curious and interested in the connections between Judaism and Christianity – maybe according to the motto: what I'm not allowed to do, makes me curious.. In addition, the tweets seem to indicate that there is currently more awareness of religious festivals, after participation was significantly hampered during the pandemic. But we have also to consider a possible artifact here, because we have to take into account the Jewish Orthodox customs: When the feast-day is a Shabbat, many pious Jews do not unse a mobile phone or electronic equipment.

G. Relevance for Christian Churches

In Table II we summarise our findings from the previous sections. The cluster analysis was helpful in those cases where it could be carried out. Horizontally, however, we were able to identify eight themes that were particularly helpful in answering our question. Although all themes were found, some were more important than others, as highlighted in this table. Most interestingly, we found very little evidence of hate speech. However we do not know, if Twitter may have already deleted those tweets, violating their rules and regulations. Critical and distant remarks are found especially for Christian holidays. In addition, we find both explanatory and non-explanatory tweets in all cases.

Several points are relevant for Christian churches. First, there is a lack of knowledge about the biblical background and customs of the festivals. But also the connection to the Jewish roots of the festivals is rarely recognized. Thus, there is a lack of both theology and practice. In order to promote interreligious dialogue and understanding of their own festivals, churches need to reawaken awareness of the Jewish roots and clearly anchor them in doctrine, liturgy and customs. Where the reference to Judaism is clear (e.g. through the use of Jewish festival names), theological interest and knowledge is deeper and greater – and so is interreligious interest and understanding – or the desire and curiosity to understand.

Where Jewish references are clearly recognizable, references to Islam (Ramadan wishes) or understanding of the problems of the various religious festivals in corona measures and pandemic-related restrictions are also often evident. Of fundamental interest, as discussed above, is the phase of pandemic restrictions. This has led to increased communication about festivals, e.g. 2020. However, this must be seen in the context of the increased church departures in the 2nd and 3rd years. There are broader questions to be answered here, but they are not the focus of this paper.

Often, however, the use of core theological terms is merely a stepping stone into metaphorical language, usually for cynical or sarcastic remarks about the state or the church. Another question is whether there is a danger that in a secularized world theological content will have only a symbolic or linguistic effect. Is this a consequence of a liberal theology that no longer regards many biblical events as historical and thus demands a reduction to the metaphorical level?

V. CONCLUSIONS AND OUTLOOK

Our two main research questions were:

- Can we identify how people talk about holidays and especially Christian holidays on Twitter? (RQ1)
- If we find relevant information: Can we see how Christian holidays are related to or embedded in their Jewish counterparts? Is there an awareness of the Jewish roots of certain Christian holidays? (RQ2)

In this work, we could answer RQ1: Yes, we can identify how people talk about holidays. However, distinguishing between church-related and secular topics was not at hand. We could show that there is a lack of knowledge about the biblical and theological background and customs of the festivals. But also the connection to the Jewish roots of the festivals is rarely recognized. Thus, we could also answer RQ2: Where we could identify the reference to Judaism – which was mainly done through the use of Jewish festival names – theological interest and knowledge is deeper and greater. We find at least a small interest in interreligious exchange and understanding. It was interesting, that, where Jewish references are clearly recognizable, references to Islam or understanding of the problems of the various religious festivals in corona measures and pandemic-related restrictions are also often evident.

There were a number of methodological challenges. First, there is the large amount of data. Classical qualitative approaches provide a first orientation, but also show the need for quantitative work. In this step, the work could and had to be done classically by keyword searches on selected terms such as Acts, disciples, speaking in tongues, Holy Spirit, Spirit, glossalia, and so on. Some aspects had to be counted by hand, because terms have to be assigned and interpreted, e.g. with different spellings or with spelling mistakes. While K-means in Twitter data gains some insight, in another iteration of our research we plan to make use of the full text body for deriving alternative clusters.

Another aspect that arises is the question of the authors of the tweets, which, unlike the qualitative work, was not considered in this work. But who writes the tweets? Apart from private individuals, interreligious organization organisations such as the "Israel Network" or ecumenical organisations ("House of One") should be mentioned. Further analysis would have to provide more clarity here. However, this would require in-depth knowledge of Christian churches, free churches and Jewish and Islamic organisations. Obviously, the use of computational social science methods in practical theology poses new challenges, but also makes new data available for research. In particular, the methodological overlap between classical quantitative and qualitative research is small, and thus our work is also a plea for more interdisciplinary exchange. And beyond this: Actors of churches and culture should promote an awareness of the historical, theological and cultural contexts of the faith communities, especially the festivals. Because this creates a bond between people, which can be a small contribution to peace in this divided world.

***Abstract*—Smart mobility is a promising approach to meet urban transport needs in an environmentally and and user-friendly way. Smart mobility computes itineraries with multiple means of transportation, e.g., trams, rental bikes or electric scooters, according to customer preferences. A mobility platform cares for reservations, connecting transports, invoicing and billing. This requires sharing sensible personal data with multiple parties, and puts data privacy at risk.**

In this paper, we investigate if fully homomorphic encryption (FHE) can be applied in practice to mitigate such privacy issues. FHE allows to calculate on encrypted data, without having to decrypt it first. We implemented three typical distributed computations in a smart mobility scenario with SEAL, a recent programming library for FHE. With this implementation, we have measured memory consumption and execution times for three variants of distributed transactions, that are representative for a wide range of smart mobility tasks. Our evaluation shows, that FHE is indeed applicable to smart mobility: With today's processing capabilities, state-of-the-art FHE increases a smart mobility transaction by about 100 milliseconds and less than 3 microcents.

I. Introduction

GROWING cities, urban sprawls and environmental concerns demand for mobility concepts [1], [2] that go beyond individual cars [3]. A promising approach is smart mobility, also known as multi-modal mobility or intelligent mobility. It refers to the integration of advanced technologies and intelligent systems into transportation networks to improve efficiency, safety, and sustainability, to lower emissions and to enhance the overall quality of urban life. To this end, smart mobility encompasses solutions from the area of cloud computing, machine learning and artificial intelligence, that optimize the movement of people and goods within urban areas.

With smart mobility, customers can specify a mobility demand and travel preferences [4], e.g., the shortest, fastest, most inexpensive or eco-friendliest route from a starting point to a destination, or the route with the least transfers between the means of transportation. A cloud-based mobility platform [5] then lets the customer select an itinerary among some alternatives [6], [7], [8], [9], and connects to all services needed to process and settle the trip.

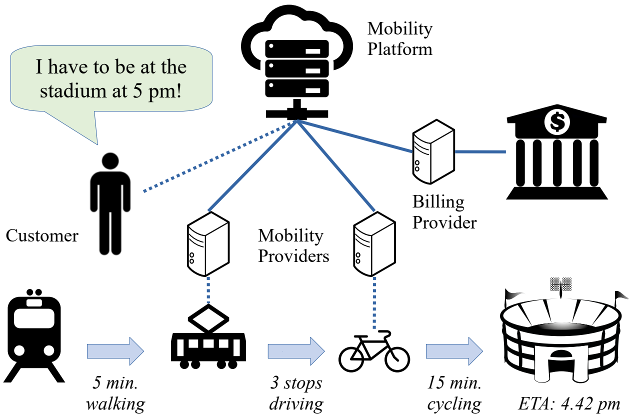

Fig. 1. Smart Mobility Scenario

***Example**: A customer might want to go from a train station to a stadium and must arrive at the beginning of a game. The mobility platform queries the databases of the connected mobility providers, and suggests three options that allow the customer to reach the destination in time: Based on an assessment of environmental impact, the most eco-friendly option is to use a tram to travel three stops to a rental bike station, as illustrated in Figure 1. As an alternative, a customer could opt to take a bus for six stops and use an electric scooter for the rest of the way. The most comfortable but expensive option would be hiring a cab. Once the customer has selected one option, the platform makes reservations. It collects the recorded distances and stations traveled. After the trip, the platform connects to a billing provider that handles invoicing and payment.*

Smart mobility approaches raise numerous privacy concerns [10], [11], [12]: Start and end of a route can reveal personal needs, e.g., if it is a church, hospital or event location. It might be possible to identify an individual by recurring ways home from work and vice versa. If customers frequently travel together, this might indicate personal relationships. If a rental sports car is preferred over a suburb train, this might tell about preferences and wealth. Travel times and frequent routes reveal habits, employment status or daily routines. What makes privacy issues even more challenging is that personal data is distributed among many parties [13], such as providers for mobility and infrastructure, and various services for payment, demand forecasting, parking space management, etc.

Existing privacy-aware smart mobility approaches make use of anonymization, e.g. by using differential privacy [14], [15], [16] or by reducing the data resolution [17], [18], [19]. Alternatively, secure multi-party computation can be used [20], [21]. This induces noise to the data and/or requires multiple rounds of computation among several parties, i.e., it reduces accuracy, efficiency and, therefore, user experience.

We investigate if fully homomorphic encryption [22] (FHE) can be an alternative. FHE allows to calculate sums or products on encrypted data without having to decrypt the data first. The decryption then provides the exact, noise-free result of the calculation. This makes FHE a natural choice for calculations with privacy-related data. However, some calculations increase the size of the data and/or make encryption, calculations or decryption computationally expensive. Some years ago, this limited the practical applicability of FHE in any real setting.

However, vast advances in FHE programming libraries such as SEAL [23], HElib [24] or OpenFHE [25], new paradigms such as edge computing, and a huge computing power available at little costs both at edge nodes and cloud services give reasons for new analyses. For example, in May 2023, a cloud instance with 128 XEON CPU cores at 3.5 GHz and 512 GiB RAM and 50 Gbps network bandwith costs only 8 USD per hour. Our concern is to find out whether the overhead of FHE for typical smart mobility transactions is reasonable to support privacy-compliant business models in this application domain.

In this paper, we make the following contributions:

- We identify three distributed transactions that are representative for a smart mobility scenario and benefit from FHE, i.e., require noise-free results and cannot be readily secured by simpler means such as one-time pseudonyms [18].
- We implement a prototype based on Microsoft SEAL [23], which uses the state-of-the-art FHE schemes BGV [26], BFV [27] and CKKS [28].
- We measure memory consumption and execution times, and we compare them with the resources available in the cloud or on a smartphone.

Our evaluation shows that with CKKS, encrypted transactions add approx. 100 ms to the CPU time of unencrypted transactions. This does not impact user experience [29]. With parallel processing, this time can be reduced, and it costs less than 3 microcents on a current cloud instance. Thus, we have confirmed that FHE is indeed feasible for smart mobility business models, where such transaction fees are several orders of magnitude smaller than the billing amount on the customer's invoice, but privacy is an important factor.

Paper structure: The next section reviews related work. In Section III, we derive our smart mobility transactions with fully homomorphic encryption. Section IV contains an experimental evaluation, and Section V concludes.

II. Related Work

In this section, we explain the state-of-the-art in (fully) homomorphic encryption, and we briefly review smart mobility approaches.

A. Homomorphic Encryption

Homomorphic Encryption (HE) is a well-established technique that enables third-party computation on encrypted data, without requiring the data to be decrypted beforehand. HE allows for data to be encrypted while keeping the features of the function and format of the encrypted data, supporting privacy-preserving data processing. Although this property of HE is known already for over than 30 years, the first plausible FHE approach was proposed by Gentry et al. in 2009 [30]. However, HE is costly in terms of computation and is, therefore, still subject of ongoing research [22].

The homomorphic property of HE allows certain operations to be computed over the encrypted data, with the resulting values also being encrypted. For two messages $\forall m_1, m_2 \in \mathcal{M}$ of a message space $\mathcal{M}$, Eq. 1 shows an HE scheme that supports any operation on their respective ciphers c_1, c_2. In the context of a public-key cryptosystem, the public key is denoted as k_e, the private key as k_d, and the encryption and decryption functions as Enc and Dec, respectively.

$$\begin{aligned} c_1 = Enc(k_e, m_1), \quad c_2 = Enc(k_e, m_2) \\ m_1 \oplus m_2 = Dec(k_d, c_1 \oplus c_2) \end{aligned} \tag{1}$$

Formally, a homomorphic encryption scheme is a quadrupel HE=($KeyGen$, Enc, Dec, $Eval$) with $KeyGen$, Enc, Dec and $Eval$ being probabilistic polynomial time algorithms:

KeyGen generates a public key k_e, a private key k_d and an evaluation key k_{eval} given some security parameter λ for the asymmetric version of HE: $KeyGen(1^{\lambda}) \rightarrow (k_e, k_d, k_{eval})$
For the symmetric version, only a secret key k_d and an evaluation key k_{eval} are created.

Enc encrypts a plaintext message $m \in \mathbb{Z}_n$ to a ciphertext c using the public key, which is shared: $Enc(k_e, m) \rightarrow c$

Dec uses the private key, which is kept secret, to decrypt a ciphertext c to a plaintext message m: $Dec(k_d, c) \rightarrow m$

Eval applies an operation $f : \mathbb{Z}_n^l \rightarrow \mathbb{Z}_n$ to a given ciphertext $c_1, ..., c_l$ and outputs a ciphertext c_f using the evaluation key k_{eval}: $Eval(k_{eval}, f, c_1, \cdots, c_l) \rightarrow c_f$
k_{eval} is generated uniquely for every computation and, therefore, does not pose a privacy threat. With $Eval$, homomorphism of the scheme can be proven.

B. Fully Homomorphic Encryption

Depending on the support of the operations applied in the $Eval$ function, HE can be categorized into **fully homomorphic encryption** (FHE), **partially homomorphic encryption** (PHE) and **somewhat homomorphic encryption** (SHE), each of them with different limitations and capabilities. PHE allows $Eval$ for one operation $\oplus$, either addition of multiplication, for an unlimited number of times. SHE allows both addition and multiplication, but with a limited number of operations due to the increasing size of the ciphertext. FHE allows an unlimited number of operations $\oplus$ for an unlimited number of times. Addition and multiplication operations as well as comparison and branching are supported. Therefore, FHE is the most powerful approach of HE and, therefore, implemented in this work.

FHE is a form of ring homomorphism with structure preserving characteristics [30]. This allows for arbitrary computations to be performed, as the homomorphic properties of the ring ensure that the results of the computations can be obtained without requiring decryption. Which operation is allowed depends on the FHE scheme; in this work the well known Brakerski-Fan-Vercauteren (BFV) [27], Brakerski-Gentry-Vaikuntanathan (BGV) [26] and Cheon-Kim-Kim-Song (CKKS) [28] schemes are implemented and evaluated. They are based on on the hardness of the (Ring) Learning With Errors (RLWE) problem. Learning with Errors is considered to be one of the hardest, post-quantum problems to solve in polynomial time: Given (x, y) where $y = f(x)$ for some linear function f, f can be easily learned. Now, when adding errors to the algorithm's input such that $y \neq f(x)$ for a small probability, it is assumed that the problem can not be solved in polynomial time and is, therefore, hard [31].

A subproblem is the Ring Learning with Errors (RLWE), an extension of the LWE problem for polynomial rings over finite fields. A major advantage of RLWE is the key size: While the private and public keys of LWE-based cryptography can become large, RLWE-based keys are roughly the square root of LWE [32].

For FHE, there are methods for maintaining the ciphertext, without modifying the message, such as bootstrapping and relinearization. In bootstrapping, the evaluation key k_{eval} is used to control noise. Thus, any number of FHE operations can now be computed without noise becoming uncontrollable. In this context, noise refers to a measure to prevent unauthorized decryption of encrypted data using the secret key, and it does not affect the precision of the computation outcome. Relinearization handles a common problem of RLWE-based FHE, whose ciphertext sizes increases with every homomorphic multiplication. During homomorphic evaluation, relinearization limits the expansion of the ciphertext to prevent high computation costs.

The variety of supported operations allow for a wide range of computations to be performed on encrypted data, making FHE powerful and versatile and applicable in multiple settings. In Cloud Computing, FHE is used to protect the client's data privacy to process them on an external party [33], [34]. The line of FHE works on Machine Learning aim to protect the training data's privacy in either a collaborative setting [35], [36] or a federated learning setting [37], [38]. Another relevant application specifically for this work is private fog computing for the Internet-of-Things (IoT) which enables multiple users to authenticate and aggregate data collected with edge devices [39], [40]. Another work at the intersection of the previously mentioned areas is the work of Zhang et al. with an approach to privacy preserving federated learning with IoT-enabled healthcare system [41].

C. Smart Mobility

The use of IoT technologies has proven to be an appropriate response to the growth of cities and the associated impact on traffic and transportation. It has brought up the concept of smart mobility, which refers to the optimal combination of various modes of transportation, including e-bikes, e-rollers, buses, shared cars, tramways, and trains, as well as infrastructure components such as roads, bridges, airports, and train stations. As transportation modes continue to grow and become more interconnected, the resulting complexity can make it increasingly challenging to efficiently use and combine available options. To tackle this problem, relevant related work has been done concerning urban mobility and multi-modal routing planning. [6], [7], [8], [9], [42] proposed a mobile recommender system for personalized multi-modal routes by utilizing a hybrid approach combining various IoT devices, primarily targeted for private cabs and taxis. The focus of a contribution of Al-Rahamneh et a. is on creating an multi-modal urban data platform with context-awareness [2].

[1] provides an analysis on the potentials of multi-modal travel support, but does not provide a framework or architecture. A mathematical model for preference-aware transport matching is contributed by [4]. The European Platforms Initiative project BIG IoT has been initiated to implement smart mobility services and applications for Barcelona, Piedmont, and Berlin/Wolfsburg. It aims to solve the interoperability gap by defining a generic, unified Web API for smart object platforms [5].

D. Security and Privacy Issues in Smart Mobility

Smart mobility offers many benefits for urban areas, users and the environment. However, there are also many privacy concerns. Smart mobility approaches manage and share both sensed and user-generated data to a large extent, which are associated with user identities, spatial information and temporal information [11], [43], [44]. This might allow to infer sensitive personal information based on location homogeneity, location distribution, probability distributions of locations, and background knowledge, even if the location data is anonymized [45]. Statistical analyses show that even the distribution of locations where users stay for some time, e.g., to switch from one vehicle to another one, is a sensitive information [12]. In addition to that, smart mobility approaches depend on a complex IT ecosystem with many different parties, which increases the likelihood of security incidents. Finally, the IoT technologies used enable new kinds of cyber-physical attacks [10].

Secure and privacy-aware smart mobility is of interest to both the research community and society. Nevertheless, there are are only a few studies targeting smart mobility with Homomorphic Encryption. For example, [46], [47] provide a privacy preserving solution for mobile cloud computing using IoT devices with HE. However, they do not propose a framework or analysis of the application on smart mobility.

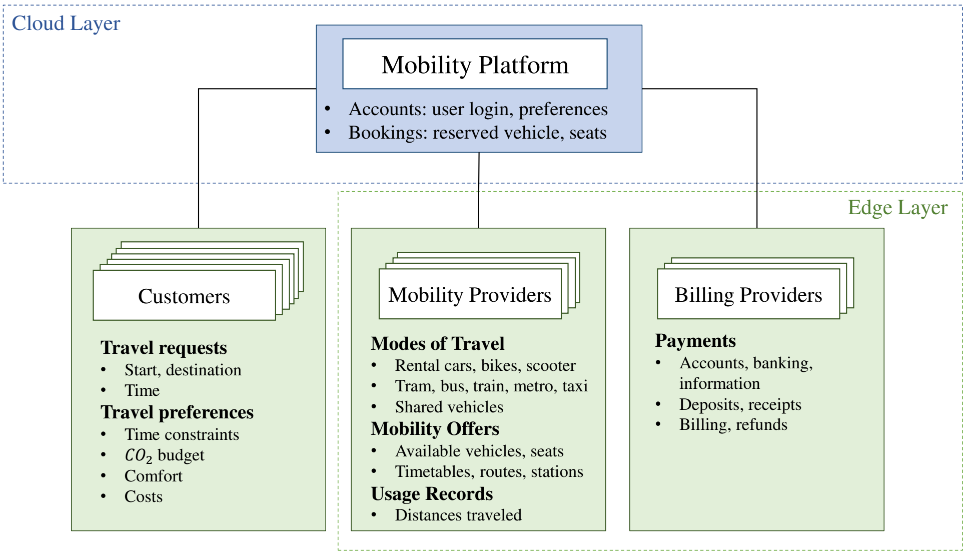

Fig. 2. Smart Mobility Architecture

III. Smart Mobility with Fully Homomorphic Encryption

In this section, we will introduce our system architecture, and we derive privacy requirements. Furthermore, we describe transactions that are representative for smart mobility and can be implemented with fully homomorphic encryption.

A. *Smart Mobility Architecture*

To find out if FHE is applicable to smart mobility, we use a generalized architecture model, as shown in Figure 2. This model is in line with existing work [5].

Customers issue travel requests via resource-constrained devices such as smart phones. Travel requests have a start point, a destination and a start/end time. A travel request can be constrained by the customer's budget and preferences regarding speed, comfort, eco-friendliness, etc.

The **mobility platform** manages user accounts, connects all parties with each other, and provides platform services such as identifying potential mobility providers for a travel request and booking seats or vehicles at the mobility providers selected by the customers. The mobility platform is part of the *Cloud Layer* of our architecture model. Thus, the mobility platform has extensive processing resources. This includes a high network throughput, plenty of primary and secondary storage, and a high processing capacity.

Mobility providers deploy various means of transportation, e.g., rental/shared vehicles or seats in a public transportation service. Furthermore, mobility providers log the actual distances traveled with each vehicle or on each seat. Mobility providers are located in the *Edge Layer*, i.e., they run services on a cloud instance that is one order of magnitude smaller than the mobility platform.

Finally, **billing providers** invoice the trips made by each means of transportation. Similarly to mobility providers, the billing providers are part of the *Edge Layer*.

Observe, that in this architecture only the customers are natural persons in the sense of the GDPR [48]. All other parties are institutions that are not covered by the data protection regulations. Thus, only customer data needs to be protected.

B. *Privacy requirements*

The components of our architecture model process five distinct categories of data:

Insensitive data cannot be related to a person, and does not carry sensible information. Any information from an institutional party such as the mobility platform or a mobility provider is insensitive data, e.g, the public keys of those parties. We also consider the aggregated values calculated with FHE to be insensitive, e.g., total travel costs, duration of a trip or CO_2 budget.

Identifiers such as a name or a bank account reveal the identity of a person. A trip can be an identifier, if it ends at the customer's home.

Pseudonyms such as a login name can be changed easily. We assume that a pseudonym only allows to recognize a person during one transaction. The public key of a customer is also a pseudonym.

Sensitive data, refers to personal information, e.g., habits, social life (persons traveling together), mobility preferences or travel costs. Note that sensitive data is not necessarily identifying.

Finally, **secret data** includes all information that must not be shared, e.g., the private keys of the various parties. From this categorization, we derive three privacy requirements:

R1 The mobility platform connects customers with two kinds of providers. Therefore, it needs to maintain user pseudonyms and transaction IDs. The platform does not need to learn identifiers or sensitive data, e.g., travel data forwarded to mobility providers.

R2 Mobility providers must learn which vehicles or seats are booked for which periods of time, and where a rented vehicle is left at the end of the trip. To create an invoice, the actual usage must be recorded. This requires pseudonymous information and sensitive data. It must be impossible to join sensitive data from multiple transactions or across multiple mobility providers.

R3 A billing provider needs to know identifiers (names, addresses, bank accounts) and invoice amounts. It is also acceptable if the billing provider learns pseudonyms. Except from that, it should learn only insensitive data.

Our privacy requirements are summarized in Table I.

Data Categories	*Mobility Platform* (R1)	*Mobility Provider* (R2)	*Billing Provider* (R3)
Insensitive Data	✓	✓	✓
Identifiers	✗	✗	✓
Pseudonyms	✓	✓	✓
Sensitive Data	✗	✓	✓
Secret Data	✗	✗	✗

TABLE I
PRIVACY REQUIREMENTS

We assume that a combination of one-time pseudonyms and traditional encryption helps to mitigate any privacy problem that relates to data-management transactions, e.g., marking a certain seat in a database as “reserved”, searching for available modes of transportation at the last stop of a tram, or recording the time a rental bike has been used.

This leaves open privacy issues related to calculations. For example, consider the billing process. In traditional smart mobility scenarios, the cloud platform might calculate the invoice total by asking each mobility provider, that was involved in the trip of a certain customer. By doing so, the smart mobility platform learns the exact movement patterns of each customer.

FHE might be able to execute such calculations without revealing personal details. The advantage of using FHE over alternatives from the realm of secure multiparty computation is that FHE does not depend on privacy models where multiple semi-honest parties execute protocols in multiple rounds of communication. If each transaction is secured with its own pair of one-time keys, the security and privacy of the approach only depend on the formal guarantees of the FHE schemes used. We also do not need to make assumptions about colluding parties.

C. Experiment Design

As we explore the applicability of FHE for smart mobility, we rule out transactions without sensitive/pseudonymous data or where encryption, decryption and computations take place on a cloud instance. An application of the privacy requirements (Table I) on our architecture model (Figure 2) has shown that the billing provider has similar properties as the mobility provider: It learns identifiers instead of pseudonyms, and it has comparable computational means and data flows. Thus, we also leave aside experiments that specifically address billing providers. We experiment with three transactions T1–T3. Each transaction contains a small number of additions and multiplications. This is typical for business transactions that compute arrival times, discounts or usage fees. With FHE, such a transaction requires one relinearization operation.

a) T1: Centralized calculations: This transaction is representative for operations where encryption and decryption takes place at the customer’s smartphone, while the calculation is executed at the mobility platform. For example, the mobility platform might add up encrypted prices, travel times, CO_2 budgets, etc., whose summands stem from the mobility providers. It might also multiply discounts or subtract bonuses. Then the mobility platform sends the encrypted result to the customer for decryption. The mobility providers might not want to reveal bonus schemes, mutual price agreements or internal calculations. Thus, it is not an option to send plain values to the customer and let the smartphone do any calculation. Instead, FHE can be applied. Figure 3 illustrates T1. Thick lines in the figure refer to encrypted data.

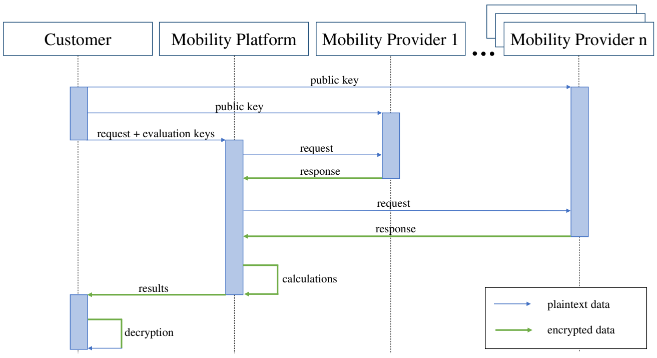

Fig. 3. T1: Centralized Calculations

With this transaction, numerous parallel transactions must not overload the computational resources of the mobility platform, and the encryption/decryption of a single transaction must be feasible on the customer’s smartphone. T1 requires the mobility providers to know the public key of the customer. This can be an one-time key, and it is a pseudonym. Each mobility provider only learns which of its own means of transport is part of the transaction. Thus, R2 is met. The mobility platform does not learn the customer’s public key, because relinearization requires evaluation keys that are used only once. To manage travels across multiple mobility providers, the mobility platform needs a transaction id, that is an one-time pseudonym. Thus, R1 is also fulfilled.

b) T2: Decentralized calculations: This transaction lets the mobility providers do the calculations. The mobility platform transfers encrypted intermediate results to different parties, e.g., to a rental car provider or a public transport provider, and orchestrates distributed computations on encrypted data there. Such parties have smaller computational resources than the mobility platform, but are also loaded with a smaller

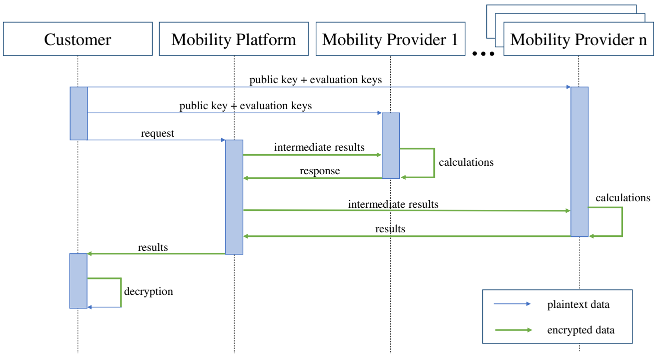

Fig. 4. T2: Decentralized Calculations

number of parallel transactions. Encryption/decryption takes place at the customer's smartphone. Figure 4 illustrates this.

Similarly to T1, the reason for using FHE is that the mobility providers might not want to share internal agreements and calculations. Again, the mobility providers need the customer's public key. Thus, the privacy properties of T2 are identical to T1, but the resources needed at the different parties are different.

c) T3: Customer-side calculations: Our third transaction performs calculations at the customer's smartphone, while the mobility providers contribute encrypted parameters, and the mobility platform is responsible for decryption (cf. Figure 5). Thus, the reason for requiring FHE is similar to T1 and T2. Such a transaction could calculate with telemetry data: Forecasting demand, costs, CO_2 per hour etc. require usage-dependent calculations with data from multiple mobility providers. But it might be sufficient for each mobility provider to learn the aggregated numbers.

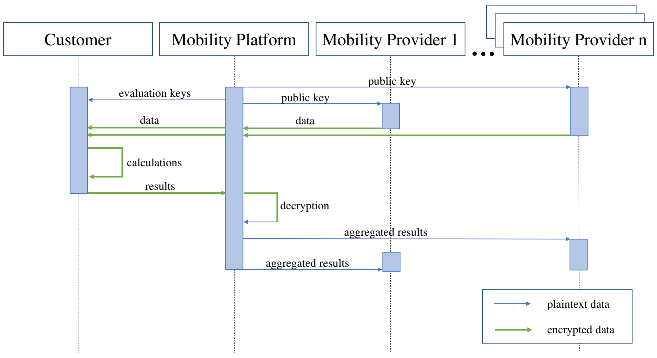

Fig. 5. T3: Customer-side Calculations

With T3, the calculations must not overload a smartphone, and decrypting many results in parallel must be feasible for a mobility platform. T3 means that the mobility providers need the public key of the mobility platform. Because it is an institutional party, this is insensitive data (cf. Table I). The mobility platform cannot learn which parameters from which mobility provider contribute to the aggregated results. Similarly, mobility providers only learn aggregated results, which is insensitive data. Thus, privacy requirements R1 and R2 are fulfilled. Our three transactions are representative for a wide number of typical real-world calculations in smart mobility scenarios. Therefore, we refrain from realizing other transactions that have the same structure and do not provide further insights. For example, in the billing process the invoice amounts could be encrypted by the mobility providers, calculated at the platform and decrypted by a billing provider, which has the same structure as T1.

IV. Experimental Evaluation

In this section, we define the computational and financial overhead we deem acceptable for smart mobility. Furthermore, we describe our prototypical implementation of our transaction, and we evaluate it with a series of experiments.

A. Resources and Costs

To find out if FHE can be applied to smart mobility scenarios, we need an understanding of the resources available and the costs involved. The *mobility platform* is a cloud service with plenty of computational resources for massive parallel processing. However, it must handle a very large number of requests at the same time. Furthermore, some FHE operations cannot be parallelized. An Amazon AWS instance "m6i.32xlarge" [49] serves as a reference for the computing costs of a large cloud instance. It is equipped with 128 XEON CPU cores at 3.5 GHz, 512 GiB RAM, 50 Gbps network bandwith. In July 2023, a m6i.32xlarge instance costs approx. 8 USD per hour, i.e., one second of one core 0,017 millicents.

The *mobility providers* are part of the edge layer of our architecture model. Thus, such providers would operate its services on a cloud instance that is one order of magnitude smaller and less expensive than those of the mobility platform. As multiple mobility providers exist, each of them has a much smaller individual load of parallel transactions than the mobility platform. A "m6g.8xlarge" cloud instance with 32 XEON CPU cores at 3.5 GHz and 128 GiB RAM might be suitable for the edge layer. Such an instance costs approx. 1.5 USD per hour.

Customers connect via smartphone to the mobility platform. A smartphone has comparatively scarce computing resources. However, as it is the customer's property, it does not need to execute multiple transactions in parallel. As a reference for computing times on a current mid-range smartphone, consider a "Fairphone 4" [50]. It has a CPU with 8 cores at 2.2 GHz and 8 GiB RAM and 128 GiB internal storage. We assume that it is acceptable for a customer and any other party if a transaction takes at most two seconds to complete. This time is comparable to starting an app on a smartphone, i.e., it does not impact the user experience. For comparison, humans do not perceive a reaction time below 400 ms as an interruption, and cannot sense delays below 100 ms [29]. Furthermore, a few seconds computing time on a small number of cores of a large cloud instance does not contribute much to the total travel costs of the customer.

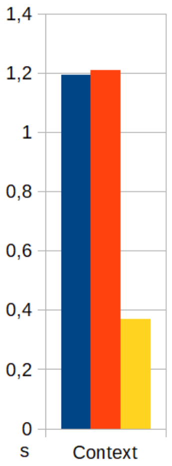

Fig. 6. Runtimes of the Context Creation

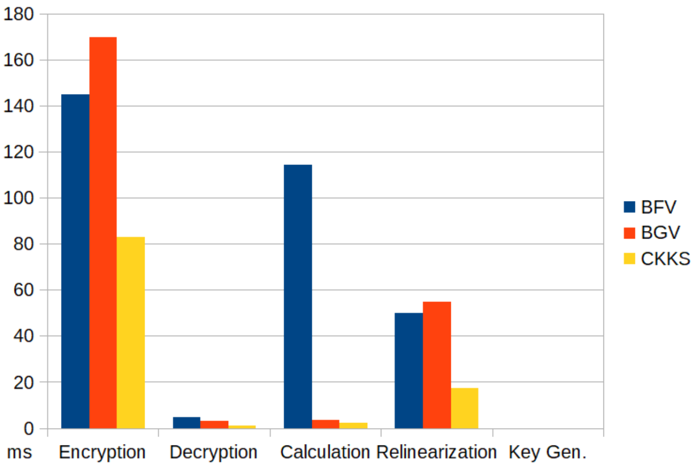

Fig. 7. Runtimes of the Operations

B. Implementation

For each of our three distributed transactions, we have implemented a FHE-encrypted variant, and a non-encrypted one for comparison. We decided to implement our transactions in C++ with Microsoft SEAL [23], because it is the most advanced implementation of the three state-of-the-art schemes BGV [26], BFV [27] and CKKS [28]. While the first two schemes compute with integers, the last one supports float-point operations. The length of the integers and the precision of float-point operations depend on the size of the modulus degree. The modulus determines how much noise can be accumulated during computations, before a relinearization operation with a pre-calculated evaluation key is needed. The noise is an internal measure to avoid that encrypted data can be decoded without knowing the secret key, i.e., it has nothing to do with the accuracy of the computation result. We used a polynomial modulus degree of 16384 and a plain modulus degree of 1024, which is the recommended setting in SEAL. For performance reasons, we disabled the debug mode and enabled batch processing, i.e., the SEAL library did not encrypt or decrypt any value individually.

We executed our experiments on a host with a 2.8 GHz Intel i7 CPU with 8 cores and 32 GiB RAM. Thus, one CPU core of our experimental host is approx. 25% slower than a core of an “m6i.32xlarge” instance and 30% faster than a core of a “Fairphone 4”. We have started one customer, one mobility platform and two mobility providers as separate processes, and we have repeated each experiment 500 times and computed the averages. We want to measure the processing time and the size of the encrypted data at each party separately. This allows us to find out if a FHE scheme exceeds the time budget of 2-3 seconds in total, or if one of the parties might be potentially drained of resources, when handling many customers in parallel.

In order to execute the measurements, we have implemented our experiments as test cases with the DOCtest framework [51]. This allows to implement experiments as a batch, and to verify that the computed results are correct. We used log4cplus [52] to monitor the execution, and we measured with the Google Benchmark v1.7.1 [53] microbenchmarking framework. Google Benchmark ensures that the compiler does not change the execution, e.g., to optimize 500 repetitions of the same execution. It delivers the values measured in a JSON format. We also evaluated the individual method calls with Intels VTUne profiler [54].

C. Evaluation Results

First we analyze the performance of BGV, BFV and CKKS. For comparability, we have measured the runtimes as CPU time on a single core. After that, we measure the memory consumptions.

a) Runtime Performance: Context creation takes only once at startup of a service or application. The purpose of this operation is to initialize and configure the SEAL library with the appropriate credentials, seeds, buffers etc. for the respective FHE scheme. As Figure 6 shows, we have measured an average context-creation time of up to 1.2 s. Thus, it is mandatory for any application not to shut down and start up the FHE library for each operation, but to preserve its state. Note that context creation can be executed in parallel with the normal launch of an application. Since even today’s smartphones have multiple CPU cores, this overhead does not necessarily increase the application’s startup time.

Figure 7 shows the runtimes in milliseconds of the FHE operations. Encryption and decryption refer to the respective cryptographic operations. With calculation, we denote to a basic mathematical operation consisting of a few additions, multiplications and subtractions. Surprisingly, this was a time-consuming operation with BFV, which took approx. 115 ms on our 2.8 GHz Intel i7 CPU. The other schemes required 4 ms and 2.3 ms. Relinearization is needed after some calculations to ensure that the decryption produces correct results. The relinearization requires an one-time evaluation key, whose creation time is depicted in the last column of Figure 7.

As the figure shows, CKKS consumes approximately half the CPU time of the two other schemes, and the most expensive operations are encryption and relinearization. The runtimes for computations on encrypted data are orders of magnitude higher than on plain-text values. However, humans do not perceive reaction times below 400 ms as annoying, and do not recognize a delay below 100 ms at all [29]. Note that our measures only consider the runtimes of the FHE operations, i.e., we leave aside context creation, operating system, start-up times of applications and network delays.

We want to find out if those runtimes add up to a disruptive amount for our three transactions T1, T2 and T3. Therefore, we measured and aggregated the CPU times for any operation on any party, again for each of the schemes BFV, BGV and CKKS. We have left aside the context creation.

To avoid confounding the effects of parallelization with the CPU times needed at the various parties, we have structured our experiment so that all mobility providers operate independently in parallel, while the customer and the mobility platform wait for all other parties. For the same reason, we do not measure network delays, effects of the operation system, etc. In a real setting, each party would start encrypting, decrypting or calculating values as soon as the first chunk of data has arrived, i.e., the total runtimes would be smaller.

To foster comparability among the transactions, we also ensured that T1-T3 used the same set of operations, and differed only in the place where each encryption, decryption, calculation etc. took place. The set of operations contained a number of additions and calculations that was large enough to require one relinearization. Having said this, the BFV scheme required a total of 314 ms CPU time on average to complete a transaction. BGV needed an average of 232 ms, and CKKS had the best runtime performance with only 104 ms on average.

Figures 8-10 show for centralized, decentralized and customer-side calculations at which party how much CPU time is consumed. For comparability, each party uses the same CPU and is limited to one core. Figures 8 and 9 confirm that centralized and decentralized calculations do not burden the smartphone of the customer. With such transactions, the customer is responsible for generating evaluation keys and decrypting values, which are fast operations (Figure 7).

Figure 8 corresponds to a centralized transaction where any computation and relinearization takes place at the mobility platform. Encrypting values must be performed at the data sources. With the mobility providers as data sources, this corresponds to an edge computing scenario, where all time-consuming operations are executed on a centralized or decentralized cloud instance.

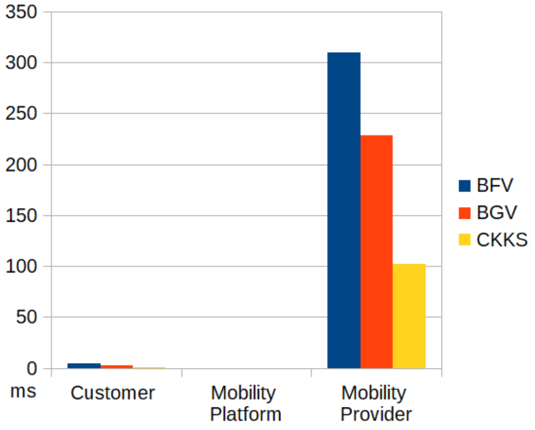

Fig. 9. T2: Decentralized Calculations

Figure 9 transfers any computationally expensive operation in the domain of the mobility providers. If we take a m6i.32xlarge cloud instance for comparison, each transaction costs each mobility provider less than 0,003 millicents, even with the slowest FHE scheme. Figure 10 confirms that even customer-side calculations incur negligible overhead on a smartphone. Similarly to T1 and T2, with T3 the encryption of the data takes place at the mobility providers.

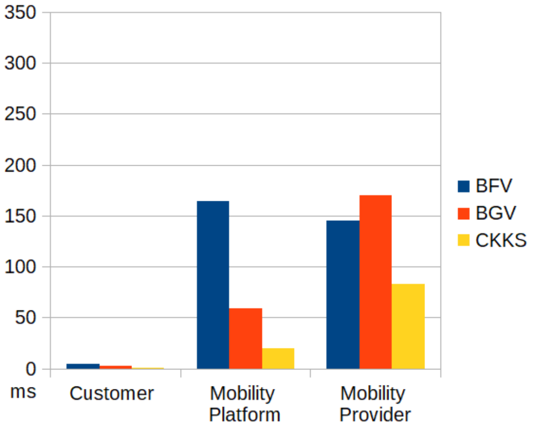

Fig. 8. T1: Centralized Calculations

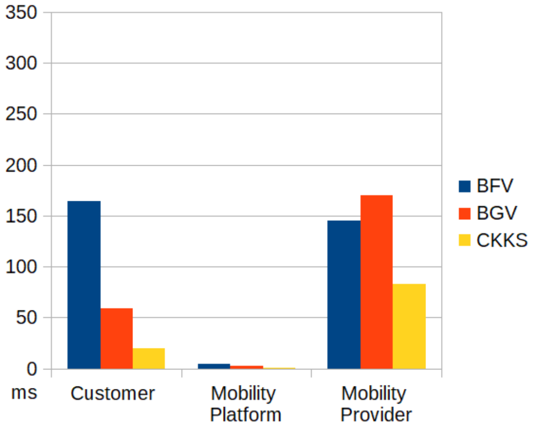

Fig. 10. T3: Customer-side Calculations

Note that for to calculations with unencrypted values at the cost of privacy, the runtimes and the costs of a single calculation are below measurement accuracy, and virtually zero. Thus, FHE is not suitable for any big-data problem, or for scenarios where numerous transactions must be executed to the smallest possible costs. However, in the field of smart mobility, such transaction fees are several orders of magnitude smaller than the billing amount on the customer's invoice, but privacy is an important factor. Thus, we have confirmed that FHE schemes are feasible for business models in the field of smart mobility.

b) Approximated Memory Comsumption: In order to have a practical estimate of the memory consumption incurred by FHE, we have implemented each customer, mobility platform and mobility provider as an individual application. Thus, we have measured the total amount of memory of the application, libraries, runtime variables and the buffers where encrypted values are stored. The isolated increase in buffer sizes needed to store encrypted intermediate results can be found in [27](BFV), [26](BGV) and [28](CKKS). Table II summarizes this.

FHE Scheme	*Memory Consumption*
Plain Text	76 – 104 MB
BFV	207 – 321 MB
BGV	216 – 306 MB
CKKS	146 – 188 MB

TABLE II
APPROXIMATED MEMORY CONSUMPTION

With our experiments, we measured a memory consumption between 207 MB and 321 MB for BFV. We measured between 216 MB and 306 MB for BGV, and 146 MB to 188 MB for CKKS. A large memory consumption corresponds to more expensive operations (encryption and calculations including relinearization). This was because such operations require many runtime variables and, therefore, a large and deep stack. In comparison, an execution on unencrypted values resulted in applications with a memory footprint between 76 MB and 104 MB. Thus, none of the FHE schemes utilized memory resources that exceeded even the capacity of a smartphone.

V. Conclusion

In the upcoming years, the planning of cities and transportation logistics for moving people and goods will undergo significant changes. The conventional concept of mobility using individual transportation modes, such as a car, is not longer useful due to environmental reasons and growing cities. The demand for multi-modal transport solutions that allow users to move flexible and eco-friendly is high. However, the implementation of this approach requires the sharing of sensitive personal data with various parties, creating potential privacy risks.

This paper explored the potential use of fully homomorphic encryption as an efficient and noise-free solution for data privacy concerns in the implementation of smart mobility. Initially, privacy requirements for such a smart mobility approach were formulated, based on which three multi-party computations were identified that benefit from FHE. An implementation was provided using state-of-the-art FHE schemes BGV [26], BFV [27] and CKKS [28] based on Microsoft SEAL [23]. Finally, memory consumption and execution times were measured, evaluated and compared with a non-encrypted benchmark. To provide optimal experimental results, a benchmark framework was used to monitor memory consumption and execution times. To test the applicability of FHE in a real-life smart mobility scenario, the ressources used in the implementation were analyzed and compared to available resources on smartphones and cloud instances.

Based on the experiments conducted, encrypting transactions with FHE increases CPU time by approximately 100 milliseconds compared to unencrypted transactions. However, this additional processing time does not adversely affect the user experience [29]. The use of parallel processing can significantly reduce this time, and the cost of such encryption on a current cloud instance is less than 3 microcents. We conclude that FHE is a cost-effective means of ensuring privacy, and a viable option for a smart mobility business model.

For future research, it would be beneficial to scale the implementation to a real-life scenario involving multiple smartphones functioning as edge devices, and leveraging cloud instances for both the mobility platform and service providers. Hence, experiments could be extended to measure actual runtimes including side effects of operating systems, and delays of a virtualization environment. Also, delays of network connection could be reported. Furthermore, it would be worthwhile to evaluate and compare other libraries such as OpenFHE [55] and other state-of-the-art FHE schemes.

Acknowledgment

We would like to thank Yasin Akbas for his excellent implementation and evaluation of the smart mobility model with fully homomorphic encryption.

***Abstract*—The Hydro Unit Commitment problem (HUC) specific to hydroelectric plants is part of the electricity production planning problem, called Unit Commitment Problem (UCP). More specifically, the studied case is that of the HUC with a single plant, denoted 1-HUC. The plant is located between two reservoirs. The horizon is discretized in time periods. The plant operates at a finite number of points defined as pairs of the generated power and the corresponding water flow. Several constraints are considered. Each reservoir has an initial volume, as well as window resource constraints, defined by a minimum and maximum volume per time period. At each time period, there is an additional positive, negative or zero intake of water in the reservoirs. The case of a price-taker revenue maximization problem is considered. An efficient exact A* variant, so called HA*, is proposed to solve the 1-HUC accounting for window constraints, with a reduced search space and a dedicated optimistic heuristic. This variant is compared to a classical Resource Constrained Shortest Path Problem (RCSPP) algorithm and a Mixed Integer Linear Programming formulation solved with CPLEX. Results show that the proposed algorithm outperforms both concurrent alternatives in terms of computational time in average on a set of realistic instances, meaning that HA* exhibits a more stable behavior with a larger number of instances solved.**

I. Introduction

AN ELECTRICITY producer aims at meeting the demand at any time. This is because electricity can hardly be stored, meaning that any excess is lost. Scheduling the short-term production in order to meet the demand defines the Unit Commitment Problem (UCP), which is solved for the day ahead. At Electricité de France (EDF), large-scale UCP instances are solved by Lagrangian decomposition [1], yielding subproblems of the same nature (thermal, hydraulic, solar,...). As each subproblem has different constraints, specific approaches are developed for each of them. Among these subproblems, the Hydro Unit Commitment (HUC) has received a lot of attention, due to the large size of its instances. Indeed, instances of the HUC involve valleys, which can be constituted of up to twenty plants, linked with reservoirs.

At EDF, the HUC is modeled as a Mixed Integer Linear Program (MILP) and solved with CPLEX [2]. This MILP considers operating points, which are pairs (water flow, corresponding generated power). In practice, the HUC is not solved to optimality within the time limit set, as such a representation induces an exponential number of solutions and large computational times. More recent work [3] have pointed out the interest of solving the HUC using a Lagrangian relaxation algorithm, where subproblems are single plant HUC (1-HUC). The main benefit of this relaxation is that the 1-HUC can be solved with dynamic programming, while the master problem handles the coupling constraints. It is shown that such a relaxation can lead to overall better results than solving the HUC as an MILP, which emphasizes the relevance of an efficient algorithm to solve the 1-HUC.

In this paper, we consider the 1-HUC with a single plant located between two reservoirs. A diagram, taken from [4] and shown in Figure 1, is sketching the 1-HUC. The principle of hydroelectric production is the following: the water from the upstream reservoir flows into the downstream reservoir through the units of the plant, thus driving the turbines of the units, which in turn power the generator to produce electricity. When operating in reverse, the pumps of the units can move the water from the downstream reservoir to the upstream reservoir, which consumes electricity. The plant operates on M turbining points, N pumping points and an idle operating point. With $I = \{-N, \dots, 0, \dots, M\}$, each operating point $i \in I$ is defined as a pair formed by a water flow D_i and a generated power P_i. Both D_i and P_i are positive (resp. negative) for turbining (resp. pumping) operating points, i.e., with $i > 0$ (resp. $i < 0$), and are 0 for the idle operating point $i = 0$. The operating points are defined in a cumulative fashion meaning that if a plant is at turbining (resp. pumping) operating point i, then order constraints apply, involving all points $1 \leq j < i$ (resp. $-1 \geq j > i$) to also be operated. At each time period, the plant cannot turbine and pump simultaneously. The time horizon is discretized into T time periods. At each time period t, the plant turbines (resp. pumps) a water flow and produces (consumes) an amount of energy that is considered to be constant for the duration of the time period. Resource window constraints state that the volume of each reservoir $n \in \{1, 2\}$ lies between a lower bound $\underline{V}_t^n$ and an upper bound $\overline{V}_t^n$ that are time-dependent. At each time period, the reservoir n receives an additional intake of water A_t^n. The additional intake can be positive to represent rain, melting snow etc., or negative to represent the use of water for local agriculture etc.

The revenues take into account the unit value Φ^n of the water in each reservoir n at the end of the time horizon, and the value of the energy produced or consumed at a time-dependent unit value Λ_t. The problem is to maximize the total revenue,

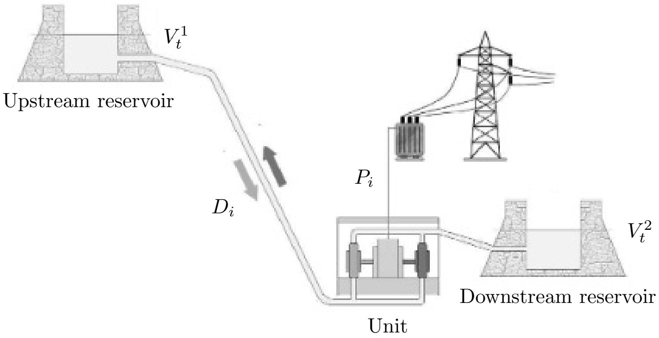

Fig. 1: Diagram of the 1-HUC

while satisfying the reservoir capacities at each time period.

In practice, water management policies require that reservoirs should meet target volumes ($\underline{V}_t^n = \overline{V}_t^n - \epsilon$) at the end of the time horizon. Due to these target volumes and the finite set of operating points, the 1-HUC may not have any feasible solution. However, it is possible to adjust [5] or relax [6] the target volumes in order to obtain feasible instances. Hence, we consider in this paper only 1-HUC instances admitting feasible solutions.

In this paper the aim is to propose a dynamic programming algorithm dedicated to the 1-HUC, modeled as a Resource Constrained Shortest Path Problem (RCSPP) with resource window constraints. The algorithm we propose is an exact variant of the A* algorithm [7] used to compute the shortest path in a graph. To obtain an efficient algorithm, the bounds of the windows are first tightened by propagating them from any time period to another, and a dedicated heuristic is developed. As we propose an exact algorithm, we compare it with two other exact methods, namely an MILP solved by default CPLEX as currently done at EDF and a classical RCSPP algorithm. The corresponding evaluation of performance is done on various realistic instances. The numerical results show that our algorithm yields smaller computational time variations compared to both the MILP formulation solved by CPLEX and the RCSPP algorithm.

The remainder of the paper is organized as follows. In Section II, a literature review of dynamic programming algorithms for related problems is reported. In Section III, a formulation of the 1-HUC is proposed. In Section IV, graph representations of the 1-HUC are provided. In Section V, the bound tightening procedure and the exact A* variant are described. In Section VI, numerical results are presented. In Section VII, concluding remarks and perspectives for further research are drawn.

II. State of the art

In this section, we first present a literature review of dynamic programming algorithms developed for the UCP and for the HUC. As the HUC can be represented as an RCSPP, we also include in this review dynamic programming algorithms for the RCSPP.

A. Dynamic programming for the Unit Commitment Problem

A dynamic programming algorithm for a single Unit Commitment (1-UC) with ramp and min up/down constraints is presented in [8]. The algorithm is based on a graph with a source vertex and several groups of T vertices. For each even (resp. odd) group, vertex t indicates that the unit is turned off (resp. on) at time period t. The arcs connect the vertices of a group to the next groups, from a time period t to a time period $t' > t$. Finding a path in this graph allows one to find an on-off schedule for the unit. The difference between the 1-UC and the 1-HUC is that there is no resource in the 1-UC, while in the 1-HUC, the presence of reservoirs with minimum and maximum volumes requires to account for the water resource.

B. Dynamic programming for the Hydro Unit Commitment

In this part we focus on dynamic programming algorithms for the HUC, most of them being cited in the survey [9].

In [1] the author presents a two phase approach to solve the HUC, solving an LP for the first phase and using a dynamic programming algorithm for the second phase. More precisely, the second phase consists of solving the 1-HUC for each plant of the valley with dynamic programming, aiming to get the closest solution to the LP solution while taking into account constraints omitted in the LP. For this phase, the considered underlying graph is as follows. The reservoir volume is discretized, yielding hundreds of possible volume values for a reservoir. Then, a vertex is defined for each volume value and each time period, thus leading to hundreds of vertices per time period. A Bellman-Ford algorithm [10] is used to find a path in this graph. Such a discretization discards a lot of realistic states. In this paper, we consider all possible states with respect to the operating points, which can be exponential for instances with a large number of time periods. With an exponential number of states, the Bellman-Ford algorithm becomes far less efficient.

In [6] a method for solving a non-linear 1-HUC with a target volume is described. To solve this problem with dynamic programming, a state diagram is constructed. In a similar fashion as in [1], evenly discretized volumes are considered, yielding a limited number of states per time periods. In order to have feasible solutions, the target volume is relaxed to match this discretization. The state diagram is constructed by generating the possibilities to reach the target volume from the initial volume, satisfying the upper and lower bounds on the volume at each time period. Starting from the state at the end of the time horizon, the dynamic programming algorithm maximizes the value of the generated power. As we consider 1-HUC instances with and without target volumes, a backward algorithm may not be practical with large volumes and no target volume.

In [3], a decomposition method for solving the HUC with shortest paths is described. The considered HUC is a valley where each plant has a finite number of operating points. The topology of the valley is not restricted to a chain, as each plant (resp. reservoir) can have a set of upstream and downstream reservoirs (resp. plants). There are additional ramping constraints, namely the flow variation is limited from one time period to another. This HUC also takes into account a target volume for each reservoir, at the last time period. Note that the latter target volume is a minimal bound, meaning there is no equality constraint. The solution approach decomposes this HUC into multiple 1-HUC. Some 1-HUC without resource constraints are solved by a shortest path algorithm, while others with resource constraints are solved by a labeling algorithm defined in [11]. The latter algorithm is adapted from a classical RCSPP algorithm [12] to take into account a minimum bound for the resource. It is mentioned that this labeling algorithm loses its dominance properties between two labels if one of them does not verify the minimum bound on the resource. Such a case is more frequent when the target volume is considered with equality constraints, making this algorithm less efficient.

There are also other problems solved by dynamic programming, related to the 1-HUC. In [13] a dynamic programming approach is described to solve an HUC on instances of the Itaipù plant (Brazil, Paraguay). This problem differs from ours as the only constraint is to satisfy the minimum and maximum number of turbines running at each time period. No volume is considered, therefore there are neither bounds on the volume, nor a target volume. In [14] the Hydro Unit Load Dispatch problem (HULD) is presented. This problem differs from the HUC, as the water flow is known, and solving the HULD is to provide the most economic distribution of the water through the different turbines, while verifying the flow capacity of the turbines at each time period.

C. Shortest path with resource constraints

As the HUC can be seen as a shortest path problem with a water resource bounded both from below and above, we are interested in the solution methods for the RCSPP (Resource Constrained Shortest Path Problem).

There are works on the RCSPP to solve the thermal problem on EDF instances [15]. In that paper it is indicated that the resource has an upper bound but no lower bound. However, as specified in [3], the difficulty of the HUC comes from the lower bound on the volume, which prevents the use of dominance rules.

In the survey [16], a state of the art review of different shortest path variants is described. More specifically, it is indicated that there is little work on the RCSPP with equality constraints, or window constraints (such as in the HUC). Three papers are cited, namely [17] describing a heuristic, [18] presenting an integer formulation and [19] proposing a dynamic programming algorithm. As we look for an exact algorithm, we will focus on the three-phase algorithm described in [19]. The presented algorithm solves the RCSPP with window constraints on acyclic graphs. The main idea, further detailed in [20], is to extend the graph, such that if multiple paths lead to the same vertex from the source, a new vertex is created for each of these paths. Once the graph has been extended in this way, the problem is solved with a pseudo-polynomial time algorithm. Such a graph extension seems difficult to apply to the 1-HUC. Indeed, graph representations of the 1-HUC (see Section IV) solely have arcs from time period t to time period $t+1$. Hence, the extension can lead up to M^T vertices at time period T. Even a pseudo-polynomial algorithm on the extended graph could be impractical in the case of the 1-HUC.

III. Integer linear programming

With $x_{t,i}$ the binary variable indicating whether the plant is at least at operating point $i \in I$ at time period $t \leq T$, we obtain the following formulation:

$$\begin{aligned}
\max \quad & \sum_{t=1}^{T} \sum_{i \in I} \Lambda_t P_i x_{t,i} + \Phi^1 \Big(\sum_{t=1}^{T} (A_t^1 - \sum_{i \in I} D_i x_{t,i}) \Big) \\
& + \Phi^2 \Big(\sum_{t=1}^{T} (A_t^2 + \sum_{i \in I} D_i x_{t,i}) \Big) \\
\text{s.c.} \quad & V_0^1 + \sum_{t=1}^{t'} (A_t^1 - \sum_{i \in I} D_i x_{t,i}) \leq \overline{V}_{t'}^1, \quad \forall t' \leq T \qquad \text{(a1)} \\
& V_0^1 + \sum_{t=1}^{t'} (A_t^1 - \sum_{i \in I} D_i x_{t,i}) \geq \underline{V}_{t'}^1, \quad \forall t' \leq T \qquad \text{(b1)} \\
& V_0^2 + \sum_{t=1}^{t'} (A_t^2 + \sum_{i \in I} D_i x_{t,i}) \leq \overline{V}_{t'}^2, \quad \forall t' \leq T \qquad \text{(a2)} \\
& V_0^2 + \sum_{t=1}^{t'} (A_t^2 + \sum_{i \in I} D_i x_{t,i}) \geq \underline{V}_{t'}^2, \quad \forall t' \leq T \qquad \text{(b2)} \\
& x_{t,i} \geq x_{t,i+1}, \quad \forall t \leq T, \forall i \in \{1, \dots, M-1\} \qquad \text{(c)} \\
& x_{t,i} \geq x_{t,i-1}, \quad \forall t \leq T, \forall i \in \{-1, \dots, -N+1\} \qquad \text{(d)} \\
& x_{t,1} + x_{t,-1} \leq 1, \quad \forall t \leq T \qquad \text{(e)} \\
& x_{t,i} \in \{0,1\}, \quad \forall t \leq T, \forall i \in I \qquad \text{(f)}
\end{aligned}$$

In this formulation, the objective function maximizes the total revenue. Constraints (a1) to (b2) ensure that the minimum/maximum bounds on the volume are verified for both the upstream and downstream reservoirs at each time period. Constraints (c) and (d) correspond to the order of the operating points. Constraints (e) prevent the plant from turbining and pumping simultaneously. Lastly, constraints (f) indicate that all variables $x_{t,i}$ are binary.

A. Shifting all operating points

In the following, it will be convenient to only have operating points with non-negative power and flow. In [3] a modification on the flows and the volume bounds is considered to only have such operating points. First, each turbining operating point i, for $i \in \{1, .., M\}$ is renumbered $i+N$, yielding operating point (D'_{i+N}, P'_{i+N}) with $D'_{i+N} = D_i$ and $P'_{i+N} = P_N$. For each pumping operating point $i \in \{-N, \dots, -1\}$, a turbining operating point numbered $N+i+1$ is created, yielding operating point (D'_{N+i+1}, P'_{N+i+1}) with $D'_{N+i+1} = |D_i|$ and $P'_{N+i+1} = |P_N|$. Operating point 0 remains unchanged. As such, all the operating points have non-negative cumulated flows. For a given $t \leq T$, the bounds on the volume $\overline{V}_t^1$

and $\underline{V}^1_t$ (resp. $\overline{V}^2_t$ and $\underline{V}^2_t$) are shifted in order to keep the same feasible solutions: $\overline{V'}^1_t = \overline{V}^1_t - t\sum_{i=-1}^{-N}|D_i|$ and $\underline{V'}^1_t = \underline{V}^1_t - t\sum_{i=-1}^{-N}|D_i|$ (resp. $\overline{V'}^2_t = \overline{V}^2_t + t\sum_{i=-1}^{-N}|D_i|$ and $\underline{V'}^2_t = \underline{V}^2_t + t\sum_{i=-1}^{-N}|D_i|$).

Example 1. Consider an instance of the 1-HUC with $M = 3$ turbining operating points $(D_1 = 3, P_1 = 3)$, $(D_2 = 4, P_2 = 3)$, $(D_3 = 2, P_3 = 2)$ and $N = 2$ pumping operating points $(D_{-1} = -3, P_{-1} = -5)$, $(D_{-2} = -2, P_{-2} = -4)$. The initial volumes are $V^1_0 = 50$, $V^2_0 = 30$. With $T = 3$, upstream reservoir bounds are $\overline{V}^1 = [100, 100, 20]$ and $\underline{V}^1 = [0, 0, 20]$, and downstream reservoir bounds are $\overline{V}^2 = [60, 60, 60]$ and $\underline{V}^2 = [0, 0, 0]$.

The renumbering is such that the 3 turbining operating points, of index 1 to 3 are now of index $1 + N$ to $3 + N$, i.e., $(D'_3 = 3, P'_3 = 3)$, $(D'_4 = 4, P'_4 = 3)$ and $(D'_5 = 2, P'_5 = 2)$ From pumping operating point -1 a turbining operating point $N - 1 + 1 = 2$ is created, and similarly from the pumping operating point -2 operating point $N - 2 + 1 = 1$ is created, i.e., $(D'_1 = 2, P'_1 = 4)$ and $(D'_2 = 3, P'_2 = 5)$.

The upstream reservoir upper bounds are modified as follows $\overline{V'}^1_1 = \overline{V}^1_1 - 1\cdot(2+3) = 95$, $\overline{V'}^1_2 = \overline{V}^1_2 - 2\cdot(2+3) = 90$, $\overline{V'}^1_3 = \overline{V}^1_3 - 3\cdot(2+3) = 5$. Similarly, we obtain the following upstream reservoir lower bounds $\underline{V'}^1 = [-5, -10, 5]$. The shift is done in the opposite way for the downstream reservoir, $\overline{V'}^2 = [65, 70, 75]$ and $\underline{V'}^2 = [5, 10, 15]$.

In the following, we only refer to the 1-HUC with operating points of non-negative flow and power, i.e., with $I = \{0, \ldots, M\}$. In this case, only constraints (a1) to (b2), (c) and (f) are necessary to model the constraints of the 1-HUC, and no renumbering is required.

B. Rewriting the formulation

The formulation defined previously is a classical MILP model for the 1-HUC. We rewrite the formulation in order for the window constraints to appear more clearly. Constraints (a1), (a2), (b1) and (b2) can be rewritten as follows, considering $\underline{V'}^1_t$ $\overline{V'}^1_t$, $\underline{V'}^2_t$ and $\overline{V'}^2_t$:

$$\sum_{t=1}^{t'}\sum_{i=1}^{M} D_i x_{t,i} \geq V^1_0 + \sum_{t=1}^{t'} A^1_t - \overline{V'}^1_{t'}, \quad \forall t' \leq T \qquad \text{(a1')}$$

$$\sum_{t=1}^{t'}\sum_{i=1}^{M} D_i x_{t,i} \leq V^1_0 + \sum_{t=1}^{t'} A^1_t - \underline{V'}^1_{t'}, \quad \forall t' \leq T \qquad \text{(b1')}$$

$$\sum_{t=1}^{t'}\sum_{i=1}^{M} D_i x_{t,i} \leq \overline{V'}^2_{t'} - V^2_0 - \sum_{t=1}^{t'} A^2_t, \quad \forall t' \leq T \qquad \text{(a2')}$$

$$\sum_{t=1}^{t'}\sum_{i=1}^{M} D_i x_{t,i} \geq \underline{V'}^2_{t'} - V^2_0 - \sum_{t=1}^{t'} A^2_t, \quad \forall t' \leq T \qquad \text{(b2')}$$

There are redundancies between (a1') and (b2'), and between (a2') and (b1'). Let us introduce bounds $\beta_{t'}$ and $\alpha_{t'}$ in the following way with $t' \leq T$:

$$\beta_{t'} = \max(V^1_0 + \sum_{t=1}^{t'} A^1_t - \overline{V'}^1_{t'}, \underline{V'}^2_{t'} - V^2_0 - \sum_{t=1}^{t'} A^2_t)$$

$$\alpha_{t'} = \min(V^1_0 + \sum_{t=1}^{t'} A^1_t - \underline{V'}^1_{t'}, \overline{V'}^2_{t'} - V^2_0 - \sum_{t=1}^{t'} A^2_t)$$

By using $\beta_{t'}$ and $\alpha_{t'}$, and rewriting the objective function, we obtain the formulation F_{1HUC} defined as follows:

$$\begin{aligned}
\max \quad & \sum_{t=1}^{T}\sum_{i=1}^{M}(\Lambda_t P_i - \Phi^1 D_i + \Phi^2 D_i)x_{t,i} \\
& + \Phi^1 \sum_{t=1}^{T} A^1_t + \Phi^2 \sum_{t=1}^{T} A^2_t \\
\text{s.c.} \quad & \sum_{t=1}^{t'}\sum_{i=1}^{M} D_i x_{t,i} \geq \beta_{t'} \quad \forall t' \leq T && \text{(a)} \\
& \sum_{t=1}^{t'}\sum_{i=1}^{M} D_i x_{t,i} \leq \alpha_{t'} \quad \forall t' \leq T && \text{(b)} \\
& x_{t,i} \geq x_{t,i+1} \quad \forall t \leq T, \forall i \leq M-1 && \text{(c)} \\
& x_{t,i} \in \{0, 1\} \quad \forall t \leq T, \forall i \leq M && \text{(f)}
\end{aligned}$$

With this formulation, the objective function is to maximize the value of each active operating point, plus a constant. Also, one can see (a) and (b) as resource window constraints, or (a) as nested cover constraints and (b) as nested knapsack constraints. This formulation can also be improved by tightening the window constraints, as shown at the end of Section V-A.

IV. Graph representation

The 1-HUC can be represented graphically in two ways, namely in a fashion similar either to the knapsack problem, or to the RCSPP. In the following we describe both representations and their dominance rules. We first introduce the cumulated flows between two time periods.

Definition 1 (Cumulated flow $\mathcal{D}_{t',t}$)**.** The cumulated flow $\mathcal{D}_{t',t}$ is the sum of the flows from time periods t' to t:

$$\mathcal{D}_{t',t} = \sum_{t''=t'}^{t}\sum_{i=1}^{M} D_i x_{t'',i}$$

A. Representation as a knapsack problem

Let $G_{KP} = (V_{KP}, A_{KP})$ defined as follows. Each vertex $u \in V_{KP}$ is defined as a pair $u = (t, d)$ with t the time period, and d the cumulated flow $\mathcal{D}_{1,t}$ with variables x associated to a path that reaches u. Without loss of generality, $u = (t, d)$ is considered only if $d \in [\beta_t; \alpha_t]$. The source vertex s is defined as $s = (0, 0)$. For each vertex $u = (t, d)$ and $v = (t + 1, d + \sum_{j=0}^{i} D_j)$ with $t < T$ and $i \in \{0, \ldots, M\}$ there is an arc $(u, v) \in A_{KP}$, of value $\sum_{j=0}^{i} \Lambda_t P_j - \Phi^1 D_j + \Phi^2 D_j$.

The downside of such a graph is its exponential number of vertices. However, by tightening the bounds as shown in Section V-A, it is possible to drastically reduce the number of vertices in G_{KP}. Furthermore, we can use classical dominance rules for the longest path:

Definition 2 (Dominance rule 1)**.** Let p and q be two paths from s to a vertex u. By induction the path with the lowest value is dominated, as it cannot lead to an optimal solution.

Definition 3 (Dominance rule 2)**.** Let p be a path from s to u going through a vertex v, and q be a path from s to v. Let $p_{s,v}$ be the subpath of p, from s to v and $p_{v,u}$ the subpath of p from v to u. If the value of $p_{s,v}$ is larger than that of q, then q is dominated. If the value of q is larger than that of $p_{s,v}$, then p is dominated by the path concatenating q and $p_{v,u}$.

Example 2. Consider an instance of the 1-HUC with $T = 3$, $M = 3$. The operating points are $(4, 4)$, $(6, 5)$ and $(8, 6)$. The bounds are $\beta{=}[0, 0, 5]$ and $\alpha{=}[12, 12, 10]$. Fig. 2a represents the graph G_{KP} associated to this instance.

B. Representation as an RCSPP

Let $G_R = (V_R, A_R)$ be defined as follows. Each vertex $u \in V_R$ is defined as a pair $u = (t, i)$, with t the time period and i the operating point. The source s is defined as $s = (0, 0)$. From each vertex $u = (t, i)$, with $t < T$, and $v = (t + 1, i')$ with $i' \in \{0, \ldots, M\}$ there is an arc $(u, v) \in A_R$. Arc a towards v has value $\sum_{j=0}^{i'} \Lambda_t P_j - \Phi^1 D_j + \Phi^2 D_j$ and consumes $\sum_{j=0}^{i'} D_j$ amount of the resource.

The downside of G_R, is that there are paths in this graph which do not verify the resource constraints, hence one needs to verify the resource constraints for each path. Note that the resource in this case is $\mathcal{D}_{1,t}$ for variables x associated to the path. On the positive side, the number of vertices is polynomial, and it is possible to use a classical dominance rule for the RCSPP as defined in [3]:

Definition 4 (Dominance rule 3)**.** If there are two partial paths from s to the same vertex u, by induction if a path has a lower value and uses more resource than another one, then this path is dominated provided both partial paths use sufficient resource to verify all lower bounds on the resource.

Note that the condition on the resource usage to ensure that the lower bounding constraints (a) are satisfied seriously weakens the dominance rules when these constraints are active.

Example 3. Consider the instance of Example 2. Fig. 2b represents the graph G_R associated to this instance.

There are two other graph representations for the 1-HUC described in the literature. In [20], the original graph defined for the RCSPP is similar to the one depicted in Fig. 2b. However, as mentioned in Section II-C, this graph is extended such that if multiple paths exist from vertex s to a vertex u, then u is duplicated such that only a single path leads to each vertex. The extended graph would be larger than the one depicted in Fig. 2a, as even with an exponential number of vertices, there are still multiple paths between s and most of the vertices. In [6], as described in Section II-B, the volume is evenly discretized. The resulting graph has similar vertices as in Fig. 2a, but at each time period, vertices only exist for volumes within the set of discretized volumes. In the experimental results of [6], it is stated that the discretization is ranging from 0.3% to 0.5% of the difference between the minimum and maximum volume of the reservoir, which represents about 300 vertices at each time period. Such a graph heavily differs from the graph we consider, as there can be a very large number of vertices at each time period.

(b) Graph representation as an RCSPP

Fig. 2: Graph representations of the 1-HUC

V. Exact A* variant for the 1-HUC

In this section, we describe the new algorithm proposed to solve the 1-HUC. The aim of this algorithm is to find the longest path in graph G_{KP} as described in Section IV-A. A difficulty of this graph is the exponential number of vertices, which is why we resort to a variant of the A* algorithm [7]. The A* algorithm is particularly efficient when the number of vertices is large as it involves an optimistic heuristic to guide the search, and to discard sub-optimal partial solutions. We denote the proposed exact variant of the A* algorithm for the 1-HUC by HA*. This algorithm involves a dedicated optimistic heuristic for the 1-HUC. To further improve the performance of this algorithm, we also present a pre-processing bound tightening procedure in order to reduce the number of vertices in G_{KP}.

In the following, we first present the bound tightening procedure, then the optimistic heuristic, i.e., an upper bound on the optimal value and finally the HA* algorithm.

A. Tightening the bounds

The bounds α_t and β_t from inequalities (a) and (b) can directly be used to prune infeasible vertices. Thus, tightening these bounds may lead to a smaller number of vertices, thus reducing the search space.

In order to tighten the bounds, we use the cumulated flow $\mathcal{D}_{t',t}$ as previously defined. At each time period, the flow is between 0 and $\sum_{i=1}^{M} D_i$. For any pair of time periods (t', t), $t' < t$, the lower bound $\underline{\mathcal{D}}_{t',t} = 0$ and the upper bound $\overline{\mathcal{D}}_{t',t} = (t - t' + 1)\sum_{i=1}^{M} D_i$ will never be violated by a feasible solution. Note that α_t and β_t are not bounds on the flow at time period t, but rather bounds on $\mathcal{D}_{1,t}$. If the gap between β_t and α_t is large, then one may develop a large number of vertices, sometimes leading to intractable instances. For example, in the case of the HUC, it is very common to have upper bounds α_t very large compared to the flows, and negative lower bounds β_t. We can therefore introduce bounds $\hat{\alpha}_t$ and $\hat{\beta}_t$ in the following way:

$$\hat{\alpha}_t = \min(\alpha_t, \overline{\mathcal{D}}_{1,t})$$
$$\hat{\beta}_t = \max(\beta_t, \underline{\mathcal{D}}_{1,t})$$

By using bounds $\hat{\alpha}_t$ and $\hat{\beta}_t$, we can drastically reduce the number of vertices. However, it is still possible to further reduce it. Suppose that at time period t the bounds are such that $\hat{\beta}_t > \hat{\beta}_{t+1}$. As the water flows are all non-negative, any vertex $u = (t+1, d)$ with $d < \hat{\beta}_t + \underline{\mathcal{D}}_{t+1,t+1}$ cannot be part of a feasible solution. Similarly, if $\hat{\beta}_{t-1} < \hat{\beta}_t$, any vertex $u = (t-1, d)$ with $d < \hat{\beta}_t - \overline{\mathcal{D}}_{t,t}$ cannot be part of a feasible solution. Extending this logic to the upper bounds on d, we can tighten the bounds of any time period from the bounds of any other time period, following the rules below. Let a pair of time periods (t', t) with $t' < t$. Then, $\mathcal{D}_{1,t}$ must stay in $[\hat{\beta}_{t'} + \underline{\mathcal{D}}_{t'+1,t}; \hat{\alpha}_{t'} + \overline{\mathcal{D}}_{t'+1,t}]$ and $\mathcal{D}_{1,t'}$ lies in $[\hat{\beta}_t - \overline{\mathcal{D}}_{t'+1,t}; \hat{\alpha}_t - \underline{\mathcal{D}}_{t'+1,t}]$.

Let us define $\tilde{\alpha}_t$ and $\tilde{\beta}_t$ as follows:

$$\tilde{\alpha}_t = \min(\min_{t'<t}(\hat{\alpha}_{t'} + \overline{\mathcal{D}}_{t'+1,t}), \min_{t'>t}(\hat{\alpha}_{t'} - \underline{\mathcal{D}}_{t+1,t'}))$$
$$\tilde{\beta}_t = \max(\max_{t'<t}(\hat{\beta}_{t'} + \underline{\mathcal{D}}_{t'+1,t}), \max_{t'>t}(\hat{\beta}_{t'} - \overline{\mathcal{D}}_{t+1,t'})$$

Tight bounds α^*_t and β^*_t are calculated as follows:

$$\alpha^*_t = \min(\hat{\alpha}_t, \tilde{\alpha}_t)$$
$$\beta^*_t = \max(\hat{\beta}_t, \tilde{\beta}_t)$$

Note that computing all bounds β^*_t is of complexity T^2. Indeed, for a given t, computing β_t as well as $\tilde{\beta}_t$ both require one comparison, computing $\tilde{\beta}_t$ needs T comparisons and computing β^*_t requires one comparison. Hence, computing all β^*_t is of complexity T^2. We obtain a similar complexity for upper bounds α^*_t.

Example 4. Let us define an instance of the 1-HUC with $T = 6$. Bounds are $\beta_3 = 2$, $\beta_6 = 5$, $\alpha_3 = 2$, $\alpha_6 = 5$, and $\beta_t = -2$, $\alpha_t = 10$ for t in $\{1, 2, 4, 5\}$. The operating points are such that at each time period, the maximum flow is 2. By applying tighter bounds we can see that we drastically reduce the possibilities, thus the number of vertices potentially developed by dynamic programming. In Table Ia the invalid values for the total flow at each time period, with respect to bounds β_t, are marked with a cross. Table Ib is similar to Table Ia with tighter bounds $\hat{\alpha}_t$ and $\hat{\beta}_t$, the crosses being in bold to emphasize the tightening of the bounds. Table Ic follows the same representation with the tightest bounds β^*_t and α^*_t.

As previously mentioned, formulation F_{1HUC} can be improved, considering bounds β^*_t and α^*_t instead of β_t and α_t in constraints (a) and (b). We denote by F^+_{1HUC} the formulation F_{1HUC} with the bound tightening.

In the following, we consider the graph G_{KP} with the tightest bounds β^*_t and α^*_t, denoted by G^*_{KP}.

B. Optimistic heuristic

In the case of the 1-HUC, an optimistic heuristic overestimates the value of the objective function because we are solving a maximization problem. Let p be a path from time period 1 to t representing already taken decisions. The heuristic aims at computing an optimistic cost from time period $t+1$ to T. The idea of the proposed optimistic heuristic is to compute an improved linear relaxation on time periods $t+1$ to T. To do so, we define quadruplets $(t, i, val, flow)$, with t a time period, i an operating point, val the value of any arc $\big((t-1, d), (t, d+\sum_{j=1}^{i} D_j)\big)$ in G^*_{KP}, and $flow$ the value $\sum_{j=1}^{i} D_j$. The aim is to progressively increase the values of variables $x_{t,i}$ depending on their profitability, being $val/flow$.

Algorithm 1 describes how to compute a linear relaxation on time periods $t+1$ to T from a partial path in graph G^*_{KP}, as detailed in the following four steps.

Step 1: Initialize a fractional solution with $x_{t',i} = 1$ if the partial solution represented by path p requires operating point $i \leq M$ at time period $t' \leq t$, $x_{t',i} = 0$ otherwise. This step is represented by lines 1 to 8 of Algorithm 1

Step 2: Initialize a list with all the quadruplets at time period $t' \in [t+1; T]$ by decreasing profitability $val/flow$. This step is represented by lines 9 to 14 of Algorithm 1

Feasibility step 3: This step is repeated as long as lower bounding constraints (a) are not verified (the while loop at line 15 of Algorithm 1). The algorithm looks for the smallest time period t' such that (a) is not satisfied, and for $x_{t'',i}$ with $t'' \in [t+1; t']$ maximizing profitability $val/flow$. The variable $x_{t'',i}$ is increased depending on its profitability:

- If the profitability is positive, fractionally increase $x_{t'',i}$ as much as possible provided all upper bounds α are satisfied.
- Otherwise, fractionally increase $x_{t'',i}$ as little as possible provided all upper bounds and the lower bound $\beta_{t'}$ are satisfied.

All variables $x_{t'',i'} < x_{t'',i}$ with $i' < i$ must be set to the same value as $x_{t'',i}$ in order to satisfy the order constraints. Also, for any $i' > i$, quadruplets (t'',i',val',$flow'$) are updated as (t'',i',$val' - val$,$flow' - flow$). This is because as $x_{t'',i} > x_{t'',i'}$, one can increase $x_{t'',i'}$ without increasing $x_{t'',i}$ while still verifying order constraints. All variables that cannot be further increased due to the upper bounds are removed from the list.

Optimality step 4: This step is repeated as long as there is a variable of positive profitability in the list of variables (again the while loop at line 15 of Algorithm 1). Select the first variable of the list, and fractionally increase its value as much as possible provided all upper bounds are satisfied. Remove from the list all variables that cannot be further increased due to the upper bound.

Property 1. *The fractional solution returned by Algorithm 1 verifies order constraints.*

Proof. Consider two quadruplets (t,i,val,$flow$) and (t,i',val',$flow'$), with t a time period considered in the heuristic, and $i' > i$. At the start of the algorithm, $x_{t,i} = x_{t,i'} = 0$. If $x_{t,i'}$ is increased, then $x_{t,i}$ is increased by the same amount, hence order constraints are verified. If $x_{t,i}$ is increased, it means that $val/flow > val'/flow'$. Hence, $val/flow > (val' - val)/(flow' - flow)$. Consequently, the algorithm will increase $x_{t,i'}$ only if $x_{t,i} = 1$, hence order constraints are verified. □

Theorem 1. *Algorithm 1 defines an optimistic heuristic.*

Proof. Let s be an integer solution for the 1-HUC, for which variables $x_{t,i}$ verify constraints (a) (b) (c) and (f). Let $\hat{s}$ be a fractional solution for the 1-HUC obtained with Algorithm 1, for which $\hat{x}_{t,i}$ verify all constraints (a), (b) (c), and constraint (f) only for time periods 1 to $t \leq T$. Consider $\hat{s}$ and s to be identical for time periods 1 to t.

Let $\mathcal{X}$ (resp. $\mathcal{Y}$) be the variables such that $x_{t',i} < \hat{x}_{t',i}$ $\forall x_{t',i} \in \mathcal{X}$ (resp. $x_{t',i} > \hat{x}_{t',i}$ $\forall x_{t',i} \in \mathcal{Y}$).

Clearly, for each variable $x_{t',i} \in \mathcal{X}$ of positive profitability, a fractional value for $x_{t',i}$ increases the value of the objective function compared to $x_{t',i} = 0$. Similarly, for each variable in $\mathcal{Y}$ of negative profitability, a fractional value for $x_{t',i}$ increases the value of the objective function compared to $x_{t',i} = 1$.

Let $\mathcal{X}^- \subseteq \mathcal{X}$ and $\mathcal{Y}^- \subseteq \mathcal{Y}$ be the variables with negative profitability. Suppose $|\mathcal{X}^-| > 0$. By construction of $\hat{s}$, the variables of $\mathcal{X}^-$ have value greater than 0 only in order to yield a feasible solution, with respect to a lower bound $\beta_{t'}$. In such a case the total flow of $\hat{s}$ from time period 1 to t' is exactly $\beta_{t'}$ by construction of $\hat{s}$. As solution s also verifies all lower bounds, we deduce $|\mathcal{Y}^-| > 0$. Otherwise there is either a contradiction with the construction of $\hat{s}$, or s does not verify all lower bounds. Hence, the total flow of s from time period 1 to t' is at least $\beta_{t'}$. By definition, s and $\hat{s}$ are identical from time period 1 to t, consequently the only difference is on time periods $t+1$ to t'. By construction of $\hat{s}$ the variables of $\mathcal{X}^-$ are the most profitable and have fractional value in $\hat{s}$. Consequently, their weighted value in the objective function must be higher than those of $\mathcal{Y}^-$ in the integer solution s.

A similar proof can be made for variables in $\mathcal{Y}^+ \subseteq \mathcal{Y}$ and $\mathcal{X}^+ \subseteq \mathcal{X}$ the variables with positive profitability.

The value of $\hat{s}$ is then greater or equal to the value of s. □

It is possible to tighten the fractional solution returned by Algorithm 1 while keeping it optimistic. Clearly, an integer solution is necessarily of a total flow which is a combination of the flows from the operating points. Therefore the flow of an integer solution is necessarily a multiple of the greatest common divisor (GCD) of the operating points' flows. When the heuristic increases the value of a variable, we can increase or reduce this value so that the total flow of the returned solution remains a multiple of the GCD relative to the operating points' flows. Note that since the flows are identical from one time period to another, we can quickly compute the GCD by considering only the flows of a single time period.

C. HA* algorithm

For a 1-HUC with an objective function to maximize, the principle of HA* is the following. Consider a pool of partial solutions evaluated with the heuristic. At each iteration, the partial solution with the highest heuristic value is considered and removed from the pool. From the partial solution considered, we complement it by adding neighbors relative to its last vertex. Once a solution is found, its value is used as a bound to remove some more partial solutions from the pool. Indeed, if the solution's value is higher than a partial solution's heuristic

Algorithm 1 Algorithm OptimisticHeuristic

```
Require: A path $p$ from time period 1 to $t$, a graph $G^*_{KP}$, $GCD$ the GCD of the flow
Initialize a fractional solution $\hat{x}$ with all variables to 0
for $t' \in [1;T]$ and $i \in [1;M]$ do
    if $t' \leq t$ AND $p$ requires operating point $i$ at time period $t'$ then
        $\hat{x}_{t',i} = 1$
    else
        $\hat{x}_{t',i} = 0$
    end if
end for
Initialize a list $L = []$
for $t' \in [t+1;T]$ and $i \in [1;M]$ do
    $flow \leftarrow \sum_{i'=1}^{i} D_{i'}$
    $val$ the value of an arc towards $(t', i)$ in $G^*_{KP}$
    add $(t', i, val, flow)$ in $L$, sorted by decreasing $val/flow$
end for
while $\exists t' \in [t+1, T]$ such that $\hat{x}$ does not verify $\beta_{t'}$ OR exists quadruplet in $L$ with $val > 0$ do
    $(t'', i, val, flow) \leftarrow$ first in $L$ with $t'' \leq t'$
    if $val \leq 0$ then
        set $\hat{x}_{t'',i}$ to minimum such that $\beta_{t'}$ verified and $x_{t'',i}{\cdot}flow \mod GCD = 0$; if $\beta_{t'}$ cannot be verified $\hat{x}_{t'',i} \leftarrow 1$
    else
        set $\hat{x}_{t'',i}$ to maximum such that all upper bounds are verified and $x_{t'',i} \cdot flow\%GCD = 0$
    end if
    for $i' \in [1;i]$ do
        $\hat{x}_{t'',i'} = \max(\hat{x}_{t'',i'}, \hat{x}_{t'',i})$
    end for
    for $(t'', i', val', flow') \in L$ with $i' \in ]i;M]$ do
        $val' \leftarrow val' - val$
        $flow' \leftarrow flow' - flow$
    end for
    for $(t'', i, val, flow) \in L$ such that $\hat{x}_{t'',i}$ cannot be increased do
        remove $(t'', i, val, flow)$ from $L$
    end for
end while
return the value of $\hat{x}$
```

value, then the partial solution can be removed from the pool. Once the pool of partial solutions is empty, the algorithm stops and the best solution found is the optimal solution.

We underline the need of a tight optimistic heuristic. If the heuristic is not optimistic, or optimistic but too loose, there are fewer cases where one can prune partial solutions while guaranteeing optimality. Hence, more vertices are developed which can exponentially increases the computational time.

For readability purposes, we introduce three structures:

Definition 5 (Path structure)**.** The path structure has three attributes: $vertices$ the list of vertices of the path; val the value of the path with respect to the objective function; $heur$ the optimistic heuristic value.

Definition 6 (Vertex structure)**.** A vertex structure has two attributes: t the time period and d the cumulated flow $\mathcal{D}_{1,t}$, as defined for the vertices of G^*_{KP} in Section IV.

Definition 7 (Arc structure)**.** The arc structure has one attribute: val the value as defined for the arcs of G^*_{KP} in Section IV.

Algorithm 2 presents the pseudo-code of HA*, using the three previously described structures as well as $OptimisticHeuristic$. The considered graph is G^*_{KP}, which is G_{KP} as illustrated in Fig. 2a with bounds β^*_t and α^*_t. The dominance rules used in Algorithm 2 are the dominance rules 1 and 2.

Algorithm 2 Algorithm HA*

```
Require: A graph $G^*_{KP}$
Initialize a path $p$ as follows: $p.vertices = \{(0,0)\}$, $p.val = 0.0$, $p.heur = OptimisticHeuristic(p)$
Initialize a list of paths $L_p = [p]$
Initialize the value of the best solution $bestVal = -\infty$
while $L_p$ not empty do
    $p \leftarrow$ first path in $L_p$
    remove $p$ from $L_p$
    $v \leftarrow$ last vertex of $p.vertices$
    for arc $a$ from $v$ to $u$ do
        $q.vertices = p.vertices \cup u$, $q.val = p.val + a.val$, $q.heur = OptimisticHeuristic(q)$
        if $|q.vertices| = T + 1$ then
            $bestVal \leftarrow \max(bestVal, q.val)$
            remove $q' \in L_p$ with $q'.val + q'.heur \leq bestVal$
        else
            $dom \leftarrow FALSE$
            for $q' \in L_p$ do
                if $q'$ dominates $q$ then
                    $dom \leftarrow TRUE$
                end if
                if $q$ dominates $q'$ then
                    remove $q'$ from $L_p$
                end if
            end for
            if $dom = FALSE$ and $q.val + q.heur > bestVal$ then
                add $q$ in $L_p$ by keeping $L_p$ sorted by decreasing $q.val + q.heur$
            end if
        end if
    end for
end while
return the solution of value $bestVal$
```

VI. Experimental results

Results are computed on a single thread of an Intel(R) Core(TM) i7-9850H CPU @ 2.60GHz processor, with 2 CPUs of 8 cores, with Linux as operating system. All algorithms are developed with C++. Version 12.8 of CPLEX with default setting is used to solve the MILP formulation F_{1HUC}.

A. Instances

From a large set of realistic instances derived from a real EDF plant, a first set A of 13 instances is obtained. These 13 instances are retained as preliminary results have shown that formulation F_{1HUC} is not trivially solved. This emphasizes the need of an efficient alternative in these cases. Table II depicts for each instance the main characteristics, namely the number of time periods, the number of operating points and the presence of a constraining minimum (resp. maximum) bound on the volume at the last time period. The instances cover three cases, namely when there is only an upper bound, only a lower bound, or a target volume with a constraining upper and lower bound. In the case of an equality constraint, the instance becomes infeasible, which is out of the scope of the instances considered in this paper. Hence, the target volumes are not equality constraints, but rather tight window constraint. For instances with a target volume, more resource window constraints are obtained by propagating the bounds β^* and α^* from the bounds at the last time period to the previous ones.

The water flows D and powers P are in the order of 10^3 to 10^4, with volumes in the order of 10^7. For target volumes, the difference between the upper and lower bound is in the order of 10^3, which is small enough with respect to the flows to yield very few vertices at time period T in G^*_{KP}.

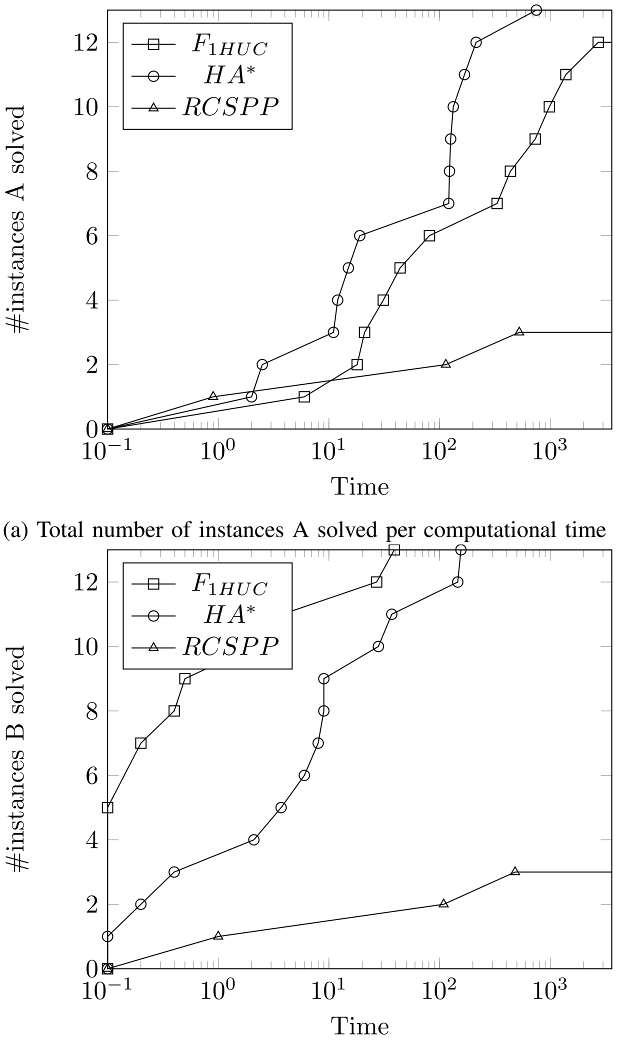
TABLE II: Main characteristics of instances set A

instance	T	M	minimum volume	maximum volume
1	96	4	✗	✓
2	96	4	✓	✗
3	96	4	✓	✓
4	96	7	✗	✓
5	96	7	✓	✗
6	96	7	✓	✓
7	96	8	✗	✓
8	96	8	✓	✓
9	96	15	✗	✓
10	96	17	✗	✓
11	96	18	✓	✗
12	96	21	✗	✓
13	96	18	✗	✓

A second set B of 13 instances, similar to the first set, is also constructed. The only differences are bounds β_T and α_T that are shifted as follows. Let an instance with bounds β^A_T and α^A_T be in set A. A random value $k \in [-9999; -1000] \cup [1000; 9999]$ is chosen. Bounds of an instance for set B are $\beta^B_T = \beta^A_T + k$ and $\alpha^B_T = \alpha^A_T + k$. Note that this shift is very small for these instances. Indeed, the water flows can be in the order of 10^4, there are nearly 100 time periods and the cumulated flow $\mathcal{D}_{1,T}$ is in the order of 10^6. The shift k is at most 1% of $\overline{\mathcal{D}}_{1,T}$. As shown in the following results, slightly modifying an instance can drastically impact the computational time.

B. Experimental results

In order to benchmark HA*, all instances are solved with HA* as well as with two alternative methods. The first alternative is a classical RCSPP algorithm [12] adapted to the 1-HUC [11]. The second alternative is to use CPLEX to solve F_{1HUC} described in Section III. A third alternative is solving F^+_{1HUC}, which is formulation F_{1HUC} described in Section III with tighter bounds described in Section V-A. However, solving F^+_{1HUC} leads to very similar results to F_{1HUC}, hence results for F^+_{1HUC} are not included in the following. All algorithms use a single thread, with a time limit of one hour.



(a) Total number of instances A solved per computational time

(b) Total number of instances B solved per computational time

Fig. 3: Total number of instances A and B solved per computational time

Figures 3a and 3b represent the number of instances solved by each algorithm with respect to the computational time.

Clearly, for instance set A, HA* is the most efficient alternative. Indeed, it solves every instance and requires less time than the other alternatives. For instance set B, solving F_{1HUC} is the most efficient alternative. Note that the difference between the solving times of F_{1HUC} and HA* is only of a few seconds for instance set B, as most instances are solved in less than 10 seconds with HA*. Solving F_{1HUC} is the least robust alternative when it comes to computational times. Indeed, when comparing the results between instance sets A and B, the computational times are drastically different with F_{1HUC}, whereas for HA* there is a smaller difference, and for the RCSPP algorithm the results are the same. The RCSPP algorithm fails to solve 10 out of 13 instances, for both instance sets A and B. This shows that the RCSPP algorithm is inefficient at solving the 1-HUC. We further explain the results in the following, by introducing Tables III and IV with detailed results.

Tables III and IV give, for each instance, the value of the objective function and the computational times obtained for all algorithms, as well as the optimality gap and the number of Branch & Bound nodes returned by the MILP solver. If the MILP solver proves optimality, the gap is noted "opt". When the time limit is reached, the time is noted "-". Results are presented for each instance individually, as well as the average (avg) and the standard deviation (sd) for the solved instances. When the time limit is reached, a computational time of 3600 seconds is accounted for in the average and the standard deviation. The computational time of the most efficient algorithm is emphasized in bold for each instance, as well as the average and the standard deviation for each set of instances.

There is a clear difference in computational time between set A and B. Indeed, F_{1HUC} is solved for 12 out of the 13 instances of set A, and needs between 6 and 2713 seconds, while it is solved for all instances of set B, most of them instantaneously. Similarly, HA* solves all instances of set A and needs between 2 and 748 seconds, while it solves all instances of set B in less than 156 seconds. Note however that there is no noticeable computational time difference between solving instance set A and B with the RCSPP algorithm.

The RCSPP algorithm is only able to solve instances 2, 5 and 11, for both sets. This is because for any other instance, the maximum volume of the upstream reservoir is constrained at the last time period. In this case, the value β_T becomes positive, meaning that there is a minimum bound on the resource. As mentioned in [3], when there is a minimum bound on the resource, the dominance properties of the RCSPP algorithm cannot always be applied, thus leading to large computational times. Clearly, HA* outperforms the RCSPP algorithm. Even when there is no minimum bound on the resource, the RCSPP algorithm yields larger computational times for all instances of set B and instance 5 of set A.

When comparing HA* algorithm to solving F_{1HUC} on the most difficult instances, the former outperforms the latter in terms of computational time and number of instances solved. On the one hand, HA* is more stable with respect to the computational times. Indeed, HA* only requires more than 10 minutes once (instance 12 of set A), while solving F_{1HUC} requires more than 10 minutes for 5 of the 26 instances (instances 1, 3, 10, 11 and 12 of set A). Moreover, F_{1HUC} is not solved to optimality for instance 12 of set A, and the best value found is not the optimal value obtained with HA*. On the other hand, solving F_{1HUC} appears to be more efficient on easier instances than HA*. In this case, there are numerous instances where the difference between the two approaches is within a few seconds (instances 1, 2, 3, 4 and 6 of set B).

The stability with respect to the computational time is noticeable on the average and standard deviation. Indeed, the average time difference between set A and B is much smaller for HA* than for the MILP solver. The standard deviation for HA* is much smaller on set A, and slightly higher for set B when compared to solving F_{1HUC}. Besides, one can compute the total average and total deviation of the resolution time for all 26 instances. The total average time and standard deviation are 402.1 seconds and 873.7 seconds for the MILP solver, and 80.3 seconds and 149.0 seconds for HA*.

VII. Conclusion

In this paper, the HA* algorithm is proposed as an exact variant of the A* algorithm dedicated to the 1-HUC. It has been adapted through a dedicated optimistic heuristic and a bound tightening pre-processing, propagating lower and upper bounds from any time period to another. On a set of realistic instances, algorithm HA* is shown to be both more stable and more efficient on average in terms of computational times compared to solving F_{1HUC}. Also, HA* outperforms the standard labeling algorithm for the RCSPP.

A natural direction for a future work would be to extend the proposed algorithm in order to take into account additional constraints of the 1-HUC. A promising perspective is to include the HA* algorithm in a decomposition of a hydraulic valley with multiple plants. Beyond the HUC, another interesting perspective could also be to try and generalize such an algorithm for other problems with window resource constraints.

***Abstract*—Performing data mining tasks in the medical domain poses a significant challenge, mainly due to the uncertainty present in patients' data, such as incompleteness or missingness. In this paper, we focus on the data mining task of clustering corticosteroid (CS) responsiveness in sepsis patients. We address the issue and challenge of missing data by applying Game-Theoretic Rough Sets (GTRS) as a three-way decision approach. Our study considers the APROCCHS cohort, comprising 1240 sepsis patients, provided by the Assistance Publique–Hôpitaux de Paris (AP-HP), France. Our experimental results on the APROCCHS cohort indicate that GTRS maintains the trade-off between accuracy and generality, demonstrating its effectiveness even when increasing the number of missing values.**

I. Introduction

DUE TO its high mortality, incidence, and morbidity, sepsis is regarded as one of the most serious diseases that impact people's lives. The Third International Consensus Definition for Sepsis and Septic Shock (Sepsis-3), in 2016, defined sepsis as a "life-threatening organ dysfunction resulting from dysregulated host responses to infection" [1]. Immunologically, the human body releases some immune chemicals into the blood to fight the encountered infection. These released substances cause extensive inflammation, resulting in blood clots and leaking blood vessels. As a consequence, blood flow is disrupted, depriving organs of nutrition and oxygen, and hence, resulting in organ damage. The Sequential Organ Failure Assessment (SOFA) score [2] is used to codify the degree of organ dysfunction. It is difficult to estimate the global burden of sepsis. The study conducted in [3], estimated that in 2017 there were 48.9 million cases and 11 million sepsis-related deaths all over the globe, which accounted for almost 20% of all global deaths. There is no current diagnostic test for sepsis.

Knowing that there are still no specific interventions to control immune responses to invading pathogens [4], for sepsis, researchers have looked at the biological underpinnings of sepsis to see if there are any treatments that could help. Because of their impact on the immune system, corticosteroids have received a lot of attention [5]. The hormonal route from the hypothalamic-pituitary gland to the adrenal glands promotes corticosteroid synthesis in sepsis [6], [7]. These hormones affect inflammation through the formation of white blood cells, cytokines, and nitric oxide. The timing of corticosteroid administration may be a key component in therapy response. Short-term mortality was found to be higher in observational studies when hydrocortisone was started later. It is expected that corticosteroid treatment is advantageous for sepsis patients for these reasons and that variations in dose, timing, or duration of corticosteroid treatment may alter the patient response to treatment differently [8].

This paper delves into the data mining task [9] of clustering corticosteroid (CS) responsiveness in sepsis patients using the APROCCHS cohort provided by Assistance Publique–Hôpitaux de Paris (AP-HP), France. The cohort includes 1240 sepsis patients. A key challenge in this task is the presence of missing data.

Grouping data with missing values is one of the primary difficulties in clustering. There are commonly two strategies to deal with missing values [10]. The first strategy is based on preprocessing techniques [11]. Generally, it adopts deleting the whole row containing missing values or replacing the missing values based on experts' rules [12]. Some common missing values imputation techniques include replacing missing values with the mean, median, or mode of the available data for that feature [13]. The hot Deck Imputation method is replacing missing values by randomly selecting a value from another similar data point in the same dataset [14]. Using the values of K-nearest neighbors in the feature space to estimate the missing value [15]. Linear Regression Imputation aims to predict the missing values using linear regression based on other variables in the dataset [16].

The process of filling in missing values can potentially introduce a significant amount of imputation bias and uncertainty. It is important to recognize that missing values can be informative and carry meaningful implications. In certain instances, the absence of data itself can convey valuable information or signify a particular category or state. Imputing these missing values may result in distorting the original meaning or introducing artificial patterns into the dataset. In such situations, it is advisable to treat the missing values as a distinct category or conduct a separate analysis specifically on the subset of data that contains missing values. Also, imputation during preprocessing has reportedly been found to compromise the accuracy and consistency of classification outcomes. Thus, these methods are not recommended specifically when we deal with medical data because they can bias the medical results.

The second strategy relies on incorporating mechanisms in the clustering model [17] which means that we will not impute or preprocess the missing values, but the internal functioning of the algorithm will handle automatically the missing values. Examples of works belonging to this strategy are [18] which allocated missing value objects to a cluster with a large number of missing values and [19] which assigned objects containing missing data to clusters based on their neighbors.

Moreover, the theory of rough sets provides a valuable framework for analyzing incomplete information through the use of approximations [20]. This approach allows us to delve into the realms of uncertain and imprecise data, aiding in our understanding of complex systems. According to the research conducted by [21], the application of rough set theory has been observed across various fields and domains. In [22], authors integrated the Variable Precision Rough Set (VPRS) approach with Bayesian principles. In [23], the idea is to combine VPRS with fuzzy rough set methods to create flexible decision rules. In essence, both papers share a common objective of tackling information imprecision by employing probabilities (within the framework of VPRS) and fuzziness (which allows for handling partial matching of rules' antecedents). Their ultimate aim is to derive interpretable decision models from the available data. Authors in [24] introduced the Learn++.MF, an innovative ensemble-of-classifiers algorithm designed to address the challenge of missing features in supervised classification. It creates an ensemble of classifiers, each trained on a random subset of available features. When classifying instances with missing values, the algorithm employs majority voting from classifiers that were trained without the missing features. The study demonstrates that Learn++.MF effectively handles significant amounts of missing data, with only a gradual decline in performance as the missing data increases. In biomedicine and healthcare, rough set theory has been applied for disease diagnosis [25], medical image analysis [26], and patient profiling [27].

Focusing on the second strategy, mentioned above, and tackling the challenge of missing data in sepsis patients' records, we apply Game-Theoretic Rough Sets (GTRS) as a three-way decision approach. The aim is to assign patients with incomplete records to the appropriate clusters automatically. In order to study the efficiency of the algorithm application on our clinical data, we aim to answer the following research questions:

- **RQ1:** How can the percentage of missing values affect the performance of the algorithm?
- **RQ2:** Does the k nearest neighbors has an impact on the results?
- **RQ3:** Can the percentage of increasing and decreasing initial values of α and β influence the results?

The rest of this paper is structured as follows. Section II presents the fundamentals of three-way decisions using GTRS. Section III details the application of GTRS, as a three-way decision approach for handling missing data, for clustering CS-responsiveness in sepsis patients. The experimental setup is introduced in Section IV. The results of the performance analysis are discussed in Section V, and conclusions are presented in Section VI.

II. Three-way decisions using rough sets

A. Three-way clustering

The theoretical foundation of three-way clustering is based on the theory of three-way decisions introduced by Yao [28]. Assuming the existence of a set $U = \{o_1, o_2, o_3, ...\}$ which is referred to as the universe of objects, a clustering method will produce a collection of sets $\{c_1, c_2, c_3, ...\}$, where each set c_k contains a group of objects belonging to that specific cluster. Every object o_i in the set has A attributes, represented as $o_i = (o_i^1, ..., o_i^A)$, with o_i^a indicating the value of the a^{th} attribute associated with the i^{th} object.

In traditional clustering, a cluster is usually represented by a single set, indicating that objects within the set definitely belong to a cluster and those outside the set definitely do not belong to it. In situations characterized by uncertainty and a lack of information, two-way decisions are not always feasible from a decision-making perspective, such as in the case of clustering.

A practical and reasonable alternative is to adopt a three-way decision approach, which introduces three options for decision-making, rather than the traditional binary choice. Specifically, we can decide whether an object belongs to a cluster, whether it does not belong to a cluster, or whether it is uncertain whether the object belongs to a cluster or not. This concept of three-way decision-making leads to what is known as three-way clustering.

To define three distinct regions - inside, partial, and outside - an approach involving an evaluation function and a set of thresholds can be employed. The evaluation function quantifies the association or correlation between an object and a cluster, while the thresholds set limits on this relationship for inclusion in each of the regions. Let $e(c_k, o_i)$ be an evaluation function that represents the association between a specific cluster c_k and an object o_i, and let (α, β) be a pair of thresholds. The three regions are defined as follows.

$$Inside(c_k) = \{o_i \in U | e(c_k, o_i) \geq \alpha\}, \tag{1}$$

$$Outside(c_k) = \{o_i \in U | e(c_k, o_i) \leq \beta\}, \tag{2}$$

$$Partial(c_k) = \{o_i \in U | \beta < e(c_k, o_i) < \alpha\}, \tag{3}$$

This means that when the evaluation of an object is equal or above the threshold α, it is considered to be part of the Inside(c_k) group. Conversely, if the evaluation is at or below the threshold β, the object is regarded as being in the Outside(c_k) group. If the object's evaluation falls between the two thresholds, it is included in the Partial(c_k) group. Thus, inclusion in distinct regions is governed by the thresholds (α, β), and varying their settings results in different regions. The automatic determination of these thresholds is a crucial research topic in this context.

In this regard, and based on the work proposed in [29], we utilize the three-way framework to handle data with missing values which involves three steps. The overall functioning is presented in Figure 1. Initially, the set of objects U is partitioned into two sets: C and M. Set C comprises objects that have no missing data, while set M contains those that have missing values. Objects in set C are clustered using conventional algorithms, such as K-means [30], under the assumption that since these objects have no missing values, the level of uncertainty is low, and conventional approaches are more suitable for clustering such objects (Figure 1 (1)).

The second step (Figure 1 (2)) involves creating an incomplete data set from C while maintaining a similar rate of missing values to that of dataset U. For instance, if 30% of objects in the original dataset has missing values, approximately 30% of objects will be randomly chosen from C to induce missing values. This results in partitioning C into two additional sets: the constructed dataset comprising objects with missing values denoted as U_m, and the remaining objects in C with no missing values designated as U_c. This step assists in selecting appropriate values for (α, β) thresholds that will enable the clustering of objects with missing values.

The third step (Figure 1 (3)) involves determining the inclusion of objects with missing values, denoted as M, in the three-way framework. To employ three-way clustering on data with missing values, it is necessary to calculate the evaluation function $e(c_k, o_i)$, as specified in Equations 1, 2, and 3. This function measures the association between an object o_i and cluster c_k and can be defined in various ways. In our case, and as proposed in [29], we utilize an evaluation function that is based on the proportion of nearest neighbors for object o_i that belongs to cluster c_k:

$$e(c_k, o_i) = \frac{\text{Number of } o_i \text{ neighbors belonging to } c_k}{\text{Total neighbors of } o_i} \tag{4}$$

In order to determine the neighbors, a specific distance metric is required. For this example, we utilize the euclidean distance as follows:

$$d(i, j) = \sqrt{\sum_{a=1}^{A} \left(O_i^a - O_j^a\right)^2} \tag{5}$$

Here, o_i^a represents the value of the a^{th} attribute of the i^{th} object and any attributes with missing values are disregarded during distance computation. By utilizing the aforementioned distance metric, it is possible to calculate the distances of each o_i with missing values from all objects in U_c. After sorting these distances, the nearest neighbors for each o_i can be determined. Upon sorting these distances, the nearest neighbors can be identified. After determining the evaluation functions, Equations 1, 2, and 3 can be employed to determine the inclusion of objects into one of the three regions.

The goal of this approach is to enhance the clustering quality of data containing missing values. In this regard, two metrics need to be calculated based on the thresholds (α, β) as follows:

$$Accuracy(\alpha, \beta) = \frac{\text{Correctly clustered objects}}{\text{Total clustered objects}}, \tag{6}$$

$$Generality(\alpha, \beta) = \frac{\text{Total clustered objects}}{\text{Total objects in } U} \tag{7}$$

where *Accuracy* refers to how well we cluster objects with missing values, whereas *generality* refers to the fraction of objects that were clustered in the first place. Thus, as defined in [29], this goal can be approached from the perspective of a trade-off between accuracy and generality of the clustering.

B. Game theoretic rough sets

GTRS is based on a game-theoretic concept and formulation to estimate thresholds of the three-way decisions [31], [32]. The thresholds are interpreted based on a trade-off solution between numerous criteria used to analyze rough sets in a game scenario [33], [32]. Specifically, to increase the overall quality of three-way decisions, GTRS formulates strategies for players in the form of adjustments in thresholds. Each player contributes to the game by configuring the thresholds in order to optimize the game's benefits/rewards and utilities. The overall goal of a game in GTRS is to choose appropriate thresholds for three-way decisions with respect to the available criteria and presented information.

In GTRS (Figure 1 (4)), a typical game consists of three main elements: (i) game players, (ii) strategies, and (iii) payoff or utility functions. These components are usually defined as a tuple $\{P, S, u\}$, where [34]:

- **Game players:** The game players are denoted by a set P. The players in the game are selected to reflect the overall purpose of the game.
- **Strategies:** In the game, each player contributes by playing different strategies. The set of strategies available to player i is denoted by S_i. All possible strategy sets are denoted by the following Cartesian product: $S = S_1 \times S_2 \times \ldots \times S_n$, where S contains ordered pairs of the form $(s_1, s_2, \ldots, s_n)$ such that $s_1 \in S_1, s_2 \in S_2$ and $s_n \in S_n$. Each ordered pair in S is called a *strategy profile* and represents a certain situation encountered in a game.
- **Payoff functions or utility:** The payoff function, also called utility, for the players are defined via a set $u = (u_1, \ldots, u_n)$; where each u_i represents a real-valued utility function for player i and it maps the strategy profiles to real values ($u_i : S \mapsto \Re$). The payoffs reflect the utilities of performing or selecting a specific strategy.

Every player in a game seeks to execute a strategy that maximizes its payoff. The players' strategies, on the other hand, have an impact on their opponents' payoffs. The game solution is used to select a balanced and trade-off point based on all players' utilities. The *Nash equilibrium* is generally used to determine game solution or game outcome in GTRS.

Let us consider a strategy profile $s_{-i} = (s_1, s_2, \ldots, s_{i-1}, s_{i+1}, \ldots, s_n)$. s_{-i} is a strategy profile of all the players in the game except player i, and which can be further denoted as $s = (s_i, s_{-i})$. This means that all the players except i are committed to play s_{-i} and player i choosing s_i. The strategy profile $(s_1, s_2, \ldots, s_n) = (s_i, s_{-i})$ is a Nash equilibrium, when [35],

$$\forall i, \forall s_i^{'} \in S_i, u_i(s_i, s_{-i}) \geq u_i(s_i^{'}, s_{-i}), where(s_i^{'} \neq s_i) \quad (8)$$

This means that for all players i, their respective strategies, i.e., s_i is the best response to s_{-i}. In other words, a strategy profile constitutes a *Nash equilibrium* when no player is benefited from changing his/her strategy alone. The description presented above formulates a game in GTRS. It is to be noted that we may not be able to reach effective thresholds that meet the demands of the underlying applications with a single and non-repeated game. We, therefore, need to play the game several times; where in each play the goal is to keep modifying and refining the thresholds until we attain certain performance goals; e.g., a balance between accuracy and generality. The GTRS seeks an appropriate design of the threshold levels that are used in the three-way decisions framework, presented in Section II-A, by forming a game and applying concepts such as game solution and repeating games.

III. Application

A. Data Source

RECORDS[1] is a European research project that aims to quickly detect whether a patient is sensitive or resistant to the treatment of sepsis with corticosteroids. The project's clinical trial is an adaptive clinical trial that evaluates the efficacy of biomarkers and machine learning algorithms in defining patients' corticosteroid resistance, with the goal of optimizing their management. The project has adopted a distinctive approach to effectively analyze the severity of sepsis cases by collecting data on patients' demographics, health outcomes, and samples. This data collection has resulted in the creation of a first sepsis cohort, known as APPROCHS, which serves as an exceptional resource for medical research.

The paper considers the APROCCHS cohort that has been provided by the Assistance Publique–Hôpitaux de Paris (AP-HP) which is the university hospital trust operating in Paris, France, and its surroundings. It is the largest hospital system in Europe and one of the largest in the world. The goal of the cohort is to allow the investigation of qualitative interactions between clinical phenotypes and survival benefits or harms from corticosteroids (CS), i.e., to permit defining sensitivity and resistance to CS.

B. Data Description

The APROCCHS cohort gathers 1240 adult septic shock patients who are treated with or without CS. Each patient is characterized by 5645 features, also, called *risk factors* reflecting characteristics until Day 90.

Data were collected with a specification indicating whether the patients were treated with corticosteroid or with a placebo. A placebo is a substance or treatment that is given in the same manner as an active drug or treatment being tested but does not have any active ingredients or therapeutic effects [36].

C. Data Pre-processing

In this section, we explain the different data pre-processing tasks that we have performed on the APROCCHS cohort, namely: feature selection, data enrichment, data labeling and data cleaning.

1) Feature selection: Because sepsis is a time-sensitive disease, the likelihood of survival is significantly increased by early detection and treatment. This study focuses on using variables accessible at the earliest stage, especially at Day 0 of hospitalization, for predicting patients' responsiveness to corticotherapy in order to optimize accurate intervention. Specifically, from the initial pool of 5645 features –which reflects features from Day 0 until Day 90–, and by focusing only on features at Day 0, we were able to carefully choose a selection of 24 critical attributes following significant consultation with the respected medical specialists at APHP. This selection procedure entailed careful study and examination of each feature's relevance and significance in regard to our research with respect to the guidance and experience of the APHP healthcare experts.

The collected data is divided into two categories: static and dynamic. The first category includes information on the patient's current condition as well as personal information such as identification number, sex, weight, age, origin, date of hospitalization, and whether or not an antibiotic was administered before Day 0. These traits are noted at the time of admission and remain constant during hospitalization. The second category consists of dynamic elements that can be captured once or more times daily during hospitalization and are related to patient vital signs and laboratory testing. Admission type, infection date, infection place, and examination type are a few examples of dynamic characteristics that have only been once recorded. These data are often gathered before administering treatment. The sequential organ failure assessment (SOFA) score [37], ventilation, vasopressor use, and prescribed therapy dose are a few examples of characteristics that were recorded during the whole hospital stay and are associated with patients' responsiveness to treatment.

2) Data enrichment: Data enrichment relies on the process of adding new variables based on pre-existing ones in order to further explain the data and increase the precision of prediction algorithms. It improves detecting previously hidden relationships and patterns in the data. Following the guidelines of the APHP medical specialists, we generated the variable AR_INF_Type, which represents the source of infection and which was obtained from the diagnosis date and the hospital admission date variables. Furthermore, the values of the cortisol variable have been adjusted using a dataset that was given

[1] https://www.fhu-sepsis.uvsq.fr/rhu-records-4

by medical professionals and provides appropriate values for this characteristic. For a proper diagnosis and treatment plan, it is essential to know whether a patient received an antibiotic before being brought to the hospital. The medical staff's choice of the proper doses for the patient during their hospital stay will depend on this information, in addition to the machine learning model. A new feature entitled "ANTIBIOTIC" was created in order to acquire this information. A value of 1 of this characteristic implies that the patient took an antibiotic while a value of 0 means that he/she did not. The new variable "ANTIBIOTIC" comprises information on 690 patients who did not receive antibiotics prior to admission to the hospital and 550 patients who did.

3) Data labelling: For a patient who is enrolled in the study on Day 0, either corticosteroid medication or a placebo is administered every 4 to 6 hours while a number of features that indicate the patient's improvement are tracked. Daily feature values are recorded while each patient is observed for 90 days. The APHP healthcare experts have created precise standards for figuring out whether a patient would benefit from corticotherapy or not. Patients are specifically categorized as cortico-sensitive (i.e., responders) if all four of the following conditions are satisfied after 14 days of therapy:

- The patient survived.
- For at least 24 hours, there has been no vasopressor treatment.
- For at least 24 hours, the patient has been off of mechanical ventilation.
- The SOFA score is under 6.

The patient is generally considered cortico-resistant or a non-responder if the conditions are not satisfied, which is regarded a negative therapy response. As a result, the label is set to 1 or 0, indicating whether or not the patient reacted to the therapy on Day 14. Finally, patients who did not adhere to the aforementioned rule were eliminated from the cohort, leaving 1234 patients. This was done to preserve the integrity of our data and in accordance with the guidelines provided by medical specialists. The distribution of patients in the APPROCCHS cohort is shown in Table I.

4) Data cleaning: Particularly in important domains such as health, data cleaning and feature engineering are crucial steps in the data analysis process. These aspects have a significant impact on the decision-making process and the performance and accuracy of machine learning models. Dealing with the raw sepsis data that was gathered presented multiple challenges for this investigation. The APROCCHS cohort has a low rate of duplicate data, but in order to have accurate results with the three-way approach clustering, we have dropped duplicated patients. As a result, 1233 sepsis cases were still included in the cohort.

D. Three-way clustering with Game-theoretic rough sets

In this section, the application of the three-way clustering with GTRS, recently proposed in [29], is demonstrated using the pre-processed APROCCHS cohort. The objective is to cluster sepsis patients into two groups to reflect their responsiveness or not to CS while the model internally handles missing values.

1) Missing data description and handling: The only data pre-processing step that was not applied so far to the APROCCHS cohort is the task of handling missing values. As previously mentioned in Section I, the fact of imputing (replacing) or deleting the tuples containing missing values may significantly influence the conclusions drawn from the applied data mining task; specifically when it comes to a sensitive and critical domain as such is the medical domain. Pre-processing missing values may jeopardize the quality and reliability of the machine learning results; which is in our case the clustering task. As mentioned in Section I, a more appropriate and suitable strategy, to handle missing values, is to equip the clustering model with a mechanism able to handle data with missing values. In our study, this will be achieved by applying GTRS for three-way clustering.

However, it is still important to mention that, with respect to the medical experts' guidelines, some missing values had to be filled based on the following received recommendations:

- *Risk factors which are tied to the vasopressor treatment, life status, mechanical ventilation, and SOFA score:* Replace the missing value found at Day_i using the same non-missing value which is registered at Day_{i-1}. This is explained by the fact that if the value has not been registered at Day_i then this means that there has been no change in the patient's risk factor at Day_{i-1}.
- *The label:* To ensure the data's integrity and in accordance with the guidelines of medical experts, some patients have been updated from cortico-sensitive to cortico-resistant.

By applying these guidelines, the APROCCHS cohort still witnesses some missing values. These are distributed over 7 risk factors which are tied to the *KNAUS* score indicating the impact of a disease (i.e., sepsis) on the patient's activities, the *MACCABE* score indicating the presence of an additional fatal disease and its severity, the *SOFA* score in the last 3 hours after admission to intensive care, the *body temperature* at the entrance to the unit of intensive care, the *severity index*, the *glycemic index*, and the *blood lactate level*.

These will be taken care of at the GTRS clustering model level instead of modifying the data itself, i.e., will neither be imputed nor deleted; as will be explained in the next sections.

2) Game formalization: As described in Section II-B, the players, the strategies, and the payoff or utility functions, are the three components which are needed to be defined to analyze problems with GTRS. The game formalization is as follows:

a) The objective of the game: The aim of this game is to improve the clustering performance of datasets with missing values. As stated in [29], this objective can be achieved by balancing the accuracy and generality of the clustering, as described by Equations 6 and 7.

b) The players: The game's ultimate objective and goal should be reflected in the players. In this regard, the players in this game present the clustering's accuracy and generality

TABLE I
DISTRIBUTION OF PATIENTS IN APPROCCHS

Cohort		APPROCCHS		
Group	Features	Sensitive/Improved	Resistant/Not improved	Total
Corticosteroid	5645	233	379	612
Placebo		213	409	622
Total	5645	446	788	1234
Characteristic		APPROCHS randomized controlled trial		

features. Let A denote player *Accuracy* and let G denote the player *Generality*. P = {A, G} represents the player's set.

c) The strategies: The strategies denote the different actions that a player can take in a game. To maximize her/his rewards/benefits, each player adopts a strategy. As demonstrated in [29], when different thresholds are used in the game, the properties of accuracy and generality are influenced differently. Consequently, changes and variations in thresholds can be considered as feasible strategies. Three strategies are considered in our context:

- Decreasing the threshold α — defined as $(\alpha \downarrow)$
- Increasing the threshold β — defined as $(\beta \uparrow)$
- Decreasing α and increasing β simultaneously — defined as $(\alpha \downarrow \beta \uparrow)$

d) The utility functions: The outcomes of choosing a specific strategy are measured using a payoff function. The utility function is defined to reflect a player's potential performance gains or benefits from pursuing a specific strategy. As previously mentioned, different threshold values effect the two players A and G. Considering a certain strategy profile, say (s_m, s_n) leading to thresholds (α, β), the associated payoffs of the players are described as follows:

$$u_A(s_m, s_n) = Accuracy(\alpha, \beta), \tag{9}$$

where u_A is the payoff function of player A, and $Accuracy(\alpha, \beta)$ is defined in Equation 6, and

$$u_G(s_m, s_n) = Generality(\alpha, \beta), \tag{10}$$

where u_G is the payoff function of player G, and $Generality(\alpha, \beta)$ is defined in Equation 7.

For player A and player G, a value of 1 refers to a maximum utility while a value of 0 reflects a minimum payoff.

3) The trade-off between accuracy and generality:

a) Determining the Nash equilibrium: The game is viewed as a competition between the accuracy and generality measures of clustering. This is highlighted in Table II, where the table's rows refer to the strategies of player A and the columns refer to the strategies of player G. Each cell in Table II corresponds to a strategy profile, (s_m, s_n), where s_m represents player A's strategy and s_n represents player G's strategy. The goal of each player is to choose a strategy that configures the (α, β) thresholds in order to maximize her/his utility. $u_A(s_m, s_n)$ and $u_G(s_m, s_n)$ are the payoffs for players A and G, respectively, according to the strategy profile (s_m, s_n).

The logic in a game is that a player chooses a strategy with a larger payoff over other strategies with a lower payoff. For the two-player game under consideration, a strategy profile will be Nash equilibrium, with respect to the definition given in Equation 8, if,

$$Accuracy : \forall s_m \in S_A, u_A(s_m, s_n) \geq u_A(s_m^{'}, s_m), \tag{11}$$

where $(s_m^{'} \neq s_m)$, and

$$Generality : \forall s_n \in S_G, u_G(s_m, s_n) \geq u_G(s_m, s_n^{'}), \tag{12}$$

where $(s_n^{'} \neq s_n)$. This signifies that no player will gain from changing her/his strategy other than the strategy specified by the profile (s_m, s_n).

b) Determining the changes in the thresholds: Essentially, there are four ways for changing the thresholds (α, β) [29]:

1) A single player proposes to decrease the value of α — denoted as $(\alpha-)$;
2) Both of the two-game players propose to decrease the value of α — denoted as $(\alpha--)$;
3) A single player proposes to increase the value of β — denoted as $(\beta+)$;
4) Both of the two-game players propose to increase the value of β — denoted as $(\beta++)$;

These four ways can be used to associate threshold pairs with a certain strategy profile. For example, a strategy profile with (s_2, s_2) which is equal to $(\beta \uparrow, \beta \uparrow)$ is represented as $(\alpha, \beta++)$, since player A and player G propose to increase the value of β.

4) The learning mechanism defining the values of the thresholds: A single game run has minimal utility in terms of finding appropriate values for the (α, β) thresholds. A learning process will emerge as a result of iteratively changing the thresholds with the goal of improving the payoffs for the players. In this regard, the learning rule or criterion is based on the relationship between threshold modification and the influence on the players' utility. This relationship is used to define the four variables $(\alpha-, \alpha--, \beta+, \beta++)$. This is accomplished through the use of an iterative game.

Let (α, β) be the initial thresholds for a particular iteration of an iterative game. As previously mentioned, the Nash equilibrium will be utilized to compute and decide the game solution as well as the associated thresholds; which will be denoted as (α', β'). The four variables $(\alpha-, \alpha--, \beta+, \beta++)$ are calculated based on a fixed percentage of either increasing or decreasing the strategies' values in every iteration. For example, if the initial values of (α, β) = (1, 0), the percentage of increasing and decreasing the strategies is equal to 5%, and

TABLE II
PAYOFF TABLE FOR THE GAME.

		Generality (G)		
		$s_1 = \alpha\downarrow$	$s_2 = \beta\uparrow$	$s_3 = \alpha\downarrow\beta\uparrow$
Accuracy (A)	$s_1 = \alpha\downarrow$	$u_A(s_1, s_1)$, $u_G(s_1, s_1)$	$u_A(s_1, s_2)$, $u_G(s_1, s_2)$	$u_A(s_1, s_3)$, $u_G(s_1, s_3)$
	$s_2 = \beta\uparrow$	$u_A(s_2, s_1)$, $u_G(s_2, s_1)$	$u_A(s_2, s_2)$, $u_G(s_2, s_2)$	$u_A(s_2, s_3)$, $u_G(s_2, s_3)$
	$s_3 = \alpha\downarrow\beta\uparrow$	$u_A(s_3, s_1)$, $u_G(s_3, s_1)$	$u_A(s_3, s_2)$, $u_G(s_3, s_2)$	$u_A(s_3, s_3)$, $u_G(s_3, s_3)$

a strategy profile with (s_1, s_2) which equals to ($\alpha\downarrow, \beta\uparrow$) is represented as ($\alpha-$, $\beta+$). The new values of (α, β) = $(0.95, 0.05)$. The process can be halted once a satisfactory level of performance has been attained.

IV. Experiment setup

In this section, we will present a comprehensive description of the experimental setup for the three-way clustering with the GTRS approach to cluster Corticosteroid sensitivity with missing values.

A. Considered cohort

The used APROCCHS cohort includes patients who received corticotherapy and placebo treatment. A total number of 1233 patients is maintained after selecting the most important features, applying data enrichment, labeling the data, and deleting the duplicates (1 duplicate raw was found in the data and was deleted). In our preliminary study, and based on a ranking strategy, we worked with only 10 risk factors, presented in Table III, among the 24 features. The initial APROCCHS dataset contains 26 instances having missing values (i.e., 2%) which will form the set M.

B. Experimental Plan, Tests, and Tools

Our experimental protocol is divided into three stages. The first stage focuses on simulating data with missing values that aims to answer the question of the performance of the algorithm when adding more missing values. The second stage is devoted to exploring the impact of a parameter of the algorithm. Specifically, we study the impact of changing the value K of the nearest neighbors component which is part of the evaluation function $e(c_k, o_i)$ (see Section II-A). Finally, in the third stage, various percentages of the strategies' initial values are considered to study the influence of these values on the obtained results. Below is an outline of the three stages:

- Experiment 1: We evaluated the performance of the three-way clustering approach by using in each experiment several percentages of the missing values. As a first investigation, the algorithm was tested on four different missing data versions. The rate of missing values randomly chosen in this regard is based on 5%, 10%, 15%, and 20%. This experiment will enable us to respond to the following research question (**RQ1**): How can the percentage of missing values affect the performance of the algorithm?
- Experiment 2: The aim of this experiment is to explore the k nearest neighbors used in calculating the evaluation function to investigate its impact on the results. For this purpose, we choose to work with k = 5 and k = 7. Conducting this experiment will lead us to answer the following question (**RQ2**): Does the k nearest neighbors has an impact on the clustering results?
- Experiment 3: We assessed the choice of the strategies' initial values percentages and their effect on the obtained results. In this experiment, the algorithm takes as input a different set of $\alpha-$, $\alpha--$, $\beta+$ and $\beta++$. In our case, we tried to decrease α and increase β by 7% having initial values of $\alpha-$ equals to 0.93, $\alpha--$ equals to 0.86, $\beta+$ equals to 0.07, and $\beta++$ equals to 0.14, and by 10% having initial values of $\alpha-$ equals to 0.90, $\alpha--$ equals to 0.80, $\beta+$ equals to 0.10, and $\beta++$ equals to 0.20. By carrying out this experiment, we will be able to respond to the following question (**RQ3**): can the percentage of increasing and decreasing initial values of α and β influence the results?

Although the number of iterations is not defined, a maximum number is given to prevent the algorithm from continuing in an endless loop if it does not converge. While setting a maximum iteration of 20, the algorithm often converged between 3 and 4 iterations, based on the APROCCHS cohort. As for the clustering part, the k-means algorithm was used with k=2.

V. Results and discussion

A. Experimental results of GTRS approach

The results obtained from different GTRS-based approach runs with the various percentages of missing values inputs are shown in Tables IV – VII. The tables present the following observations:

- From Table IV (and similarly to all other Tables V – VII), it can be observed that in most runs the algorithm converge in the third iteration. We can also see how the thresholds are altered across the game's several iterations and how this affects generality and accuracy. For the experiment with 5% missing values, the initial thresholds of (α, β) = (1, 0) are set before the game starts, resulting in an accuracy of 0.98 and a generality of 0.88. However, in the second iteration, the accuracy and generality are still the same, while the threshold α is decreased and β increased by 0.14. For the experiment with 10% missing values, the accuracy is stable while the generality increased from 84% to 93%. For 15% and 20% missing values, we can notice a slight decrease in the accuracy (for 15% missing values: from 1 to 98%, for 20% missing values: from 99% to 96%) with an

TABLE III
CONSIDERED SET OF RELEVANT FEATURES AT DAY 0

Reference	Description	Format
DATINF	Diagnosis date	Precision = JJ/MM/YYYY, Min = DATHOSP (Hospital admission date), Max = Current date
SITINF	Infection location	0 = Lung, pleura, 1 = Peritoneal, 2 = Urogenital, 3 = Central Nervous System (CNS), 4 = Endocarditis, mediastinum, 5 = Sepsis, 6 = Soft tissue, 7 = Bones and joints, 8 = Other
SEX	Indicates patient sex	1 = Male, 2 = Female
PATWGHT	Indicates the weight of the patient	Min = 36, Max = 154
ORIGIN	Indicates the patient ORIGIN	1 = City, 2 = Hospital, 3 = Institution
AGE	Indicates patient age	Min = 18, Max = 97
KNAUS_J0	Activity and medical follow-up in the six months prior to admission	1 = Stage D Major activity restriction due to illness, including bedridden or hospitalized patients, 2 = Stage C Chronic illness causing significant but not total activity restriction, 3 = Stage B Moderate or moderate activity limitation due to illness (limited work activities), 4 = Stage A Good health, no activity limitation
MACCABE_J0	Description of the patient's condition before the episode leading to ICU	1 = Absence of underlying disease or underlying disease not life-threatening, 2 = Underlying disease life-threatening within 5 years, 3 = Underlying disease estimated to be fatal within one year
SOFA_ADM	Indicates the worst case value up to 3 hours after admission	Min = 2, Max = 16
IGSII_ADM_TYP	Indicates the admission type of the patient	0 = Scheduled surgery, 6 = Medical, 8 = Unscheduled surgery

increase in generality (for 15% missing values: from 87% to 94%, for 20% missing values: from 83% to 91%) – a trade-off maintaining the required balance. To explore the research question **RQ1** of whether the percentage of missing values affects the performance of the algorithm, we performed the first experiment. By examining the outcomes of the GTRS algorithm via results presented in Tables IV – VII, when increasing the number of randomly chosen missing values, the trade-off accuracy/generality will not be lost.

- In the results presented in Table V, we have increased the value of k from 5 to 7. In comparison with the initial thresholds $(\alpha,\ \beta)$ = (1, 0) and when testing with only 5% of missing values, we can observe that there is a slight decrease in accuracy (i.e., 1%) while the generality improved with 9% reaching 95%. When testing with 10% and 20% missing values, the GTRS algorithm shows a minor reduction in accuracy varying from 1% to 3% with an increase in generality (between 8% and 13%). Thus, the GTRS model delivers an acceptable trade-off between accuracy and generality. For the experiment with 15%, and while comparing the results to the 5%

missing values, we can note that there is an increase in the accuracy showing 98% (97% with 5% missing values) with a 1% decrease in generality. In order to investigate the research question of whether the value of k nearest neighbors has an impact on the results **RQ2**, Experiment 2 was carried out. Through the interpretation of the results obtained from the GTRS algorithm, when increasing the percentage of missing values, and by increasing k to 7, we can notice a slighter loss in the trade-off accuracy/generality in comparison to k = 5.

- Table VI and Table VII show the results obtained when varying the strategies' initial values with decreasing α and increasing β by 10% having initial values of $\alpha-$ equals to 0.90, $\alpha--$ equals to 0.80, $\beta+$ equals to 0.10, and $\beta++$ equals to 0.20. Consistent with the findings in Table IV, from Table VI, we can notice that from 5% to 15% of missing values the accuracy demonstrates stability in its values with 98% while the generality presents a significant increase varying from 88% to 94%. For 20% missing values, the obtained results show a slight decrease in accuracy with 3% (reaching 96%) and a slight increase in generality with 2% (reaching 91%).

  As was the case in Table V, by analyzing the obtained results in Table VII, we can notice that when compared to the initial thresholds (α, β) = (1, 0) and tested with only 5% of missing values, we observed a slight decrease in accuracy (by 1%), but a significant improvement in generality (by 9%). Moreover, for experiments with 10%, 15%, and 20% one can observe that accuracy values were decreased by approximately 2% while generality increased by up to 14%. Also, for instance, with initial values equal to 7%, k = 5, and 20% of missing values (Table IV), the final values are 96% and 91% for accuracy and generality, respectively. With initial values equal to 10%, k = 5, and 20% of missing values (Table VI), the final values are the same registering 96% and 91% for accuracy and generality, respectively. To answer the third research question **RQ3** to what extent can variations in the percentage of initial values of α and β, whether increased or decreased, impact the results, Experiment 3 was implemented. By looking at the obtained results and interpreting them (Table IV, V, VI, and VII), it is noticeable that the final output of the GTRS algorithm is relatively stable regardless of the initial values of the strategies.

As expected, from the different tables, when using k = 5, the execution time is observed to be lower than when using k = 7, indicating that a smaller value of k can lead to faster computations. However, for more exploration, the execution time can be minimized by using several techniques such as Multithreading [38], Single Instruction Multiple Data (SIMD) [39], and Open Multi-Processing (OpenMP) [40]. By employing these parallelism techniques, the GTRS algorithm execution time can be reduced, leading to marked improvements in both its performance and efficiency.

B. Three-way clustering approach evaluation

The previously obtained results show the effectiveness of the three-way clustering approach with GTRS in handling missing values. Therefore, in almost all the experiments, for clustering CS responsiveness, the trade-off accuracy/generality is maintained. The best trade-off found is with an accuracy value of 97%, and the generality presents 95%; with k =7 and 5% of missing values.

The final step (Figure 1 (3,5)) in the GTRS algorithm is to evaluate objects with missing values in M using Equation 4 and then select the best values of (α, β) and test them on the set M with missing values. As mentioned in Section IV-A, set M contains 26 patients having missing data (i,e., only 2%). Table VIII summarizes the obtained results after applying the three-way clustering approach on the set M and using k = 7 as value of k nearest neighbors. It can be observed that the accuracy/generality trade-off was preserved, presenting 96% accuracy and 92% generality. The results revealed that the best thresholds values for (α, β) = (0.58, 0.42). These final (α, β) values are used for assigning objects to different regions of a clusters as follows:

$$Inside(c_k) = \{o_i \in U | e(c_k, o_i) \geq 0.58\}, \tag{13}$$

$$Outside(c_k) = \{o_i \in U | e(ck_, o_i) \leq 0.42\}, \tag{14}$$

$$Partial(c_k) = \{o_i \in U | 0.42 < e(c_k, o_i) < 0.58\}, \tag{15}$$

.

After applying Equations 13, 14, and 15 to assign objects in set M to clusters, we observed that the algorithm's non-deterministic nature resulted in some sepsis patients being found in the partial region. This means that these sepsis patients could not be clustered to a specific region as CS(placebo) sensitive(improved) or resistant(not improved); despite that we had their correct label in the cohort. In addition to this, when we examined the patients clustered by GTRS, we found some false negatives. This suggests that the results were not entirely deterministic, and further statistical analysis is required to validate them. One possible explanation to these preliminary results is that we have only considered 10 risk factors out of the 24 variables. Despite this, we still can consider that the initial results in terms of trade-off accuracy and generality are promising and indicate that GTRS has potential in addressing the issue of missing data in sepsis patients.

VI. Conclusion

The aim of this paper is to investigate the issue of clustering with missing values in clinical data using a three-way approach with GTRS. The study utilized data from the APPROCHS cohort, which included 1240 sepsis patients enrolled in a randomized controlled trial, and collected by clinicians from APHP. An important challenge in implementing this approach was setting appropriate thresholds to determine the three types of decisions. GTRS was found to be a promising alternative for clustering objects with missing values.

To evaluate the effectiveness of the GTRS model, three experiments were conducted. In the first experiment, the algorithm was tested with varying percentages of missing data, and the results showed that accuracy and generality can be preserved despite an increase in the number of missing values. The second experiment examined how the selection of the k nearest neighbors in the evaluation function affected the results. The third experiment evaluated the impact of the percentages of initial values of the strategies on the results, and the stability of the final output of the GTRS algorithm was apparent as it did not significantly vary with the initial values of the strategies.

As future work, we aim to use four clusters, instead of two, to further represent sepsis patients (Cortico-sensitive, Cortico-resistant, improved status with placebo, and unimproved status with placebo). This may improve the performance of the algorithm. Also, we aim to explore alternative approaches such as Reinforcement learning [41]. This approach would consider accuracy and generality as agents, and increasing and decreasing α and β strategies as actions to be taken in the environment. Players would learn a policy through trial and error that maximizes their rewards. Additionally, one can expand the evaluation of the results achieved by taking into account the quality of the model to address concerns related

***Abstract*—The average tenure of Chief Information Officers (CIOs) has increased over the past few years. Nevertheless, the average tenure of CIOs is shorter than that of Chief Executive Officers (CEOs). While most studies on tenure and background are based on data from US IT executives, studies on German CIOs are missing. This study analyzes the tenure of German CIOs as a proxy for management effectiveness and how certain factors influence it. An original and unique dataset of 384 IT executives from German companies is examined. The data include the size and industry sector of the companies, educational and professional backgrounds of the CIOs, and the CIOs' reporting lines. Data were analyzed using the chi-square test and Fisher's exact test. The German CIOs had a median tenure of 4.0 years. However, if we examine executives who are currently in office and executives with a completed term of office separately, the median tenure differs. The results also show that German CIOs do not have shorter tenures than German CEOs. When compared with US CIOs, the results depend on the values selected for comparison. In addition, the analysis shows that neither the size and industry sector of the companies nor the educational and professional backgrounds of the CIOs and managers of the CIO reports have a statistically significant influence on the tenure of IT executives. The factors examined in this study can be considered as preconditions for the CIO position. In the future, factors that play a role during tenure should be examined.**

***Index Terms*—CIO, Chief Information Officer, CIO tenure, CIO background**

I. Introduction

A LONG tenure for Chief Executive Officers (CEOs) is linked to superior firm performance [1]. This indicates successful work by the executives. Consequently, the CEO is often replaced when the company performs poorly because there is doubt about his or her ability to effectively implement strategies to increase the company's value [1].

In addition to the CEO, the Chief Information Officer (CIO), as the top information technology (IT) executive, has been an established position in companies for several years. The average tenure of CIOs has increased over the past 10 years but has stagnated in recent years [2]. Despite this increase, CEOs on average still have a longer tenure; according to a study by the consulting firm Korn Ferry, CIOs have significantly shorter tenures at 4.6 years compared to CEOs at 6.9 years [3].

Although other studies have examined the tenures of CIOs during a similar period, they have arrived at different conclusions. CIO Magazine's 2020 State of the CIO Report shows that CIOs have an average tenure of 6.5 years in 2020 [4]. This result is consistent with that determined by Kappelman et al. [2]. Nevertheless, all studies conclude that most IT executives hold their positions for only three or fewer years [2, 4].

Many factors can influence the tenure of CIOs. Dawson et al. [5] examine the tenure of senior executives, particularly CIOs. The aim of their work was to determine differences in tenure based on factors such as gender, size, and type of organization. Recently, Jones et al. [6] examined the background of CIO. Their findings suggest that the background of a CIO has little to do with what a CIO does once in office. For example, they found that whether an IT executive was hired externally or promoted internally did not influence their reporting line. However, this study did not investigate whether these factors had an impact on the tenure of CIOs.

All the previously mentioned studies were based on data from American CIOs. German IT executives were not included in these studies. This is consistent with the results of a recent literature review, which found that quantitative research on IT executives is primarily based on data from the US [7].

This study aims to address these gaps. It examines the tenure of CIOs in Germany and attempts to answer the following research question: 'Which factors significantly influence the tenure of CIOs?'

To address this question, the remainder of this article is structured as follows. First, the existing literature is reviewed, and hypotheses are derived. Next, the methodology used is described, including the collection of data, description of the data sample, and statistical methods. The results of the analysis are presented and discussed in the following section. Finally, we present the limitations of this study and avenues for future research.

II. Literature Review and Hypotheses Building

A long CEO tenure is linked to superior firm performance and can indicate a successful executive [1]. Therefore, in this study, long tenure was used as a proxy for successful work. Even though the CIO has different tasks and responsibilities than the CEO, it can be assumed that if a CIO performs poorly, he or she will also be dismissed. In the following section, we hypothesize the factors that may influence tenure and, thus, the success of CIOs.

Studies have yielded different results regarding the tenure of CIOs. According to a study by the consulting firm Korn Ferry, CIOs have significantly shorter tenures at 4.6 years compared to CEOs at 6.9 years [3]. Other studies arrive at an average tenure of 6.5 years and 6.6 years respectively [2, 4]. There may be cultural differences between Germany and the US.

However, organizational culture, rather than the societal culture of each country, largely influences how the CIO operates in its role [8]. Therefore, the tenure of the CIOs should not differ by country. Based on these arguments, we propose the following hypothesis H1.

H1: The tenure of German CIOs is comparable to that of US CIOs.

In 2018, German-speaking CEOs who left office had an average tenure of 6.6 years [9]. In a study of how CEO age and CEO tenure moderates the relation between certain financial factors, Neifar and Ajili [10] determined a tenure of 6.5 years for German CEOs. These figures are consistent with the average tenure of US-American CEOs, which is 6.9 years [3]. Since the CIO has a significantly shorter tenure than the CEO, we propose the following hypothesis H2.

H2: The tenure of German CIOs is shorter than that of German CEOs.

Dawson et al. [5] analyzed the tenure of executives in relation to company size. They also found that managers in smaller organizations had the longest tenures, followed by slightly shorter tenures in larger organizations. According to this study, executives have the shortest tenures in medium-sized companies. They argue that medium-sized companies could be used as steppingstones, or that large companies could attract better pay. To measure size, we used turnovers from companies. It is therefore interesting to see whether the results differ when the number of employees is used to measure size. In summary, we propose hypotheses H3a and H3b.

H3a: The tenure of CIOs differs according to the size of the company, based on the number of employees.

H3b: The tenure of CIOs differs according to the size of the company, based on turnover.

The role of IT is unique to different organizations and industries. Therefore, the role of the CIO differs depending on whether companies have a high or low level of operational and strategic dependence on IT [11]. Industry-specific experience and knowledge of a CIO could therefore be particularly helpful for new business-oriented opportunities [6]. However, in a survey conducted by Mazzola et al. [12], IT executives changed industries particularly frequently on their way to become top IT executives. In addition, the industry in which they started their careers was often not the one in which they became CIO [12]. Mazzola et al. [12] concluded that IT skills are either industry-independent, or that industry knowledge is not a significant factor in the success of a CIO. Therefore, hypothesis H4 is proposed.

H4: The tenures of CIOs do not differ by industry.

CIOs are perceived as innovative and technologically knowledgeable, yet highly detail-oriented [13]. Many CIOs have a technological or engineering background. They often seem to lack political skills or the ability to communicate technical problems in such a way that other executives understand their messages [11]. These skills are relevant to an increasing business focus, and IT executives are expected to actively participate in business discussions [14]. Moreover, a CIO should be a business leader, rather than an IT manager [11]. Managers with an economic background already possess these skills.

Regardless of the subject area, a high level of education is an important prerequisite for becoming a CIO [12]. Therefore, we propose the following two hypotheses H5a and H5b.

H5a: CIOs with a background in economics have the longest tenures.

H5b: A higher level of education is associated with a longer tenure.

Whether a CIO has been promoted to this position internally or externally depends on the circumstances. For example, a successful CIO is often followed by an executive from within the organization to sustain success. The new manager already knows the organization and does not have to familiarize himself with it first [15]. In addition, companies with the primary goal of increasing efficiency beyond their IT function are more likely to hire a CIO from their ranks [6]. Companies that want to make strategic changes tend to hire a CIO outside the organization [15]. An externally hired CIO can use the beginning of his or her tenure to influence perception through the choice of activities [13]. However, a disadvantage is that they do not know the organization and may find conditions other than expected [15]. Whether a CIO is promoted internally or hired externally has advantages and disadvantages and depends on the circumstances of the organization. Therefore, hypothesis H6 is proposed.

H6: There is no difference in tenure whether CIOs were hired internally or externally.

Most CIOs in the US come to office from an IT position. However, this number has steadily decreased in recent years [2]. Furthermore, internal promotions mostly occur in the IT position [12]. The steady decline in previous IT positions and the need for a stronger business focus may indicate that a previous IT position is no longer the most promising [14]. However, according to Jones et al., the background of a CIO has little influence on the tasks a CIO performs once in office [6]. Thus, we propose the following hypotheses: H7a, H7b, and H7c.

H7a: The tenure of the CIOs is independent of the previous position.

H7b: Similar to findings from the US, the majority of externally hired CIOs in Germany also come from a position outside IT.

H7c: Similar to findings from the US, the majority of internally hired CIOs in Germany also rise from an IT position.

Most US CIOs report to the CEO, followed by the Chief Financial Officer (CFO). The number of CIOs reporting to the CEO has increased in recent years, while the number of CIOs reporting to the CFO has decreased [2, 16]. Whether a CIO is promoted within the organization or hired from outside the organization can affect CIO reports. According to Jones et al., internally promoted IT executives are more likely to report to the CFO and IT executives hired from outside the organization are likely to report to the CEO [6]. Based on this finding, we propose the following hypotheses H8a, H8b, and H8c.

H8a: Similar to findings from the US, the majority of German CIOs also report to the CEO.

H8b: Similar to findings from the US, the majority of German CIOs who have been promoted internally also report to the CFO.

H8c: Similar to findings from the US, the majority of German CIOs who are hired externally also report to the CEO.

III. Methodology

A. Data Collection

To test the hypotheses, data from two sources were collected and combined into a single dataset. The basis for the selection of CIOs is the "Top-500" company database of the German edition of CIO Magazine [17]. The database lists companies based in Germany with a turnover of more than one billion euros and was chosen for several reasons: (a) it contains information on companies, such as turnover, number of employees, and type of industry; (b) key figures on the company's IT organization are available; and (c) current IT executives are already listed. Companies with more than 5,000 employees were included in this study. Smaller companies often do not have their own separate IT organizations and therefore do not have a CIO. After applying this criterion, 330 companies remained for further investigation. The database was queried in mid-October 2020. No updates or changes after that date were included in the study.

The LinkedIn social network is primarily used to gather information about CIOs. On LinkedIn, users can create profiles that contain information about their professional careers. If a CIO did not have a LinkedIn profile, the German social network alternative Xing or press releases were used. The following information was collected from these sources: (a) the beginning and end of tenure, (b) previous position, (c) degree and specialization of education, and (d) current title of the CIO. The previous position was used to determine whether the CIO was promoted internally or externally. In addition, the department in the previous position was determined. Current IT executives of a company and their predecessors were included in the analysis. The LinkedIn and Xing data were collected until the end of October 2020. Thus, the length of the tenures spans until and included October 2020. All transitions of the CIOs to new positions from this date were not included in this data sample.

B. Data Sample

Data were collected from 384 CIOs from the previously mentioned 330 companies. However, CIOs could only be identified for 268 companies. Thus, no data on IT executives were available for these 62 companies. The tenures of all CIOs cover the period from 1990 to 2020, but only nine CIOs became CIO before 2000. Sixty CIOs took office between 2000 and 2010 and 315 from 2010 onwards.

Table I shows the distribution of the previously mentioned 268 companies based on (a) revenue, (b) IT expenditure, (c) number of employees, and (d) number of IT employees. The companies in which CIOs are employed have a median turnover of €4.5 billion, with most having a turnover of €2 to €5 billion. The median number of employees at these companies was 16,885. IT organizations have a median IT budget of € 77.50 million available for IT expenditure. However, at 32.6%, most companies had a budget of only €2 million. The CIOs had a median number of 365 IT employees. However, many companies have only 100–250 IT employees.

TABLE I. Company Profiles

Turnover in billion €	N	Percentage
<= 2	38	14.2
> 2 to 5	114	42.5
> 5 to 10	48	17.9
> 10 to 20	31	11.6
> 20 to 50	24	9.0
> 50	13	4.9
Total	268	100.0
IT budget in million €	**N**	**Percentage**
<= 50	93	34.7
> 50 to 100	73	27.2
> 100 to 250	51	19.0
> 250 to 500	22	8.2
> 500 to 1,000	17	6.3
> 1.000	12	4.5
Total	268	100.0
Number of employees€	**N**	**Percentage**
5000 to 10,000	72	26.9
> 10,000 to 20,000	89	33.2
> 20,000 to 50,000	60	22.4
> 50,0000 to 100,000	25	9.3
> 100,000	22	8.2
Total	268	100.0
Number of IT employees€	**N**	**Percentage**
<= 100	20	7.5
> 100 to 250	87	32.5
> 250 to 500	69	25.7
> 500 to 1,000	45	16.8
> 1,000 to 5,000	36	13.4
> 5,000	11	4.1
Total	268	100.0

Table II presents the distribution of the CIOs by industry type. Most CIOs in this dataset are from the (a) manufacturing, (b) retail, and (c) automotive sectors.

TABLE II. Industry Types of CIOs

Industry type	N	Percentage
Automotive	43	11.2
Chemical	34	8.9
Construction	11	2.9
Energy and raw materials	23	6.0
Finance	8	2.1
Food	16	4.2
Health	9	2.3
Manufacturing	128	33.3
Media	15	3.9
Retail	59	15.4
Transportation	38	9.9
Total	268	100.0

Table III shows that most of the CIOs (94%) were male. Only 23 of 384 CIOs in this dataset were female. This is well below the 17% reported by Fortune 500 companies in 2016 [16]. However, in 2018, only 2.1% of new German-speaking CEOs were female, which suggests that a low percentage of women were not limited to the position of the CIO [9].

TABLE III. Gender of CIOs

Industry type	N	Percentage
Female	23	6.0
Male	361	94.0
Total	384	100.0

As indicated in Table IV, responsible IT executives in Germany have different titles. By far the most common title is "CIO / Group CIO", which is held by 65% of IT executives. Furthermore, 28 executives hold the title "Director / Managing Director IT" and 37 hold the title "Head of IT /Group IT". However, in some companies, the Chief Digital Officer (CDO) and Chief Technology Officer (CTO) are responsible for IT. This could indicate that there is no CIO position in the organization.

TABLE IV. TITLES OF CIOS

Industry type	N	Percentage
CDO	5	1.3
CIO & CDO	12	3.1
CIO & additional title	13	3.4
CIO (Regional /BU)	7	1.8
CIO / Group CIO	252	65.6
CTO	7	1.8
Director / Managing Director IT	28	7.3
EVP/SVP/VP Group IT	11	2.9
Head of IT /Group IT	37	9.6
Other	12	3.1
Total	384	100.0

As Table V shows, most CIOs have a degree in economics followed by science and engineering. In this study, business informatics and industrial engineering were attributed to economics. These figures clearly show that German CIOs not only have technical or engineering backgrounds [11]. Only three CIOs came from a discipline that could not be assigned. Data were missing for 49 CIO because the field of education could not be specified.

TABLE V. CIOS' FIELDS OF EDUCATION

Field of education		N	Percentage	Valid Percentage
Valid	Engineering	58	15.1	17.3
	Science	97	25.3	29.0
	Economics	177	46.1	52.8
	Other	3	0.8	0.9
	Total	335	87.2	100.0
Missing	Not specified	49	12.8	
Total		384	100.0	

As shown in Table VI, almost all the CIOs have an academic degree. Most CIOs have a master's degree or are equivalent to their highest educational level. 74 CIOs also had doctorate holders. The category "Other" includes non-academic educational backgrounds. If a higher degree means a higher qualification, it is notable that ten people in this dataset have become IT executives without academic education. Data were missing for 36 CIO because the degree of education could not be specified.

TABLE VI. CIOS' DEGREE OF EDUCATION

Degree of education		N	Percentage	Valid Percentage
Valid	Bachelor	12	3.1	3.4
	Master	252	65.6	72.4
	Doctorate	74	19.3	21.3
	Other	10	2.6	2.9
	Total	348	90.6	100.0
Missing	Not specified	36	9.4	
Total		384	100.0	

In addition to education, the previous positions a CIO has held also shape his skills and experience. To test the hypotheses regarding the professional background of the CIO, previous positions were divided into three categories. The entry "CIO" indicates that the executive was already the CIO of another company in the previous position. "IT" stands for a previous position within an IT organization. "Business unit" includes all positions outside the IT organization. As shown in Table VII, the previous positions were distributed almost equally. The percentage of German CIOs who come from a business unit is similar to 31.1% of CIOs in the US [2]. The previous position could not be specified for eight CIOs.

TABLE VII. CIOS' PREVIOUS POSITIONS

Previous position		N	Percentage	Valid Percentage
Valid	CIO	114	29.7	30.3
	IT	138	35.9	36.7
	Business unit	124	32.3	33.0
	Total	376	97.9	100.0
Missing	Not specified	8	2.1	
Total		384	100.0	

As illustrated in Table VIII, most CIOs were hired externally. The percentage of externally hired individuals was 79.3%, which was significantly higher in the US. [2]. It would be interesting to learn the reasons for this discrepancy through future research. Data are missing for five CIO because it could not be specified if the CIO was promoted internally or hired externally.

TABLE VIII. CIOS HIRED INTERNALLY OR EXTERNALLY

Previous position		N	Percentage	Valid Percentage
Valid	Internal	138	35.9	36.4
	External	241	62.8	63.6
	Total	379	98.7	100.0
Missing	Not specified	5	1.3	
Total		384	100.0	

Table IX shows that the CIO reports to many executives. The majority of German CIOs report to the CFO, followed by the CEO. Therefore, hypothesis H8a, which states that CIOs in Germany also report to the CEO by a majority, is not supported. 13 CIOs in this data sample report to the Chief Digital Officer (CDO). This is surprising because the position of the CDO is quite new compared to the CIO. Data are missing for 163 CIOs because the reporting structure could not be specified.

TABLE IX. CIOS' REPORTING STRUCTURES

Previous position		N	Percentage	Valid Percentage
Valid	CDO	13	3.4	5.9
	CEO	55	14.3	24.9
	CFO	95	24.7	43.0
	COO (Operating)	9	2.3	4.1
	CTO	15	3.9	6.8
	Group CIO	4	1.0	1.8
	Other C-Level	17	4.4	7.7
	Is a board member	13	3.4	5.9
	Total	221	57.6	100.0
Missing	Not specified	163	42.4	
Total		384	100.0	

As Table X shows, most CIOs under two-thirds have a tenure of less than five years. However, 59 CIOs had been in office for more than 10 years and had an above-median tenure.

TABLE X. TENURES OF CIOS

Tenure	N	Percentage	Cumulated Percentage
<= 1	41	10.7	10.7
> 1 to 3	114	29.7	40.4
> 3 to 5	87	22.7	63.0
> 5 to 10	83	21.6	84.6
> 10 to 20	50	13.0	97.7
> 20	9	2.3	100.0
	384	100.0	

As shown in Figure 1, CIO tenures were not normally distributed. In addition, owing to the chosen data collection approach, the dataset contained many CIOs that are currently in office. As a result, the average tenure may be distorted. Therefore, current and completed tenures must be considered separately. Figure 1 shows that 36 CIOs had only recently moved to their positions and still had a tenure of less than one year. In addition, most IT executives currently in office have tenures between one and three years. If, on the other hand, one looks at CIOs with a completed tenure, it is noticeable that the tenures are more evenly distributed.

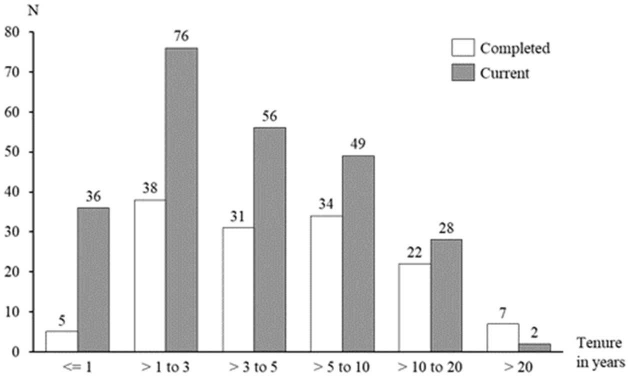

Fig. 1. Distribution of completed and current tenures.

Table XI displays the descriptive statistics for tenure. The median tenure of all 384 is 4.0 years while it is 4.7 years for completed tenures and 3.7 years for current tenures. The arithmetic mean is given in Table XI because it was used to test Hypotheses 1 and 2.

TABLE XI. CIOS HIRED INTERNALLY OR EXTERNALLY

Tenure	N	M	SD	Mdn
Current	247	4.76	4.15	3.70
Completed	137	6.57	5.51	4.70
Total	384	5.50	4.80	4.00

The tenure of the CIOs was analyzed using statistical tests. As shown in Table XI, most CIOs (64%) are currently in office. It was not possible to determine the length of tenure of these CIOs. To avoid excluding 247 CIOs, two groups were formed based on the median of the completed tenures. One group includes all CIOs who have a tenure above or equal to 4.7 years, regardless of whether they are currently in office or not. The other group includes all CIOs with a completed tenure of less than the median of 4.7 years. Figure 2 illustrates the formation of the two groups and highlights the CIOs included in the tests in grey. 152 executives are currently in office and have below-median tenure at the time of October 2020. However, these CIOs may also have an above-median tenure of a few years and might be deemed “successful” in the future. However, since the length of tenure cannot be predicted, and thus it cannot be determined whether the CIOs will be successful in the future, they are excluded from the tests.

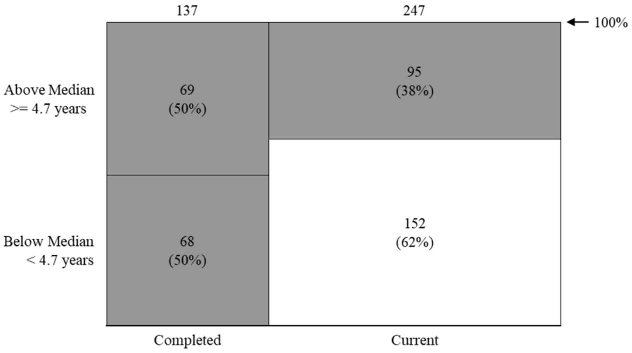

Fig. 2. Distribution of **completed** and current tenures.

As shown in Table XII, 232 CIOs consisting of two groups were used for the statistical tests. Of these, 164 had tenures greater than or equal to 4.7 years. 68 CIOs had tenures of less than 4.7 years.

TABLE XII. GROUPS OF CIOS FORMED

Groups of CIOs	N
Above Median >= 4.7 years (Completed & Current)	164
Below Median < 4.7 years (Completed)	68
Total	232

C. Statistical Methods

IBM SPPS Statistics 27 was used to analyze the dataset and test the hypotheses. As the CIOs were split into two groups, tenure was now a categorical variable. The data collected on the CIO background were categorical variables. Therefore, the chi-squared test was used for the analysis. The chi-squared test can be used to determine whether two or more independent samples differ in their distribution over a variable. A significant test statistic indicated that the groups differed in the distribution of the variables of interest. However, the test did not indicate which group was different [18]. These differences were identified in a post-hoc analysis using Bonferroni correction. If the cells of a cross table had an expected frequency of less than five, Fisher’s exact test was used.

IV. Results

A. Tenure

Since no statistical test was necessary for the first two hypotheses, 384 CIOs were examined here. The average completed tenure shown in Table XI corresponds to the values of 6.5 years and 6.6 years [2, 4]. The average current tenure is also close to the value of 4.6 years [3]. However, it is unclear whether the abovementioned studies included only completed or current tenures. Whether German CIOs have a longer tenure than their US counterparts depends on comparative values. Therefore, H1 was only partially supported.

With 6.6 years, the average tenure of CEOs leaving office corresponds to the mean value of the completed tenures of CIOs, as shown in Table V [9]. This comparison shows that German CIOs do not have shorter tenures than German CEOs do. Therefore, H2 was not supported.

B. Size of the Organizations

Next, we examined whether being a CIO in a large organization can be advantageous for an above-average tenure. A chi-squared test showed that there was no statistically significant difference in corporate turnover between CIOs with below-median and above-median tenures ($\chi 2(5, N = 232) = 6.128, p = .294$). Figure 3 illustrates these results. Even if the difference is not statistically significant, it is noticeable that more CIOs in companies with turnover equal to or less than €2 billion have a tenure that is below average.

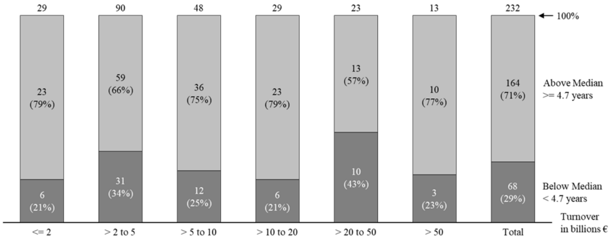

Fig. 3. Comparison of above-/below-median tenures by turnover

In the same way, there is no statistically significant difference in the number of employees of organizations between CIOs with an above-median tenure and CIOs with a below-median tenure, $\chi 2(4, N = 232) = 3.316, p = .506$. Figure 4 shows that the percentage of CIOs with above-median tenure differs between companies with 50,000 and 100,000 employees and companies with more than 100,000 employees.

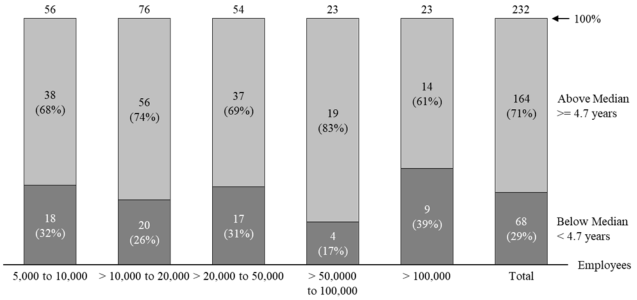

Fig. 4. Comparison of above-/ below-median tenures by employees

Therefore, CIOs in large companies do not have a longer tenure than those in smaller companies, which is why Hypotheses H3a and H3b are not supported. It must be considered that this study only considered companies with more than 5,000 employees. Therefore, further investigations should be conducted without limiting the number of employees.

C. Industry Type of the Organizations

Next, the industry type of the organization in which the CIOs operate is analyzed. An Exact Fisher test was conducted to determine whether there was a difference in the industry type between CIOs with below-median and above-median tenures. The results of this test also showed no statistically significant difference (p = .756). Although Figure 5 shows that all the CIOs in the construction industry have above-median tenures, this can be neglected because of the small number of CIOs. Hypothesis H4, which states that CIOs' tenure does not differ by industry type, is supported.

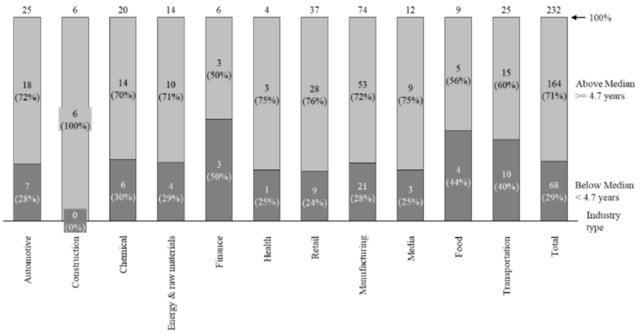

Fig. 5. Comparison of above-/ below-median tenures by industry type

D. Educational Background

The next step was to examine educational background in more detail. This includes the fields of education and the degree of education. An Exact Fisher test was conducted to determine whether there was a difference in the field of education between CIOs with below-median and above-median tenures. The results of this test also showed no statistically significant differences (p = .200). It should be noted that the field of education could not be specified for the 29 CIOs. Even if the difference is not statistically significant, Figure 6 shows that CIOs with a degree in economics are the only group of CIOs with below-median rather than above-median tenure. The test rejects hypothesis H5a, that CIOs with a degree in economics have the longest tenure. Thus, a degree in economics is not a factor that automatically leads to long-term office.

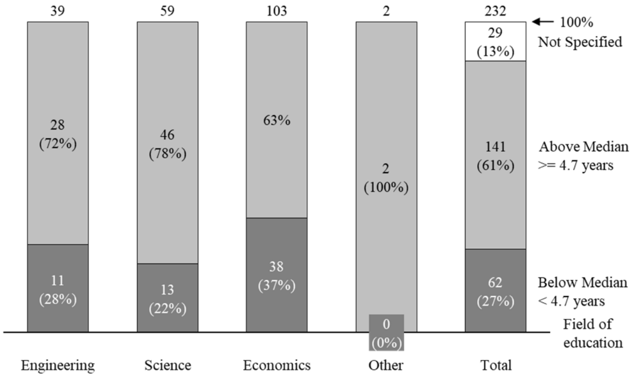

Fig. 6. Comparison of above-/ below-median tenures by field of education

In addition, we examined whether there was a difference in the degree of education between CIOs with below-median and above-median tenure. The results of Fisher's exact test showed no statistically significant difference (p = .751). Therefore, CIOs with above-median tenures do not have a certain degree of education more often than expected. The test shows that a higher degree is not associated with longer tenure. Thus, Hypothesis H5b was not supported. Figure 7 also shows that more CIOs with a doctorate degree have below-median tenures than those with above-median tenures. An additional doctorate did not extend the average tenure of the CIOs. However, the frequency of CIOs with a master's or doctorate degree shows that a higher education degree is a prerequisite for the position of the CIO. It should be mentioned again that the degree of education could not be specified for 20 of the 232 CIOs.

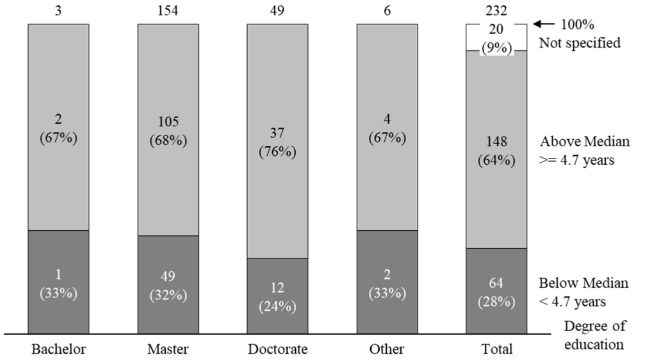

Fig. 7. Comparison of above-/ below-median tenures by the degree of education

E. Professional Background

Next, their professional background was examined. The focus here is on the previous position and whether the CIOs have been promoted internally or moved externally. First, we examined whether there was a difference in the previous position between below-median and above-median tenures. A chi-square test showed no statistically significant difference ($\chi 2(2, N = 225) = 1.059, p = .589$. This supports hypothesis H7a, which states that CIO tenure is independent of the previous position. The results show that there is no position that is a particularly good prerequisite for long tenure. Figure 8 illustrates the results because only the previous CIO position is more likely to have a below-median tenure than an above-median tenure. The previous position could not be determined for 7 of the 232 CIOs.

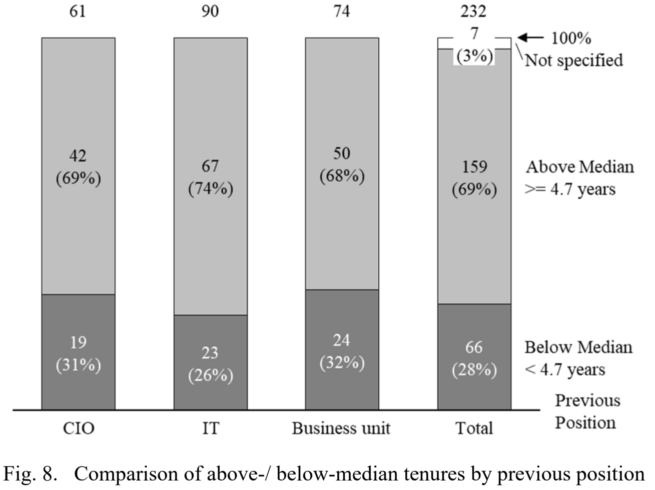

Fig. 8. Comparison of above-/ below-median tenures by previous position

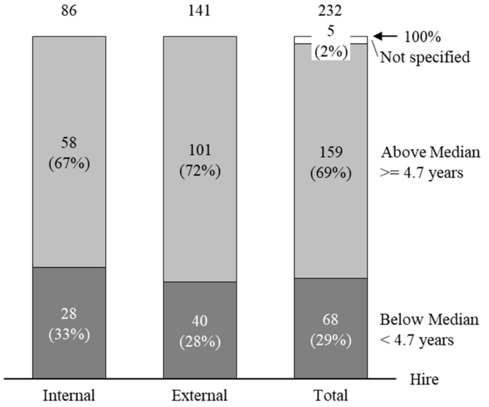
Second, we analyzed whether there was an impact on whether CIOs would be promoted internally or hired from outside. A comparison of above- and below-median tenures showed no statistically significant difference between internally and externally hired CIOs, $\chi 2(2, N = 227) = 0.447$, p = .504. The results of the chi-square test indicate that CIOs with above-median tenures are not promoted internally or hired externally more often than expected. Figure 9 illustrates the results. At approximately 70%, the proportion of CIOs with below-median tenure is similar for both internal and external hires. The previous position could not be determined for 7 of the 232 CIOs. In summary, Hypothesis H6 is supported.

Fig. 9. Comparison of above-/ below-median tenures by internal/ external hire



The next step was to determine whether there was a connection between the previous position and an internal or external hire. As tenure was not a factor, 384 CIOs were included. A chi-square test was carried out to check whether the majority of externally hired CIOs came from a business unit and whether the majority of internally hired CIOs were promoted from an IT position. The test showed a statistically significant difference in the previous position between internally and externally hired CIOs, $\chi 2(2, N=376) = 104.679$, $p < .001$. The effect size for these results was relatively strong (Cramer's V = 0.528) (Cohen, 1988). Post-hoc comparisons using the Bonferroni correction showed that only the difference in the previous IT position was statistically significant. Thus, CIOs with previous IT positions are promoted internally more often than expected. Figure 10 shows that the difference was also significant for the previous CIO positions. However, this difference can be neglected because of the categorization used. The previous position could not be determined for 8 of the 384 CIOs. Therefore, Hypothesis H7c, which states that internally hired CIOs in Germany also rise from an IT position by a majority, is supported. In contrast, IT executives from a position outside IT are not increasingly hired externally. Therefore, Hypothesis H7b is not supported.

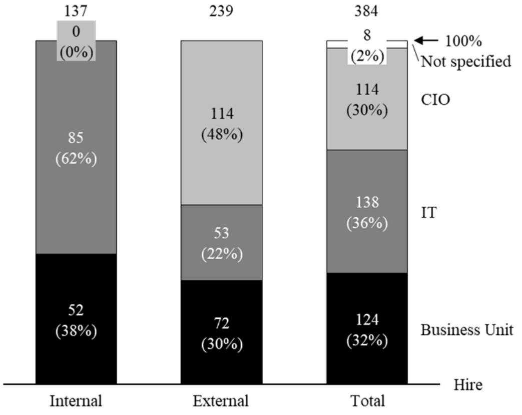


Fig. 10. Percentage of the previous position by internal/ external hire

F. Reporting Structure

Finally, the reporting structure was examined. As Figure 11 shows, the majority of German CIOs report to the CFO, followed by CEO. A more detailed report structure is provided in Table IX. Therefore, Hypothesis H8a, which states that the majority of CIOs in Germany also report to the CEO, is not supported. To test the other hypotheses, the CIOs who report to the CEO or the CFO are primarily relevant. All others were grouped under "Other." To test whether externally hired CIOs reported by a majority to the CEO and internally promoted CIOs reported by a majority to the CFO, a chi-square test was performed. The results show no statistically significant difference in the reporting structure between internally and externally hired CIOs, χ2(2, N = 206) = 2.121, p = .346. Thus, Hypotheses H8b and H8c were not supported. Whether a CIO is promoted internally or hired externally, therefore, has no effect on the executive he reports to. Figure 11 shows the distribution of CIO reports and whether they were hired internally or externally. There were also no differences in the category "Other." When analyzing the reporting structure, it should be noted that for many CIOs, the reporting structure could not be specified.

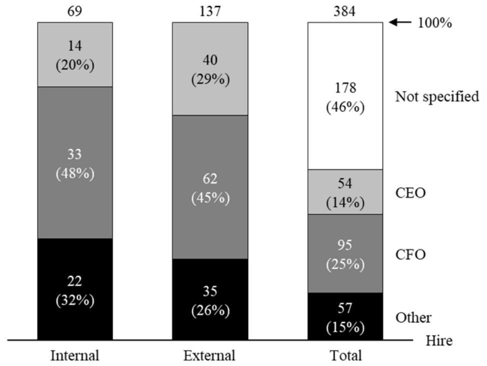

Fig. 11. Percentage of the previous position by internal/ external hire

G. Summary

Table XII summarizes all of the hypotheses tested, the tests used, and the results.

TABLE XIII. SUMMARY OF THE TESTED HYPOTHESES AND RESULTS

Hypothesis	Support	N	χ2	p-value	Effect size
H1: The tenure of German CIOs is comparable to that of US-American CIOs.	Partially *	384	-	-	-
H2: The tenure of German CIOs is shorter than that of German CEOs.	No	384	-	-	-
H3a: The tenure of CIOs differs according to the size of the company, based on the number of employees.	No	232	3.316	.506	-
H3b: The tenure of CIOs differs according to the size of the company, based on turnover.	No	232	6.128	.294	-
H4: The tenures of CIOs do not differ per industry.	Yes	232	**	.756	-
H5a: CIOs with a background in economics have the longest tenures.	No	203	**	.200	-
H5b: A higher level of education is associated with a longer tenure.	No	212	**	.751	-
H6: There is no difference in tenure whether CIOs were hired internally or externally.	Yes	227	0.447	.504	-
H7a: The tenure of the CIOs is independent of the previous position.	Yes	225	1.059	.589	-
H7b: The majority of externally hired CIOs come from a position outside IT.	No	376	104.679	.120	-
H7c: The majority of internally hired CIOs rise from an IT position.	Yes	376	104.679	<.001	Relatively strong
H8a: The majority of German CIOs report to the CEO.	No	384	-	-	-
H8c: The majority of externally hired CIOs report to the CEO.	No	206	2.121	.346	-
H8b: The majority of internally promoted CIOs report to the CFO.	No	206	2.121	.346	-
** Depends on values selected for comparison. ** Fisher's Exact test was used*					

V. Discussion

The results show that neither (a) the size of the company, (b) the industry type, (c) the educational background, (d) the previous positions, nor (e) the reporting structure have a significant impact on the tenure of CIOs. However, several findings require further investigation.

When examining tenures, perspectives and comparative values play a decisive role. The mean value of completed tenures of 6.6 years paints a picture of relatively long tenures. The median of 4.7 years of service paints a more differentiated picture. The perception that CIOs have a short tenure is possibly influenced by the large number of position changes in recent years. For example, the average tenure of IT executives currently in office is only 4.8 years. The median value were 3.7 years. However, the fact that CIOs have only short tenures was not proven by the analysis in this study.

The size of the companies was examined based on their turnover and the number of employees. Due to the exclusion criteria, the companies had a minimum size. Therefore, it cannot be excluded that this is the reason why no differences were observed. An investigation without limitations could provide further insights into whether company size influences CIO tenure.

The analysis clearly shows that German CIOs do not only have a technical or engineering background. Half of CIOs have a degree in economics. However, IT executives with a degree in economics do not have the longest tenures. This study cannot confirm that German CIOs are only technically oriented managers.

IT executives in Germany are well-educated. The vast majority of CIOs have at least one master's degree or diploma at the highest educational level. Many also have doctorate degrees. In terms of current tenure, the proportion of CIOs with only a bachelor's degree increased. An additional master's degree or even a doctorate degree takes more time. It would therefore be interesting to examine whether there is a trend towards an earlier career start and an increase in other forms of further education.

Even if the differences in completed tenures are not statistically significant, a previous position as a CIO does not automatically result in a long tenure in the next CIO position. For example, executives who have moved from an IT position or business unit have a longer tenure. This is surprising, because the executive has already gained experience in the same position in another company. It is also possible, however, that higher expectations are associated with the new manager. For example, a CIO may have been hired for strategic change and may not have been fully implemented.

CIOs that move upward internally are particularly likely to move from an IT position. One reason for this could be that IT executives are familiar with the IT organization and landscape and do not require a long transition period.

Most German CIOs moved to office from an external position. In addition, external hires are most often obtained from previous CIO positions. However, this is not surprising. If an external CIO is hired, he should have already demonstrated leadership qualities in the previous CIO position.

In this study, we only examined whether CIOs moved to the CIO position from a certain previous position, particularly frequently either internally or externally. Therefore, it would be interesting to investigate whether a combination of these criteria allows for long tenure.

Unlike IT executives from the US, German CIOs do not report most frequently to the CEO but to the CFO. As the results show, the German CIO reports to many different managers. Surprisingly, 13 IT executives in this data sample reported to the CDO. This could indicate that IT on its own cannot contribute sufficiently to the digitization of the company. It would therefore be interesting to learn in interviews why the CIOs in these companies are located under the CDO.

VI. Conclusion

This study examines the tenure and background of German CIOs and thereby adds to the current body of knowledge of CIO research [19].

The results show that two-thirds of IT executives have tenures of less than five years. However, almost 15% of CIOs have a tenure of more than 10 years. Furthermore, the results of the statistical tests show that none of the factors considered has a decisive influence on the length of tenure of CIOs alone. Future research could combine these factors to obtain more detailed results.

Besides this limitation, this study also has several other limitations that offer possibilities for further research. The CIO Magazine's Top 500 database and profiles in social networks were chosen as sources for data collection. Therefore, the results of this study depend on the reliability of the data. Not all relevant information can be collected from every executive through these sources. Therefore, future research should focus on other sources of data.

The dataset contains the current CIO of a company, as well as its predecessor. In the case of a predecessor, the length of tenure can be specified, whereas in the case of the current CIO, the length of tenure is still uncertain. Therefore, the two groups were considered separately. However, whether the frequencies of these factors have changed over time has not been examined. For example, the proportion of CIOs from the US that came into office from an IT position has fallen in recent years [2]. Further studies should investigate whether this development can also be observed among German IT executives.

Although the results show that none of the factors significantly influence tenure, we cannot conclude that the background of the CIO is unimportant. For example, a non-IT background does not necessarily mean that the CIO has no IT knowledge or experience [6]. When appointing new CIO positions, the skills of the CIO should align with the company's requirements. The type of CIO organization needs vary with time and industry [6]. Based on this background, an organization can select a suitable IT executive. However, the CIO must understand why he was hired [15]. This allows him to align his studies with the expectations of the organization.

In this study, we examined factors that can be regarded as preconditions for the position of the CIO. These factors do not significantly influence IT executives' tenure. Therefore, we endorse Jones et al. 's proposal to investigate what a CIO does once he is in office, regardless of his background [6]. This will help to draw a more complete picture of the factors that significantly influence the tenure of CIOs.

***Abstract*—Use-case models play an essential role in software development processes. They are used to specify functional requirements, estimate software development project efforts, and plan iterations. The use-case model is subject to change as requirements are modified, or the model is refactored. Therefore, it is essential that the use-case model is not redundant and its parts are reusable. Existing approaches for use-case model specification support reusability in a limited way. This paper fills the gap. It introduces a new approach to conveniently yet semi-formally specifying the entire use-case model. The paper presents the Use-Case Flow Language metamodel, consisting of its abstract syntax and a description of the semantics of the metamodel elements. A concrete textual syntax of the language is also provided and informally described. An example of a use-case model specified in the proposed notation is presented in the paper.**

I. Introduction

THE SOFTWARE requirements specification (SRS) is one of the most important artifacts documenting the qualities of a software product. It is always produced regardless of the development methodology used. The SRS can take different forms, including use-case models, product backlogs with user stories, or documents written in free natural language. In the case of a use-case model, the SRS consists of a use-case diagram and the associated use-case specification documents, typically documented using structured texts, tables, or graphical notations (e.g., activity diagrams).

Textual specifications are the most widely used because they are easy to understand and quick to define, even for non-technical people. Still, on the other hand, they can be misinterpreted or incomplete [1]. Therefore, many researchers (e.g., [2], [3], [4]) try to define templates, a set of patterns or rules that help to keep use-case specifications complete, coherent, and consistent.

The important aspect of use-case specification, not fully covered by the existing research, is the specification reusability. The same steps, step sequences, flows, or subflows can be applied in many places when the change in one place will influence all their instances. There are already defined some reusability mechanisms in the UML, like «include» and «extend» dependencies and generalization. However, they are defined at the use-case level. To have an advantage of these mechanisms for use-case fragments, one should introduce new use-cases just for the reusability, which would increase the use-case number significantly, making the use-case diagram and the whole use-case model more complicated.

The paper aims to define a general-purpose language for writing textual use-case model specifications, emphasizing reusability. The proposed notation is consistent with existing good practices, and the result of their application, i.e., the textual use-case specification should have the necessary features to allow its further processing, e.g.:

- Checking use-case models' completeness and correctness.
- Bi transformation into diagrammatic notations, e.g., activity diagrams or flow visualization.

The motivation to cover the use-case model by a standardization process was and still is very strong. The reasons for standardization efforts are as follows:

- The use-case model is used for the specification of functional requirements.
- Use-cases are the source information not only for the implementation of a software product but also for the verification of the product by functional tests; the functional tests can be implemented directly from the use-cases in parallel with the implementation.
- The use-case model is used to estimate the development efforts (use-case points method [5]).
- Use-cases play a crucial role in iterative software development projects as the iteration plans are organized for a set of use-cases or similar constructs.

The contribution of this paper is a notation specification of a use-case model flow language (Use-Case Flows Language, UCFL) used for scenario definition as a supplementary part of a use-case diagram. The specification includes the language metamodel (abstract syntax) – see section III, and concrete textual syntax (T-UCFL) – see section IV. The metamodel takes the form of a UML class diagram, while the concrete syntax is given in the form of context-free grammar. The notation is presented with several examples. It is characterized by a minimal set of keywords used in use-case flow steps. Examples of the T-UCFL usage are contained in section V. And, finally, the content of the research presented in the paper is summarized in section VI.

II. Related Work

A metamodel is a typical form of abstract syntax representation, also used for use-case models ([6], [7]). Such a metamodel can have many different representations, both graphical and textual. The authors decided to propose their own metamodel for the use-case specification formalism in order to overcome the limitations of existing, e.g., the lack of iterations or interruptions.

The concrete syntax of UCFL called T-UCFL takes the form of a free context grammar – such a solution was used in [8] for a similar purpose. The grammar has been developed with best practices in mind. As this is a textual specification, the authors draw inspiration from many existing books [2]-[4] and papers [9]-[10]. These references suggest, among others, different templates of use case scenarios, keyword sets, and ways of identifying steps. To the best of the authors' knowledge, none of them pay attention to the reusability of the step, step ranges, or global flows. The existing reusability mechanisms are defined as reusable templates [11] or patterns [6], [7].

Use-case specifications with globally visible flows are collected in a use-case model. A similar idea is given in [12], where the authors suggest using "several mechanisms to factor out common usage like error handling from sets of use-cases", but the idea is not formalized.

Common elements proposed in this paper include:

- use case name,
- documentation – can be a substitute for a goal, brief description, primary and secondary actors,
- pre- and post-conditions – similar to [13], post-conditions can be divided into subgroups depending on the scenario and return a specific state [9]; such a construct can be used to model minimal guarantees and success guarantees,
- subflows – as potential elements of reuse,
- the main flow of events – sometimes called scenario ([4]) or basic/normal course of events ([8], [12]),
- flows – called alternative flows ([4]), alternative courses (e.g. [2]), or extensions (e.g. [3]).

Use-case flow is typically expressed in terms of actions. Sometimes these actions have no implicit structure, e.g. [12], [4], when the scenario is simply a sequence of sentences. In the proposed approach, the actions are classified and uniquely identified by step identifiers, which enables their reusability. The step identification resembles the one proposed in [2], [11] and implemented in some tools, e.g., CaseCompleted [14] or Enterprise Architect [15].

The use-case semantics, especially the control flow, must be clearly defined. This can be achieved by using specific keywords. The keywords used in the literature to represent the control flow are as follows:

- GOTO step ([11]) or USE-CASE CONTINUES AT step ([14]).
- IF-THEN-ELSE-ELSEIF-ENDIF, MEANWHILE, VALIDATES THAT, DO-UNTIL, ABORT, RESUME step, INCLUDE use-case, EXTENDED BY use-case ([13]).
- IF, VALIDATES, RESUME FLOW, goto, and resume statements are also defined indirectly in separate columns with appropriate names (alternative FlowId, resume FlowId) as identifiers to steps ([16]).
- USE-CASE CONTINUES AT, RETIRED n TIMES, ENDS IN state ([9]).
- COND, INVOKE, REJOIN, FINAL: state ([7]).

Most of them were adapted in the proposed language, e.g., goto, validates that, includes, extends, and final.

III. UCFL Metamodel

This section presents the abstract syntax and semantics of the Use-Case Flow Language specification. The UCFL abstract syntax, in the form of the UML class diagram, is shown in Fig. 1. As the notation focuses on the specification of use-case behavior, the UCFL abstract syntax does not contain either actors or the relationships between them.

A. UCFL Containers

Container is a named element containing flows or their refinements – subflows. We have two types of containers: use-case model and use-case.

1) Use-Case Model: Use-case model is a container of use-cases. It can define publicly visible flows and subflows. Optionally, the use-case model can specify so-called use-case model interruptible regions or flow-interruptible regions (see section III-G) and be documented by a string.

2) Use-Case: Use-case is a basic modeling element that represents interactions between the system and its actors via flows and subflows. It may have optional documentation describing the use-case goal. The use-case may also specify use-case interruptible regions (see section III-G).

Pre and postconditions: A use-case may require some preconditions to be met in order to enable the use-case behavior. These preconditions (if any) are sentences in natural language. The use-case behavior can change the state of the system. The state changes are represented by postconditions. Each postcondition is a sentence in natural language with a state name, e.g., success, partial success, failure, or other, defined by a modeler.

Generalization: Use-cases can be related to each other with generalization relationships. A use-case can be the parent of many use-cases (children). Only leaves of the inheritance tree can have flows defined. A justification for this decision is given later in this section.

B. UCFL Container Elements

1) Flow: Flow is a key element used to structure the use-case behavior. It is a sequence of steps referring to actions performed either by an actor or by the system. A step has a sequence number and a step identifier constructed from the flow identifier.

From the perspective of a graphical language representation, a flow is a path (possibly looped) in the graph without any branches. Flows can be assembled into a graph using specific actions, e.g., conditional. The first action in the flow can

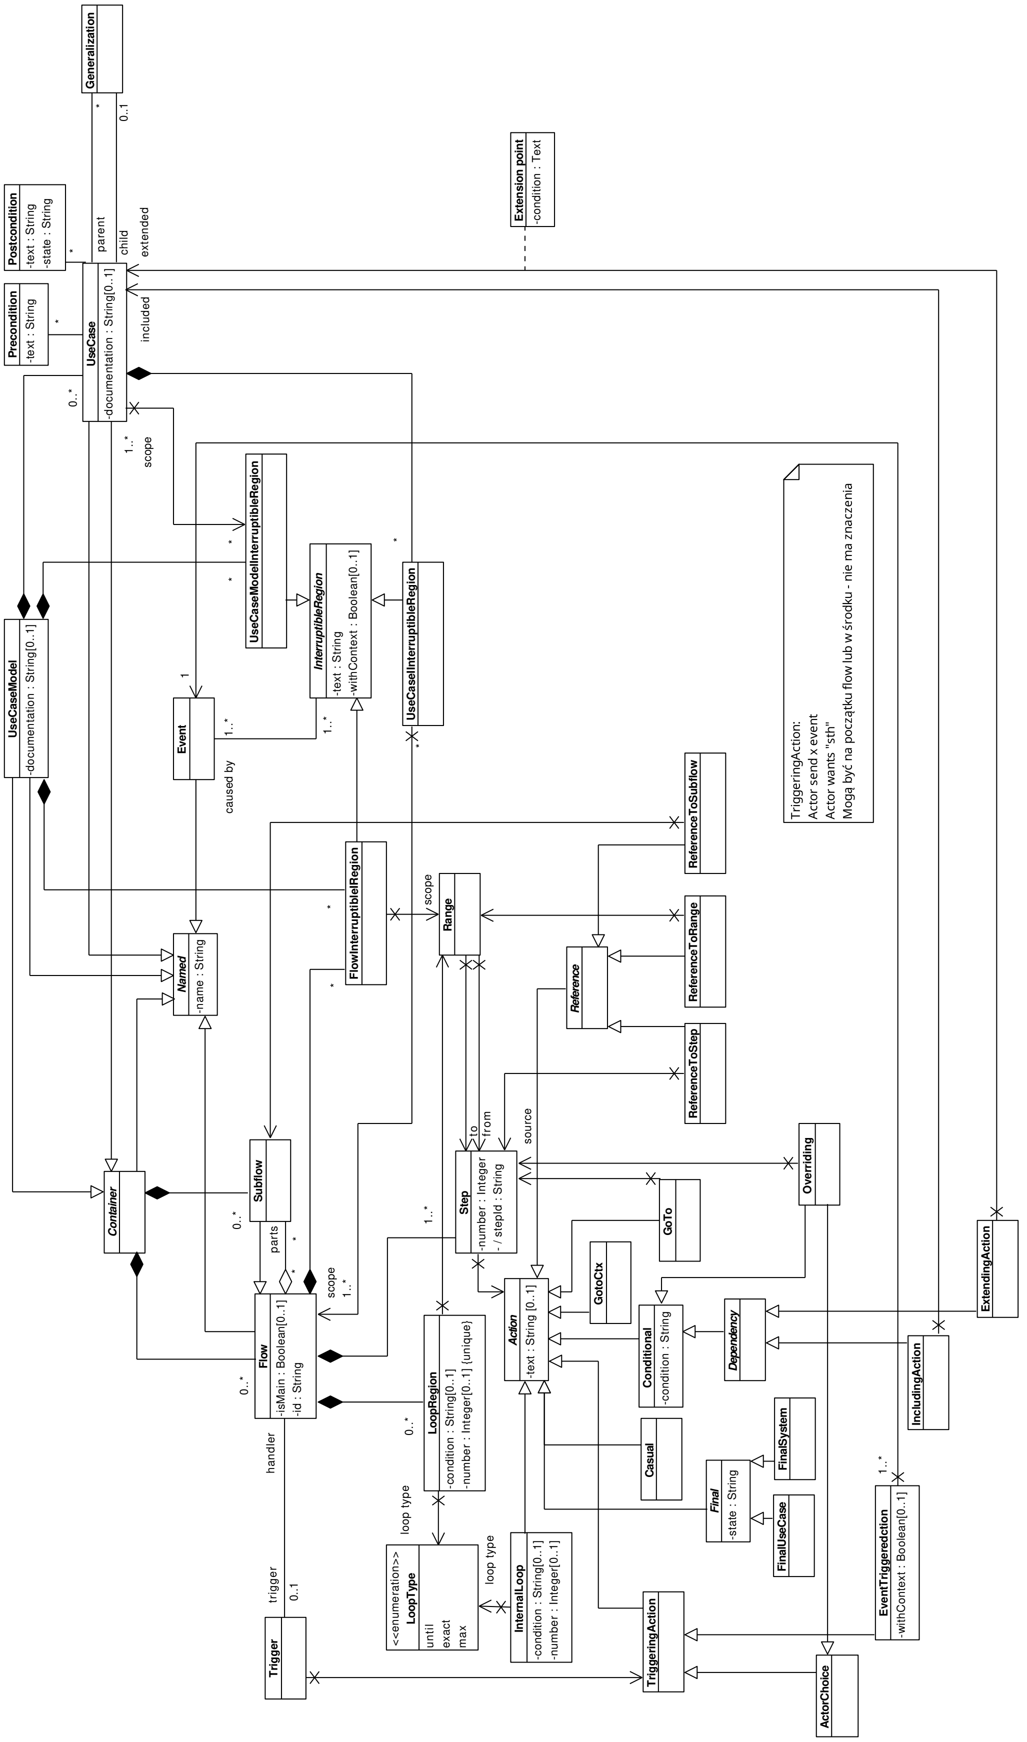

Fig. 1. UCFL abstract syntax

connect it to another flow (as a branch of another flow) - see Fig. 2.

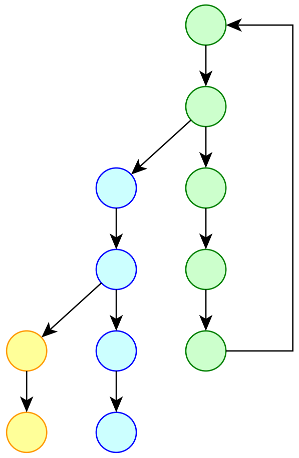

Fig. 2. Flow visualization – different flows are represented by different colors

The flow declaration introduces a flow identifier and a name (both of which must be unique within the context of the flow owner) and, optionally, a trigger. A trigger specifies an action (called a triggering action) that enables the flow. If the flow has a trigger, the flow is called a handler. If the owner of the flow is a use-case then the flow can be marked as a main flow (a use-case must define exactly one main flow; other flows are alternatives).

A flow can additionally define flow interruptible regions (see section III-G) and loop regions (see section III-E).

A flow can be constructed from subflows.

2) Subflow: Subflow is a specialized flow with the restriction that its steps must refer to actions that form a sequence that is casual, finals, and internal loops actions (see section III-F). The subflow is a primary reusable element. It can be shared by several flows; however, a subflow cannot contain interruptible regions or loop regions.

C. Range

Range is a sequence of steps (from–to) included in one flow. Ranges define the scope of flow interruptible regions (see section III-G) or loop regions (see section III-E).

D. Loop Type

Loop type is an enumeration of literals defining different types of loops: `until` (do something until condition), `exact` (do something the exact number of times), `max` (do something the maximum number of times). The type is specified when defining a loop region or an internal loop action.

E. Loop Region

Loop region is the specification of a range that can be repeated in the manner defined by a Loop type. If the Loop type is set to `until`, the condition for the loop region must be defined. Otherwise, the number attribute must be set.

F. Actions

Each step of the flow must refer to one action describing the actor-system interaction in an informal way (*text* attribute in *Action* metaclass).

1) Triggering Actions: A trigger specifies an action (so-called triggering action) that enables the flow. It is the only action that does not need to be referenced by a flow step because it is assumed that it will be performed by an actor to start the flow. There are two types of triggering actions: actor choice action and event-triggered action.

Actor choice action: A flow can be started at the request of the actor, represented by the Actor's choice triggering action.

Event-triggered action: A flow can be started by an actor sending an event to the system, which is modeled by an event-triggered action.

The event-triggered action must refer to an event and optionally can contain a request to store the context before the event is handled (attribute *withCtx*). The event is understood as something that happens at a specific time that requires the system reaction. The event has a name that serves as an event identifier. The context defines the name of the running flow or subflow within the region scope (if any) and its running step, which allows the behavior to be resumed later.

2) Casual action: Casual action is the most general. It is used to model anything the actor or system must do, that cannot be expressed by other actions.

3) Finals: A modeler can define a final action to express that the system has completed its operation (Final system action) or that a use-case has completed its operation in a particular state (Final use-case action). Such an action should be the last one in the flow (or subflow in the case of the final system action).

4) Conditional: Conditional action represents a decision made by the system under specific conditions. Such an action may check whether another use-case has ended in a particular state. It is usually the first action of the alternative flows.

5) Internal Loop: Internal loop represents a case where a particular action is to be repeated in the manner defined by the loop type (see section III-D for details).

6) GoTos:

GoTo: Goto action is used to define unconditional loops. You can jump to a particular step in the same flow or any flow in the same use-case provided that the referenced step exists.

GoTo Ctx: The special version of goto action - `Goto ctx` - allows you to return to the previously saved context (the interrupted action is executed again).

7) Overriding: Overriding is a specific action used as a branching mechanism in the flow definition. This action points to the step in the base flow that is being overridden. The action in the source step must be of the same type as the parent of the overriding action (Actor choice or Conditional).

8) References: References represent the reusable elements of the T-UCFL. Depending on the scope of reusability, three types of reference are distinguished: reference to step, reference to subflow, and reference to range.

Reference to step: Reference to step is the simplest reference action, where the scope of reusability is limited to a single action defined in the step to which the reference action refers. You can imagine that the reused action is copied in place of the reference to the step action.

Reference to subflow: Reference to subflow is the reference action in which the scope of reusability is a particular subflow. When the subflow activity is finished, the control flow is passed back to the original flow.

Reference to range: Reference to the range is the reference action in which the scope of reusability is limited to a specific range.

9) Dependencies: Including: A use-case can include the behavior of another use-case. The semantics of this action is similar to the «includes» relationship in the UML [17] where the including use-case is the owner of the flow with the including action, and the included use-case is the one indicated by the including action.

Extending: The flow of a use-case can contain an extending action. The semantics of this action is like the «extends» relationship in the UML [17] where the extended use-case is the flow owner with the extending action, and the extending use-case is that indicated by the extending action. The extension point describes a condition that must be satisfied for the extension to take place.

G. Interruptible Regions

The UCFL allows the definition of interruption (exception) handling mechanisms using so-called interruptible regions. Such a region points to its scope. The scope of the region can be either a set of use-cases (use-case model interruptible region), a set of flows defined within a use-case model, or a use-case (use-case interruptible region), a range (flow interruptible region). The scope can be interrupted by any event, that caused the interruption.

1) Use-case model Interruptible Region: Use-case model Interruptible Region enables specification of the interruption mechanisms at the use-case model. The interruption scope can refer to any flow or a use-case defined in this container.

2) Use-case Interruptible Region: Use-case Interruptible Region enables specification of the interruption mechanisms at the use-case level. The interruption scope can refer to any flow defined in this container.

3) Flow Interruptible Region: Flow Interruptible Region enables specification of the interruption mechanisms at the flow level. The interruption scope can refer to a range (step from, step to) defined in the flow context.

H. Use-case generalization relationship

Use cases are classifiers and can inherit one from another. An example of such inheritance is shown in Fig. 3. Assuming that the use-case specification is given in natural language, the question arises of how the use-case generalization influences their specification, which can "include possible variations of its basic behavior, including exceptional behavior and error handling" [17].

Generally, a behavior is a specification of events that may occur during the use-case lifetime. The specification must contain at least one event – the event of its invocation [17]. The behavior is invoked when an instance of the owning classifier (i.e., use-case) is created.

In the case of use-case inheritance, a child's specification of events (including the triggering one) is inherited from the parent use-case, which makes the whole specification ambiguous. Therefore, to avoid possible problems and misinterpretations, we assume that any parent use-case must serve only as a root of a use-case hierarchy. Use-case triggers for the hierarchy leaves should determine which child to run.

IV. T-UCFL Informal Description

This section demonstrates the use of the T-UCFL concrete syntax ([18]) with several examples. The language grammar has been designed to keep the language flexible and concise. However, as the specification is intended to be processed by computers, the grammar may impose some constraints on the use of the language, such as the need to enclose elements in quotes or the use of certain keywords.

A. T-UCFL Containers

The container – as an abstract class – has no textual representation.

1) Use-case Model: A use-case model is a container and a namespace for all other elements. Its declaration defines the model's name (e.g., Buying) and optional documentation. Its definition contains shareable elements with global visibility (flows and subflows), an optional declaration of interruptible regions, and a list of use-cases. The concrete syntax assumes that the documentation is textual; however, for readability purposes, the authors decided to use a graphical version in the example presented below (see Fig. 3).

```
Use-Case Model: Buying
Documentation:
```

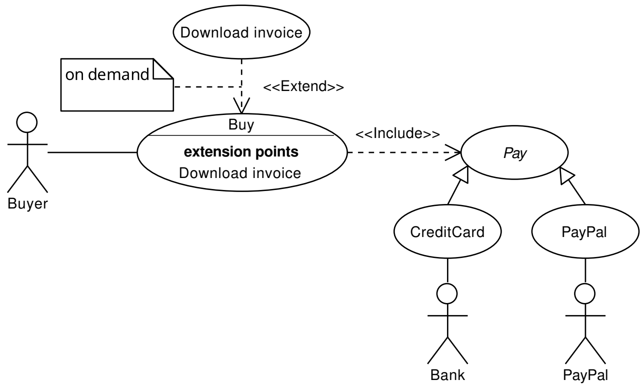

Fig. 3. Buying use-case model documentation in the form of a use-case diagram

2) Use-case: Use-case specification consists of a use-case declaration followed by the use-case definition. The use-case declaration defines a unique use-case name within the use-case model (e.g., `CreditCard`) and, optionally, use-case documentation.

```
Use-Case: CreditCard
Documentation: "Use-case enables payment
  with a credit card."
```

3) Pre and postconditions: A use-case declaration can also contain pre- or post-conditions placed after documentation (if any). The precondition section has one or more statements expressing conditions, for example

```
Preconditions:
- "Actor is logged in the system."
```

Quotation marks are required by formal grammar and can be skipped if the use-case specification is not going to be automatically translated.

Each post-condition section, if any, should define a name of a final system state name (e.g., success, partial-success, error) followed by one or more conditional statements, e.g.,

```
Postcondition(success):
- "An order is stored by the system."
```

4) Generalization: If a use-case has a parent, its name follows the child use-case name and "`-->`" symbol, e.g., `Pay` is the parent use-case for the `CreditCard` use-case:

```
Use-Case: CreditCard --> Pay
```

B. T-UCFL Container Elements

1) Flow: Flow is a named element with an additional string identifier. A flow can be defined in the context of a use-case model, typically as a handler for some event or in the context of a particular use-case. A use-case should have exactly one flow with the reserved name: `Main flow`, and any number of alternative flows with unique identifiers.

Each flow defines a sequence of numbered steps. The step number is constructed with a sequence number preceded by the flow identifier (skipped for the main flow), e.g.:

```
Use-Case: Buy
Trigger: ...
Main flow:
  1. ...
  2. ...
Flow B: The_order_data_invalid
  B1. ...
Flow C: Unsuccessful_payment
  C1. ...
```

The example shown above presents the `Buy` use-case with the main flow and two alternative flows `B` and `C` (`B` is the identifier, `The_order_data_invalid` – is the flow name). The main flow of the use-case has a triggering action defined.

2) Subflow: A subflow is an element of reuse. It can be visible globally (subflows defined at the use-case model level) or locally (subflows defined at the use-case level). They serve to split long flow definitions into manageable fragments. Only casual, final, and internal loop actions are allowed in the subflow definition.

A subflow example is given below:

```
Subflow P: Car_info
  P1. ...
  P2. ...
```

C. Range

Range defines a subsequence in a flow, identified by two steps identifiers, e.g., `2.-3.` consists of 2 steps (2 and 3 in the `Main flow`), `A.5.-A.7.` consists of 3 steps in the flow `A`.

D. Loop Type

Loop type is a keyword (one of `until`, `exact`, `max`) used together with a loop region or internal loop action to specify the loop type – see section V for examples.

E. Loop Region

The loop region works in a similar way to an interruptible flow region. It specifies a range of steps to be repeated as specified by the associated loop type. The loop region is placed after all the steps of the flow, e.g.,

```
Main flow:
  1. ...
  2. ...
Steps 1-2 can be repeated exactly 3 times
Steps 1-2 can be repeated
  until "condition."
```

F. Actions

1) Triggering Actions: A triggering action is typically used to specify how an actor starts a particular flow. In this case, it is specified before the flow, after the `Trigger` keyword. Examples of triggering actions include Actor choice action or Event-triggered action. However, the triggering actions can also be referenced by flow steps.

Actor choice action: A flow can be started by an actor (their decision). Such action must start with `Actor wants` and be followed with "decision" written in quotation marks, e.g.,

```
Use-Case: CreditCard --> Pay
Trigger: Actor wants "to pay with a credit
card"
Main flow: ...
```

2) Event-triggered action: A flow can also be started by an event sent asynchronously by an actor. Such an action must start with `Actor sends` and be followed with the event name and one of `event` or `event with ctx`, e.g.,

```
Actor sends cancelling_service event
Actor sends cancelling_service event
```

```
  with ctx
```

The latter action contains the request to store the context before the event is handled.

3) Casual action: Casual action is the most general. It is a free text without keywords present in other types of actions like `verifies`, `includes`, `ends with` or `goto` (e.g., `"System asks about the order data"`), representing something that the actor or the system must do. The grammar requires this action to be enclosed in quotation marks.

4) Finals: The modeler can define a final action expressing that the system finishes operation (`The system ends`) or a use-case finishes in a specific state (e.g., failure) with the phrase: `The use-case ends with failure`. Such an action should be the last one in the flow. The first one means that the system stops running.

5) Conditional: The conditional action represents a decision made by the system. It must contain the phrase `System verifies` or `System verifies that`, followed by a phrase containing a condition, e.g., `System verifies that "the order data are valid"`. Such an action may check whether another use-case ended in a specific state, e.g. (`System verifies that Pay use-case ended with failure`).

6) Internal loop: One can define that a given action should be repeated a specific number of times specifying its loop type, e.g.,

- `"Actor selects products" max 3 times.`
- `"Actor selects products" until "he is satisfied".`

7) GoTos: GoTo: GoTo action is used to define unconditional loops. We can jump to a particular step in any flow defined in the specific context (a use-case model or a use-case) provided that the referenced step exists, e.g., `Goto 2.` (a jump to the 2nd step in the `Main flow`), `Goto A3.` (a jump to the 3rd step of flow `A`).

GoTo Ctx: GoTo ctx is a special version of the goto action that passes the control flow to the previously saved context (if any). If no context is stored, the semantic is undefined. The interrupted action defined by the context is executed again.

8) Overriding: Overriding actions are used to link flows in a graph. They point to the action in another flow and should be of the same type as the overridden action. Typically, they start alternative flows in a use-case. An example of an overriding action when a decision is made by the system might look like this:

```
B1.3. System verifies that "the order
      data are invalid"
```

The 3rd step in the main flow will be overridden in the `B` flow with the action given above.

9) References: A reference is a basic reusability mechanism. One can reuse another step, step range, or subflow behavior. Examples of such actions are given below:

- `A1.2.` (a step reference; in the 1st step of flow `A`, the 2nd step of the main flow is reused)
- `A2.B3.` (a step reference; in the 2nd step of flow `A`, the 3rd step of flow `B` is reused)
- `B3.A1.-A2.` (a range reference; in the 3rd step of the flow `B`, the range of two steps 1-2 from the flow `A` is reused)

Technically, the reference to a singular step or step range can be thought of as a shortcut for a preprocessing mechanism that copies the referenced elements to the places where they are used and renumbers the steps respectively. Let us assume that flow A contains the steps:

```
A3. Action 1
A4. Action 2
```

and that flow B contains the steps:

```
B1. Action 3
B2. A3.-A4.
B3. Action 4
```

The result of such preprocessing can look like this:

```
B1. Action 3
B2.a. Action 1
B2.b. Action 2
B3. Action 4
```

Subflows must be directly referenced (keyword `subflow` followed by the subflow name) in the appropriate actions, e.g.

```
A2.subflow Car_Info
```

10) Dependencies: Including: One use-case can include or extend another use-case behavior. This is modeled with dependency actions: including or extending. An example of the including action is given below:

```
System includes Pay use-case.
```

When the included use-case reaches the final action, the control returns to the including use-case.

Extending: Two use-cases can also be linked with an extension relationship. The flow of the extended-use case should contain the extension point definition, e.g.,

```
Extension point: "Actor requires the
  invoice downloading."
```

The flow is extended with `Download_invoice` use-case

The extension point specifies a condition under which the flow is extended with another behavior (here: "Actor requires the invoice downloading"). The control returns to the extended use-case when the extending use-case reaches the use-case final action.

G. Interruptible Regions

An interruptible region defines a scope for which the normal operation of the system can be interrupted by a specific event (its name is given) coming from an actor.

1) Use-case model Interruptible Region: Use-case model interruptible region is the one with the widest scope. If it is present, it is placed at the beginning of the use-case model definition, e.g., where any use case can be interrupted by the `close_system` event.

```
Use-Case Model: Document_Editor
Any use-case can be interrupted
  by close_system event
```

2) Use-case Interruptible Region: The scope of a use-case interruptible region is limited to a specific use-case. If it is present, it is placed at the beginning of the use-case definition, e.g.,

```
Use-Case Model: Buy
Any flow can be interrupted by
  close_system event
```

3) Flow Interruptible Region: The scope of a flow interruptible region is limited to a range within a specific flow. If it is present, it is placed after all flow actions, e.g.,

```
1. ...
10. The use-case ends with success
Steps 1.-3. can be interrupted by
  cancelling_service event with ctx
```

The flow interruptible region narrows the scope of the event handling mechanism, e.g., the interruption will be only handled within between steps 1-3 (inclusively).

V. Example Specification

This section contains a small example of a use-case model from Fig. 3, which presents most of the constructs introduced informally in section IV.

The first part of the T-UCFL model specification is related just to the model:

```
Use-Case Model: Buying
Trigger: Actor sends
  cancelling_service event
Flow A: Cancelling_service_event_handler
  A1. "System asks
      for cancellation confirmation"
  A2. Actor wants
      "to cancel the operation"
  A3. The use-case ends with failure

Flow B: Cancellation_denied
  B1.A2. Actor wants "to deny cancellation"
  B2. Goto ctx
```

This part of the model specification is composed of the use-case model called `Buying`; global flow `A` named `Cancelling_service_event_handler`, which is shared among all use-cases and can be triggered by the `cancelinig_service` event generated by an actor; the global flow `B` named `Cancellation_denied` which is a branch of the `A` flow (see a reference step `B1.A2.`). The `Goto ctx` action (if performed) will pass the control flow to the context.

The remaining parts of the T-UCFL specification contain subsequent use-case specifications.

```
Use-Case: Buy
Postcondition (success):
- "An order is stored by the system"
- "An invoice is generated, assigned
  to the order, and stored by the system"

Trigger: Actor wants "to buy an item"
Main flow:
  1. ...
  2. "System asks about order data
     (including payment method)"
  3. "Actor delivers the order data"
  4. System verifies that "the order
     data are valid"
  5. System includes Pay use-case
  6. System verifies that "the Pay
     use-case ended with success"
  7. "System stores an order,
     generates an invoice,
     and sends it by e-mail"
  8. "System informs about
     order completion and enables
     an option to download the invoice"
  9. Extension point: "Actor requires
     invoice downloading"
The flow is extended with
  Download_invoice use-case
  10. The use-case ends with success

Steps 1.-3. can be interrupted
  by cancelling_service event with ctx
```

The main flow contains several conditional actions (e.g., 4, 6). The 5th step contains an including action (`Pay` use-case is included). The 9th step contains an extending action with the condition defined. Finally, there is a flow interruptible region consisting of step range `1.-3.`.

Then two alternative flows (`B` and `C`) are defined:

```
Flow B: The_order_data_invalid
  B1.4. System verifies that
        "the order data are invalid"
  B2. "System informs about invalid data"
  B3. Goto 2.

Flow C: Unsuccessful_payment
  C1.6. System verifies that
        "the payment ended with failure"
  C2. "System informs about the lack
     of payment"
  C3. Goto 2.
```

In both cases, the first step refers to the step with conditional action in the main flow and contains the condition, which complements the condition from the main flow.

The specification continues with the `Download_invoice` use-case specification:

```
Use-Case: Downolad_invoice
Postcondition (success):
- "An invoice is downloaded to
   the Buyer's computer"

Main flow:
  1. "System presents the invoice details
     and asks for confirmation
     of the invoice download"
  2. Actor wants "to download the invoice"
  3. "System sends the last buyer invoice
     to the buyer's computer"
  4. The use-case ends with success
Steps 1.-3. can be interrupted
  by cancelling_service event with ctx

Flow B : Downloading_not_confirmed
  B1.2. Actor wants "to skip downloading"
  B2. The use-case ends
      with partial success
```

The use-case has only one alternative flow `B`, which – in contrast to the `Buy` use-case, is started by the actor's choice action.

There is also a group of three interrelated use-cases in the `Buying` use-case model. The first is the `Pay` use-case, which is abstract and has no flow. It has the following form:

```
Use-Case: Pay
Documentation: "Abstract use-case.
  A root hierarchy for different
  payment methods"
Postcondition (succes):
- "payment succesfull"
Postcondition (failure):
- "payment unsuccesfull"
```

The specification also contains two concrete use-cases (`CreditCard`, `PayPal`) that inherit from the `Pay` use-case. Because of limited space only the first is presented:

```
Use-Case: CreditCard --> Payment
Documentation: "Use-case enables payment
  with a credit card"
Trigger: Actor wants "to pay with a
  credit card"
Main flow:
  1. "System asks for credit card details"
  2. "Actor delivers credit card details"
  3. "System sends a request to a bank
     for payment and waits
     for bank response"
  4. System verifies that "the payment
     was successful"
  5. The use-case ends with success
Steps 1.-3. can be interrupted
  by cancelling_service event

Flow B: Payment_unsuccessfull
  B1.4. System verifies that
        "the payment was unsuccessful"
  B2. The use-case ends with failure
```

Other examples, together with the language abstract and concrete syntax, are available at [18].

VI. Summary

The concept of a new use-case model specification language (UCFL) consisting of the metamodel, and a textual concrete syntax (T-UCFL) was introduced in the paper. The main purpose of the language is the specification of use-case behaviors. It has commercial origins, as the need for the reusability-oriented approach to use case modeling was recognized during the authors' commercial activities.

The T-UCFL syntax was stabilized on plenty of advanced experiments focused on modeling non-trivial behaviors of some invented software systems. The UCFL metamodel was inferred from these experiments.

Concepts introduced in the paper are designed to extensively support the reusability and avoid redundancy in use-case flows for the whole use-case model. The reusability is achieved at different granulation levels, from a singular step, steps' range to a subflow. Flow initial fragments are reused by definition as they are shared with alternative flows. Inclusion, extension, and generalization between use-cases are also supported.

The language helps to introduce changes into the use-case model. A change made in one place "is visible" in many places referring to the changed element.

The UCFL introduced in the paper seems to be very promising and could be further developed. It is internally consistent, concise, and semi-formal - the specification mimics those written in natural language.

It is worth noting that the paper only introduces a textual concrete syntax. However, other syntaxes may be introduced, especially graphical ones.

In the future, the authors intend to extend the proposed notation with tool support. They also work on graphical concrete syntax and bidirectional transformations between concrete syntaxes. Of course, the usability of the language needs to be validated by external users, first in academia and then in industry.

***Abstract*—Artificial intelligence (AI) is used more heavily in agricultural applications. Yet, the lack of wireless-fidelity (Wi-Fi) connections on agricultural fields makes AI cloud services unavailable. Consequently, AI models have to be processed directly on the edge. In this paper, we evaluate state-of-the-art detection algorithms for their use in agriculture, in particular plant detection. Thus, this paper presents the *CornWeed* data set, which has been recorded on farm machines, showing labelled maize crops and weeds for plant detection. The paper provides accuracies for the state-of-the-art detection algorithms on the CornWeed data set, as well as frames per second (FPS) metrics for the considered networks on multiple edge devices. Moreover, for the FPS analysis, the detection algorithms are converted to open neural network exchange (ONNX) and TensoRT engine files as they could be used as future standards for model exchange.**

***Index Terms*—plant detection, deep learning, agriculture, maize data, data acquisition, vision transformer**

I. Introduction

When it comes to smart agriculture on farm devices, the evaluation speed of obtained images plays a crucial role [1]. If the processing of the images is too slow, the farm device has to adjust its speed, which results in a lower time efficiency. Object detection algorithms are already capable to provide object recognition at real-time speed. Especially neural networks are utilized for fast object detection, but the performance of a neural network - inference speed and accuracy - is influenced by its structure and size which determines if the network can run on an edge device.

Often the desired detection is marked by a bounding box which surrounds the identified object. Object detectors that use bounding boxes can be categorized into one-stage and two-stage detectors. Two-stage detectors first identify regions of interest using a heuristic and, then, detect the object in this region. One-stage detectors do both tasks in a single network. One-stage detectors are therefore easier to train and are considered to be computationally faster than two-stage detectors [2], [3]. Two-stage detectors generally have a higher accuracy on the location information of the object and they identify smaller objects much better. For one-stage detectors this lower accuracy often originates from poor anchor boxes and the class imbalance problem. Recently, one-stage detectors with an anchor-less approach yielded better accuracy for smaller objects [4]. This is useful for agricultural applications as plants need to be detected in early growth stages and as farm machines might have limited computational power. Also, nowadays an new form of object detectors emerged - transformer networks for object detection [5]. Such networks tend to be large, but they yield high accuracies.

Yet, does it make sense to deploy algorithms directly on farm machines? In [6], the authors discuss the importance of deploying algorithms directly on the farm machines for better responsiveness and reducing the load on cloud computing. On larger farmlands the network connection might be unreliable such that no cloud services are reachable. It might also be possible to use alternative sensors that are already available such as satellite images and drone imagery. These could be preprocessed before the field work. However, satellite imagery can only give guidance for larger patches of land and can not provide insightful information on individual plants due to limited geometric resolution [7]. Even the alternative of using drones prior to field cultivation or the application of herbicides, is not scaling well as presented in [8]. For example, drone imagery is expensive, as it requires additional personnel, and it is most often limited to good weather [9]. Moreover, the collected information can be outdated by a few days or even a week. For weeding applications, these delays can be critical because weeds can be growing fast. Thus, sensor data should be directly processed on the farm machine especially because the capabilities of edge devices are increasing [10].

For example, in [11], the authors present an object detection algorithm for sugar beets that is able to detect the sugar beets and count their leaves based on red, green, and blue (RGB) and

*Both authors contributed equally.

near infra red (NIR) data. The data set is described in [12]. In [13], a robotic platform is presented that utilizes the detector from [11]. This system is able to distinguish weeds from crops such that it can destroy the weeds with a mechanical stamp. As this robot relies on the aforementioned object detector, the system requires RGB and NIR data. However, often only RGB data is available.

In this paper, we empirically evaluate typical object detection networks for their applicability on the edge for the detection of maize and weeds with RGB data. Because such networks require large amounts of data to be trained, we also present a data set that provides box labelled maize and weeds. The networks are then trained from scratch with the presented data set. Our contribution is therefore as follows:

- We present an agricultural dataset, named CornWeed dataset where maize and weeds plants have been labelled for box object detection[*].
- We evaluate object detection algorithms with various neural network architectures based on their detection accuracy (mean average precision (mAP)).
- Each of the detection algorithms is evaluated on farm edge devices based on a Nvidia Jetson Xavier NX and Jetson AGX Orin regarding their real-time capabilities (frames per second).

II. Data Set

A. Hardware Setup and Data Acquisition

For data acquisition, we utilized a previously designed sensor system [14]. This system comprises a computer, power supplies, and sensors. System and sensors communicate via the robot operating system (ROS)[†] such that data can be stored into *ROS Bags* (see Fig.1) which is a ROS specific data format for time-dependent data. The benefit of this system is that it is sensor agnostic, i.e. any sensor can be integrated and connected. Here we used an Intel Realsense D435i (3D stereo camera) and a real time kinematic (RTK) enabled global navigation satellite systems (GNSS) receiver, as presented in Fig. 1. For a robust and consistent data base, data collection was conducted using two different agricultural machines, an implement on a tractor and on a remotely steered research platform BoniRob [15], see Fig. 2. In a first step, we integrated the sensor system into the BoniRob platform (Sensorbox 2) to evaluate optimal camera angles, heights, resolution, light conditions, etc. on a small scale.In a second step, the sensor system (Sensorbox 1) was mounted on a conventional hoe with a shifting frame and pulled through the field trials with a tractor. For this setup, based on the first data acquisition with Sensorbox 2 (640 x 480 pixel), the resolution of the RGB camera on Sensorbox 1 was increased to 1280x720 pixel for a higher quality of the image data. Yet, both resolutions are kept in the data set for variability. In both sensor setups, the Intel Realsense D435i camera with a vertical field of view (FOV) of 69 ° was mounted at a height of 0.5 m, looking downwards. Therefore, the geometric size of the each obtained image spans a distance of 0.68 m along the driving direction.

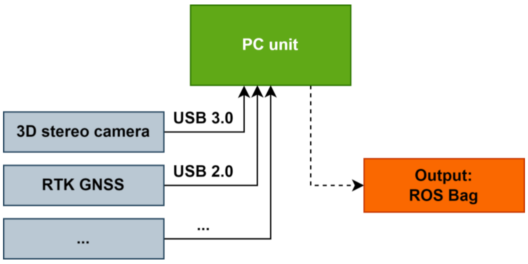

Fig. 1. System perspective of the utilized sensor system.

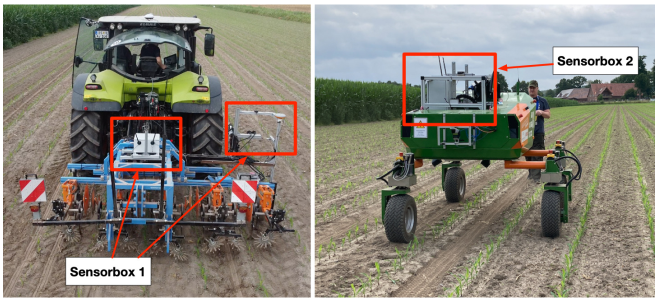

Fig. 2. Platforms for data acquisition. On the left an implementation on the tractor on a conventional hoe with shifting frame (Sensorbox 1). On the right the BoniRob with Sensorbox 2.

B. Data Variability

To represent different stages of growth and weed pressures, we conducted the field trials on multiple days. Therefore, the data samples were recorded over a period of three weeks to ensure different growth stages. Here, the primary focus of the application was to root out the weeds early enough to ensure maximum crop growth. Thus, only the early growth stages of maize crops were considered for the detection application because only at that time crops compete with weeds for resources (water, sunlight, etc.) and otherwise the crops outgrow the weeds. Hence, later growth stages of maize are less relevant for weeding applications. The data set only contains samples in the daylight with cloudy and sunny weather conditions, however, evening and early morning samples in future could be added to extend the domain knowledge for deep neural networks. The field trials always took place on the same field such that the same soil conditions and the same types of weeds persist throughout the data set.

C. Data Labelling

The number of detected weeds instances plays a crucial role for selective weeding. To keep track of the number of detected objects, bounding boxes were chosen as the medium of annotation. The data set contains 3574 outdoor field images of *maize and weeds*, which are also the annotated classes in the data set. An example image of the data set

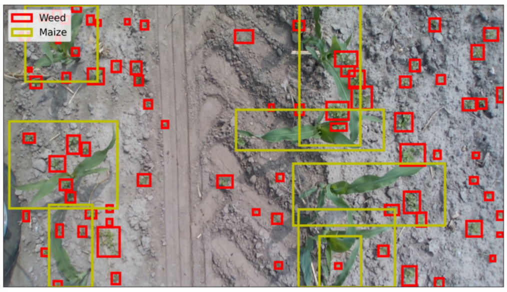

Fig. 3. An example image of the data set taken with the setup on the conventional hoe (Sensorbox 1). The images have resolutions of 640 × 480 pixel with Sensorbox 2 and 1280 × 720 pixel with Sensorbox 1. Here, the labelled instances of Maize are shown in yellow and the weed instances are shown in red.

for Sensorbox 1 with labels is displayed in Fig. 3. The annotations were generated by human annotators and reviewed by a different human reviewer. We used the open-source computer vision annotation tool (CVAT) labelling tool [16] provided by CVAT.ai corporation. The model trained on the data set can be subsequently incorporated into this tool to further reduce the average labelling time. Thus, to speed up the process of annotation, intermediate object detectors have been trained during the annotation process with the interim data to provide proposal annotations. The annotator then fine tuned the proposed annotations by adding not detected weeds and maize, adjusting the class labels of false positives, and changing the sizes of the boxes. Such an interim detector can also be provided by models trained on a synthetic training data as done by Naeem et. al. [17] for a similar use-case.

III. Detection algorithms

For a real-time detection scenario the accuracy is as important as the achievable detection rate. In the considered use-case of selective weeding, the movement speed of the farm device constraints the minimum frames per second (FPS). To cover the whole ground with an average velocity of 8 km/h (2.2 m/s), we require at least 3-4 FPS. Higher frame-rates are of course desirable and would make the system more reliable. Given the low frame-rate requirement, two-stage detectors such as Faster region-based convolutional neural network (R-CNN) [18] can be used also as they have higher accuracy than single stage detectors as shown by Garcia and Mateo et. al. [19]. The authors show that while one-stage detectors are generally faster in inference speeds at lower image resolution, two-stage detectors outperform in terms of accuracy and detecting small objects in the image. This is especially relevant for the considered use-case here, since most of the weeds should be rooted out in the early growth stages, when they are small, before they start competing with the actual crop for resources.

This leads to an accuracy aspect: while weeds are small, detectors might have poor object detection performance. For example, anchor-based approaches [18], [20], [21] have difficulties to find very small objects in the image if the anchor boxes are not small enough. There are, however, object detectors that use an anchor-free approach [4], [22] and these are supposed to have a substantially better performance on small objects. More recently, object detectors based on transformer networks yield high accuracies in multiple applications [5]. Accordingly, for the considered use-case, we chose networks of the aforementioned categories. The networks are introduced in the following subsections.

A. Faster R-CNN

R-CNN is a two-stage detector where the first stage produces region proposals that are then fed into the second stage where the object detection takes place. First versions of R-CNN have been published in 2014 [23] and the following versions have improved to be more computationally effective and more accurate. In this paper, the considered version is the Faster R-CNN [18]. This version uses a convolutional neural network (CNN) as backbone to identify feature maps, which are then sent to a region proposal network and a detection network.

B. RetinaNet

The RetinaNet [21] is a one-stage object detector that is based on the single-shot detector (SSD) [24]. The main idea of SSD is that the detection requires information at different scales. Therefore this network pools directly from multiple convolutional layers, which are referred to as *convolutional predictors for detection*. This network utilizes default boxes and aspect ratios, which have to be determined beforehand. Each default box is then used for prediction on a grid on the image. As the number of predicted boxes can become large, hard negative mining is applied. Due to this only few candidate boxes are considered during the training of an SSD network, which is also known as the foreground-background class imbalance problem [25]. To address this problem, RetinaNet introduces the focal loss to put more emphasis on the hard training examples instead of easy ones. The authors showed that the focal loss substantially improves the performance of one-stage detectors.

C. FCOS

Another one-stage detector that does not use anchor boxes is the fully convolutional one-stage (FCOS) detector [4]. This detector does a pixel-wise detection and computes then a *center-ness* of each pixel according to the ground-truth boxes. The benefits of this are that the intersection over union (IoU), which is computationally expensive, does not need to be computed and that no anchor boxes are required. A downside of this approach is that in the detection ambiguities can occur as one pixel might be the center of multiple boxes. In such cases the larger box is ignored such that the detector has a better accuracy for smaller objects. For the use-case at hand, this is actually good as there are many small weeds.

D. YOLO

The you only look once (YOLO) detector, initially published in [26], has become very popular and has been extended in various aspects. It is a single-stage detector that outputs class probabilities and bounding box coordinates in a single step that are filtered with non-maximum suppression. The YOLOv5 is an efficient implementation [27] in PyTorch, which uses basically the same network as introduced in [28]. In this detector, the authors make excessive use of the so called *bag of freebies* – methods that only change the training strategy or the training cost – and *bag of specials* – methods of plugins that have a good performance to inference cost ratio. The bag of freebies are, for example, data augmentation methods that increase the robustness of the detector. The bag of specials on the other hand are spatial pyramid pooling, a spatial attention module, or other activation functions.

YOLOv5 comes with many variants with different model layers and backbones. For the scope of this paper, we only use YOLOv5 medium and large variants of the YOLO architecture.

E. DINO Transformer

Most of the above object detection models require a prior knowledge of the task in the form of anchors (one-stage) or region proposals (two-stage). The prior knowledge makes the model specialized to a specific task but loses performance when moved to a different detection task making transfer learning difficult. Carion et. al. [29] propose detection transformer (DETR) that is an end-to-end object detection transformer. With this architecture, there is no need to post process the bounding boxes or risk counting the same object twice due to its bipartite matching loss function. Following the DETR architecture, Zhang et. al. [30] came up with an improved variant of DETR called DETR with improved denoising anchor boxes (DINO) transformer. Zhang et. al. proposed the following improvements to the DETR architecture: 1) Adding a noisy version of the ground truth labels during training to speed up the training process. 2) Mixed query selection 3) Box update based on the current layer and the next layer during back propogation. Despite the recent trends in the transformer-based detector architectures, Carion et. al. pointed out the reduced performance of DETR in detecting small objects in the image, while Zhang et. al. argued that the anchor-based approaches still show superior accuracy compared to the transformers. For our experiments, we used the DINO transformer to represent the transformer-based family of object detectors.

IV. Experimental Setting

This section goes through the lifecycle of the neural networks:

1) Training a neural network and selecting the best variant from the *training pipeline*.
2) *Deployment pipeline* which explains how the network is optimized for a particular edge device to maximize performance throughput.
3) Edge devices used to evaluate inference speed of neural networks on an agricultural use-case.

A. Training Pipeline

For all the models mentioned above, official Github repositories already exist [31] [32] [27]. Thus, for the Faster R-CNN, the RetinaNet, and the FCOS, we used the Detectron2 repository from Meta [31]. For each of these models, we set the batch size to 32, the learning rate to 0.01, and the optimizer was stochastic gradient decent. For YOLOv5, we utilized the implementation of Ultralytics [27]. There, we set the batch size to 32 and 16 for YOLOv5 medium and YOLOv5 large variants, respectively. Also, we specified the image size to be 800 pixel and to be rectangular to have comparable results with the other networks. During training, we also used the *multi-scale* option, where the image size is varied during training. For the DINO transformer, we used the Detrex research platform [32], which is based on the Detectron2 repository. Due to the size of the DINO transformer, we had to set the batch size to 4. The learning rate was set to 0.0001. All other parameters of the algorithms were left to the default values. Also, we did not tune the augmentations if any are used by the model.

We trained each model on a NVidia Tesla V100 DGXS 32GB GPU with the CUDA Version 11.1, and used a train-validation split of 80% (2862 images) and 20% (712 images), respectively.

B. Deployment Pipeline

After training, the best model file is selected based on the validation data split and then converted to an open neural network exchange (ONNX) model. ONNX is a framework that optimizes and acts as an intermediate representation of neural networks to support conversion to any standard frameworks such as PyTorch, TensorFlow, OpenVINO, TensorRT, etc. However, a user can also use this intermediate representation directly. In this paper, both the ONNX models and TensorRT models are evaluated to highlight the impact of framework choices. The code repository for testing all the trained models is provided at this link [‡]. The ONNX models of the DINO transformer and YOLO network were then converted to a TensorRT engine file with precision of 16-bit and 32-bit floating points and 8-bit integer. The different precision can make the model more memory efficient and also advanced build-in function can be used for faster computation [33]. The other models consist of the layers that can not be optimized by the TensorRT engine (up until version 8.5[§]), hence failing to do the conversion to a TensorRT engine. At the time of this publication, TensorRT version 8.5 was available.

[‡] Inference speed testing: https://github.com/niqbal996/deployment_testing

[§] We are hopeful that with upcoming TensorRT 8.6, the performance metrics can be updated for remaining networks in Table V-A

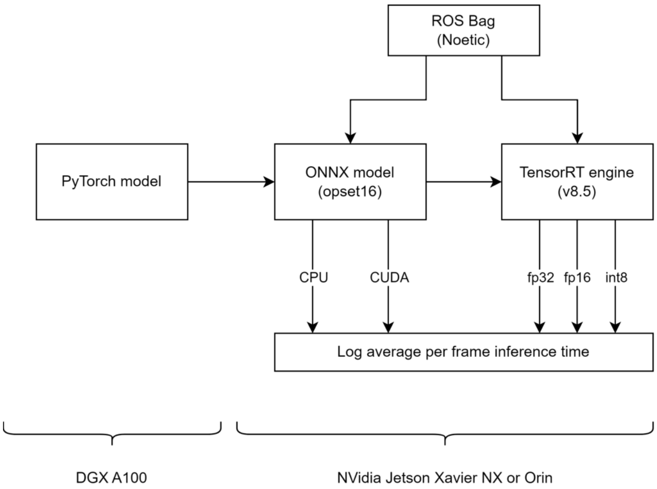

Fig. 4. Deployment workflow showing how the models are trained in PyTorch, converted to open neural network exchange (ONNX) models, and then to TensorRT engine files.

C. Edge Device

For all the experiments in this paper, two NVIDIA Jetson devices were used:

1) the Jetson Xavier NX and
2) the Jetson AGX Orin.

Both edge devices have L4T 35.3.1 with Ubuntu 20.04, *ROS Noetic*, CUDA 11.4 running on them. Jetson devices come with predefined power modes utilizing a varying number of on-board CPUs and online CPU cores. For the experiments shown in Table V-A (see later in Sec. V-B), the Xavier NX was set to mode ID 6 with all cores online and 1400 MHz CPU frequency. In this mode, the Xavier NX board consumes about 20 W of power. Similarly, we activated the MAXN power profile on the AGX Orin to utilize all GPU and CPU cores and to remove clock restrictions. In this power profile, the AGX Orin consumes about 60 W. The input to the model is fed in the form of image sequences via a *ROS Bag*. Each consecutive image sample is read from the *ROS Bag*, downscaled, and normalized according to the input size expected by the model. The performance metrics are logged from the moment an image is received until the detections are ready to be published into the ROS ecosystem as detection messages.

V. Results

This section presents the accuracy results of the presented networks for the data set and the speed results on the considered edge devices.

A. Training Results

TABLE I
Mean average precision (mAP) of all object detectors at various confidence values and class IDs for Maize and weeds

Model	mAP50	mAP50:95	AP50 Maize	AP50 Weeds
Faster R-CNN FPN	71.6	41.8	88.1	55.1
RetinaNet R50 FPN	68.0	40.2	**89.7**	46.3
FCOS R50 FPN	69.3	39.8	87.0	51.7
YOLOv5 medium	**85.4**	**53.3**	**93.0**	**77.8**
YOLOv5 large	**85.4**	**53.9**	**93.7**	**77.0**
DINO Transformer	75.8	45.0	92.3	59.3

Table I shows the mAP with the mean over both classes (namely *Maize* and *Weeds*) at 50 % confidence value i.e. mAP50 in the first column. The second column shows cumulative average of mAP varied from 50 % to 95 % with step size of 5 % i.e. mAP50:95. In the last two columns, we show the average precision (AP) per class at 50 % confidence to show the accuracy trend on larger sized *maize* objects and smaller sized *weed* objects.

Across all networks, the YOLOv5 networks have the highest performance of 85.4 and 53.9 for mAP50 and mAP50:95, respectively. The larger variant YOLOv5 large does not proportionally increase the performance while being much larger in size than YOLOv5 medium. This implies that the accuracy has already saturated and increasing network size does not always necessarily lead to increased performance. In terms of comparison, the YOLOv5 repository already offers many variations and augmentations to the input data, see bag freebies in Sec. III-D. This bag of freebies is also optimized during training by the code in the repository. The networks based on Detectron2 do not have such an optimization. Thus, if only the networks based on the Detectron2 repository are compared with each other, the DINO transformer stands out in detecting maize but still gives a lower accuracy of 59.3 for AP50 for weeds compared with YOLOv5. This is due to its reduced capability to detect tiny objects such as weeds which can be in some instances only be a few pixels in size. This behaviour was first brought to light by Carion et. al. [29] for the detection transformers.

If the one-stage networks of the Detectron2 repository are compared with the two-stage detector Faster R-CNN, the RetinaNet reached a better performance of 89.7 on detecting maize but surprisingly a lower AP of 46.3 on weeds. This higher accuracy of 89.3 than 88.1 from Faster R-CNN is due to the usage of Focal loss proposed by [21]. While focal loss helps in outperforming a two-stage detector such as Faster R-CNN, the AP for weeds is still lower. We believe the lower accuracy of 46.3 on weeds to be an outlier due to anchor boxes not modified to the task of weed detection prior to training. Comparing RetinaNet with YOLOv5, the Detectron2 framework does not provide any flexibility to change the anchor boxes to the task of maize or weed detection prior to training. This leads to reduced performance. Ahmed et. al. [34] observed similar behaviour from RetinaNet in detecting tiny objects from aerial images and used anchor optimization to mitigate that.

To achieve the best possible accuracy from an anchor-based detector architecture, the anchor boxes have to be modified to the specific use-case. Task specific modification of anchor

TABLE II

AVERAGE INFERENCE RATE (IN FRAMES PER SECOND (FPS)) FOR ALL THE DETECTORS FROM TABLE I ON EDGE DEVICES WITH ONNX *CUDA Execution Provider* (CEP) AND TENSORRT. THE INPUT IMAGE RESOLUTION WAS 800 X 1067 PIXEL FOR THE THREE NETWORKS (FCOS, RETINANET, FASTER R-CNN), 800 X 1088 PIXEL FOR BOTH YOLO NETWORKS, AND 512 X 683 PIXEL FOR THE DINO TRANSFORMER. THE VALUES MARKED WITH A * WERE DUE TO A TENSORRT BUG WHERE THE DINO MODEL NOT UTILIZED CUDA.

Framework	**ONNX with *CEP***		**TensorRT**					
Edge device	**Jetson Xavier NX**	**Jetson AGX Orin**	**Jetson Xavier NX**			**Jetson AGX Orin**		
			int8	**fp16**	**fp32**	**int8**	**fp16**	**fp32**
Faster R-CNN FPN	0.62	1.8	X	X	X	X	X	X
RetinaNet R50 FPN	1.37	4.3	X	X	X	X	X	X
FCOS R50 FPN	1.30	4.0	X	X	X	X	X	X
YOLOv5 medium	**2.5**	**6.0**	**19.3**	**12**	**3.7**	**51**	**33.5**	**16.8**
YOLOv5 large	1.4	4.0	12.7	6.5	1.65	37	22	10.9
DINO Transformer	0.24	0.55	1.35*	1.47*	0.86*	3.2*	3.1*	3*

boxes can be crucial in choosing optimum network architecture for any agricultural use-case where each crop has different size in different growth stages. DINO Transformer, FCOS and other anchor-less implementations reduce the complexity of the task by not having to provide any prior knowledge or anchor optimization before training while giving slightly lower accuracy in general.

B. Speed Results

As described in section IV-B, the trained models are optimized and then deployed for both NVIDIA Jetson Xavier NX and Jetson AGX Orin. The average FPS were logged based on the input image which was fed from a ROS bag recorded with Intel RealSense D435i camera for testing purposes. For anchor-based implementations (e.g. RetinaNet, YOLO), the non-maximum suppression is also part of the inference time. This creates a fair comparison between anchor-based and anchor-free models. The corresponding FPS metrics are shown in Table V-A. For the first three models (Faster R-CNN, RetinaNet, and FCOS), the model contains layers that cannot be converted into a TensorRT engine with version 8.5. With the next release of TensorRT v8.6 accompanied with the new Jetpack release, these models should also be convertible to a TensorRT engine. Comparatively looking at the numbers, in general, the ONNX inference framework gives lower inference rates than TensorRT, even when using *CUDA execution provider*. However, the ONNX model serves as a good intermediate model representation that can be later converted to any other inference framework such as TensorFlow, TensorRT, or PyTorch.

The TensorRT engine files with different floating point and integer precisions yield higher FPS in general, see Table V-A. For example, YOLOv5 medium yields 33.5 FPS on fp16 precision via TensorRT compared to a mere 6 FPS via ONNX on Jetson Orin. Especially, the 8-bit integer precision yields the highest inference rate for each network, about 6-9 times faster compared with the ONNX models. When comparing different networks, YOLOv5 gives the highest FPS.

Though the model conversion from PyTorch or Tensorflow to ONNX or TensorRT comes with its own challenges. Depending upon the layers that constitute a particular model, not all layer components are easily convertible to an TensorRT engine. While some architectures are easily transferrable to a TensorRT engine, other model architectures while giving more accuracy may be more difficult in transferring to a TensorRT engine. This makes the model deployment to an edge device more difficult and impacts the choice of model architecture.

When comparing the accuracy (see Table I) versus the inference rate (see Table V-A), the YOLOv5 medium version has the same accuracy as the YOLOv5 large variant but has more FPS e.g., 33.5 versus 22 FPS on Jetson Orin (fp16). This implies that increasing the model size does not necessarily lead to improved performance while the medium variant gives more inference speed on the edge device. On the other hand, the DINO transformer provides high mAP50 on the maize class, but surprisingly lower values on weed class[¶]. While vision transformers usually outperform most networks, they may not always give the best performance depending on the size of the objects. The GPU memory size and the input image resolution also plays a critical role in deciding for the neural network architecture.

VI. CONCLUSION

This paper shows how multiple one-stage object detectors (RetinaNet, FCOS, YOLO), a two-stage object detector (Faster R-CNN), and a transformer object detector (DINO) perform on an agricultural use-case on different edge systems. With an accompanying data set, we found out that the YOLOv5 object detector performed well on detecting maize and reasonably well on detecting tiny objects such as small weeds. For the other neural networks, characteristics are highlighted such as a low accuracy on detecting tiny objects which is a common challenge in agricultural perception tasks. These shortcomings are not immediately visible when training on a different domain data set such as autonomous driving. The model deployment pipeline is also included for readers who embark on a different use-case and want to optimize their model's inference speed. Generally speaking, it is always

[¶] The DINO transformer was set to lower resolution of 512 x 683 because otherwise it does not fit onto Jetson Xavier NX with 8GB VRAM. For a fair comparison between Xavier NX and AGX Orin, it was set to that resolution.

better to convert a well trained model to an edge device specific engine such as the TensorRT engine. This way the FPS can increase by factors up to 8, if additionally the integer precision is reduced. Thus, using TensorRT yields faster networks, not only in the agricultural domain but also other domains, e.g. [35]. Inference framework-wise, ONNX has a relatively simplified model conversion process that works with most of the models and transferable across edge devices with different GPU architecture. By comparison, TensorRT has a more complicated GPU-specific model conversion process e.g. Jetson Orin needs a separate engine than Jetson Xavier and does not work successfully on all models.

BIGOS - Benchmark Intended Grouping of Open Speech Corpora for Polish Automatic Speech Recognition

Michał Junczyk
Adam Mickiewicz University
email: michal.junczyk@amu.edu.pl

Abstract—**This paper presents a Benchmark Intended Grouping of Open Speech (BIGOS), a new corpus designed for Polish Automatic Speech Recognition (ASR) systems. This initial version of the benchmark leverages 1,900 audio recordings from 71 distinct speakers, sourced from 10 publicly available speech corpora. Three proprietary ASR systems and five open-source ASR systems were evaluated on a diverse set of recordings and the corresponding original transcriptions. Interestingly, it was found that the performance of the latest open-source models is on par with that of more established commercial services. Furthermore, a significant influence of the model size on system accuracy was observed, as well as a decrease in scenarios involving highly specialized or spontaneous speech. The challenges of using public datasets for ASR evaluation purposes and the limitations based on this inaugural benchmark are critically discussed, along with recommendations for future research. BIGOS corpus and associated tools that facilitate replication and customization of the benchmark are made publicly available.**

I. Introduction

AUTOMATIC Speech Recognition (ASR) is used in various applications and usage scenarios. Given that multiple aspects impact the difficulty of ASR tasks (vocabulary, acoustic conditions, speech type, etc.), the quality of target systems heavily depends on the effectiveness of the evaluation process. Benchmarking and evaluation ultimately aim to validate the system's ability to adapt to novel and unseen data.[1] To achieve this, multiple evaluation methods, datasets, and metrics are needed. The most commonly used metric for ASR evaluation is the Word Error Rate (WER), which quantifies word-level insertions, deletions, and substitutions between a system and reference transcriptions. WER has known limitations [2, 3]. When used on a narrow set of evaluation data, the assessment of the capabilities of the models, particularly in terms of generalization to unseen data, may be unclear.

Unlike English [4, 5, 6], German [7] and recently Hungarian [8], the Polish language lacks a common public-domain reference dataset for ASR benchmarking. Consequently, the results of Polish speech recognition studies are generally not directly comparable. Although transcribed recordings are available, it is often not practical to find or use all available public-domain datasets.

This study introduces BIGOS, a resource intended to enable systematic benchmarking and tracking of Polish ASR systems over time across a diverse range of publicly available corpora. The primary purpose of BIGOS is to alleviate the painstaking efforts required to discover and compile speech corpora from multiple sources. To ensure that original licenses are respected by BIGOS users, the corpus is distributed on the Hugging Face platform[1], which allows gated access. Alternatively, scripts for self-curation and customization of the dataset are also provided. [2] The first iteration of the benchmark presented in this work is performed using 1,900 utterances sourced from 10 corpora and 3 commercial ASR systems and 5 freely available.

The remainder of this paper is structured as follows: Section 2 reviews the relevant literature, and Section 3 outlines the construction of the BIGOS benchmark and dataset, detailing the source speech corpora, corpus statistics, and ASR systems evaluated. Section 4 presents an exemplary application of BIGOS for the evaluation of ASR systems, Section 5 describes the limitations, and Section 6 concludes the paper by outlining the directions for future research.

II. Related work

A. *ASR evaluation datasets*

Prominent English-only datasets for ASR research and evaluation include the Wall Street Journal, VoxForge, Fisher, CHiME, LibriSpeech, TED-Lium, Common Voice, and Earnings. Wall Street Journal corpus covers news broadcast recordings, while SwitchBoard and Fisher include spontaneous telephone conversations. LibriSpeech [9] and MLS [10] feature narrated audiobooks, while VoxForge includes narrated Wikipedia articles. The TED-LIUM corpus [11] contains oratory educational talks, while the CHiME [12] dataset represents recordings of noisy environments in the real world. Earnings-21 and Earnings-22 contain conversational speech from earnings call recordings [4, 5]. The most voluminous dataset in terms of both the duration of speech content and language coverage is the MLS (Multilingual Librispeech), which contains 41,000 hours of material [10] for 8 languages. The Mozilla Common Voice dataset covers speech for more than 55 languages and boasts the largest number of contributing speakers, with over 10,000 as of March 2023 [13]. Both Common Voice and MLS include Polish language data. All of the aforementioned datasets offer a diverse range of speech sources, speaker demographics, and speech types,

[1] https://huggingface.co/datasets/michaljunczyk/pl-asr-bigos
[2] https://github.com/goodmike31/pl-asr-bigos-tools

providing researchers with valuable resources to investigate various aspects of ASR and to train new systems.

B. ASR benchmarks

The idea of using available speech datasets to benchmark the quality of ASR systems was first implemented nearly a decade ago. Gaida et al. [14] were the first to conduct a comprehensive evaluation of several open-source speech recognition tools. Dernoncourt developed a framework to evaluate seven ASR systems in two different collections and provided scripts to format Common Voice and LibriSpeech.[3] Moore et al. [15] introduced a meta-dataset containing reference text, hypotheses from two separate ASR systems, the Word Error Rate (WER), and annotations about speech intelligibility. Ulasik created a multilingual CEASR dataset for English and German[7], based on reference transcriptions from popular public-domain datasets and transcripts from four undisclosed ASR systems. Siegert et al. [16] performed a longitudinal study and found no significant changes in WER for 4 commercial systems over 8 months. Aksenova et al. [1] conducted a comprehensive survey on existing ASR benchmarking methodologies and proposed a systematic benchmarking framework for the most common use cases. Xu et al.[17] compared 4 commercial ASR services with respect to robustness to acoustic background noise. Varod et al. highlighted that ASR performance is language and system specific and that low-resource languages such as Hebrew can have a performance comparable to high-resource languages such as German.[18] The ASR4REAL benchmark [19] revealed significant accuracy variations depending on the accent of the speaker and socioeconomic status. Papadopoulou evaluated four commercial ASR systems in the context of translation post-editing effort [20]. The challenges associated with the recognition of spontaneous and accented speech were further analyzed in the benchmarks organized by the Rev and Google companies. [4, 5, 21]. Pasandi et al. highlighted that conversational speech is the most challenging and environmentally relevant type of data for speech recognition. Pires et al. constructed the Portuguese Evaluation Benchmark[22] using the Mozilla Common Voice and Voxforge datasets and five commercial ASR engines. Mihajlik et al. conducted an evaluation of open-source Hungarian ASR systems using a comprehensive linguistic dataset [8]. Extending the studies by Ulasik et al. for English and German, Wirth et al. [3] questioned the prevailing statistical ASR evaluation paradigm by performing a manual recognition error assessment. Of paramount importance, the study identified that 18% of the ASR errors originated from flawed ground-truth transcriptions and another 18% from flawed or ambiguous audio within publicly accessible datasets.

C. Polish ASR benchmarks

The first evaluation of commercial ASR systems for the Polish language was carried out in 2018 [23]. The first open benchmark for ASR systems was organized by Korzinek [24]. In 2019, Unai et al. [25] evaluated a self-developed Polish ASR system using 223 hours of speech collected from six datasets, including the Clarin-PL Studio Corpus (EMU)[26], the PELCRA family of corpora [27, 28], the Polish Senate recordings corpus [29], the Simple4All Tundra Corpus, and the test results for the PolEval 2019 competition [24]. The most extensive benchmark to date is Diabiz *Diabiz* performed using a set of 400 dialogs in eight domains and three commercial ASR systems. [30, 31].

III. BIGOS CORPUS DESIGN AND CURATION

As indicated by the Polish ASR Speech Data catalog [4] as of March 2023, approximately 5300 hours of speech in 51 datasets are available for Polish ASR development. Roughly 1000 hours of transcribed speech spread across 13 datasets is freely accessible under permissive licenses, facilitating the curation of a new evaluation dataset detailed in the following section.

A. BIGOS corpus overview

Table III-A summarizes the properties of the BIGOS dataset.

Table I
BIGOS DATASET PROPERTIES

Attribute	Value
Datasets sourced	10
Speech material (hours)	4.5
Test cases total	1900
Speakers	71

B. Sourcing and pre-analysis

Polish ASR Speech Data Catalog was used to identify suitable datasets to be included in the benchmark. The following mandatory criteria were considered:

- Dataset must be downloadable.
- The license must allow for free, noncommercial use.
- Transcriptions must be available and align with the recordings.
- The sampling rate of audio recordings must be at least 8 kHz.
- Audio encoding using a minimum of 16 bits per sample.

The following is an overview of 10 datasets that meet the criteria and were chosen as sources for the BIGOS dataset.

- The Common Voice dataset *(mozilla-common-voice-19)*, developed by Mozilla, is an open source multilingual resource [13]. This project aims to democratize voice technology by providing a wide-ranging, freely available dataset that covers many languages and accents. Contributors from around the globe donate their voices, reading out pre-defined sentences or validating the accuracy of other contributions. Common Voice is recognized as the most comprehensive and diverse voice dataset available, spanning more than 60 languages and representing many underrepresented groups. Datasets are released every

[3] https://github.com/Franck-Dernoncourt

[4] https://github.com/goodmike31/pl-asr-speech-data-survey

three months under a permissive Creative Commons 0 license.

- The Multilingual LibriSpeech (MLS) dataset *(fair-mls-20)* is a large, multilingual corpus created for speech research by Facebook AI Research (FAIR)[10]. This dataset is derived from audiobooks from LibriVox and covers eight languages, including about 44,000 hours of English and a total of around 6,000 hours for other languages. The Polish speech data include 137 hours of read speech from 25 books, recorded by 16 speakers. Humans have evaluated the transcriptions in the test sets.
- The Clarin Studio Corpus *(clarin-pjatk-studio-15)* is provided by CLARIN-PL, a subsection of CLARIN devoted to the Polish language. This corpus includes 13,802 short utterances, which add up to about 56 hours, spread over 554 audio sessions by 317 speakers. Each session contains between 20 and 31 audio files. All utterances were recorded in a studio, guaranteeing clear audio files free from background noise and other environmental factors.
- The Clarin Mobile Corpus *(clarin-pjatk-mobile-15)* is a Polish speech corpus of read speech recorded over the phone. It includes many speakers, each reading several dozen different sentences, and a list of words containing rare phonemes. It is designed for the analysis of modern Polish pronunciation in a telephony environment.
- The Jerzy Sas PWR datasets (Politechnika Wrocławska) *(pwr-viu-unk, pwr-shortwords-unk, pwr-maleset-unk).* According to the documentation available online[5] speech was collected using a variety of microphones and in relatively noise-free acoustic conditions. Three datasets are available: short words, very important utterance (VIU), and male AM set.
- The M-AI Labs Speech corpus *(mailabs-19)*, similar to the MLS corpus, was created from LibriVox audiobooks. This corpus covers nine languages and was created by the European company M AI Labs with the mission of *"enabling (European) companies to take advantage of AI & ML without having to give up control or know-how."* [6] The M-AILABS Speech Dataset is provided free of charge and is intended to be used as training data for speech recognition and speech synthesis. The training data consists of nearly a thousand hours of audio for all languages, including 53.5 hours for Polish.
- The AZON Read and Spontaneous Speech Corpora [7] *(pwr-azon-spont-20, pwr-azon-read-20)* is a collection of recordings of academic staff, mainly in the physical chemistry domain. The corpus is divided into two parts: supervised, where the speaker reads the provided text, and unsupervised spontaneous recordings, such as live-recorded interviews and conference presentations by scientific staff. The dataset contains recordings of 27 and 23 speakers, totaling 5 and 2 hours of transcribed speech, respectively. The AZON database is available under a CC-BY-SA license.

Two additional corpora, the Spelling and Numbers Voice database (SNUV) from the University of Łódź's PELCRA group and the CLARIN Cyfry corpus, initially met the necessary requirements for this study. However, their unique transcription conventions led to high error rates during initial tests. For example, the word *"pstrąg"* in *SNUV* corpus is transcribed as *"py sy ty ry ą gy"*. The conventional normalization employed by most ASR systems is *"p s t r ą g"*. In the case of *Cyfry* corpus, only numeric expressions are transcribed, hence high error rates are produced for correctly recognized nonnumeric expressions. As such, these corpora will be included in the next iteration of the benchmark, following a thorough manual retranscription process to mitigate these issues.

C. Curation and selection

Necessary preprocessing parameters were consolidated into specific configuration files for each dataset, including download links, metadata fields to be extracted, etc. Subsequently, the text data and audio were extracted and encoded in a unified format. Dataset-specific transcription norms are preserved, including punctuation and casing. To strike a balance in the evaluation dataset and to facilitate the comparison of Word Error Rate (WER) scores across multiple datasets, 200 samples are randomly selected from each corpus. The only exception is 'pwr-azon-spont-20', which contains significantly longer recordings and utterances, therefore only 100 samples are selected. Finally, the first version of the BIGOS corpus contains 1900 recordings of the 115,915 available in the 10 datasets (1. 64% of the total available transcribed speech). The table II provides detailed information on the composition of the BIGOS 1.0 corpus.

Table II
NUMBER OF RECORDINGS AND AVERAGE DURATIONS

Dataset	Size[h]	Files	Average length[s]
fair-mls-20	0.81	200	14.52 ±2.82
clarin-pjatk-mobile-15	0.72	200	13.05 ±3.51
pwr-azon-spont-20	0.72	100	25.75 ±7.12
clarin-pjatk-studio-15	0.56	200	10.10 ±4.32
pwr-azon-read-20	0.48	200	8.72 ±1.95
mailabs-19	0.42	200	7.60 ±3.10
mozilla-common-voice-19	0.27	200	4.89 ±1.50
pwr-shortwords-unk	0.24	200	4.41 ±1.42
pwr-maleset-unk	0.19	200	3.44 ±0.44
pwr-viu-unk	0.08	200	1.49 ±0.22
Total	4.49	1900	-
Average	-	-	9.39 ±2.64

D. Preprocessing and format standardization

The following curation methods were applied to the baseline version of the BIGOS dataset:

- validation of audio file availability and validity,
- unification of audio format to WAV 16 bits/16 kHz,
- normalization of audio amplitude to -3 dBFS,
- unification of text encoding to UTF8,

hyp_azure_default	Hypothesis of Azure cloud service default model
hyp_whisper_tiny	Hypothesis of Whisper local tiny model
hyp_whisper_base	Hypothesis of Whisper local base model
hyp_whisper_small	Hypothesis of Whisper local small model
hyp_whisper_medium	Hypothesis of Whisper local medium model
hyp_whisper_large	Hypothesis of Whisper local large model

- extraction of original transcription,
- removal of redundant characters
- extraction and unification of metadata.

E. Validation and ASR transcripts generation

Upon completing the preprocessing of the entire dataset, the number of obtained recordings, transcriptions, and metadata records in the compiled dataset were checked for consistency. If the validation was successful, the ASR hypotheses for the locally hosted Whisper models were generated. ASR transcriptions for cloud services like Google, Azure, and Whisper were obtained via respective APIs. Table III presents the object of the resulting BIGOS utterance data.

IV. ASR SYSTEMS EVALUATION

A. Evaluated ASR systems

Below is an overview of the ASR systems evaluated in the first iteration of the BIGOS benchmark.

- Google Cloud Speech-to-Text [8] supports more than 125 languages and variants. The "default" model from May 2023 was used for this benchmark.
- Microsoft's Azure Speech Service [9] as of May 2023 supports more than 100 languages and variants. The "default" model from May 2023 was used for this benchmark.
- Whisper is an ASR system developed by the OpenAI company. It is trained on a large amount of weakly supervised multilingual and multitask data collected from the Internet [32]. The web-hosted model available via API and the locally hosted models from May 2023 were used for this benchmark.[10]

B. Metrics

ASR systems predictions were evaluated against the target transcriptions using 3 industry-standard metrics:

- Sentence Error Rate (SER) calculates the proportion of sentences that are not perfectly recognized, i.e., sentences that contain at least one error.
- Word Error Rate (WER) is defined as the minimum number of operations (substitutions, insertions, and deletions) required to transform the system output into the reference transcript, divided by the total number of words in the reference.
- Character Error Rate (CER) metric calculates the minimum number of character-level operations (substitutions, insertions, and deletions) needed to change the system's output into the reference transcript, divided by the total number of characters in the reference.

V. BENCHMARK RESULTS

This section provides an overview and analysis of the results obtained.

A. Quality per system and model type

The performance of various systems was evaluated using average SER, WER, and CER values obtained from ten test datasets available in BIGOS. The "large" model of the Whisper system achieved the highest accuracy, outperforming all other systems in every metric. The "medium" model of the Whisper system came second, and the "cloud" model of the same system came third. Google and Azure's services followed these, with the remaining Whisper models trailing behind.

Interestingly, the two most accurate systems are both freely available. Despite using the same "large-v2" model, the cloud-based variant was outperformed by the locally hosted "large" variant and, even more surprisingly, by the "medium" variant, which theoretically should be less advanced. On average, free systems outperformed well-established paid services.

To understand why this is the case, a more detailed and manual examination of the evaluation results is required. However, it is crucial to note that lower scores in this evaluation do not necessarily indicate inferior performance in real-world scenarios.

One hypothesis is that commercial systems, despite their ability to handle advanced normalization conventions, might actually perform worse when evaluated on publicly available datasets that use written forms of numerals (e.g., "one", "six o'clock") instead of numeric forms (e.g., "1", "6:00"). This paradox suggests that the use of automated evaluation metrics and publicly available datasets used "as-is" (without transcription unification) may not fully represent real-world performance and capabilities.

Tables IV present the average SER, WER, and CER scores for the Azure, Google, and Whisper systems.

B. Quality per dataset

The best overall performance was observed for the PWR corpora, which contain recordings from a single speaker in

[8] https://cloud.google.com/speech-to-text

[9] https://azure.microsoft.com/en-us/products/cognitive-services/speech-to-text

[10] https://github.com/openai/whisper/blob/main/model-card.md

Table IV
AVERAGE SER, WER AND CER OF EVALUATED POLISH ASR SYSTEMS

Service	System	Variant	SER	WER	CER
paid	Azure	default	64.3 ±39.2	18.3 ±12.6	10.2 ±9.3
paid	Google	default	59.9 ±38.5	16.1 ±10.0	7.4 ±5.7
paid	Whisper	large	58.7 ±34.6	11.0 ±8.0	4.1 ±3.9
free	Whisper	tiny	90.3 ±14.6	46.8 ±9.4	14.7 ±6.1
free	Whisper	base	83.7 ±19.9	32.9 ±9.9	10.1 ±4.7
free	Whisper	small	67.6 ±28.2	16.5 ±6.5	5.5 ±3.0
free	Whisper	medium	55.4 ±34.1	9.3 ±4.6	3.7 ±2.6
free	**Whisper**	**large**	**50.1 ±34.4**	**7.6 ±3.8**	**3.1 ±2.4**

a quiet acoustic environment. This limited variability led to perfect performance for the Whisper Cloud and Azure systems in *PWR VIUa* and the best average WER for the *Male* set. Interestingly, for single-word utterances, the limited context led the Google and Whisper local systems to recognize foreign language words instead of Polish words. For example, the word 'zapisz' was recognized as a Russian word 'Запись', the word 'zakończ' as the English word 'the coins', and words 'małe litery' and 'duże litery' as the Italian words 'ma vedi tere' and 'due lettere', respectively. The PWR male set dataset had the second-best performance. A median WER of 6% suggests that modern Polish ASR systems handle short utterances from contemporary literature quite effectively.

Slightly worse performance (average WER over 10% for all systems) was observed for the *MLS, M-AI Labs*, and *Common Voice* datasets. Given the widespread use and accessibility of the *MLS* and *Common Voice* datasets within the global ASR community, it is likely that these datasets were used during training, allowing all systems to efficiently handle in-domain recordings and transcriptions. This hypothesis is supported by the performance of Whisper systems family on the *MLS* corpus; however, Google's performance on the *Common Voice* dataset was nearly twice as bad as other systems. Given that Whisper is trained mostly on publicly available data, while commercial systems leverage proprietary datasets, the impact of training and evaluation data leakage is more significant in the case of Whisper.

Performance for the CLARIN mobile dataset was slightly inferior, possibly due to longer utterances and the use of commercial *default* models, which are not optimized to handle speech recorded with an 8 kHz sampling frequency.

As expected, performance declined for the AZON read and spontaneous corpora, which contain scientific vocabulary from the chemistry field. However, the Google and Whisper local systems handled both types of AZON corpora proficiently, despite containing fillers and hesitations.

Table V-B presents the median WER for specific datasets sourced in BIGOS for Azure, Google, Whisper Cloud and Large systems.

VI. LIMITATIONS

The initial version of the benchmark comes with several limitations. First, the quantity and specificity of the datasets, along with the metadata about speakers and acoustic conditions, are limited. To examine ASR performance for particular sociodemographic groups, such as non-native Polish speakers or specific types of speech, such as whispery speech, dedicated datasets[33] should be used. Second, the unification of normalization relies solely on automatic methods and does not involve manual re-transcription. Lastly, the initial evaluation uses a limited number of test recordings, systems, and models, which constrains the precision and breadth of the benchmark.

Table V
AVERAGE WER PER DATASET FOR SELECTED SYSTEMS

	Paid			**Free**	
Dataset	**A**	**G**	**W**	**W**	**WER avg**
pwr-maleset	6.6	**3.2**	6.1	**3.2**	4.8±1.8
pwr-shortwords	7.1	**4.4**	7.8	4.8	6.0±1.7
pwr-viu	0.3	24.4	**0.0**	7.9	8.1±11.4

VII. CONCLUSION AND FUTURE WORK

This work addresses the lack of a publicly available ASR evaluation suite for Polish by providing BIGOS, Benchmark Intended Grouping of Open Speech corpora. BIGOS, as its name suggests, was compiled from 10 existing publicly accessible Polish speech corpora. A test sample comprising 1900 recordings from 71 distinct speakers was used to gauge the performance of 3 commercial ASR systems against 5 freely available ones. Through automatic evaluation metrics, it was discovered that Whisper Cloud consistently outperforms more established services from Google and Azure on the test set representing publicly available speech datasets for Polish. Interestingly, the largest and second largest of the Whisper models exhibit superior performance compared to its paid version. The BIGOS corpus[11] and tools[12] for corpus curation and evaluation of ASR systems are available to the community, allowing reproduction and extension of this benchmark.

As indicated in the Limitations and Related Work sections, there are many interesting research directions to explore. The primary objective of the next BIGOS iteration is to include a subset of manually verified reference transcriptions. Comparison of error rates, calculated using original and manually verified transcriptions, will reveal the evaluation bias resulting from differences in normalization standards in various public-domain corpora. Furthermore, the reliability and informativeness of the evaluation could be significantly improved if the evaluation results were manually annotated, similar to the German study [3], which revealed that the evaluation errors may be caused by the poor quality of the evaluation data and that not all errors are of equal importance. Lastly, it will be interesting to measure the robustness of the systems using larger samples, new data sources, and automatically perturbed recordings.

Abstract—**In recent years, complex networks have gained significant attention for their practical potential in data analysis and decision-making. However, assessing node relevance in complex networks poses challenges, including subjectivity and difficulty reproducing criteria relationships. To address these issues, we propose MLP-COMET. This novel approach combines the Multi-Layer Perceptron (MLP) with the Characteristic Objects Method (COMET) in Multi-Criteria Decision Analysis (MCDA). MLP-COMET aims to re-identify decision models using MLP to evaluate characteristic objects. We evaluate the approach to assessing the complex network and demonstrate its effectiveness in evaluating without heavy reliance on domain experts. The MLP-COMET performance is evaluated through ranking comparisons, showing a strong correlation with reference expert rankings. We also analyze the impact of training sample size and number of characteristic objects on ranking similarity, observing high stability and similarity using the r_w metric. MLP-COMET offers an effective and reliable tool for evaluating complex networks and facilitating decision-making processes.**

I. Introduction

COMPLEX networks have been significantly developed in recent years due to their high practical potential [1]. They have been used effectively in the areas of quantum systems [2], information processing [3], decision tree analysis [4], or node relevance assessment problems [5]. The increasing computational capabilities of computer technology allow more complex and efficient solutions to be developed [6]. It has also translated into strengthening the position of techniques included in complex networks in their use for data analysis [7]. By using such approaches in a wide range of practical problems, more efficient and effective solutions can be achieved, and benefits can be derived from the conclusions drawn from the analyzed data.

One highly popular area considering the developed models based on complex networks is connected to blockchain and cryptocurrencies [8]. Since the field related to virtual payments is expanding, there was a need to propose solutions that could be used to make more rational and conscious decisions. Complex networks are applied for analyzing the blockchain structure [9], the performed transactions [10], or for the automation processes [11], among others. Those techniques can be used to extract knowledge that can be used for further analysis and constitute making more effective steps in the area of blockchain and cryptocurrencies.

Complex networks are based on the usage of nodes in the analysis process [12]. It often leads to incompatible nodes assessment taking into account the centrality measures. Since the occurrence of this phenomenon should be limited, various techniques are used to reduce it. For this purpose, Multi-Criteria Decision Analysis (MCDA) methods can be used [13]. The MCDA techniques allow for assessing decision variants regarding multiple criteria that are considered in the evaluation process [14], [15]. Moreover, those methods enable modeling different preferences depending on the outcome and objectives that are expected as the final results [16], [17]. It can be achieved by modifying the criteria weights, representing the relevance of subsequent decision factors [18]. With this approach, the determined models are highly configurable and reusable in different initial conditions.

To model the criteria importance, different approaches can be used [19]. Many decision models rely on professional knowledge and experience that is extracted from the domain expert through the criteria judgment process [20]. The subjective weighting methods can be used for this purpose [21]. They allow for a structured and systematic judgment process, indicating assessment steps that aim to simplify the criteria importance evaluation for the expert. Multiple approaches can be used since various techniques are being developed in this area. One of the most popular methods is the Analytical Hierarchy Process (AHP) [22], which is based on the criteria pairs comparison aiming to establish the relationship between assessed criteria. The other approach that can be applied to extract expert knowledge is the new method of Ranking Comparison (RANCOM) [23], which proved to handle expert judgment inaccuracies significantly better than the mentioned AHP method. The other techniques that can be used for this purpose are Best-Worst Method (BWM) [24], Full Consistency Method (FUCOM) [25], Fixed Point Scoring [18], or Simple Multi-Attribute Rating Technique (SMART) [26], among others.

Despite multiple advantages that can be benefited from engaging the domain expert in the evaluation process, there are also some drawbacks of this approach [27]. The main disadvantages of determining the decision models based on expert knowledge are their unavailability, a certain level of hesitance and inaccuracies of the judgments, or the impossibility of reproducing the previously defined relationships between criteria relevance [28]. It can lead to multiple difficulties in making the determined model reusable in various applications. However, it is worth developing ready-to-use models that guarantee highly effective and reliable results.

In this paper, we propose a multi-criteria decision analysis model for evaluating complex networks, which is an artificial expert in the form of a MultiLayer Perceptron (MLP) combined with a Characteristic Object METhod (COMET). The MLP-COMET approach aims to re-identify the decision model based on the evaluated decision variants. The MLP in the regressor variant is used to represent the domain expert that assesses the Characteristic Objects (COs) in the COMET method. The practical problem of assessing the Bitcoin network is used to verify the model's performance. The main contributions of the study are

- presenting an approach that enables re-identification of decision model
- indicating the methodology that can be used to replace the domain expert in the decision process
- analyzing the Bitcoin network with the determined MLP-COMET technique

The rest of the paper is organized as follows. Section 2 presents the literature review on centrality metrics in complex networks and MCDA and its usage in the practical problems connected to the blockchain field. Section 3 presents the preliminaries of the complex network and MCDA. Section 4 presents the proposed approach for re-identifying the multi-criteria decision model. Section 5 shows the study case of using MLP-COMET to re-identify the decision model based on the evaluated alternatives in the practical problem of analyzing the Bitcoin network. Finally, Section 6 presents the conclusions drawn from the research and the further directions for developing the presented approach.

II. Literature review

A. Selection problems based on centrality metrics

In the area of complex networks, it is possible to distinguish metrics that define the attractiveness of a node concerning the others available in the analyzed network. Their analysis allows more efficient choices to be made regarding selecting nodes that are key to information propagation. Measures of centrality such as degree, closeness, betweenness, and eigenvector are a group of factors that allow efficient analysis of network nodes and their selection [29]. Alexandrescu et al. used the four mentioned centrality measures to identify the sustainability communicators in urban regeneration [30]. The presented measures were applied as the decision criteria in one of the three dimensions that were determined in the assessment, namely, the informal network influence. Karczmarczyk et al. applied the MCDA techniques to select seeds for targeted influence maximization within social networks, where the centrality, betweenness, closeness, and eigenvector centrality measures were also considered in the evaluation of the node [31]. Muruganantham et al. focused on the problem of discovering and ranking the influential users in social media networks by applying the selected MCDA methods, namely Preference Ranking Organization Method for Enrichment of Evaluations (PROMETHEE) II, ELimination Et Choix Traduisant la REalité (ELECTRE), AHP, Statistical Design Institute Matrix method (SDI), Pugh (also known as Decision Matrix Method), and Technique for the Order of Prioritisation by Similarity to Ideal Solution (TOPSIS) [32]. The authors also used the four above-mentioned measures to assess the social influence in the network. Moreover, the centrality metrics can be grouped based on their scope of operation. The closeness, betweenness, eigenvector, coreness, average clustering coefficient, average shortest path length, and PageRank measures belong to global measures, while degree or semi-local centrality are classified as measures with local scope [33]. The global measures are identified based on the necessity of having access to the whole network to determine the global information for the specific factor. On the other hand, local measures can be calculated using the local information of the node.

B. Blockchain and cryptocurrencies in MCDA

MCDA methods are used in many application areas due to the ability to flexibly select decision criteria based on which decision variants are assessed. This configurability and versatility allow decision-making models to be used in the area related to blockchain and cryptocurrencies. Lai and Liao proposed an approach for MCDM based on Double Normalization-based Multiple Aggregation (DNMA) and Criteria Importance Through Inter-criteria Correlation (CRITIC) for blockchain platform evaluation [34]. The authors considered 8 decision criteria, namely performance efficiency, interactivity, scalability, reliability, security, portability, maintainability, and cost. Erol et al. examined blockchain applicability in sustainable supply chains by the MCDM framework determined with Fuzzy Step-wise Weight Assessment Ratio

Analysis (SWARA), Complex Proportional Assessment (COPRAS), Evaluation based on Distance from Average Solution (EDAS) assessment, and COPELAND method [35]. The evaluation considered 6 decision variants and 8 criteria. Öztürk and Yildizbaşi focused on indicating the barriers that keep the implementation of blockchain into supply chain management [36]. Based on the Fuzzy AHP and Fuzzy TOPSIS, the assessment was conducted considering the uncertainties in the problem. The results from the research showed that high investment costs, data security, and utility play the most important role in the evaluation. Çolak et al., on the other hand, directed their research toward an assessment of blockchain technology in supply chain management [37]. Using the Hesitant Fuzzy Sets (HFS) combined with the AHP (HF-AHP) and TOPSIS (HF-TOPSIS), it was possible to examine the decision alternatives and take into account the potential uncertainties. The authors identified 5 main criteria and 17 sub-criteria, which were used to evaluate 5 decision variants. The sensitivity analysis approach was also used to examine if differences in criteria weights could significantly influence the proposed rankings. Based on the obtained results, the authors indicated that the medicine/drug industry seems to be the most suitable sector for introducing blockchain technology. Table I presents the selected approaches used in multi-criteria problems directed to blockchain and cryptocurrency fields.

C. Blockchain and cryptocurrencies in complex networks

The problems connected to blockchain analysis are also addressed by researchers using complex network techniques. Since it is important to identify the most significant nodes in the networks that play a crucial role in the information spread, many approaches have been used for this purpose. Moreover, the centrality measures are eagerly used to investigate the network structures allowing for an in-depth analysis. Tao et al. performed a complex network analysis of the Bitcoin blockchain network, using degree distribution, clustering coefficient, shortest path length, assortativity, and rich-club coefficient [10]. Bielinskyi and Soloviev attempted to identify the complex network precursors of crashes and critical events in the cryptocurrency market [38]. The authors used time series of data considering the days in correction, Bitcoin's high price in $, Bitcoin's low price in $, the decline in %, and the decline in $. As the centrality measures, the authors selected eigenvector values and average path length. Lin et al. focused on understanding Ethereum transaction records with a complex network approach [39]. The authors modeled the transaction records using time and amount features and designed several flexible temporal walk strategies. The degree distribution of the Ethereum transaction network was analyzed with an actual feasible path for money flow. Serena et al. represented cryptocurrency activities ad a complex network to analyze the transaction graphs [40]. Four prominent Distributed Ledger Technologies (DLTs), namely Bitcoin, DogeCoin, Ethereum, and Ripple, were considered. The authors considered three selected centrality measures: degree distribution, average clustering coefficient, and average shortest path length of the main component.

D. Expert knowledge in multi-criteria problems

Multi-Criteria Decision Analysis models can be personalized with the different preferences of criteria importance. This approach can be used to propose an individual and specific set of results compliant with the expert preferences and expectations. To extract experts' knowledge and use it as the input data in MCDA models, subjective criteria weighting methods are used. Since multiple techniques are being developed to assist the expert in identifying the criteria importance, it is important to select methods that are intuitive and reflects the experts' opinion reliably. Various Decision Support Systems (DSSs) were determined to evaluate alternatives using the domain expert knowledge in the specific field. Dweiri et al. proposed a DSS based on the AHP method for supplier selection in the automotive industry, where the AHP method was used to identify the expert preferences regarding the criteria importance [41]. Mahendra used the FUCOM-SAW method to determine the DSS for e-commerce selection in Indonesia [42]. The FUCOM method served as a measure for extracting the expert knowledge based on which the assessment was performed. Sarabi and Darestani applied the Fuzzy Multiple Objective Optimizations on the basis of Ratio Analysis plus full Multiplicative Form (MULTIMOORA) and BWM approach for determining the DSS for logistics service provider selection in mining equipment manufacturing [43]. The BWM method allowed for defining the criteria relevance based on the expert experience in the given field. The RANCOM method was used to identify the decision-maker preferences regarding the laptop selection, and the identified weights were then used in the selected six MCDA methods [23]. Fahlepi proposed a DSS for employee discipline identification, where the SMART method was used for establishing the criteria relevance based on the expert judgment [44]. It can be seen that various approaches are used to define the decision models based on expert knowledge. However, it should be borne in mind that the experts' availability limits these solutions. Moreover, expert knowledge can change over time, translating into assigning different criteria relevance within the same decision problem. The subjectivity of the assessment should also be considered in developing such systems. It should be limited to providing results with high objectivity of the evaluation, increasing the results' reliability. Since it could be challenging to re-identify the experts' preferences over time, it is worth proposing approaches to fill this gap. To this end, the MLP-COMET technique is proposed, which is based on the complex network analysis and aims to identify the decision model which can be applied to assess new decision variants within the same problem.

III. Preliminaries

A. Centrality measures

Complex network centrality metrics are network analysis tools used to identify nodes of high importance or influence

* where: 'No. of alts.' - Number of decision variants, 'No. of crit.' - Number of criteria.

in a network. Over the past few years, the trend of introducing new centrality metrics has continued to grow. The mainly used centrality metrics of complex networks are closeness centrality, degree centrality, eigenvector centrality, or betweenness centrality. In addition, there are also centrality metrics such as Katz centrality, harmonic centrality, or percolation centrality. In assessing the relevance of social network nodes, several centrality metrics are mainly used due to the need for knowledge related to the systematic distinction of these measures of [53]. Therefore, in this article, we will focus on the following measures of social network centrality [54], [55], [56]:

1) **Degree centrality:**

$$D_c(i) = \sum_{j}^{n} x_{ij} \tag{1}$$

where i is the considered node, j is the other nodes present in the network, n is the number of all nodes, and x_{ij} is the connection between node i and node j.

2) **Betweenness centrality:**

$$B_c(i) = \left(\sum_{s \neq i \neq t} \frac{g_{st}(i)}{g_{st}} \right) \frac{n(n-1)}{2} \tag{2}$$

where g_{st} is the count of binary shortest paths from node s to node t, and $g_{st}(i)$ is the count of those paths that pass through node i.

3) **Eigenvector centrality:**

$$E_c(i) = \lambda^{-1} \sum_{j=1}^{n} A_{ij} e_j \tag{3}$$

where e_j is the node score j, A is the adjacency matrix of the network, n is the number of nodes present in the network, and λ is a constant.

4) **Closeness centrality:**

$$C_c(i) = \frac{n-1}{\sum_{j=1}^{n} d_{ij}} \tag{4}$$

where d_{ij} is the distance from node i to node j.

5) **Harmonic centrality:**

$$H_c(i) = \frac{1}{n-1} \sum_{j \neq i} \frac{1}{\operatorname{dist}(x_i, x_j)} \tag{5}$$

where i is the considered node, j is the other nodes present in the network, d_{ij} is the distance from node i to node j.

B. The Multi-Layer Perceptron Regressor

Artificial neural networks are computational models inspired by the structure and operation of the human brain. One type of artificial neural network is the Multi-Layer Perceptron, which is widely used in classification and regression problems. It consists of multiple perceptrons, the structure of which is based on the original approach proposed by Frank Rosenblatt in 1957. A Multi-Layer Perceptron consists of three main layers: an input, hidden, and output layer. The input layer accepts input data, passed on to subsequent layers. Hidden layers are intermediate between input and output and consist of multiple perceptrons. The output layer generates the final results of the network. The connections between perceptrons in the different layers are weighted, meaning each connection is assigned a weight. These weights determine how much the output of one perceptron affects the input of other perceptrons.

A Multi-Layer Perceptron uses supervised learning, which requires a set of learning data consisting of pairs of input and expected output data. The goal is to train the network to learn a function that transforms the input data into the expected output data. The backward error propagation algorithm is most commonly used, which propagates the error from the network's output to the hidden layers and the input layer to adjust the connection weights. The effectiveness of a multilayer perceptron depends on several hyperparameters, such as the number of hidden layers, the number of perceptrons in each layer, the learning rate, and the activation function. Proper selection of hyperparameters is crucial to the effectiveness and efficiency of the network. An example of neural network visualization is shown with Fig. 1.

C. The Characteristic Objects Method

The Characteristic Objects METhod (COMET) is an approach proposed by Sałabun in 2015 to eliminate the paradox

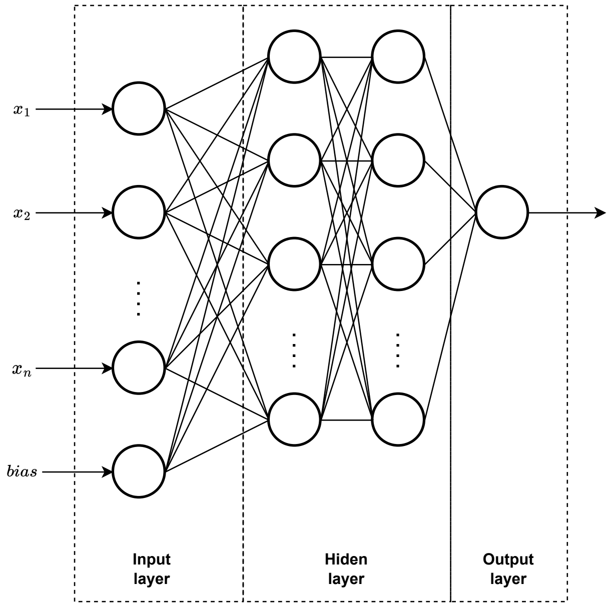

Fig. 1. Example structure of a multilayer perceptron.

of reversed rankings [57]. Here, the evaluation of decision alternatives is done by measuring the distance between them and the characteristic objects that play a key role in the model. In addition, this method has seen many extensions for uncertain environments such as Normalized Interval-Valued Triangular Fuzzy Numbers (NIVTFN) [58], Intuitionistic Fuzzy Sets (IFS) [59] and Hesitant Fuzzy Sets (HFS) [60], For the COMET method, the following sequence of steps is used:

Step 1. Identify the problem's dimensionality. Expert selects r number of criteria and their fuzzy values, which is represented by a Eq. (6).

$$\begin{array}{c} C_1 = \left\{\tilde{C}_{11}, \tilde{C}_{12}, ..., \tilde{C}_{1c_1}\right\} \\ C_2 = \left\{\tilde{C}_{21}, \tilde{C}_{22}, ..., \tilde{C}_{2c_2}\right\} \\ ... \\ C_r = \left\{\tilde{C}_{r1}, \tilde{C}_{r2}, ..., \tilde{C}_{rc_r}\right\} \end{array} \tag{6}$$

where $C_1, C_2, \dots, C_r$ are the criteria represented by the fuzzy numbers.

Step 2. Creating Characteristic Objects (COs) with the Cartesian product from fuzzy number cores. An example of the construction of characteristic objects can be illustrated by the Eq. (7).

$$CO = \langle C(C_1) \times C(C_2) \times ...C(C_r)\rangle \tag{7}$$

The result is a set of characteristic objects. This set can be expressed as follows:

$$\begin{array}{c} CO_1 = \langle C(\tilde{C}_{11}), C(\tilde{C}_{21}), ..., C(\tilde{C}_{r1})\rangle \\ CO_2 = \langle C(\tilde{C}_{11}), C(\tilde{C}_{21}), ..., C(\tilde{C}_{r2})\rangle \\ ... \\ CO_t = \langle C(\tilde{C}_{1c_1}), C(\tilde{C}_{2c_2}), ..., C(\tilde{C}_{rc_r})\rangle \end{array} \tag{8}$$

Step 3. Formation of Matrix of Expert Judgments (MEJ) using comparisons of characteristic objects among themselves. The Expert Judgment Matrix (MEJ) is represented by the Eq. (9).

$$MEJ = \begin{pmatrix} \alpha_{11} & \alpha_{12} & \dots & \alpha_{1t} \\ \alpha_{21} & \alpha_{22} & \dots & \alpha_{2t} \\ \dots & \dots & \dots & \dots \\ \alpha_{t1} & \alpha_{t2} & \dots & \alpha_{tt} \end{pmatrix} \tag{9}$$

where α_{ij} is the degree of preference of comparing one characteristic object to another. If object CO_i is more reflective than object CO_j assign the value 1. If they are equal, assign the value 0.5. If CO_i is less reflective than CO_j assign the value 0. It can be shown by the Eq. as follows:

$$\alpha_{ij} = \begin{cases} 0.0, & f_{expert}(CO_i) < f_{expert}(CO_j) \\ 0.5, & f_{expert}(CO_i) = f_{expert}(CO_j) \\ 1.0, & f_{expert}(CO_i) > f_{expert}(CO_j) \end{cases} \tag{10}$$

Once the expert matrix MEJ is determined, the Summed Judgements (SJ) vector must be determined using Eq. (11).

$$SJ_i = \sum_{j=1}^{t} \alpha_{ij} \tag{11}$$

where t is the number of characteristic objects.

After computing the Summed Judgements (SJ) vector, the vector of preferences (P) for the COs should be computed. This is shown as follows [57].

Step 4. Formation of a rule base from characteristic objects and a preference vector. This can be expressed using an Eq. (12).

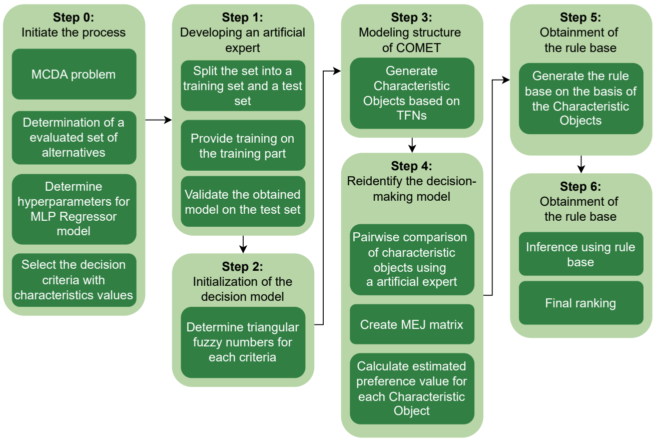
$$IF\ C\left(\tilde{C}_{1i}\right)\ AND\ C\left(\tilde{C}_{2i}\right)\ AND\ \dots\ THEN\ P_i \tag{12}$$

Step 5. Make an inference to compute the scores of the given alternatives. The alternative A_i comprises the values of every criterion, i.e., $A_i = \{\alpha_{1i}, \alpha_{2i}, \dots, \alpha_{ri}\}$. By employing Mamdani fuzzy inference, a preference P is computed for every alternative according to [61].

IV. Proposed approach

This paper proposes an approach to evaluate nodes in a complex network using the MultiLayer Perceptron Regressor (MLP Regressor) and the Characteristic Objects METhod (COMET). This approach aims to construct a multi-criteria model to evaluate network nodes. In traditional expert-based multi-criteria models, problems often arise due to dynamically changing knowledge and the limited availability of experts. Our approach uses MLP Regressor as an artificial expert trained from existing node evaluations. This allows us to avoid relying on experts and obtain node evaluations based on the artificial expert model. After constructing the artificial expert model, we use it to evaluate Characteristic Objects in the COMET approach. Characteristic Objects are reference points with information about the decision maker's preferences. This allows us to construct a multi-criteria model that considers the decision-makers preferences and allows us to evaluate the nodes with these preferences in mind. The approach described in the paper aims to combine machine learning techniques, such as MLP Regressor, with multi-criteria analysis to evaluate nodes in a complex network efficiently. This hybrid approach can be helpful in various fields where there is a need to make decisions based on network analysis considering the decision maker's preferences.

Fig. 2 represent the proposed MLP-COMET approach. The first step in this approach is to determine the set of evaluated decision alternatives, the hyperparameters for the MLP Regressor model, and the decision criteria with their characteristic values needed for the COMET method. This is followed by training the MLP-Regressor model, an artificial expert for this approach. Once a stable model maps the decision maker's preferences to the designated set of decision alternatives created, the decision model is initialized. Then the structure of the COMET method is modeled based on the characteristic values and the reidentification of the decision model using the artificial expert (model: MLP). After determining the preference of Characteristic Objects, the newly created decision options can be evaluated. In the case of this article, the implementation of the entire algorithm was created using the `sklearn` library (class: MLPRegressor) and the `pymcdm` library (class: COMET) [62], [63].



Step 0:
Initiate the process
MCDA problem
Determination of a evaluated set of alternatives
Determine hyperparameters for MLP Regressor model
Select the decision criteria with characteristics values
Step 1:
Developing an artificial expert
Split the set into a training set and a test set
Provide training on the training part
Validate the obtained model on the test set
Step 2:
Initialization of the decision model
Determine triangular fuzzy numbers for each criteria
Step 3:
Modeling structure of COMET
Generate Characteristic Objects based on TFNs
Step 4:
Reidentify the decision-making model
Pairwise comparison of characteristic objects using a artificial expert
Create MEJ matrix
Calculate estimated preference value for each Characteristic Object
Step 5:
Obtainment of the rule base
Generate the rule base on the basis of the Characteristic Objects
Step 6:
Obtainment of the rule base
Inference using rule base
Final ranking

Fig. 2. MLP-COMET approach procedure.

V. Study case

In this section, a study will be conducted related to the proposal of the MLP-COMET approach for evaluating the composite network. First, the dataset associated with the Bitcoin composite network will be described. Then, research on the accuracy of the MLP Regressor model, which will serve as an artificial decision expert, will be conducted. After the research on its accuracy, an example of re-identifying the decision model and examining the similarity of the rankings derived from MLP-COMET at different characteristic values and the size of the learning set demonstrated is.

A. Description of the data

For this article, a complex network related to cryptocurrencies and, more specifically, Bitcoin was chosen [64], [65]. The selected network is people who trust those using this cryptocurrency. The network presented has 5881 nodes and 35592 edges. In addition, the network directed is in this way, and a weight is assigned to each of its edges. For this article, the weights of each edge were taken into account in determining centrality measures such as betweenness and eigenvector. In the case of the present network, nodes will play the role of decision variants. A visualization of the Bitcoin user network is shown in Fig. 3.

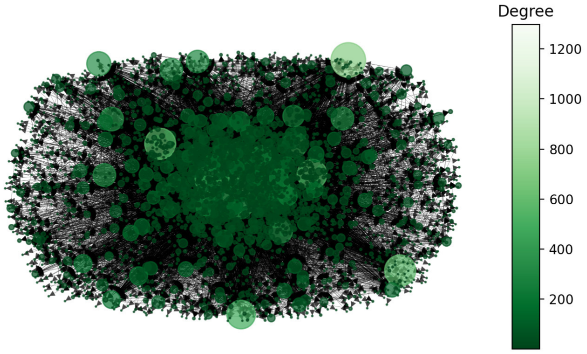


Fig. 3. Complex network of Bitcoin users [64], [65].

To evaluate the nodes of the present complex network, centrality metrics were used as criteria. Five centrality metrics were selected, i.e., betweenness centrality, degree centrality, eigenvector centrality, closeness centrality, and harmonic centrality. These metrics are presented in the Section III-A. Due to the low values found among some centrality metrics, the number of nodes is shown on histograms on a logarithmic scale.

Fig. 4 shows the distribution of values of the betweenness centrality metric, chosen as the first criterion for evaluating nodes (C_1). The minimum value of the centrality measure of indirectness is 2.89182e-08, which means that there are nodes with a shallow indirect role. The mean value of the measure is 0.01798, suggesting that most nodes have a low mediating role. The highest recorded value of the centrality of agency measure is 0.84816, suggesting the existence of a few nodes with a highly high mediating role. The standard deviation value is 0.06324, indicating some variation in the distribution of the centrality measure. The skewness value is 4.39799, indicating that the distribution of the centrality measure of intermediation is skewed to the right. This means there are a few nodes with very high centrality, which may indicate the existence of crucial nodes in the Bitcoin network.

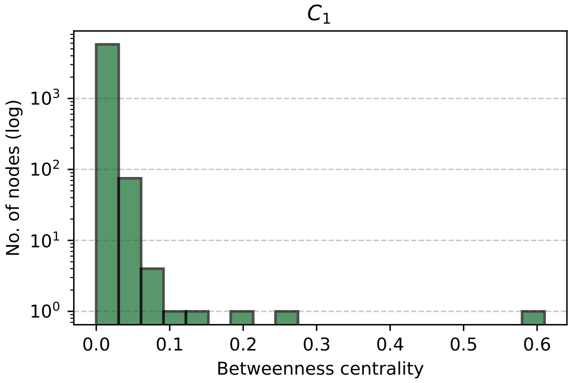

Fig. 4. Distribution of betweenness centrality values for Bitcoin users complex network.

The distribution of the degree centrality metric's value, which is selected as the second criterion for evaluating nodes (C_2), is shown using Fig. 5. The distribution of degree centrality measure values for users of the Bitcoin comprehensive network is as follows: the minimum value of the degree measure is 0.00017, indicating the existence of nodes with a low degree of connectivity. The average value of the degree measure is 0.00205, implying that most nodes have a lesser degree of connection. However, the highest recorded value of the degree measure is 0.22074, indicating a few nodes with an extremely high degree of connection. The standard deviation is 0.00651, indicating a rather diverse distribution of the degree measure. In addition, the skewness value is 13.84915, implying that the distribution is significantly skewed to the right. This means there are a few nodes with a very high degree of connectivity.

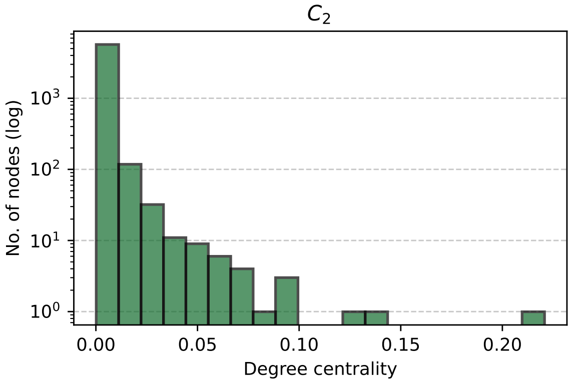

Fig. 5. Distribution of degree centrality values for Bitcoin users complex network.

Eigenvector centrality is another metric used as the third criterion (C_3) for evaluating nodes, and Fig. 6 represents it. The minimum value of the measure is -0.17028, which indicates the presence of negatively influenced nodes in the network. The mean value of the measure is 0.00038, revealing that most nodes have little influence in the network. The highest recorded value of the measure is 0.32039, indicating the existence of a few nodes with high importance in the Bitcoin network. The standard deviation value is 0.01303, which hints at some variation in the distribution of the vector centrality measure. The skewness value is 3.97669, pointing to a skewed distribution to the right.

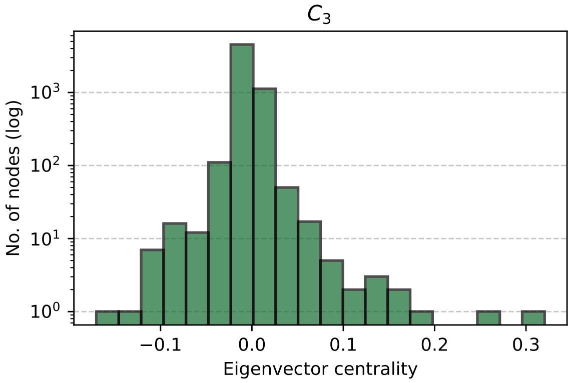

Fig. 6. Distribution of eigenvector centrality values for Bitcoin users complex network.

The closeness centrality metric for evaluating nodes was chosen as the fourth criterion (C_4), and its distribution is shown in Fig. 7. The minimum value of the measure is 0.0, which means there are nodes that not directly connected are to any other node in the network. The average value of the measure is 0.21886, which suggests that most nodes have a moderate degree of proximity to other nodes in the Bitcoin network. The highest recorded value of the measure is 0.33939, indicating that a few nodes exceptionally well connected are to other nodes. The standard deviation value is 0.03196, indicating some variation in the distribution of the proximity centrality measure. The skewness value is -1.65533, indicating that the distribution is slightly skewed to the left.

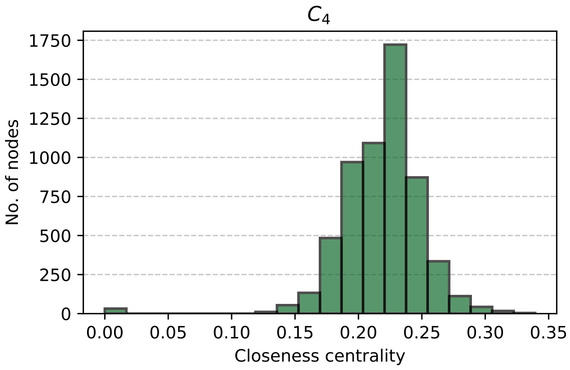

Fig. 7. Distribution of closeness centrality values for Bitcoin users complex network.

Fig. 8 shows the distribution of the value of the harmonic centrality metric, which is chosen as a criterion of the five to evaluate nodes (C_5). Based on statistical information, the minimum value of harmonic centrality in the studied network was 0.0, which means that some nodes did not have an essential role in transmitting the information. The mean value of harmonic centrality was 1346.77502, reflecting that most nodes in the network have moderate importance. The highest value recorded was 2233.24999, indicating that there are a few nodes with a vital role in the complex network. The analysis of the standard deviation of 210.28290 indicates the dispersion of harmonic centrality values in the studied network. This means there are significant variations in the level of centrality between different nodes. The value of the skewness coefficient, amounting to -1.26434, indicates an asymmetric distribution of harmonic centrality values, with a predominance of nodes with lower centrality.

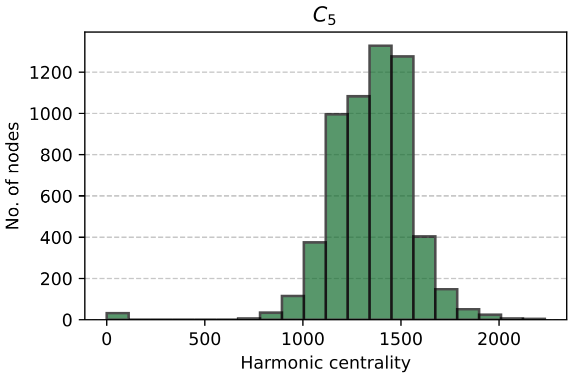

Fig. 8. Distribution of harmonic centrality values for Bitcoin users complex network.

For the studies conducted, min-max normalization was applied to the network centrality metrics. This normalization is intended to scale the values of the metrics within a fixed range to allow comparison and interpretation of the results. The model training process can be sensitive to differences in the scale of metrics values. If no normalization is performed, metrics with a more extensive range of values may significantly impact the training process, and metrics with a smaller range may be ignored. Min-max normalization allows the values of metrics to be adjusted to a range of 0 to 1, eliminating scale differences and ensuring that each metric has an equal impact on the learning process.

B. Artificial expert study: MLP regressor

In this section, a study related to the accuracy of the MLP Regressor model will be conducted. Since the MLP Regressor model will be responsible for evaluating character objects acting as reference preference points of the decision maker, it is necessary to investigate the possibilities related to the model's accuracy concerning the training sample. Therefore, a 10-fold cross-validation was carried out for a given size of the learning set. For the MLP Regressor model, its hyperparameters were adjusted using the `GridSearchCV` class, where the following results were obtained: `max_iter=1000`, `batch_size=64`, `solver= 'lbfgs'`, `hidden_layer_sizes=[1000]`, `activation='relu'`, `alpha=0.0001`.

Using Fig. 9 shows the 10-fold cross-validation on the training set. The dashed line denotes the limiting values obtained for the coefficient of determination obtained for the learning set of the obtained model. In comparison, the solid line with points denotes the average coefficient of determination values. The present results show that as the size of the training set increases, the R^2 values tend to increase. These results indicate that a larger training set size tends to translate into better results for the coefficient of determination. The R^2 values are high for all training set sizes, suggesting that the model can describe the data well.

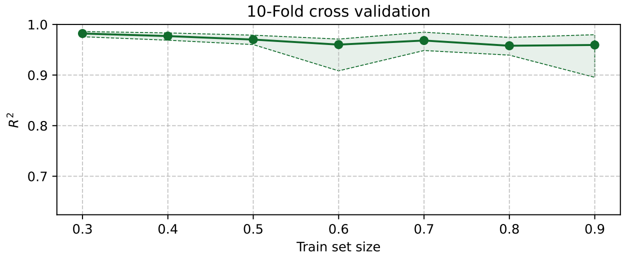

Fig. 9. Relationship between the coefficient of determination and the size of the training set for 10-fold crosvalidation(validated set: train, metric: R^2).

A 10-fold cross-validation on the test set is shown using Fig. 10. In the graph, the dashed line marks the limit values of the coefficient of determination obtained for the test set, and the solid line with points marks the average values of the coefficient of determination. Analysis of the results indicates that the model can significante explain variation in the data. The average values of the coefficient of determination are high, indicating a good fit of the model to the data. The maximum values of the coefficient of determination are also high, which means that in some cases, the model achieves a significant fit for the data.

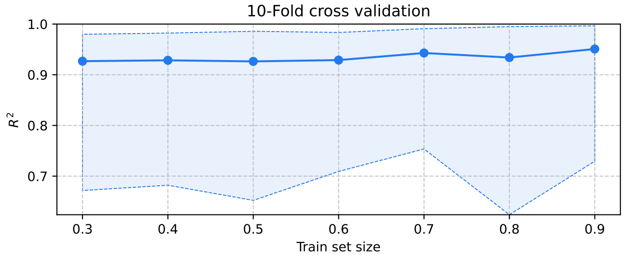

Fig. 10. Relationship between the coefficient of determination and the size of the training set for 10-fold crosvalidation(validated set: test, metric: R^2).

Using Table II, the results of 10-fold cross-validation on the learning set for different sizes of the training set are presented. Analyzing the results for a training set of size 0.3, the lowest R^2 value is 0.9859, indicating a high fit of the model to the data. In contrast, for a training set of 0.9, the lowest R^2 value is 0.8955, indicating a lower model fit to the data than other training set sizes. The average R^2 value ranges from 0.9579 to 0.9820, depending on the size of the training set. The standard deviation is most significant for a training set size of 0.9, suggesting greater variability in results for this set size.

TABLE II
10-FOLD CROSVALIDATION ON THE TRAINING SET FOR ITS PARTICULAR SIZE (VALIDATED SET: TRAIN, METRIC: R^2).

Stats	**Train set size**						
	0.3	0.4	0.5	0.6	0.7	0.8	0.9
Min	0.9757	0.9689	0.9602	0.9083	0.9485	0.9393	0.8955
Mean	0.9820	0.9770	0.9701	0.9601	0.9682	0.9579	0.9594
Max	0.9859	0.9832	0.9788	0.9711	0.9847	0.9743	0.9797
Std	0.0034	0.0047	0.0063	0.0176	0.0088	0.0109	0.0229

The Table III shows the results of 10-fold cross-validation on the learning set for different training set sizes, using the R^2 metric on the test set. The minimum values of R^2 range from 0.6522 to 0.7536, depending on the size of the training set. The average values of R^2 are high, ranging from 0.9263 to 0.9508 for different training set sizes. The maximum values of R^2 range from 0.9798 to 0.9966, indicating a high fit of the model to the data for some cases. The standard deviation of R^2 measures the variability of the results and ranges from 0.0679 to 0.1050.

TABLE III
10-FOLD CROSVALIDATION ON THE TRAINING SET FOR ITS PARTICULAR SIZE (VALIDATED SET: TEST, METRIC: R^2).

Stats	**Train set size**						
	0.3	0.4	0.5	0.6	0.7	0.8	0.9

Based on the results presented above, the MLP Regressor model is stable to perform its function in the present problem as an artificial expert.

C. Study of the stability: MLP-COMET

The study will focus on the similarity of the rankings obtained from the MLP-COMET approach. In order to test the applicability of the MLP model for evaluating the characteristic objects of the COMET method, a study related to the evaluation of 15 selected nodes of a complex network derived from a test set was conducted. In this study, a division of the set into a train set (size: 80%) and a test set (size: 20%) was used to test the MLP-COMET model. The same set was used for the hyperparameters for the MLP model, as shown in the previous study. On the other hand, for the COMET method, 2 characteristic values were selected for each criterion based on the limit values of the normalized criteria.

Table IV shows the selected 15 nodes of the network composed of the test set and their rankings obtained from the MLP-COMET model and the reference expert model. For this study, a high similarity between the two rankings can be observed, as the difference in positions occurs only for four decision variants, i.e., A_1, A_{12}, A_{13} and A_{14}. In addition, the differences in ranking positions are slight and occur mainly at the end of the ranking, which may have a negligible effect on the order.

* where: 'Obt.' - MLP-COMET rank, 'Ref.' - reference model rank.

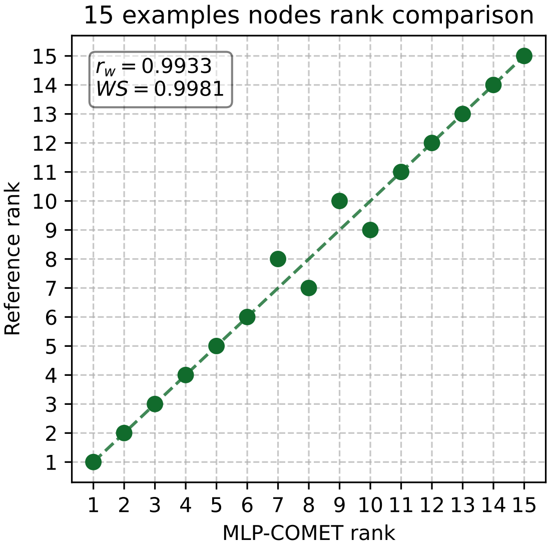

Fig. 11. Relationship between the ranking obtained from the MLP-COMET model and the reference ranking of the expert model for 15 nodes from the test set.

With the help of Fig. 11, the relationship between the ranking obtained from the MLP-COMET model and the reference ranking of the expert model is shown for 15 selected nodes of the composite network. The nodes usually occupy the same positions in both rankings, indicating high similarity. In addition, high similarity can also be observed by analyzing the similarity metrics of the rankings, such as r_w (weighted Spearman correlation coefficient) and WS (ranking similarity coefficient). The values of these metrics were 0.9933 for r_w and 0.9981 for WS, respectively.

After a sample study related to the applicability of the MLP model as an artificial expert for evaluating characteristic objects in the COMET method was performed, it was necessary to investigate the effect of the number of characteristic values on the similarity of rankings depending on the size of the training set. For this study, the r_w measure was used as a metric of ranking similarity for each case studied.

Fig. 12 shows the similarity matrix of node rankings derived from the training set for a given size of the training set and several characteristic values for each criterion. As can be seen from the heatmap, a very stable model was obtained based on samples from the training set. The values of the coefficient r_w were in the range [0.98,1.00], which shows the high similarity of the rankings. The most stable models were obtained for the learning set of 50% and 80% of the initial set and the number of characteristic values 6, 7, 8. In contrast, the slightest similarity was obtained for the learning set of 30% of the initial set.

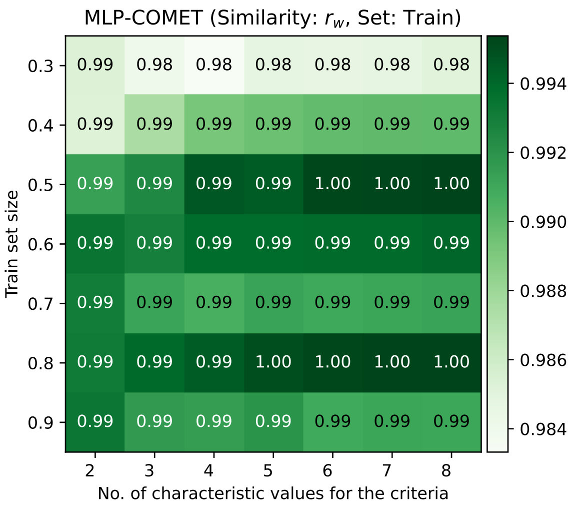

Fig. 12. Ranking similarity matrix for given learning set size and number of characteristic values (MLP-COMET, metric: r_w, studied set: train).

Using Fig. 13, the similarity matrix of node rankings derived from the test set is shown for a given size of the train set and several characteristic values for each criterion. As in the case of the learning set, the high similarity of rankings derived from comparisons of MLP-COMET rankings and reference rankings was shown on the test set. The range of obtained values of the coefficient r_w is [0.98, 1.00], which indicates a high mapping of the rankings of the complex network nodes by the MLP-COMET model. The highest similarity of rankings was obtained for a learning set of size 50% of the base set and 6,7,8 numbers of characteristic values for all considered criteria.

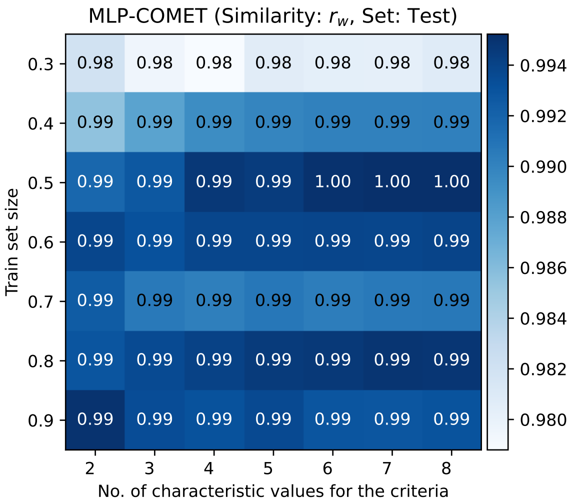

Fig. 13. Ranking similarity matrix for given learning set size and number of characteristic values (MLP-COMET, metric: r_w, studied set: test).

VI. Conclusions and Future works

This paper presents a study on applying the MLP-COMET approach to evaluating the nodes of a complex network of Bitcoin users. The accuracy of the representation of the decision maker's preferences in the decision-making process investigated was using the MLP Regressor model, which achieved high accuracy on both the test set and the training set. Therefore, another study conducted was con the MLP-COMET model, where the results indicate that the MLP-COMET model reproduces well the ranking obtained from the reference expert model, suggesting that it can be an effective tool in evaluating the nodes of a complex network.

The effect of the training sample size and the number of characteristic objects on the similarity of rankings between MLP-COMET and the reference rankings was also investigated. Similar results were obtained, where the similarity measured using the r_w metric for both the train and test sets was in the range [0.98, 1.00]. This demonstrates the tested model's high stability and applicability to the tested complex network to evaluate its nodes.

Future research directions of the proposed approach include other complex networks or multi-criteria decision-making problems. In addition, it would also be appropriate to consider a study related to the consistency of the obtained MEJ matrices of the MLP-COMET approach. Also, more research on its accuracy and consideration of the uncertain environment would need to be conducted. In addition, future research should focus on other cryptocurrencies such as Ethereum.

***Abstract*—Many applications in practice involve the search for a shortest path in a network by optimizing two conflicting objective functions. Such problems often are referred to as biobjective optimization problems. Their goal is to find special optimal paths that are *nondominated* and are also known in the specialized literature as to as *Pareto optimal*. While most of the existing methods aim to find the minimum complete set of Pareto optimal paths, we propose an approach that is able to generate a list of all Pareto optimal solutions in a given network.**

The described method solves the biobjective optimization problem in the case in which the first objective function is a linear (MINSUM), while the second objective function is from the "bottleneck" type (MAXMIN). The presented approach is based on two modifications of the Dijkstra's shortest path algorithm that solve the MINSUM and the MAXMIN problems respectively.

We prove the correctness and the computational complexity of the presented algorithms. Also, we provide detailed numerical examples that illustrate their execution.

I. Introduction

PARETO optimal solutions of biobjective (bicriterion) optimization problems are a subject of extensive research in combinatorial optimization and operation research disciplines, and in particular the biobjective shortest path problems [1]. These special type of shortest path problems can arise in numerous applications in practice including transportation problems, computer networking, robot motion, and many others.

The search of biobjective Pareto optimal solutions in a shortest path problem is an optimization problem that is a subject of two objective functions, lets say f and g. The Pareto optimal paths (also called nondominated) are a set of paths, such that for any path α in it, it is impossible to improve either f or g criterion, without getting worse the other [2].

By determining the objective functions f and g, different types of bicriterion path problems can be defined. The first notable work that examines these types of problems is [3] in which Hansen defines ten types of bicriterion path problems, and also introduces their abbreviations. In particular, the MINSUM-MAXMIN problem is solved with an algorithm with a polynomial complexity $O(m^2 \log n)$, where n is the number of vertices of the network, and m is the number of directed edges. In the MINSUM-MAXMIN problem the first objective function is a liner one, while the second objective function is from the *bottleneck* type.

In the literature actually there are quite few works that focus on the solution of the MINSUM-MAXMIN problem. One of them is [4] which proposes an extension of the Martin's algorithm [5] for a multiobjective shortest path problem with a MAXMIN objective function. Most of the methods that can be found in the literature focus on the combination of two linear functions, for example [2], [6], [7], [8] solve the MINSUM-MINSUM bicriteria path problem. Other works focus on MINMAX-MINSUM problem (see [9] and [10]), however in their case the authors do not consider the Pareto optimality, rather they aim to define a singe objective function by combining the MINMAX and MINSUM criteria.

Another subject that is rarely considered in the literature is the calculation of all Pareto optimal paths from a source vertex v_0 and a destination (target, terminal) vertex v_t. Most of the existing algorithms aim to find the minimal complete set of Pareto optimal paths, which means that from each equivalent set of Pareto optimal paths a single path is discovered (see [3]). In [11] the authors look for a set of alternative Pareto optimal paths in a method that solves a concrete practical problem for routing of Hazardous materials and propose shortest path algorithm on a network with two criteria: one that corresponds to road length, and the other that corresponds to a risk measure.

The work [2] is one of the few in the literature that pays special attention to the calculation of all Pareto optimal paths. The authors propose two algorithms depending whether the paths may contain or may not contain loops, both of them based on k shortest paths algorithms in graphs. However, as mentioned above, in this work the two objective functions are linear, and the algorithms do not cover the case in which one of the functions is a bottleneck function.

The exact methods that are present in the literature, are generally classified into *labeling* and *ranking paths* algorithms [12]. Labeling algorithms can be split into two categories: *label setting* [3], [5], [8]; and *label correcting* [6], [7], [11]. In the category *ranking paths* we can classify methods that are based on the k shortest paths algorithms, for example [2].

The other major branch of methods are based on heuristics approaches. For example, in [13] the authors propose a solution to the biobjective shortest path problem that is based on a genetic algorithm for which the authors report to find the Pareto optimal set in 77% of the instances. Also, the probabilistic technique ant colony optimization (ACO) and its modifications are adopted in the solution of various complex combinatorial problems (see for example [14]). Heuristic methods often are adopted in various practical problems, like electric vehicle shortest path problem [15].

In this paper we propose an exact method for calculation of all Pareto optimal paths for the MINSUM-MAXMIN problem in a network. We define two helper problems, MINSUM list and MAXMIN list, and we provide two algorithms that solve them, which are based on generalization of the Dijkstra's algorithm [16]. We use the solutions of the two helper problems to formulate the method for general problem solution. The correctness of all algorithms is proved, and their computational complexity is shown. Also, we illustrate the algorithms with detailed examples that show their execution.

The paper is organized as follows. In Sec. II we introduce the notations and problems formulation. In Sec. III we describe the two algorithms that solve the two helper problems. In Sec. IV we show how the Pareto optimal solutions list is constructed based on the solution of the two helper problems. Finally, Sec. V contains conclusions and discussions.

II. Problem formulation

A. Notations

Let $G = (V, E)$ is a directed graph (digraph) with $n = |V|$ number of vertices and $m = |E|$ number of directed edges. Without loss of generality we will assume that $V = \{1, 2, \dots, n\}$ and $E \subseteq V^2$.

We define the following two functions on the set of edges of the digraph, $f : E \to \mathbb{R}_+$ and $g : E \to \overline{\mathbb{R}}_+$. The function f assigns to each edge $(i, j) \in E$ the positive number $f(i, j)$, which we call the *length* of the edge $e = (i, j)$. The function g assigns to each edge $(i, j) \in E$:

$$g(i,j) = \begin{cases} +\infty, & \text{if} \quad (i,j) \in E \text{ has no restriction} \\ g_{ij} > 0, & \text{if} \quad (i,j) \in E \text{ has a restriction} \end{cases}$$

For convenience, we will call the value $g(i, j)$ the *capacity* of the edge $e = (i, j)$.

The digraph G together with the functions f and g defines the network $G = (V, E, f, g)$ (see [17]). The network is represented by the adjacency list of the outgoing neighbors [18] that is augmented with the length and capacity of the edges in the following way:

$$Adj = \{Adj(1), \dots, Adj(i), \dots, Adj(n)\}, \tag{1}$$

where $Adj(i) = \{(j, f(i, j), g(i, j)) : (i, j) \in E\}, \forall i \in V$. In this way, if $q = Adj(i, k)$ for some $i \in V$, and a positive integer k, $q(1)$ will denote the k-th outgoing neighbor of the vertex i, $q(2)$ will denote the length of the edge $(i, q(1))$, and $q(3)$ will denote the capacity of the edge. To denote the adjacency list of outgoing neighbors of a given network G, we will use the notation $G.Adj$.

Path in the network G is the finite sequence of the type

$$v_0, e_1, v_1, e_2, \dots, v_{(t-1)}, e_t, v_t, \tag{2}$$

where $v_j \in V, \forall j \in \{0, 1, \dots, t\}$ are distinct vertices, and e_i is an edge with starting vertex $v_{(i-1)}$ and ending vertex v_i, that belongs to E for all $i \in \{1, 2, \dots, t\}$. The path consists of $(t + 1)$ vertices and t edges, the vertex v_0 is the *source* of the path, and the vertex v_t is the *destination* of the path.

The path (2) with a source v_0 and a destination v_t connects v_0 with v_t and is called a (v_1, v_t)-path, which we will denote with an ordered sequence α of vertices:

$$\alpha = (v_0, v_1, \dots, v_t). \tag{3}$$

For each path $\alpha = (v_0, v_1, \dots, v_t)$ we define two functions:

$$x(\alpha) = \sum_{j=1}^{t} f(v_{j-1}, v_j) \tag{4}$$

$$y(\alpha) = \min_{j \in \{1,\dots,t\}} \{g(v_{j-1}, v_j)\} \tag{5}$$

We will call the number $x(\alpha)$ the *length* of the path, and the number $y(\alpha)$ the *capacity* of the path α. Both functions $x(\alpha)$ and $y(\alpha)$ define the objective functions of the problems that we will discuss.

We denote all $(1, j)$-paths with the shorter W_j. Then, we will call the number

$$r_j = \min_{\alpha \in W_j} \{x(\alpha)\} \tag{6}$$

a *distance* between the vertex 1 and the vertex j. Also, we will call the number

$$c_j = \max_{\alpha \in W_j} \{y(\alpha)\} \tag{7}$$

the *capacity* of the vertex j.

For each W_j the term *Pareto optimal path* is defined as follows.

Definition 1. *We call the path $\alpha \in W_j$* ***Pareto optimal*** *when there does not exist another path $\beta \in W_j$, for which any of the following two conditions is fulfilled:*

- *$x(\beta) < x(\alpha)$ and $y(\beta) \geq y(\alpha)$;*
- *$x(\beta) \leq x(\alpha)$ and $y(\beta) > y(\alpha)$.*

We say that α and β are *equivalent* ($\alpha \sim \beta$), when $x(\alpha) = x(\beta)$ and $y(\alpha) = y(\beta)$.

The path β is *dominated* by the path α, when $x(\alpha) < x(\beta)$ and $y(\alpha) \geq y(\beta)$ or $x(\alpha) \leq x(\beta)$ and $y(\alpha) > y(\beta)$.

Besides that, we will denote the distance from vertex 1 to any vertex v with $r(v)$.

B. Problems formulation

Based on the above definitions, we formulate the main problem considered in this paper:

Problem 1 (List of Pareto optimal solutions)**.** *Compute a list of all Pareto optimal solutions for W_n.*

To solve the List of Pareto optimal solutions problem, we will use the solutions of the following two helper problems.

The solution of the first helper problem requires the definition of a function $minsum(G.Adj)$ that computes a *list of all shortest paths* in the network.

Problem 2 (MINSUM list)**.** *Compute a list of all $(1, n)$-paths with minimal length, given by:*

$$S_x = \{\alpha \in W_n : x(\alpha) \leq x(\beta), \forall \beta \in W_n\}. \tag{8}$$

The solution of the second helper problem requires the definition of a function $maxmin(G.Adj)$, and it is a version of the first helper problem that computes a *list of all maximum capacity paths* in the network.

Problem 3 (MAXMIN list)**.** *Compute a list of all $(1, n)$-paths with maximal capacity, given by:*

$$S_y = \{\alpha \in W_n : y(\alpha) \geq y(\beta), \forall \beta \in W_n\}. \tag{9}$$

III. Solution of the two helper problems

To solve the two helper problems we propose two modifications of the Dijkstra's algorithm [16], in which the results hold as well in the case in which the source vertex is selected $i_0 \neq 1$. In both modifications we assume that the network $G = (V, E, f, g)$ is defined using the adjacency list of the outgoing neighbors.

In the computer program implementation of the modified versions of Dijkstra's algorithm we apply the Fibonacci heap data structure [19] for all priority queue operations. Even though the relative complexity of its implementation, this advanced data structure introduces a significant speedup of the algorithm to $O(n \log n + m)$, which is proved based on amortized analysis [18].

A. List of all shortest paths

We will solve the problem of computing of a list of all $(1, n)$- shortest paths by finding the subnetwork $\widehat{G} = (V, \widehat{E}, f, g)$ of the shortest paths.

Definition 2. *We will say that $\widehat{G} = (V, \widehat{E}, f, g)$ is a* ***subnetwork of the shortest paths*** *in the network $G = (V, E, f, g)$, if the following two properties hold:*

1) *Every $(1, n)$- shortest path in G is also a $(1, n)$-path in $\widehat{G}$.*
2) *Every $(1, n)$-path in $\widehat{G}$ is a $(1, n)$- shortest path in G.*

The solution of the MINSUM list helper problem is given by the definition of a function $minsum(G.Adj)$ (Alg. 2), which for a given network G calculates the adjacency list of the outgoing neighbors of the shortest paths subnetwork $\widehat{G}$. The implementation of the $minsum(G.Adj)$ function is based on a modification of the Dijkstra's algorithm [16], as follows.

The algorithm splits the set of network vertices in into subsets. The first subset V_0 denotes the vertices that are not yet traversed by the algorithm. The second subset $U = V \setminus V_0$ stores the traversed vertices. The procedure that traverses the network guarantees that

$$r(v) \geq r(u), \tag{10}$$

for each vertex $v \in V_0$ and each vertex $u \in U$. Initially, $V_0 = V$ and $U = \varnothing$. In each of n consecutive iterations of execution the function $minsum(G.Adj)$ a selected vertex is transferred from V_0 into U.

Algorithm 1 Function $relaxS(u, v, d, pr)$

```
Input: vertices $u$, $v$, and vectors $d$, $pr$
Output: vectors $d$, $pr$
  $q \in G.Adj(u)$, such that $q(1) = v$
  $r \leftarrow d(u) + q(2)$
  if $d(v) > r$ then
      $d(v) \leftarrow r$
      $pr(v) \leftarrow \{u\}$
  else if $d(v) = r$ then
      $pushback(pr(v), u)$
  end if
  return $\{d, pr\}$
```

The algorithm uses two vectors d and pr, both of them with n components. Initially, $d(1) = 0$, and all other components of d are ∞. The initial values of pr are equal to the empty set $\varnothing$. After the completion of the algorithm, d will store the distances from the source vertex to each of the other vertices in the network, in other words $d(j) = r(j), \forall j \in V$, and pr will store the adjacency list of the ingoing neighbors of the digraph $(V, \widehat{E})$. The last step of the $minsum(G.Adj)$ function composes the adjacency list of the outgoing neighbors of the shortest paths subnetwork $\widehat{G}$.

In the proposed variant of the Dijkstra's algorithm that solves Prob. 2, the function that implements the relaxation procedure is modified. We define the function $relaxS(u, v, d, pr)$ that performs relaxation of the edge (u, v) by changing the current state of d and pr, as it is given in Alg. 1.

We use two more helper functions in our modified Dijkstra's implementation of the $minsum(G.Adj)$ procedure: $extract(V_0)$ and $outadj(pr, G.Adj)$.

The input of $extract(V_0)$ is the subset $V_0 \subset V$, and the output is $\{v_1, V_1\}$, where $v_1 \in V_0$, $V_1 = V_0 \backslash \{v_1\}$ and $d(v_1) = \min\limits_{v \in V_0}\{d(v)\}$.

The purpose of the $outadj(pr, G.Adj)$ function is to build the adjacency list of the outgoing neighbors of the network $\widehat{G}$ out of the digraph presented by the adjacency list of the ingoing neighbors pr. The function composes each edge $e = (i, j)$ from the digraph given by pr, and takes the corresponding edge length $f(i, j)$ and capacity $g(i, j)$ from the outgoing adjacency list of the original input network $G.Adj$.

Proposition 1. *The function $minsum(G.Adj)$ is correctly defined.*

Proof: The proof of the correctness of the function $minsum(G.Adj)$ is analogous to the proof of the Dijkstra's

Algorithm 2 Function $minsum(G.Adj)$

```
Input: $G.Adj$
Output: distance $d_0$ to vertex $n$, and $\widehat{G}.Adj$
  $V_0 \leftarrow \{1, 2, \dots, n\}$
  $d \leftarrow (0, \infty, \dots, \infty)$
  while $V_0 \neq \varnothing$ do
      $\{u, V_0\} \leftarrow extract(V_0)$
      for each $q \in G.Adj(u)$ do
          $\{d, pr\} \leftarrow relaxS(u, q(1), d, pr)$
      end for
  end while
  $\widehat{G}.Adj \leftarrow outadj(pr, G.Adj)$
  return $\{d(n), \widehat{G}.Adj\}$
```

algorithm (see [18]). We will only note that after the each iteration of the **while** loop the following properties hold for each vertex $v \in V_0$:

1) $d(v) \geq r(v)$;
2) $pr(v)$ is the set of all vertices $u \in U$ for which there exists a path $\alpha = (i_0, i_1, \dots, i_k, u, v)$ with length $x(\alpha) = d(v)$.

Besides that, when $v_1 \in V_0$ and $d(v_1) = \min\limits_{v \in V_0}\{d(v)\}$, then following the proof of the Dijkstra's algorithm, we find out that $d(v_1) = r(v_1)$. Then in the set V_0 does not exist a vertex that is the one before the last one in a (i_0, v_1)-path with length $d(v_1)$. In fact, if we assume that for the path $\alpha = (i_0, i_1, \dots, i_k, v_1)$ holds $i_k \in V_0$ and $x(\alpha) = d(v_1)$, we reach contradiction because

$$r(v_1) = d(v_1) = \sum_{s=1}^{k} f(i_{s-1}, i_s) + f(i_k, v_1) \geq r(i_k) + f(i_k, v)$$

and using the inequality (10), we get $r(v_1) \geq r(v_1) + f(i_k, v)$.

The **while** loop of the algorithm stops when $V_0 = \varnothing$, and then $d(j) = r(j), \forall j \in V$.

We define the network $\widehat{G} = (V, \widehat{E}, f, g)$, where $\widehat{E} = \{(i, j) \in E : i \in pr(j)\}$. In this way, $\widehat{G}$ is the shortest paths subnetwork of the network G, and pr is the adjacency list of the ingoing neighbors of the digraph $(V, \widehat{E})$, which is verified directly, by using the fact that $pr(v)$ is the set of those vertices $u \in V$ for which there exists a path $\alpha = (i_0, i_1, \dots, u, v)$ such that $x(\alpha) = r(v)$. ■

It is clear that using the adjacency list $\widehat{G}.Adj$, it is easy to compose the list of all $(1, n)$- shortest paths. The following example illustrates this observation.

Example 1. *Let G_1 is the network given on the Figure 1. We will find all $(1, 5)$- shortest paths in G_1.*

Solution: The outgoing adjacency list of G_1 is given by:

$$\begin{aligned} G_1.Adj = \{&\{(2,2,4),(3,5,3)\},\\ &\{(3,3,5),(4,6,4),(5,5,3)\},\\ &\{(4,3,6),(5,1,1)\},\{(5,1,7)\},\{\}\}. \end{aligned} \tag{11}$$

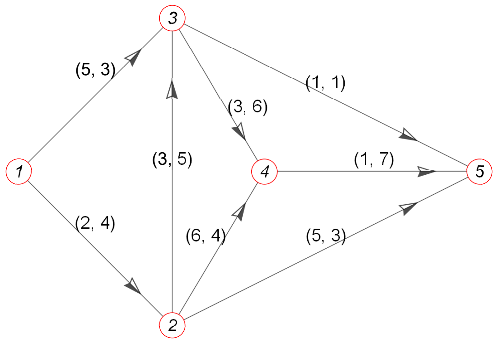

Fig. 1. Example network G_1 composed by five vertices with length and capacity of each edge given next to it

The function $minsum(G_1.Adj)$ produces the following result:

$$\{d_0, \widehat{G}_1.Adj\} \leftarrow minsum(G_1.Adj), \tag{12}$$

where $\widehat{G}_1.Adj = \{\{(2,2,4),(3,5,3)\}, \{(3,3,5),(4,6,4)\}, \{(4,3,6),(5,1,1)\}, \{\}, \{\}\}$ and $d_0 = 6$.

The network with outgoing adjacency list $\widehat{G}_1.Adj$ has exactly two $(1, 5)$-paths

$$\alpha = (1, 3, 5) \text{ and } \beta = (1, 2, 3, 5).$$

Obviously, $x(\alpha) = x(\beta) = 6 = d_0$.

Proposition 2. *The function $minsum(G.Adj)$ has computational complexity $O(n \log n + m)$.*

The proof follows directly from the computational complexity of the Dijkstra's algorithm, in the case in which the Fibonacci heap data structure is used for the implementation of the priority queue operations (refer to [18]).

B. List of all maximum capacity paths

We denote the capacity of each vertex of the network $v \in V$ with $c(v)$.

Definition 3. *We say that $\widetilde{G} = (V, \widetilde{E})$ is a **maximal capacity** digraph of the network $G = (V, E, f, g)$, if the following two properties hold:*

1) *Every $(1, n)$- maximal capacity path in G is also a $(1, n)$-path in $\widetilde{G}$.*
2) *Every $(1, n)$-path in $\widetilde{G}$ is also a $(1, n)$- maximal capacity path in G.*

In this section we will define the function $maxmin(G.Adj)$ which calculates the adjacency list of the outgoing neighbors $\widetilde{G}.Adj$ of the maximal capacity graph $\widetilde{G} = (V, \widetilde{E})$. For its implementation, first we will formulate the function $capacity(G.Adj)$ (Alg. 3) which calculates the capacity of a vertex n in the network G, again following the Dijkstra's algorithm.

We denote with d a vector of n components that initially has all its elements equal to $-\infty$, except the first element $d(1) = \infty$. During the calculations of the function $capacity(G.Adj)$ the components of d are growing, and when the function

Algorithm 3 Function *capacity*$(G.Adj)$

```
Input: $G.Adj$
Output: the capacity $c_n$ of the vertex $n$
  $V_0 \leftarrow \{1, 2, \dots, n\}$
  $d \leftarrow (\infty, -\infty, \dots, -\infty)$
  while $V_0 \neq 0$ do
      $\{u, V_0\} \leftarrow extract(V_0, d)$
      for each $q \in G.Adj(u)$ do
          $relax(u, q(1), G.Adj, d)$
      end for
  end while
  return $d(n)$
```

Algorithm 4 Function $maxmin(G.Adj)$

```
Input: $G.Adj$
Output: the capacity $c$ of the vertex $n$ and $\widetilde{G}.Adj$
   $c \leftarrow capacity(G.Adj)$
2: for $i \leftarrow 1$ to $n$ do
       for each $q \in Adj(i)$ do
4:         if $q(3) \geq c$ then
               $pushback(\widetilde{G}.Adj, q(1))$
6:         end if
       end for
8: end for
   return $\{c, \widetilde{G}.Adj\}$
```

completes, the j-th component of d stores the capacity of the vertex j, or in other words $d(j) = c(j)$. Note that by definition $c(1) = \infty$.

We will use the following helper functions in the implementation of *capacity*$(G.Adj)$.

The function $extract(V_0, d)$ for an arbitrary subset $V_0 = \{j_1, j_2, \dots, j_k\} \subseteq V$ and using the vector d, calculates the pair $\{j_s, V_1\}$, where

$$j_s \in V_0,\ d(j_s) = \max_{j_p \in V_0}\{d(j_p)\} \text{ and } V_1 = V_0 \setminus \{j_s\}. \quad (13)$$

The function $relax(i, j, G.Adj, d)$ for each two vertices i and j, and based on $G.Adj$ and d, performs the following calculations:

1) Defines $r = \min\{d(i), g(i, j)\}$.
2) If $d(j) < r$, it sets $d(j) = r$.

Proposition 3. *The function capacity*$(G.Adj)$ *is correctly defined.*

Proof: Let $1 \leq k < n$. We assume that after k iterations of the **while** loop (see Alg. 3), from the initial set $V_0 = V = \{1, 2, \dots, n\}$ are excluded k number of vertices u_s, and for the resulting set $V_0 = V \setminus \{u_1, \dots, u_k\}$ the following properties hold:

1) For each $u \in U = \{u_1, \dots, u_k\}$ it holds that $d(u) = c(u)$.
2) For each $u \in U$ and each $v \in V_0$ it hods that $d(u) \geq d(v)$.
3) Let $v_k \in V_0$ and $d(v_k) \geq d(v)$ for each $v \in V_0$. Then $d(v_k) = c(v_k)$.

The above three properties are true for $k = 1$.

After the $(k+1)$-st iteration of the **while** loop, the vertex v_k is excluded from v_0 and we get $V_0' = V_0 \setminus \{v_k\}$. We will prove that the three properties hold for the set V_0'.

From the definition of v_k and the fact that the three properties hold for V_0, it follows directly that properties 1) and 2) are fulfilled for V_0'.

Now, let $v_{k+1} \in V_0'$ and $d(v_{k+1}) \geq d(v)$ for each $v \in V_0'$. We denote $U' = U \cup \{v_k\} = V \setminus V_0'$. Also, let α be an arbitrary $(1, v_{k+1})$-path and

$$\alpha = (1, u_1, \dots, u_s, v_{j_1}, \dots, v_{j_r}, v_{k+1}),$$

where $u_i \in U', \forall i \in \{1, \dots, s\}$ and $v_{j_1} \in V_0'$.

From the definition of $d(v_{j_1})$ it follows that for the capacity $y(\beta)$ of the path $\beta = (1, u_1, \dots, u_s, v_{j_1})$ it is fulfilled that $y(\beta) \leq d(j_1)$. Then, for that capacity $y(\alpha)$ of the path α we have that

$$y(\alpha) \leq y(\beta) \leq d(v_{j_1}) \leq d(v_{k+1}),$$

which proves that $d(v_{k+1}) = c(v_{k+1})$. ■

Having the function *capacity*$(G.Adj)$, we can define the function $maxmin(G.Adj)$, given in Alg. 4.

Proposition 4. *The function* $maxmin(G.Adj)$ *is correctly defined.*

Proof: Since the function *capcity*$(G.Adj)$ that is triggered on the first line of the Alg. 4 is correct, it follows that c is the capacity of the vertex n. The outer **for** loop on the line 2 defines that adjacency list $\widetilde{G}.Adj$ of the graph $\widetilde{G} = (V, \widetilde{E})$, where $\widetilde{E} = \{(i, j) \in E : g(i, j) \geq c\}$. Now we will prove that the graph $\widetilde{G} = (V, \widetilde{E})$ is the maximum capacity graph.

If α is a $(1, n)$-path in the network G with capacity $y(\alpha) = c$, then for each edge (i, j) of α it holds that $g(i, j) \geq c$, and hence, $(i, j) \in \widetilde{E}$. This shows that α is a $(1, n)$-path of $\widetilde{G}$.

Now, let β is a $(1, n)$-path in $\widetilde{G}$. This means that β is a $(1, n)$-path in the network G, and for each its edge (i, j) it is fulfilled that $g(i, j) \geq c$. From here it follows that $y(\beta) \geq c$. However, since c is the capacity of the vertex n, then $y(\beta) = c$. ■

Proposition 5. *The computational complexity of the function* $maxmin(G.Adj)$ *is* $O(n \log n + m)$.

The proof follows directly from the complexity of the Dijkstra's algorithm implemented with Fibonacci heap, since the function *capacity*$(G.Adj)$ repeats exactly it steps.

We will introduce the function $list(m, \widetilde{G}.Adj)$ that will help us to clarify the following examples. The argument of the function m is a natural number or ∞. The function maps a list S of $(1, n)$-paths in $\widetilde{G}$ that satisfies the following properties:

1) If $m = \infty$, the list S contains all $(1, n)$-paths of $\widetilde{G}$.
2) If m is a natural number, S contains all $(1, n)$-paths of $\widetilde{G}$ if their number is not greater than m. Otherwise, S contains m number of all $(1, n)$-paths of $\widetilde{G}$.

Example 2. *For the network G_1 (see Fig. 1) we will compose the list S_y (9) of all $(1,5)$-paths with maximal capacity.*

Solution: The solution is composed by the following two steps:

1) $\{c, \widetilde{G}_1.Adj\} \leftarrow maxmin(G_1.Adj)$.
2) $S_y \leftarrow list(\infty, \widetilde{G}_1.Adj)$.

On the first step, using the function $maxmin(G_1.Adj)$, we calculate that:

$$c = 4 \text{ and } \widetilde{G}_1.Adj = \{\{2\},\{3,4\},\{4\},\{5\},\{\}\}.$$

On the second step, the function $list(\infty, \widetilde{G}_1.Adj)$ calculates the list

$$S_y = \{(1,2,4,5),(1,2,3,4,5)\}.$$

Then, it is directly verified that

$$y((1,2,4,5)) = y((1,2,3,4,5)) = 4 = c.$$

IV. Pareto optimal solutions set

We denote with P the set of Pareto optimal paths in the network $G = (V, V, f, g)$. It is clear that

$$P = \bigcup_{i=1}^{k_0} P_i, \tag{14}$$

where P_i are the classes of Pareto equivalent paths.

We will find the set P by composing a list Q of all classes of Pareto equivalent paths P_i. We will compose the list Q using the following procedure, which we will call *Pareto Optimal Paths (POP)*:

1) Set $W = W_n$.
2) Calculate $d = \min\limits_{\beta\in W}\{x(\beta)\}$ and define $X = \{\alpha \in W : x(\alpha) = d\}$.
3) Calculate $c = \max\limits_{\beta\in X}\{y(\beta)\}$ and define $P_0 = \{\alpha \in X : y(\alpha) = c\}$. Store P_0 into the list Q.
4) Define $Y = \{\beta \in W : y(\beta) > c\}$.
5) Define $Z = W \setminus (Y \cup P_0)$.
6) If $Y = \varnothing$, then end. Otherwise, set $W = Y$ and go back to step 2.

Lemma 1. *The POP procedure correctly composes the list Q.*

Proof: We will prove the correctness of the POP procedure by induction.

Base case. The *first iteration* of POP defines:

$$d_1 = \min_{\beta\in W_n}\{x(\beta)\}, X_1 = \{\alpha \in W_n : x(\alpha) = d_1\},$$
$$c_1 = \max_{\beta\in X_1}\{y(\beta)\}, P_1 = \{\alpha \in X_1 : y(\alpha) = c_1\}, Q = \{P_1\},$$
$$Y_1 = \{\beta \in W_n : y(\beta) > c_1\}, Z_1 = W_n \setminus (Y_1 \cup P_1).$$

The following properties hold:

1) From the definitions of the sets P_1, Y_1 and Z_1 it follows:

$$W_n = Z_1 \cup P_1 \cup Y_1, Z_1 \cap P_1 = \varnothing,$$
$$Z_1 \cap Y_1 = \varnothing, Y_1 \cap P_1 = \varnothing.$$

2) If $\alpha \in P_1$, then by the definition of P_1 the equalities $x(\alpha) = d_1$ and $y(\alpha) = c_1$ hold. Hence, the paths that belong to P_1 are equivalent.
3) If $Z_1 \neq \varnothing$ and $\beta \in Z_1$, then from step 5 it follows that one of the following two statements is fulfilled:
   a) $y(\beta) < c_1$ and $x(\beta) \geq d_1$, or
   b) $y(\beta) = c_1$ and $x(\beta) > d_1$.

   Hence, β is dominated by each $\alpha \in P_1$.

If $Y_1 = \varnothing$, then $W_n = P_1 \cup Z_1$ and P_1 is the set of Pareto optimal paths. This means that in (14) the constant $k_0 = 1$, and the calculations of the POP procedure will stop.

If $Y_1 \neq \varnothing$, then the constant $k_0 > 1$. In this case, for each $\beta \in Y_1$ the inequalities are fulfilled:

$$c_1 < y(\beta) \text{ and } d_1 < x(\beta). \tag{15}$$

As a result, also in this case P_1 is a set of equivalent Pareto optimal paths α, and it is correctly included in the list Q. Here, we set $W = Y_1$, and we go back to step 2 of the second iteration of the procedure.

The *second iteration* of the POP procedure defines:

$$d_2 = \min_{\beta\in Y_1}\{x(\beta)\}, X_2 = \{\alpha \in Y_1 : x(\alpha) = d_2\},$$
$$c_2 = \max_{\beta\in X_2}\{y(\beta)\}, P_2 = \{\alpha \in X_2 : y(\alpha) = c_2\},$$
$$Q = \{P_1, P_2\}, Y_2 = \{\beta \in Y_1 : y(\beta) > c_2\},$$
$$Z_2 = Y_1 \setminus (Y_2 \cup P_2).$$

In analogy with the first iteration of POP, the following properties are proved.

1) From the definitions of the sets P_2, Y_2 and Z_2 it follows:

$$\begin{aligned} Y_1 = Z_2 \cup P_2 \cup Y_2, Z_2 \cap P_2 = \varnothing, \\ Z_2 \cap Y_2 = \varnothing, Y_2 \cap P_2 = \varnothing \end{aligned} \tag{16}$$

2) If $\alpha \in P_2$, then by the definition of P_2 the equalities $x(\alpha) = d_2$ and $y(\alpha) = c_2$ hold, and hence the paths that belong to P_2 are equivalent. Besides that, from (15) follows that $d_1 < d_2$ and $c_1 < c_2$.

If $Z_2 \neq \varnothing$, then for each path $\beta \in Z_2$ holds that $x(\beta) \geq d_2$ because $\beta \in Y_1$. Besides that, $y(\beta) \leq c_2$, because $\beta \notin Y_2$. Then, for β one of the following statements hold:

- $y(\beta) < c_2$ and $x(\beta) \geq d_2$, or
- $y(\beta) = c_2$ and $x(\beta) > d_2$, because $\beta \notin P_2$.

Therefore, each path $\beta \in Z_2$ is dominated by any path from P_2.

Let $\alpha \in P_2$, and β is such a $(1,n)$-path, so that $\beta \notin Y_1$. Then $y(\beta) \leq c_1 < y(\alpha)$. The following two cases are possible:

- $x(\beta) \geq d_2 = x(\alpha)$. In this case α dominates β.
- $x(\beta) < d_2 = x(\alpha)$. In this case α and β cannot be compared.

That proves that if $Y_2 = \varnothing$, then the elements of P_2 are Pareto optimal and the equation (14) has the form $P = P_1 \cup P_2$, in other words, $k_0 = 2$. From here it follows that P_2 is correctly included in the list Q, and the termination of the computation of POP procedure is correct.

If $Y_2 \neq \varnothing$, then $k_0 > 2$. In this case, for each $\beta \in Y_2$ the following inequalities are fulfilled.

$$c_2 < y(\beta) \text{ and } d_2 < x(\beta) \tag{17}$$

The first inequality follows from the definition of Y_2, and the second one – from the definition of d_2 and c_2.

Therefore, also in the case in which $Y_2 \neq \varnothing$, the set P_2 is a set of Pareto optimal paths, and it is correctly included in the list Q. In this case, we set $W = Y_2$ and we go back to step 2 in the procedure to start its third iteration.

It is clear that in the third iteration of the procedure $W_n = Z_1 \cup P_1 \cup Z_2 \cup P_2 \cup Y_2$.

Inductive step. We assume that after $k \geq 2$ iterations of the POP procedure, the following components are defined.

- The sets P_i, Z_i, Y_k, $i \in \{1, 2, \dots, k\}$, that have no common elements.
- The numbers d_i and c_i $i \in \{1, 2, \dots, k\}$, for which the following five properties are fulfilled.
  1) $W_n = \bigcup\limits_{i=1}^{k} (Z_i \cup P_i) \bigcup Y_k$.
  2) $P_1, P_2, \dots, P_k$ are sets of equivalent Pareto optimal paths, for which
     a) $d_i = x(\alpha)$ and $c_i = y(\alpha)$, $\forall \alpha \in P_i$ and $\forall i \in \{1, 2, \dots, k\}$;
     b) $d_i < d_{i+1}$ and $c_i < c_{i+1}$, $\forall i \in \{1, 2, \dots, (k-1)\}$.
  3) Every path $\beta \in Z_i$ is dominated by every path $\alpha \in P_i$.
  4) For every $\beta \in Y_k$ the inequalities hold:
  $$c_k < y(\beta) \text{ and } d_k < x(\beta). \tag{18}$$
  5) $Q = \{P_1, P_2, \dots, P_k\}$.

  These five properties follow directly from the proof of the *second iteration* of the procedure.

It is clear that if $Y_k = \varnothing$, then $W_n = \bigcup\limits_{i=1}^{k} (Z_i \cup P_i)$ and the list Q is correctly composed.

If $Y_k \neq \varnothing$, we implement the $(k+1)$-st iteration of the POP procedure. Using steps from 2 to 5, we define:

$$d_{k+1} = \min_{\beta \in Y_k} \{x(\beta)\}, X_{k+1} = \{\alpha \in Y_k : x(\alpha) = d_{k+1}\},$$
$$c_{k+1} = \max_{\beta \in X_{k+1}} \{y(\beta)\},$$
$$P_{k+1} = \{\alpha \in X_{k+1} : y(\alpha) = c_{k+1}\},$$
$$Q = \{P_1, P_2, \dots, P_{k+1}\}, Y_{k+1} = \{\beta \in Y_k : y(\beta) > c_2\},$$
$$Z_{k+1} = Y_k \setminus (Y_{k+1} \cup P_{k+1}).$$

Repeating the proof of the second iteration, we find out that for

- sets P_i, Z_i, Y_{k+1}, $i \in \{1, 2, \dots, k, (k+1)\}$, and
- numbers d_i and c_i $i \in \{1, 2, \dots, k, (k+1)\}$

the five properties are fulfilled.

Since W_n has finite number of elements and $P_i \neq \varnothing, \forall i$, then after a finite number of k_0 iterations the procedure POP stops, and we prove that:

1) $W_n = \bigcup\limits_{i=1}^{k_0} (Z_i \cup P_i)$;
2) $P_1, P_2, \dots, P_{k_0}$ are sets of equivalent Pareto optimal paths for which
   a) $d_i = x(\alpha)$ and $c_i = y(\alpha)$, $\forall \alpha \in P_i$ and $\forall i \in \{1, 2, \dots, k_0\}$;
   b) $d_i < d_{i+1}$ and $c_i < c_{i+1}$, $\forall i \in \{1, 2, \dots, (k_0 - 1)\}$.
3) Every path $\beta \in Z_i$ is dominated by every path $\alpha \in P_i$.
4) $Q = \{P_1, P_2, \dots, P_{k_0}\}$.

■

Corollary 1. *For the classes P_i of Pareto optimal paths the following holds*

$$P_i = \{\alpha \in W_n : \, x(\alpha) = d_i \text{ and } y(\alpha) = c_i\},$$

for each $i \in \{1, 2, \dots, k_0\}$.

Corollary 2. *For P_{k_0} the following equality hods:*

$$P_{k_0} = \{\alpha \in X_1' : \, x(\alpha) = d_1'\},$$

where $X_1' = \{\alpha \in W_n : y(\alpha) = \max\limits_{\beta \in W_n} \{y(\beta)\}$ and $d_1' = \min\limits_{\beta \in X_1'} \{x(\beta)\}$.

Remark 1. *The list Q can be composed by: first apply the Corollary 2 to separate the set P_{k_0}; after that, consecutively separate the sets $P_{k_0 - 1}$, $P_{k_0 - 2}$, and so on, until P_1 is separated.*

Every subset P_i turns out to be a set of all $(1, n)$-paths in a special digraph G_i. The algorithm that finds a *List of Pareto Optimal Paths* which we will call LPOP (given in Alg. 5), composes a list S of the adjacency lists $G_i.Adj$ for each $i \in \{1, 2, \dots, k_0\}$ by implementing the POP procedure.

We will note that once we have the list S, we can easily obtain a list P' of Pareto optimal solutions by taking predefined number of elements for each class P_i, as well we can obtain a list P of all optimal solutions.

Besides the previously defined functions $minsum(G.Adj)$, $maxmin(G.Adj)$ and $capacity(G.Adj)$, in the formulation of the LPOP algorithm (Alg. 5), we will use the function $restrict(G.Adj, c)$, that is defined as follows.

The function $restrict(G.Adj, c)$ takes as an input the outgoing adjacency list $G.Adj$ and the number c. It calculates the adjacency list of those edges (i, j) from $G.Adj$, for which $g(i, j) > c$.

Theorem 1. *The LPOP algorithm (Alg. 5) is correct.*

Proof: The correctness of the Alg. 5 follows from the correctness of the functions $capacity(G.Adj)$, $minsum(G.Adj)$, $maxmin(G.Adj)$, and from Lemma 1. It is easily verified by proving that the **while** loop of the $lpop(G.Adj)$ function implements the POP procedure using these functions.

We will examine the first iteration of the **while** loop. The function $minsum(G.Adj)$ calculates $d_0 = \min\limits_{\beta \in W_n} \{x(\beta)\}$ and defines the adjacency list $\widehat{G}.Adj$ of the shortest paths subnetwork $\widehat{G}$. From the correctness of the function $minsum(Adj)$

Algorithm 5 Function $lpop(G.Adj)$

```
Input: $G.Adj$
Output: the list $S$ with $k_0$ number of elements
    $RAdj \leftarrow G.Adj$
 2: $c_0 \leftarrow capacity(G.Adj)$
    $more \leftarrow$ true
 4: while $more =$ true do
      $\{d_0, G.Adj\} \leftarrow minsum(G.Adj)$
 6:   if $d_0 = \infty$ then
        $more \leftarrow$ false
 8:   else
        $\{c_1, \widetilde{G}.Adj\} \leftarrow maxmin(G.Adj)$
10:     $pushback(S, \widetilde{G}.Adj)$
        if $c_1 = c_0$ then
12:       $more \leftarrow$ false
        else
14:       $RAdj \leftarrow restrict(RAdj, c_1)$
        end if
16:     $G.Adj \leftarrow RAdj$
      end if
18: end while
    return $S$
```

we know that α is a $(1,n)$-path in $\widehat{G}$, exactly when α is a $(1,n)$-path in the network G and $x(\alpha) = d_0$. Hence, the set X from the POP procedure is the set of all $(1,n)$-paths of the subnetwork, defined by the adjacency list $G.Adj$.

By using the definition of the function $maxmin(G.Adj)$, we will prove that its function call implements step 3 of the POP procedure.

Indeed, when applied on the adjacency list of the subnetwork $\widehat{G}$, the function $maxmin(Adj)$ calculates the maximal capacity c_1 of a $(1,n)$-path in $\widehat{G}$, and defines the adjacency list $\widetilde{G}.Adj$ of the maximal capacity digraph $\widetilde{G}$ of the subnetwork $\widehat{G}$. This means that α is a $(1,n)$-path in the digraph $\widetilde{G}$, if and only if it is a $(1,n)$-path in the network $\widehat{G}$ and $y(\beta) = c_1$. In the notations of the POP procedure, this means that $c_1 = \max_{\beta \in X}\{y(\beta)\}$ and α is a $(1,n)$-path in the digraph $\widetilde{G}$ if and only if $\alpha \in P_0$. For that reason the adjacency list $\widetilde{G}.Adj$ is included in the list S (line 10 of Alg. 5).

The step 6 from the POP procedure is implemented in the alternative branch of the **if** statement which verifies whether the set Y, defined by the step 4 of the procedure, is the empty set. If $c_0 = c_1$, then $Y = \varnothing$, and the algorithm is terminated. Otherwise, we define the adjacency list $RAdj$ of the subnetwork for which β is a $(1,n)$-path if and only if it is a $(1,n)$-path in G, and $y(\beta) > c_1$. ■

We will illustrate the above proof with the following example.

Example 3. *For the input network G_1, given on Fig. 1, we will trace how the algorithm LPOP (Alg. 5) implements the POP procedure.*

Solution: Initially, the algorithm stores a copy of the adjacency list in the variable $RAdj$, which will be modified in the body of the **while** loop. On line 2, the $capacity(G.Adj)$ function calculates that the capacity of the vertex 5 is $c_0 = 4$.

First iteration. The $minsum(G.Adj)$ function calculates the distance $d_0 = 6$ to the vertex 5, and the adjacency list of the subnetwork $\widehat{G}$:

$$\widehat{G}.Adj = \{\{(2,2,4),(3,5,3)\},\{(3,3,5),(4,6,4)\},\\ \{(4,3,6),(5,1,1)\},\{\},\{\}\}.$$

It is apparent that the above defined subnetwork $\widehat{G}$ has exactly two $(1,5)$-paths: $\alpha_1 = (1,3,5)$ and $\beta_1 = (1,2,3,5)$. Besides that, $x(\alpha_1) = x(\beta_1) = 6$. Since the set of all $(1,5)$-paths in G_1 is $W = \{(1,2,5),(1,3,5),(1,2,3,5),(1,2,4,5),(1,3,4,5),(1,2,3,4,5)\}$, it is directly verified that α_1 and β_1 are the only $(1,5)$-paths with length $d_0 = 6$ in the network G_1. The latter follows from the correctness of the function $minsum(G.Adj)$. In the procedure POP the set $\{\alpha_1, \beta_1\}$ is denoted by X.

Since $d_0 = 6 \neq \infty$ the algorithm enters the body of the **else** statement on line 8. The function $maxmin(G.Adj)$ calculates that in the subnetwork $\widehat{G}$ the capacity of the vertex 5 is $c_1 = 1$, and:

$$\widetilde{G}.Adj = \{\{2,3\},\{3,4\},\{4,5\},\{\},\{\}\}.$$

The outgoing adjacency list $\widetilde{G}.Adj$ defines the maximal capacity digraph $\widetilde{G}$ of the subnetwork $\widehat{G}$. It is apparent that $\widetilde{G}$ has exactly two $(1,5)$-paths. In this case these are $\alpha_1 = (1,3,5)$ and $\beta_1 = (1,2,3,5)$. Also, $y(\alpha_1) = y(\beta_1) = 1$. In the procedure POP we denote the set $\{\alpha_1, \beta_1\}$ by P_0. From Lemma 1 it follows that $P_0 = \{\alpha_1, \beta_1\}$ is the first class of equivalent Pareto optimal solutions. For that reason the algorithm includes $\widetilde{G}.Adj$ in the list S.

Since $c_1 = 1 \neq c_0 = 4$, the function $restrict(RAdj, c_1)$ modifies the adjacency list $RAdj$ by removing all edges with capacity not greater than c_1. The new adjacency list is:

$$RAdj = \{\{(2,2,4),(3,5,3)\},\{(3,3,5),(4,6,4),(5,5,3)\},\\ \{(4,3,6)\},\{(5,1,7)\},\{\}\}.$$

It is directly verified that the set Y_1 of all $(1,5)$-paths in the network defined by $RAdj$ is the set of all $(1,5)$-paths in the network G_1 with capacity bigger than $c_1 = 1$, which is verified by Theorem 1. In the procedure POP Y_1 is denoted by Y and is defined in the step 4 of the procedure.

Setting $G.Adj = RAdj$ the LPOP algorithm moves to the next iteration. In the procedure POP, it corresponds to the assignment $W = Y$, and the start of the new iteration by transition to the step 2.

Second iteration. The $minsum(G.Adj)$ function calculates $d_0 = 7$ and

$$\widehat{G}Adj = \{\{(2,2,4),(3,5,3)\},\{(3,3,5),(4,6,4),(5,5,3)\},\\ \{(4,3,6)\},\{\},\{\}\}.$$

The resulting subnetwork $\widehat{G}$ has a single $(1,5)$-path $\alpha_2 = \{1,2,5\}$. The length of the path α_2 is $x(\alpha_2) = 7$. In this case $X = \{\alpha_2\}$.

The result of the function $maxmin(G.Adj)$ is:

- the capacity of the vertex 5 in the network $\widehat{G}$ is $c_1 = 3$, and
- the digraph $\widetilde{G}$ of the maximal capacity has adjacency list

$$\widetilde{G}.Adj = \{\{2,3\},\{3,4,5\},\{4\},\{\},\{\}\}.$$

The above verifies the fact that in this case $P_0 = \{\alpha_2\}$ is the second class of equivalent Pareto optimal solutions. For that reason $\widetilde{G}.Adj$ is included as second element in the list S.

Since the condition for the loop stop is not fulfilled,

$$RAdj = \{\{(2,2,4)\},\{(3,3,5),(4,6,4)\},\{(4,3,6)\},\\ \{(5,1,7)\},\{\}\}.$$

It is immediately apparent that the set Y_2 of all $(1,5)$-paths in the network defined by $RAdj$ is the set of $(1,5)$-paths of G_1, that have capacities grater than $c_1 = 3$.

Third iteration. The $minsum(G.Adj)$ function calculates that this time the distance to the vertex 5 is $d_0 = 9$, and the new minimal paths subnetwork has adjacency list:

$$\widehat{G}Adj = \{\{(2,2,4)\},\{(3,3,5),(4,6,4)\},\{(4,3,6)\},\\ \{(5,1,7)\},\{\}\}.$$

In this case the set of all $(1,5)$-paths in $\widehat{G}$ is $X = \{(1,2,4,5),(1,2,3,4,5)\}$, and these are all $(1,5)$-paths of Y_2 with length $d_0 = 9$.

Using the $maxmin(G.Adj)$ function, we find out that in the network $\widehat{G}$ the vertex 5 has capacity $c_1 = 4$, and the maximal capacity digraph $\widetilde{G}$ of the subnetwork $\widehat{G}$ has adjacency list $\widetilde{G}.Adj = \{\{2\},\{3,4\},\{4\},\{5\},\{\}\}$.

Apparently, the digraph $\widetilde{G}$ has exactly two $(1,5)$-paths $\alpha_3 = (1,2,4,5)$ and $\beta_3 = (1,2,3,4,5)$. According to Lemma 1, the set $P_0 = \{\alpha_3,\beta_3\}$ is the third class of equivalent Pareto optimal paths. In this case $x(\alpha_3) = x(\beta_3) = 9$ and $y(\alpha_3) = y(\beta_3) = 4$. $\widetilde{G}.Adj$ is included as third element in the list S.

The condition of the **if** statement on line 11 $c_0 = c_1$ will be evaluated to true. This means that there does not exist a $(1,5)$-path with a capacity greater than the current c_1. As a result, the **while** loop is terminated. In the procedure POP this means that $Y_3 = \{\beta \in W : y(\beta) > 4\} = \varnothing$, and the procedure stops.

After the end of the calculations

$$S = \{\{\{2,3\},\{3,4\},\{4,5\},\{\},\{\}\},\\ \{\{2,3\},\{3,4,5\},\{4\},\{\},\{\}\},\\ \{\{2\},\{3,4\},\{4\},\{5\},\{\}\}\},$$

where each element of S determines one class of Pareto optimal paths:

- $S(1) = \{\{2,3\},\{3,4\},\{4,5\},\{\},\{\}\}$ defines the class $P_1 = \{(1,3,5),(1,2,3,5)\}$;
- $S(2) = \{\{2,3\},\{3,4,5\},\{4\},\{\},\{\}\}$ defines the class $P_2 = \{\{1,2,5\}\}$; and
- $S(3) = \{\{\{2\},\{3,4\},\{4\},\{5\},\{\}\}\}$ defines the class $P_3 = \{(1,2,4,5),(1,2,3,4,5)\}$.

The network G_1 has the set of Pareto optimal paths $P = P_1 \cup P_2 \cup P_3$.

Theorem 2. *The LPOP algorithm (Alg. 5) has computational complexity $k_0 O(n \log n + m)$, where k_0 is the number of classes of Pareto equivalent paths.*

The proof follows from Prop. 2 and Prop. 5. It is enough to note that on line 2 of Alg. 5 the call to the function $capacity(G.Adj)$ has complexity $O(n \log n + m)$, and the **while** loop has k_0 number of iterations, where k_0 is the number of classes of Pareto equivalent classes (14). Each iteration involves a single call to the functions $minsum(G.Adj)$ and $maxmin(G.Adj)$, where both have complexity $O(n \log n + m)$. Besides that, the function $restrict(R.Adj, c_1)$ has computational complexity that is lower than $O(n \log n + m)$.

Example 4. *Let the network G_2 be defined with the adjacency list*

$$\begin{aligned} G_2.Adj = \{&\{(2,1,17),(3,1,20),(4,1,19)\},\\ &\{(5,1,7),(6,15,15),(7,1,12)\},\\ &\{(6,1,9),(7,1,18),(8,1,19),(4,1,15)\},\\ &\{(5,14,15),(6,1,12),(7,1,12),(8,1,9),\\ &(10,1,2)\},\{(9,10,22),(10,1,2),(6,1,2)\},\\ &\{(11,1,4),(9,14,20),(10,1,6),(7,1,3)\},\\ &\{(8,1,11),(10,2,7),(5,8,15)\},\\ &\{(10,7,10),(11,10,11)\},\\ &\{(11,8,19),(10,1,20)\},\{(11,3,21)\},\{\}\}. \end{aligned} \tag{19}$$

We will find the list of all Pareto optimal solutions using the LPOP algorithm.

Solution: Using the LPOP algorithm, we calculate the list

$$\begin{aligned} S = \{&\{\{2,3,4\},\{5,7\},\{6,7,8\},\{6,7,8\},\{9\},\\ &\{11\},\{\},\{\},\{\},\{\},\{\}\},\\ &\{\{2,3,4\},\{5,7\},\{6,7,8\},\{6,7,8\},\{9\},\{10\},\\ &\{\},\{\},\{\},\{11\},\{\}\},\\ &\{\{2,3,4\},\{5,7\},\{6,7,8\},\{6,7,8\},\{9\},\{\},\\ &\{10\},\{\},\{\},\{11\},\{\}\},\\ &\{\{2,3,4\},\{7\},\{7,8\},\{6,7\},\{\},\{9\},\{5\},\\ &\{11\},\{\},\{11\},\{\}\},\\ &\{\{2,3,4\},\{7\},\{7,8\},\{6,7\},\{\},\{9\},\{5\},\\ &\{\},\{10\},\{11\},\{\}\},\\ &\{\{2,3,4\},\{6\},\{7,8\},\{\},\{9\},\{\},\{5\},\{\},\\ &\{10\},\{11\},\{\}\}\}. \end{aligned} \tag{20}$$

Every element of S defines a class of equivalent Pareto optimal paths. Using the function $list(m, \widetilde{G}.Adj)$ we get the Pareto optimal paths as a sequence of vertices. For example, the first element of S defines the class P_1, that contains two equivalent Pareto optimal paths $\alpha_1 = (1,3,6,11)$ and $\beta_1 = (1,4,6,11)$.

To each $(1,11)$-path in α we will map a point

$$A_\alpha(x(\alpha), y(\alpha)) \tag{21}$$

The points defined in this way are plotted on Fig. 2. For example, to α_1 and β_1 we map a single point $A_1(3,4)$, because

TABLE I
THE ELEMENTS OF THE LIST S WITH THE CORRESPONDING PARETO OPTIMAL CLASSES P_j AND THEIR POINT REPRESENTATIONS A_j

S_j	P_k	A_j
S_1	$P_1 = \{(1,3,6,11),(1,4,6,11)\}$	$A_1(3,4)$
S_2	$P_2 = \{(1,3,6,10,11),(1,4,6,10,11)\}$	$A_2(6,6)$
S_3	$P_3 = \{(1,2,7,10,11),(1,3,7,10,11),$ $(1,4,7,10,11)\}$	$A_3(7,7)$
S_4	$P_4 = \{(1,3,8,11)\}$	$A_4(12,11)$
S_5	$P_5 = \{(1,4,6,9,10,11)\}$	$A_5(20,12)$
S_6	$P_6 = \{(1,3,7,5,9,10,11)\}$	$A_6(24,15)$

$x(\alpha_1) = x(\beta_1) = 3$ and $y(\alpha_1) = y(\beta_1) = 4$. Following this scheme, by using consecutively the elements S_j of the list S, we calculate the remaining classes P_j and we map the point A_j defined by (21), for each $j \in \{2,3,4,5,6\}$. The results are given in Tab. I.

Therefore, in example (20) the set of all Pareto optimal paths is

$$P = P_1 \cup P_2 \cup P_3 \cup P_4 \cup P_5 \cup P_6.$$

The network G_2 has 10 Pareto optimal paths, distributed in 6 classes of equivalent paths. To illustrate graphically the result in Fig. 2, we define the set $\mathcal{P}$ of all $(1,11)$ paths in digraph G_2. In the example (20) there are 118 such paths. In this case we obtain 71 points. If the point A_α illustrates the path α that is not a Pareto optimal, we plot it in black. The points given in Tab. I are plotted in white, and they represent the Pareto optimal paths. Each point A_j is a vertex of an angle γ_j with rays given in dashed lines. Let α_j be a $(1,11)$-path that is represented by the point A_j. Inside the angle γ_j lie all points that illustrate paths that are dominated by α_j. The vert. opp. angle of γ_j is plotted in gray color, and inside it might lie points that illustrate paths that dominate α_j. As we may expect, such points does not exist.

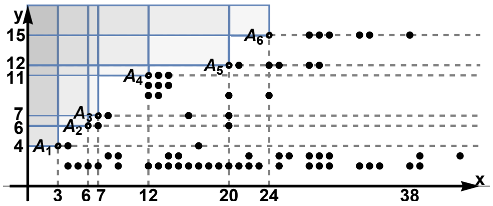

Fig. 2. Plot of the points A_j that illustrate the Pareto optimal classes P_j on the Cartesian plane defined by the values of the functions x and y

V. CONCLUSION

In [3] Hansen solves the MAXSUM-MAXMIN shortest path problem by presenting an algorithm that discovers a special subset of the Pareto optimal solutions, called "minimal complete set of efficient paths (MCS)". The list S that is composed by the LPOP algorithm presented in this paper, gives a more complete information for the Pareto optimal solutions. It is enough to select just one $(1,n)$-path from each element of S to obtain a MCS. For example, using the list S that we get for (11) that defines the network G_1, we get the following MCS: $P^{(1)} = \{(1,3,5),(1,2,5),(1,2,4,5)\}$. Besides that, apparently for the network G_1 three more different MCS can be composed.

Hansen proves that the number of Pareto optimal solutions grows exponentially with the increasing of the number of vertices in the network. However, it has been shown that in various real practical applications this number can be much smaller [20]. In the latter work authors discover key characteristics in the input data that lead to a number of Pareto optimal solutions on each vertex that is restricted by a small constant. In our case, this leads to the restriction of the constant k_0 in Theorem 2.

In Sec. III-A we solve the MINSUM list problem. We prove the correctness of $minsum(G.Adj)$ function (Alg. 2) that helps us to describe all shortest paths by calculation of the shortest paths subnetwork. We prove that its computational complexity is $O(n \log n + m)$.

In Sec. III-B we solve the MAXMIN list problem with Alg. 3 that allows us to calculate the capacity of a vertex with computational complexity $O(n \log n + m)$. Based on it, we define the function $maxmin(G.Adj)$ (Alg. 4) that describes all maximum capacity paths by defining the maximum capacity digraph of the network G. The complexity of the algorithm is again shown to be $O(n \log n + m)$.

Besides the solution of the corresponding MINSUM list and MAXMIN list problems, the two functions $minsum(G.Adj)$ and $maxmin(G.Adj)$ using Alg. 5 allow the solution of Prob. 1. The resulting description of all Pareto optimal solutions separates the classes of Pareto equivalent paths, and allows to visualize a predefined number of elements from each class of Pareto equivalent paths. The correctness of the algorithm is proved (Th. 1), and also its computational complexity is proved to be $k_0 O(n \log n + m)$ (Th. 2).

***Abstract*—Real-world manufacturing scenarios usually lead to difficult assembly scheduling problems. Besides strict precedence constraints between jobs or operations, such problems incorporate constraints related to maintenance activities on working stations (machines) and specific setup times when different operations are executed on the same machine. This paper analyzes the performance of several approaches, based on mathematical programming and on (meta)heuristics, to solve flexible assembly scheduling problems characterized by an arbitrary tree-like structure of the operation network. In this context, a specific encoding of candidate solutions and some specific perturbation operators are proposed. The encoding and the operators allow the distribution of sub(batches) of operations on several machines which leads, for some assembly scheduling problems, to a significant decrease of the makespan.**

I. Introduction

SCHEDULING represents a class of optimization problems with significant practical impact. The most studied problem is the Job Shop Scheduling problem (JSSP) [1] aiming to find an assignment of a set of inter-related jobs on a set of working resources (machines) such that some performance measures are optimized.

Assembly production scheduling is a class of scheduling problems (as identified in [2]), where a product is obtained by assembling several components (also referred to as subassemblies, subproducts or make-parts) which are a result of either some production operations or other assembling steps. Hence, the final product is the result of a particular set of operations, which are inter-related according to a hierarchical structure. Numerous factors, such as the number of operations, the number of products, the number of machines, the complexity of product structure, and the number of constraints, can increase the scheduling problem's complexity. Therefore, ongoing research in the field of scheduling is always necessary.

As is mentioned in [3] flexible assembly job-shop scheduling is less studied than job-shop scheduling. Previous work on Assembly Production Scheduling includes effective heuristics, genetic algorithms [4], or machine learning-based solutions. In [5], the authors propose a heuristic, based on the concept of the critical path, for solving the problem of large assembly production having as objective the minimization of the makespan. Another heuristic that targets the problem of assembly scheduling by taking into account the splitting of the operations in several (sub)batches was introduced in [6]. The load is distributed among the available machines using the proposed heuristic, followed by actual scheduling based on the critical path approach. In [7], the authors also include a batch splitting procedure; however, it is followed by a genetic algorithm to perform the scheduling.

The aim of this paper is to analyze several assembly scheduling strategies that are flexible enough to accommodate specific characteristics of the production process, e.g. the maintenance activities. The main contributions of the paper include:

- specific encoding of candidate solutions and specific perturbation operators which ensure the feasibility of generated schedules and allow the distribution of sub(batches) of operations on several machines, leading to a significant decrease of the makespan;
- design and implementation of a highly configurable generator of assembly scheduling test problems;
- a comparative analysis of the performance of an exact solver, a heuristic based on the critical path concept, and two metaheuristic algorithms.

The rest of the paper is organized as follows. Section II proposes a motivating manufacturing scenario, while the particularities and the formal description of the scheduling problem are presented in Section III. A short review of recent works addressing similar problems is presented in Section IV. Sections V and VI provide details on the heuristic based on the critical path and present the proposed encoding, the algorithm for generating feasible initial schedules, the decoding and evaluation procedures as well as the proposed search operators used by the metaheuristic algorithms. The data generator structure, the experimental setup and results for some test

This work was supported by project POC/163/1/3/ "Advanced computational statistics for planning and monitoring production environments" (2022-2023)

problems are presented in Section VII, while Section VIII concludes the paper.

II. A REAL-WORLD SCENARIO

A real-world problem that triggered our study is the production of flexible metal tubes for car exhaust systems. The final product is composed of subproducts that are result of production (SP) or assembly (As) operations. The manufacture process of the product is described using the bill of materials (BOM), that contains all information used to produce an item: the raw materials (RM), the (sub)products, the quantity needed to by for each manufactured product (BOM for mill-tube production - Figures 1).

A mill tube is formed from two component tubes (referred as IT and OT in Figure 1) that are covered with a metal mesh. Interlock rings are used as a fastening system. The production process can be shortly described as follows: (1) the inner tube (subproduct IT) and the outer tube (subproduct OT) are produced from a metal sheet (RM) that has to be rolled, welded and cut on a specific machine (operations O_6 and O_7); (2) the resulting tubes are transformed in bellows (subproduct E) through a stuffing process (O_5); (3) meantime: (i) the metal mesh (product F), that covers the tube built in the hydroforming process (O_4), is produced from metal wire (O_{10}, O_9, and O_8); (ii) the interlocks (subproduct C) are produced also from metal wire (O_3).

The assembling process, that has as result the product B, is executed on assembling workstations (O_2) and it consists of: (i) the bellows are wrapped with the metallic mesh; (ii) the interlocks and garnish are added; (iii) the final product is pressed; (iv) some identification information is written on the product. Then a quality assurance control (O_1) is done and the product, A, is packed.

Beside the information related to BOM other production information, like the machine characteristics on which the operations are executed, must be provided. Table I contains the characteristics (setup-time, unit processing time) of the set of machines ($\{M_1, M_2, \ldots, M_{19}\}$) that are used in mill tube production.

III. PROBLEM DESCRIPTION

The result of an assembly manufacturing process is a product that consists of many components, each of the components being either manufactured or obtained by assembling several other (sub)components (also called make-parts). The operations involved in this process are either of manufacturing type or assembling type.

The main difference between these two types of operations is that a manufacturing operation usually requires only one previously produced component (and potentially several raw materials), while an assembling operation requires several other (sub)components which should be produced by the time the assembling operation starts. In the tree-like structure of an assembly (see Figures 1 and 2) the manufacturing operations correspond to nodes having only one child, while the assembly operations correspond to nodes having at least two children.

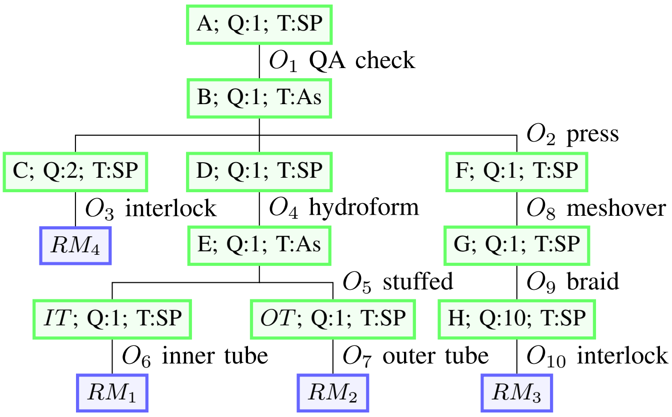

Fig. 1. Bill of materials networks for mill tube scenario. Each node contains information regarding the obtained (sub)product: name (A, B, C, . . .) quantity (Q:number), type (corresponding to a production process - SP or to an assembly process - As)

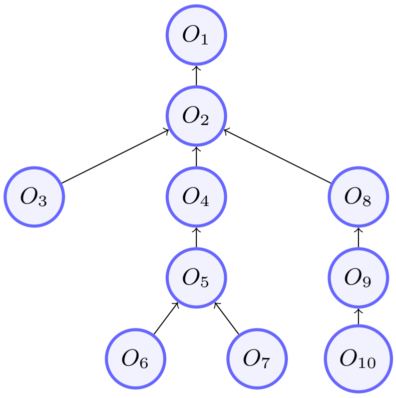

Fig. 2. Operation network for mill tube example

The Assembly Scheduling Problem (ASP) aims to schedule all types of operations on a set of machines in such a way that all make-parts are finalized before they are required for an assembly operation. The main particularity of this problem with respect to the standard Job Shop Scheduling Problem is that the precedence relation between operations corresponding to one assembly product (i.e. one job) is not a total order relation.

This allows the extension of one assembly product scheduling to several products by just considering a dummy assembly operation that would virtually group all products.

Therefore, in the following, we will consider the operations corresponding to all products (jobs) being grouped in one set of operations on which there is a partial order precedence relation.

A. *Characteristics of the assembly scheduling problem*

The class of assembly scheduling problems addressed in this paper is characterized by:

- all required raw materials are available, thus at the beginning of the scheduling time horizon all operations that do not have predecessors can start;

TABLE I
PRODUCTS, OPERATIONS, AND ELIGIBLE MACHINES FOR MILL TUBE EXAMPLE

Product	Operation	Machine (ID, setup time, unit production time)
A	O_1 QA check	(M_1, 600s, 2s)
B	O_2 press	(M_2, 600s, 40s), (M_3, 600s, 40s), (M_4, 500s, 40s), (M_5, 600s, 40s), (M_6, 500s, 40s)
C	O_3 interlock	(M_7, 600s, 4s), (M_{19}, 600s, 4s)
D	O_4 hydroform	(M_8, 800s, 1s), (M_9, 800s, 1s), (M_{10}, 800s, 1s), (M_{11}, 700s, 2s), (M_{12}, 700s, 2s)
E	O_5 stuffed	(M_{13}, 1000s, 5s)
IT	O_6 inner tube	(M_{14}, 900s, 2s),
OT	O_7 outer tube	(M_{15}, 900s, 2s),
F	O_8 meshoverline	(M_{16}, 900s, 12s), (M_{17}, 900s, 12s)
G	O_9 braid	(M_{18}, 900s, 30s)
H	O_{10} interlock braid	(M_7, 600s, 4s), (M_{19}, 600s, 4s)

- at a given moment, a machine can process only one operation and once started, an operation cannot be interrupted (non-preemptive);
- the operations can be grouped in batches and (producing a batch of components or products) started, it cannot be interrupted;
- once established, the size of a batch is not modified;
- for a given operation only one batch of executions can be scheduled on a machine (re-entrance is not allowed);
- there is no cost for transferring components between machines;
- no setup is required if the operations (corresponding to different batches of *same type* of (sub)components or products) are scheduled in sequence on the same machine;
- the setup times are sequence-independent and non-anticipatory (the machine is available and the operation is ready to be started);
- the maintenance activities are considered as machine-assigned operations with fixed starting time and duration.

B. Formal description

1) Notations and input data:

- Set of n operations: $\{O_j | j = \overline{1,n}\}$;
- Set of m machines: $\{M_i | i = \overline{1,m}\}$;
- t_{ji} = time to execute on machine M_i one unit of the (sub)component which is a result of operation O_j;
- s_{ji} = setup time for executing the operation O_j on machine M_i;
- Q_j = total number of executions of operation O_j derived from the quantities specified in the BOM structure;
- F = matrix of eligibility, an $n \times m$ matrix specifying which machines are eligible for each operation, i.e.

$$F_{ji} = \begin{cases} 1 & \text{if } O_j \text{ can be executed on } M_i \\ 0 & \text{if } O_j \text{ cannot be executed on } M_i \end{cases} \tag{1}$$

- R = array of n entries which can be used to identify the subset of maintenance operations, i.e.

$$\mathcal{O}_m = \{O_j | R_j > -1\},$$

in which case R_j denotes the maintenance starting time (SM_i) on the machine M_i which satisfies the condition $F_{ji} = 1$. More specifically, the elements of R are defined as:

$$R_j = \begin{cases} SM_i & \text{if } O_j \text{ is a maintenance operation for } M_i \\ -1 & \text{if } O_j \text{ is not a maintenance operation} \end{cases} \tag{2}$$

The maintenance starting times are fixed and known before the scheduling process is started.

- $\pi(j) = \{k | O_k$ is a child of O_j in the operation network$\}$ describes the direct predecessor relation, i.e. $\pi(j)$ is the set of indices of operations which directly precedes O_j, thus they should be finalized before the starting moment of O_j (one operation can have several direct predecessors);
- $\sigma(j) = k$ where $k \in \pi(j)$ (one operation can have only one direct successor) and $\sigma(j) = -1$ if O_j is a final operation (its result is a final product);
- Deadline for the final operations: $D_j \in [0, T]$ for any $j \in \{1, \ldots, n\}$ such that $\sigma(j) = -1$.

2) Decision variables:

For $j = \overline{1,n}$ and $i = \overline{1,m}$:

- Assignment matrix:

$$A_{ji} = \begin{cases} 1 & \text{if } O_j \text{ is executed on } M_i \\ 0 & \text{if } O_j \text{ is not executed on } M_i. \end{cases} \tag{3}$$

- Batch splitting matrix:

$$B_{ji} = \begin{cases} b_{ji} & \text{if } O_j \text{ is executed on } M_i \\ 0 & \text{if } O_j \text{ is not executed on } M_i \end{cases} \tag{4}$$

where $b_{ji} \in \mathbf{N}$ denotes the number of consecutive executions of operation O_j on machine M_i leading to the production of a batch of b_{ji} (sub)components that are specific to operation O_j;

- $S_{ji} \in [0, T)$: starting time of O_j on M_i (T is the time horizon for the assembly production);
- $C_{ji} \in [0, T]$: completion time of O_j on M_i.

C. Constraints

- (C1) All operations are assigned on eligible machines:

$$\sum_{j=1}^{n} \sum_{i=1}^{m} (1 - F_{ji}) A_{ji} = 0 \tag{5}$$

- (C2) The assignment and batch splitting matrices are consistent (an operation assigned to a machine should be executed at least once and the number of executions of an operation on a machine is nonzero only if the operation is assigned to that machine):

$$B_{ji} > 0, \quad \forall j, i \text{ such that } A_{ji} = 1 \tag{6}$$

$$B_{ji} = 0, S_{ji} = 0, C_{ji} = 0 \quad \forall j, i \text{ such that } A_{ji} = 0$$

- (C3) The completion time of any operation O_j is smaller than the starting time of its succeeding operation $O_{\sigma(j)}$:

$$C_{ji_1} \leq S_{\sigma(j)i_2} \tag{7}$$

$\forall j \in \{1, \ldots, n\}, \forall i_1, i_2 \in \{1, \ldots, m\}, A_{ji_1}{=}A_{\sigma(j)i_2}{=}1$

- (C4) The time intervals corresponding to operations executed on the same machine are disjoint:

$$[S_{j_1 i}, C_{j_1 i}) \cap [S_{j_2 i}, C_{j_2 i}) = \emptyset, \quad \forall j_1 \neq j_2, \tag{8}$$

$\forall i \in \{1, \ldots, m\}$ such that $A_{j_1 i} = A_{j_2 i} = 1$

- (C5) Completion time of a batch of operations:

$$C_{ji} = S_{ji} + s_{ji} + B_{ji} \cdot t_{ji} \tag{9}$$

$\forall j \in \{1, \ldots, n\}, i \in \{1, \ldots, m\},$ such that $A_{ji} = 1$

- (C6) The sum of all batch sizes corresponding to an operation equals the total quantity which should be produced by that operation:

$$\sum_{i=1, A_{ji}=1}^{m} B_{ji} = Q_j, \quad \forall j \in \{1, \ldots, n\} \tag{10}$$

- (C7) All final operations are finalized before the corresponding deadlines:

$$C_{ji} \leq D_j, \quad \forall j \in \{1, \ldots, n\}, i \in \{1, \ldots, m\} \tag{11}$$

such that $\sigma(j) = -1, A_{ji} = 1$.

- (C8) The starting time for maintenance operations is fixed:

$$S_{ji} = R_j, \forall j \in \{1, \ldots, n\}, i \in \{1, \ldots, m\} \tag{12}$$

such that $R_j \neq -1, A_{ji} = 1$.

D. Objective function

The goal of the scheduling is to minimize the makespan, C_{max}, defined as:

$$C_{max} = \max_{j \in E} \max_{i \in \{1, \ldots, m\}} \{C_{ji} \mid A_{ji} = 1\} \tag{13}$$

where $E = \{j | \sigma(j) = -1\}$ is the set of final operations. Thus, the optimization problem is:

$$\min_{A,B,S,C} C_{max} \tag{14}$$

IV. Related work

The authors of [8] addressed the problem of flexible assembly job-shop scheduling with lot streaming. The analyzed production structure is a two-stage one, characterized by the presence of an assembly stage at the end of a flexible job shop. The jobs in the first stage are processed in large batches which might lead to waiting time. The proposed approach is to split the batch into sub-batches, thus the initial scheduling problem is split into two sub-problems: batch splitting and batch scheduling. The proposed solution is based on an Artificial Bee Colony (ABC) algorithm using a population of candidates encoded based on four one-dimensional arrays: (i) an array containing the number of (sub)batches corresponding to each job; (ii) an array containing the size of each (sub)batch; (iii) an array encoding the sequence of all (sub)batches of operations; (iv) an array specifying the machine on which each (sub)batch of operations is assigned. The size of each candidate solution depends on the number of (sub)batches.

The idea of using sub-batches of unequal sizes is exploited also in our study but in the more general context when the production process involves several assembly stages.

An assembly scheduling problem involving several assembly stages which induce additional precedence constraints between jobs is approached in [3] where a genetic algorithm (GA) is used to solve it. Each element of the population evolved by the GA consists of two parts: (i) a one-dimensional array used to encode the machine assignment; (ii) a two-dimensional array for encoding the sequence of operations based on the concept of level in the operations' network. A schedule is constructed through a decoding process in which the operations are allocated to the first time slot where they fit, in the order given by the structure of the two-dimensional array.

With respect to the structure of the operations' network, the approach proposed in [3] is consistent with the particularities of the problem addressed in this paper, but it does not allow batch size control and to distribute sub-batches of operations to different machines.

In [9] a lot streaming technique, that splits jobs into sub-jobs, is applied on an assembly job shop scheduling problem (AJSP). The authors split the problem into two sub-problems (i) determine a sub-lot split; (ii) solve AJSP problem. In order to solve the sub-lot split, a genetic algorithm is used that uses a matrix, that stores on each line the number of lots for each operation and the quantity for each lot. In order to resolve the assembly problem four simple dispatching rules are used. The lots are scheduled by shortest/longest processing time, earliest due date, minimal slack time (difference between the due date and the total processing time of the operation) such that the constraints derived from the BOM are satisfied. In [10] the authors extend the work for [9] and use genetic algorithm and particle swarm optimization metaheuristics to solve also the second problem, by incorporating into the solutions the information related to the order of operation on each machine.

The approaches proposed in [9], [10] are different from the ones discussed in this paper by the fact that the operations can be execute on a sub-set of machines not on all available machines.

V. Heuristic based on the critical path

In [5], the authors introduced the Lead Time Evaluation and Scheduling Algorithm (LETSA) that uses a critical path heuristic in order to construct a scheduling. Based on the operation networks, the LETSA algorithm creates a list of feasible operations, $\mathcal{F}$, i.e. operations for which their successors have been already scheduled. In the beginning, $\mathcal{F}$ contains the operations generating the final product(s).

The scheduling process consists of several steps (see Algorithm 1) starting with the identification of critical paths that originate in all operations of $\mathcal{F}$. For an operation O_j, a critical path is a sequence $[O_j = O_{l_1}, O_{l_2}, \ldots, O_{l_r}]$ such that $O_{l_q} = \sigma(O_{l_{q+1}})$ and $\sum_{q=1}^{r} t_{l_q *}$ is maximal. The notation t_{j*} refers to the execution time of operation O_j on the slowest machine (if the machines would have different execution times).

It should be mentioned that if a machine satisfying all conditions specified in Step S3 of Algorithm 1 is not found, then the tentative execution interval is shifted toward the left until the first availability interval is reached. In this way, a machine is always identified.

The problem addressed in [5] is slightly different from that addressed in this paper because the operations are executed in a work-centers that contain one or more *identical* machines. In our approach, the machines are not necessarily identical, so the following adaptations were done: (i) in order to calculate the critical path in Step S1 of Algorithm 1, the maximal execution times over all eligible machines are used; (ii) the list of potential machines analyzed at Step S3 of Algorithm 1 is limited to eligible machines characterized by the smallest execution times for the corresponding operation. This has been done with the aim of increasing the chance to generate schedules with smaller makespan.

VI. Metaheuristic approaches

For the metaheuristic algorithms used in the experimental analysis, the encoding and decoding procedures, as well as the search operators are described in the following.

A. Encoding and search space

According to [8], a flexible assembly scheduling with batch splitting involves several decisions: (i) in which sequence are executed the operations on each machine; (ii) on which machine is executed each sub-batch corresponding to each operation; (iii) which is the size of each sub-batch for each operation.

In order to incorporate the information required by these decisions we propose the following encoding for a candidate solution:

- a list of distinct operation indices, $L = [o_{(1)}, \ldots, o_{(n)}]$ with $o_{(l)} \in \{1, \ldots, n\}$, such that for any $1 \leq l, r \leq n$, if $o_{(l)} \in \pi(o_{(r)})$ then $l < r$;
- the batch-splitting matrix B_{ji} defined as in Eq. (4).

The order of operations given by list L corresponds to a topological order of the nodes in the operation network. L provides the order in which the operations are dispatched to machines, during the decoding step, but not necessarily the order in which they are executed in the production stage. More specifically, if $O_{o(l)}$ and $O_{o(r)}$ belong to the same branch in the operation tree-like network, then $O_{o(l)}$ will be executed before $O_{o(r)}$, but if they belong to different branches then $O_{o(l)}$ will be dispatched before $O_{o(r)}$, but not necessarily executed before $O_{o(r)}$. It should be noted that the maintenance operations are not explicitly included in the encoding, as their starting times and durations are fixed. They are taken into consideration only during the evaluation step.

An operation list, L, corresponding to the operation network described in Figure 2 is illustrated in Figure 3 where the arrows highlight the direct predecessor relations between operations. As follows from this figure, such an operation list corresponds to a topological order of the operation network. This ordering is not unique. In fact, for an oriented tree $\mathcal{T}$ with n nodes the total number of topological orderings is $n!/\prod_{v \in \mathcal{T}} \mu(\mathcal{T}_v)$ where v denotes a node, $\mathcal{T}_v$ denotes the (sub)tree rooted in the node v and $\mu(\mathcal{T}_v)$ denotes the number of nodes in the (sub)tree rooted in v. For the tree corresponding to the operation network from Figure 2 the number of distinct topological orderings is $10!/(10 \cdot 9 \cdot 4 \cdot 3 \cdot 3 \cdot 2) = 560$.

Fig. 3. An operation list corresponding to the tree-like BOM described in Figure 1 which illustrates the topological order of the operations.

Taking into account both the operation list and the batch size matrix, B (see Table II), the proposed encoding allows solving batch splitting and batch sequencing problems simultaneously and corresponds to a structure of size $n + n \cdot m$. This size is larger than that corresponding to traditional encoding based on two one-dimensional arrays of n elements (operation sequence array and machine assignment array). However this traditional encoding does not allow to distribute batches of operations on parallel machines.

B. Generation of initial candidates

The metaheuristics start from one or several initial candidates, which are further modified with the aim of improving its/their quality. The generation of initial candidates should take into account the encoding rules and the structural constraints which should be satisfied by a feasible candidate, i.e. precedence constraints induced by the operation network and constraints related to the number of components to be produced (induced by the corresponding bill of materials). The construction of the list L, corresponding to the topological

Algorithm 1 LETSA Algorithm

```
Input: $n$, $m$, $F_{1..n\times 1..m}$, $O_{1..n}$, $t_{1..n\times 1..m}$, $s_{1..n\times 1..m}$
Output: $A_{1..n\times 1..m}$, $S_{1..n}$, $C_{1..n}$
$\mathcal{F} \leftarrow \{O_j | \sigma(j) = -1\}$
while $\mathcal{F} \neq \emptyset$ do
    (S1): select $O_j \in \mathcal{F}$ s.t. $O_j$ belongs to a critical path
    (S2): set the tentative completion time for $O_j$: $C_{j*} \leftarrow S_{\sigma(j)k}$, where $k$ satisfies $A_{\sigma(j)k} = 1$
    (S3): find $M_i$ such that $F_{ji} = 1$, $M_i$ is available in $[C_{j*} - t_{ji}, C_{j*})$ and maximizes $C_{j*} - t_{ji}$
    (S4): update the assignment matrix and the completion and starting times: $A_{ji} \leftarrow 1$; $C_{ji} \leftarrow C_{j*}$; $S_{ji} \leftarrow C_{ji} - t_{ji}$
    (S5): update the list of feasible operations: $\mathcal{F} \leftarrow \mathcal{F} \backslash \{O_j\} \cup \pi(j)$
end while
return $A$, $S$, $C$
```

O_{10}	0	0	0	0	0	0	50	0	0	0	0	0	0	0	0	0	0	0	50

order, starts from the root node, O_1, and the frontier, $\mathcal{F}$, consisting of its directly preceding operations, $\pi(O_1)$, and select, at each step, a random element from the current frontier to be added in the front of list L. As soon as an operation is included in L, it is removed from $\mathcal{F}$ which is instead extended with all operations which directly precede the operation included in L. In this way, one of the possible topological orderings of the nodes in the operation network is generated. The matrix B can be initialized using random decisions concerning both the selection of machines from the eligible list and the choice of the batch size. The `random` function used in Algorithm 2 generates an integer value in $\{0, 1, \ldots, q\}$. A minimum batch, min_{Q_j} size of 10% of operation quantity is used in order to restrict small batch sizes.

C. Decoding and evaluation

From a candidate solution, represented by the one-dimensional array L and the two-dimensional array B, a schedule is obtained through decoding. The decoding process, described in Algorithm 3 allows also the computation of the makespan value, and it is activated any time a candidate solution has to be evaluated. The operations are scheduled based on the order specified in the operations list (L). If a part of the quantity (B_{ji}) of operation O_j is planned to be scheduled on machine M_i, the decoding procedure identifies the time interval in which it can be executed on that machine. The operation is scheduled as close as possible to the completion time of all of its preceding operations ($\pi(j)$). This means that for each machine the completion time of the last scheduled operation is dynamically updated and further used to establish the starting time of next operation to be scheduled on that machine. Thus the order defined by L is preserved on each machine.

It should be mentioned that the value of the makespan is influenced by the following decisions:

- split the batch of operations scheduled in a time interval which overlaps with a maintenance interval in such a way that the maximum possible amount operation products is executed before the maintenance activity and the remaining ones immediately after the maintenance ($opt\_maintenance$ flag is activated in Algorithm 3) ;
- no setup is required when two consecutive batches involving the same operation/product are scheduled (opt_setup flag is activated in Algorithm 3).

D. Search operators

Both trajectory and population-based metaheuristics require operators which generate new candidate solutions from existing ones. The metaheuristic algorithms involved in the analysis we conducted involve two main types of operators which generate new candidate solutions:

- *Mutation-like.* This operator generates a new candidate solution in the neighborhood of an existing one by applying a perturbation strategy.
- *Crossover-like.* A new feasible candidate solution is constructed by combining information from two existing candidate solutions.

Algorithm 2 Initialization of a feasible candidate

```
Input: $n$, $m$, $F_{1..n\times 1..m}$, $Q_{1..n}$
Output: $L_{1..n}$, $B_{1..n\times 1..m}$
$L \leftarrow [1]$ // index of the root operation
$\mathcal{F} \leftarrow \pi(1)$ // direct predecessors of the root operation
while $\mathcal{F} \neq \emptyset$ do
    $j \leftarrow \texttt{select}(\mathcal{F})$ // random selection from $\mathcal{F}$
    $L \leftarrow \texttt{prepend}(L, j)$ // add in the front of the list
    $\mathcal{F} \leftarrow \mathcal{F}\backslash\{j\} \cup \pi(j)$ // update the frontier
end while
for $j \leftarrow 1..n$ do
    $q \leftarrow Q_j$; $i \leftarrow 1$
    while $(i \leq m)$ and $(q > 0)$ do
        if $F_{ji} = 1$ then
            $B_{ji} \leftarrow \texttt{max}(min_{Q_j}, \texttt{random}(0, q))$
            $q \leftarrow q - B_{ji}$
            $i_* \leftarrow i$
        end if
        $i \leftarrow i + 1$
    end while
    if $q > 0$ then
        $B_{ji_*} \leftarrow B_{ji_*} + q$
    end if
end for
return $L$, $B$
```

The way of action of these operators is shortly presented in the following, the guiding idea being to preserve the feasibility.

1) Mutation : Let us consider a candidate solution encoded by (L, B). A new candidate is generated in the neighbourhood of (L, B) by following the steps:

- randomly select $o_{(q)} \in L$;
- search for the largest $l \in \{1, \ldots, n\}$ such that $o_{(l)} \in \pi(o_{(q)})$ and for the smallest $r \in \{1, \ldots, n\}$ such that $o_{(q)} \in \pi(o_{(r)})$; if operation $o_{(q)}$ does not have predecessors then $l = 1$ and if $o_{(q)}$ does not have a successor then $r = n$;
- randomly select an insertion position $p \in \{l, l+1, \ldots, r\}$ and insert the element $o_{(q)}$ on position p in L;
- if there are several eligible machines for operation $o_{(q)}$, then randomly select two of them and move the batch (totally or partially) from the source to the destination machine; the decision to perturb B is taken with a given probability.

It is easy to observe that all operations in the sublist of L delimited by l and r ($L_{l..r}$) do not contain operations that are in a precedence relation with $o_{(q)}$, meaning that the perturbed candidate solution is still feasible.

It should be also mentioned that if the list of eligible machines for operation $o_{(q)}$ and the lists of machines corresponding to the operations in the sublist $L_{l..r}$ are disjoint, then any insertion of $o_{(q)}$ in another position of the sublist will have no impact on the makespan of the schedule obtained by decoding the candidate solution. On the other hand, if $o_{(q)}$ is one of the final assembly operations, then $l = r$ and the perturbation will be ineffective.

Algorithm 3 Decoding and evaluation of a solution

```
Input: $L_{1..n}$, $B_{1..n\times 1..m}$, $R_{1..n}$,$D$
Output: $S_{1..n}, C_{1..n}, C_{max}$ // start time, completion time
$S_{1..n} \leftarrow D$; $C_{1..n} \leftarrow 0$
$M^{FT}[1..m] \leftarrow 0$ // current makespan per machine
for $h \leftarrow 1..n$ do
    $j \leftarrow L_h$ // schedule operation $O_j$
    for $i \in \{1, \ldots, m\}$ such that $B_{ji} > 0$ do
        if $opt\_setup = True$ and $O_j$ is identical with the last operation scheduled on $M_i$ then
            $st \leftarrow 0$
        else
            $st \leftarrow s_{ij}$
        end if
        $ST \leftarrow \max(\max\{C_k | k \in \pi(j)\}, M_i^{FT})$
        $ET \leftarrow B_{ji} \cdot t_{ji}$
        if there exists $k$ such that $R_k > 0$ and
            $[ST, ST + st + ET) \cap [R_k, R_k + t_{ki}) \neq \emptyset$ then
            if $opt\_maintenance = True$ then
                $C_j \leftarrow \max\{ST + st + ET + t_{ki}, C_j\}$
            else
                $ST \leftarrow R_k + t_{ki}$
                $C_j \leftarrow \max\{ST + st + ET, C_j\}$
            end if
        else
            $C_j \leftarrow \max\{ST + st + ET, C_j\}$
        end if
        $S_j \leftarrow \min\{ST, S_j\}$
    end for
end for
$C_{max} \leftarrow \max_{j=\overline{1,n}} C_j - \min_{j=\overline{1,n}} S_j$
return $C_{max}$
```

Let us consider the L-part encoding corresponding to the example illustrated in Figure 3: $L = [10, 7, 9, 6, 8, 3, 5, 4, 2, 1]$. If the selected element is $o_{(5)} = 8$ then $l = 4$ and $r = 8$, thus there are four alternative insertion positions for the value 8. However, as the machines M_{16} and M_{17} are not used by the other operations, all of these perturbations will be without impact on the makespan.

2) Crossover : The crossover-like perturbation aims to generate a new feasible candidate solution by using information from two existing ones, usually called parents. The feasibility is preserved if the idea of precedence operation crossover is used: some elements are taken from one parent, while from the other parent is used to order in which the remaining elements are placed. Let us consider $L = [o_{(1)}, \ldots, o_{(n)}]$ and $L' = [o'_{(1)}, \ldots, o'_{(n)}]$ and the corresponding batch size matrices B and B'. The steps followed to construct a new feasible candidate, (L^{new}, B^{new}), are:

- randomly select $l < r$ from $\{1, \ldots, n\}$;
- transfer from L to L^{new} all elements with indices be-

tween l and r;

- scan the elements of L' and for each element $o'_{(l)}$ which is not yet in L^{new} append it to
  - a prefix list L_P, if $o'_{(l)}$ is the predecessor (not necessarily direct) of at least one element of L^{new};
  - a suffix list L_S if there is no element in L^{new} such that $o'_{(l)}$ is its predecessor.
- the new candidate solution is obtained by joining L_P, L^{new} and L_S;
- the rows of B^{new} corresponding to the operations taken in the first step from L will be identical to the corresponding rows from B, while the other rows are taken from B'.

Let us consider, in the case of mill tube example, two candidate solutions: $L = [6, 10, 7, 5, 9, 4, 3, 8, 2, 1]$ and $L' = [10, 7, 9, 6, 8, 3, 5, 4, 2, 1]$ In the case when $l = 4$ and $r = 9$, applying the crossover operator leads to $L^{new} = [10, 7, 6, 5, 9, 4, 3, 8, 2, 1]$ which could be also generated from L by mutation (insertion of the first element on the third position). However, the crossover-like perturbation allows the generation of new candidates which would not be generated through one-step mutation. For instance, for the same L and L' from the above example, if $l = 2$ and $r = 5$ one obtains $L^{new} = [6, 10, 7, 5, 9, 8, 3, 4, 2, 1]$ which could not be obtained by mutation neither from L nor from L'. Ensuring the feasibility of the crossover result requires checking the precedence constraints, thus this operator induces a computational cost larger than that of mutation.

VII. Experimental analysis

A. Data generator

Despite the increasing interest in ASP, there are no benchmarks for the general assembly scheduling problem. Some of the works addressing the flexible assembly scheduling problem [8], [11] use benchmarks that have been originally proposed for flexible job-shop scheduling problems, e.g. Kacem benchmark [12] and Fattahi benchmark [13]. Recently, Talens et al. [14] proposed two extensive sets of instances for the 2-stage assembly scheduling problem, one corresponding to the case of one assembly machine and the other one corresponding to the case of several assembly machines.

Since the problems included in these benchmarks do not capture all characteristics of flexible assembly scheduling, we designed a problem generator that allows the generation of a large variety of assembly scheduling problems characterized by different operation networks and different sets of eligible machines.

The problem generator has a simple architecture, as illustrated in Figure 4. The generator uses:

- a *pool of products* that represent the entities included in the bill of materials corresponding to a client order. Currently, the generator uses a list of 200 of fictitious entities (which can be interpreted as products, components or make-parts), characterized by randomly generated names;
- a *pool of machines* that can be used to execute the operations. Currently, the generator uses a list of 20 available machines.

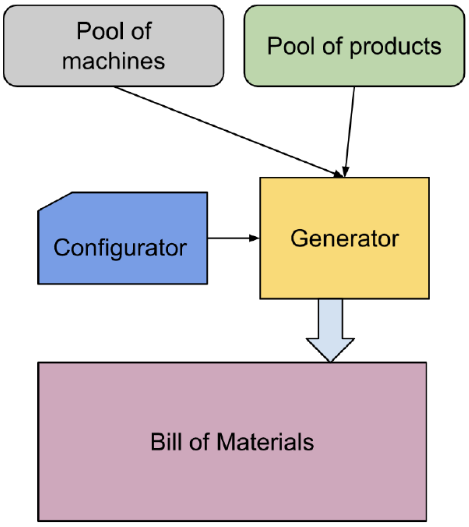

Fig. 4. Architecture of the assembly scheduling problems generator

The characteristics of a problem instance are specified in a configuration file that contains the values of the parameters describing the BOM structure.

In order to provide a high level of flexibility to the generated BOMs, the configurator module can be loaded with a multitude of parameters such as the number of levels in BOM, meaning the number of operations needed to be completed to create the final product, a maximum number of children for each node, meaning that a certain product is the result of assembling one or more simpler parts. One can specify the size of the product pool that is considered for this generator and the time horizon for scheduling. Also, the quantity of the final products can be provided. Another important characteristic that is supported is related to the maintenance applied to the machines involved in the product fabrication. The generator supports the setting of maintenance time intervals, the *Overall Equipment Effectivness* (OEE) for the machines and also one can specify the setup time for the machines if there is a need to change its purpose to support the processing of another product. The values can be generated using either an uniform distribution over the range of feasible values (the default case) or a truncated normal distribution.

The generator produces a JSON file containing the description of a tree-like structure corresponding to a BOM with a specified depth and a variable number of children, each node in the tree representing a specific product and including the generated set of eligible machines. The root node corresponds to the final product, while the children correspond to components that eventually will compose the final product.

B. Test problems

The experimental analysis is based on several problems instances/sets that have been generated such that various characteristics of the problem are emphasized:

- *A real-world case study:* the mill tube problem incorporating three orders of sizes 800, 320, and 160, each order requiring the production of the specified number of tubes according to the BOM described in Figure 1.
- *A deep BOM structure:* it is characterized by branches of up to 50 nodes in the operation network and a branching factor of 2 (for an operation there are at most two operations that directly precede it). The problem instance used in experiments contains 437 nodes.
- *A set of BOM structures with a variable number of operations:* it contains 15 problem instances corresponding to operation networks with a specified depth of 3 and a branching factor ranging between 2 and 16. The number of operations varies between 7 and 273. The quantity corresponding to each component (make-part) in the BOM is set to 10 (in this way each component on to the third level has a quantity equal to 1000). This set is characterized by rather wide structures and it was used to analyze the influence of the number of operations on the performance of exact, heuristic, and metaheuristic methods.

C. Methods and control parameters

The methods involved in the comparative analysis are:

- An *exact solver* (CPLEX) used to solve the problem described in section III-B. The solver is executed using 32 threads and CPLEX control parameters have been used with their default values. It should be mentioned that besides the problem described in section III-B which corresponds to the case when batch splitting is applied, a simplified version that does not require the B matrix as decision variables is also analyzed (referred to as standard in Tables III and IV).
- An implementation of the *LETSA heuristic* as it is described in section V. The standard variant does not use batch splitting while the variant with batch splitting (BS) applies a load-balancing strategy in order to distribute the operations per eligible machines. It should be mentioned that LETSA heuristic starts the construction of the schedule from the final operation, while the other heuristics start from the leaf operations in the operation network. Since the maintenance intervals influence the solution quality, the solution generated by LETSA is shifted such that the leaf operations are scheduled closer to the start time. LETSA does not require control parameters.
- A *Tabu Search (TS)* algorithm based on the mutation-like perturbation described in Section VI-D1. It should be mentioned that when a new candidate (neighborhood element) is constructed, the batch-size matrix (B) is perturbed with a probability equal to 0.15. The neighborhood size is set to 100 and the tabu-list size to 25. If the current candidate solution is not improved in the last 50 iterations then it is replaced with an element selected from the current neighborhood. The implementation uses 32 parallel search processes.
- A *Genetic Algorithm (GA)* which evolves a population of 100 elements by applying the same perturbation as in TS (with the same mutation probability for the batch-size matrix), the crossover operator described in Section VI-D2 and proportional selection. The crossover operator does not use control parameters.

It should be mentioned that the TS and GA implementations are adapted starting from the JSSP implementation available at [1].

All experiments have been run on a machine with 64 vCPUs and 256 GB RAM. The execution timeout was set to 1 hour for CPLEX and 3 minutes for LETSA, TS and GA. For TS and GA the reported makespan is the average value of 30 independent runs.

D. Results and discussion

The results obtained for the mill tube study case are presented in Table III which contains the makespan values (in hours) corresponding to various methods. Since the BOM structure is rather simple and most of the operations use distinct machines the optimal solution is obtained by CPLEX, TS and GA without batch splitting (BS). On the other hand, since the number of products and make-parts corresponding to all orders is rather large, the batch-splitting strategy improves the makespan by around 40% in the case of CPLEX, TS and GA, and around 20% in the case of LETSA.

The control of the maintenance intervals and setup times corresponding to successive execution of batches of identical operations can further improve the makespan but not significantly. The Gantt charts (Figure 5) illustrate the fact that the benefit of BS is influenced by the number of machines on which the batch of operations can be distributed.

The positive impact of batch splitting is illustrated also in the case of the operation networks with deep structure (see Table IV), particularly in the case of TS. The poorer behavior of GA can be explained by the fact that the crossover operator is more time expensive than mutation and, because of the imposed limit of time, the exploration of the search space is limited. It should be noted that in this case, CPLEX could not provide a solution in the allocated amount of time (one hour).

TABLE III
MAKESPAN VALUES (IN HOURS) FOR THE TUBE MILL PROBLEM. VARIANTS OF THE ALGORITHMS: STANDARD, BS (WITH BATCH SPLITTING), MSC (WITH CONTROL ON THE MAINTENANCE INTERVALS AND SETUP TIMES)

	CPLEX	LETSA	TS	GA
standard	38.47	40.53	38.47 ± 0	37.42 ± 0.01
BS	21.87	31.23	22.07± 0	24.20 ± 0.75
MSC	38.30	35.22	38.30 ± 0	32.98 ± 0
BS + MSC	21.69	30.37	**21.31 ± 0.15**	21.71 ± 0.52

(a) Standard TS

(b) TS with batch splitting

(c) TS with MSC

(d) TS with batch splitting and MSC

Fig. 5. Gantt charts for the Tube mill problem generated using Tabu Search

TABLE IV
MAKESPAN VALUES (IN DAYS) FOR THE PROBLEM INSTANCE WITH DEEP STRUCTURE. VARIANTS OF THE ALGORITHMS: STANDARD, BS (WITH BATCH SPLITTING), MSC (WITH CONTROL ON THE MAINTENANCE INTERVALS AND SETUP TIMES)

	LETSA	TS	GA
standard	36.67	36.48 ± 0.87	37.41 ± 0
BS	34.06	27.28 ± 0.46	36.43 ± 0.11
MSC	35.22	35.47 ± 0.23	36.65 ± 0.19
BS + MSC	32.51	**25.79 ± 0.35**	35.17 ± 0.20

To analyze the scalability of the investigated methods we used the set of BOM structures with variable number of operations in the context when a set of 10 machines are available and an operation can be executed on at most 5 machines with different or similar characteristics.

From Figure 6 it can be observed that the exact solver was able to find solutions for problems having up to 183 operations in a time interval of one hour. TS and GA heuristics outperform LETSA heuristic, and TS is slightly better than GA.

VIII. Conclusions and Further Work

The particularities of the addressed assembly scheduling problems required the incorporation of some specific decision variables and constraints. Most mathematical programming models used in flexible job-shop scheduling include binary variables which encode the order between any two operations scheduled on the same machine that leads to $n^2 \cdot m$ binary variables (in the case of n operations and m machines). The proposed mathematical programming model avoids the usage of such a large number of binary variables, but it uses instead the starting and completion time values to enforce the precedence constraints.

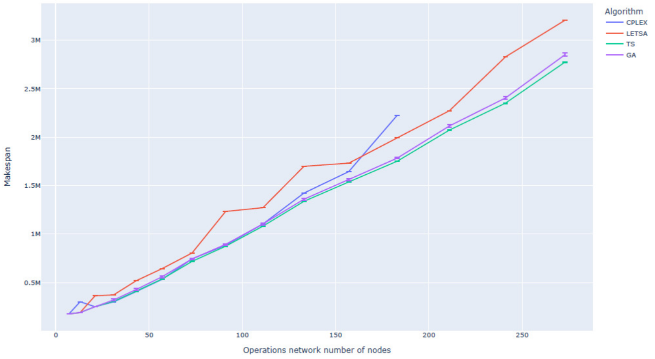

Fig. 6. Scalability results for standard variants of CPLEX, LETSA, TS, and GA for the 15 BOM structures

The proposed problem description and the candidate solution encoding allow specifying the distribution of (sub)batches of identical operations over several machines which led to a significant reduction in the makespan, particularly in the case of large orders.

The strategy that takes into account the maintenance time intervals and removes the unnecessary setup activities proved also to be beneficial but to a lesser extent.

As the operator inspired by the precedence preserving order-based crossover proved to be computationally intensive, we will further investigate other operators which preserve the feasibility of candidate solutions. Since the critical path heuristic incorporated in LETSA generates relatively good solutions in a fraction of the time required by the metaheuristic algorithms, a further step would be to consider the sub-optimal solution produced by LETSA among the initial candidate solutions for the metaheuristic algorithms.

We also plan to conduct a systematic scalability analysis based on sets of test problems including various typologies of operation networks and interactions between operations with respect to the lists of eligible machines, as reflected in the corresponding conjunctive graphs of the scheduling problem.

***Abstract*—The testing is an integral part of the software development. At the same time, the manual creation of individu-al test cases is a lengthy and error-prone process. Hence, an intensive research on automated test generation methods is ongoing for more than twenty years. There are many vastly dif-ferent approaches, which can be considered automated test case generation. However, a common feature is the generation of the data for the test cases. Ultimately, the test data decide the prog-ram branching and can be used on any testing level, starting with the unit tests and ending with the tests focused on the behavior of the entire application. The test data are also mostly independent on any specific technology, such as programming language or paradigm. This paper is a survey of existing litera-ture of the last two decades that deals with test data generation or with tests based on it. This survey is not a systematic literature review and it does not try to answer specific scientific questions formulated in advance. Its purpose is to map and categorize the existing methods and to summarize their common features. Such a survey can be helpful for any teams developing their methods for test data generation as it can be a starting point for the exploration of related work.**

***Index terms*—Software testing, test case generation, test data generation, papers survey.**

I. Introduction

TESTING is an essential part of software development. At the same time, the manual creation of individual test cases is a lengthy and error-prone process. In many real-world projects, there is not enough time to ensure sufficient testing of the developed software product, which leads to its lowered quality. The programmers of the test cases can also miss some inputs, which leads to unexpected behavior of the software product. Hence, an intensive research of automated test generation methods is ongoing for more than twenty years, as can be seen, for example, in [1] or [2].

In the existing literature, automated test case generation is used or at least proposed on various testing levels. These levels include unit testing focused on the functionality of isolated features of the developed application (usually a method, procedure, or function), but also the regression and integration testing focused on the correct cooperation of the individual parts of the application. Automated test case gene-ration can also be used during the high-level testing of the functionality of the entire application and its adherence to the specified requirements. Automated test case generation is tempting and seems to be promising, as it should reduce the time the programmers spend on manual test case preparation. Nevertheless, there are several limitations.

First of all, it is difficult to automatically verify that the tested application or its part provides correct results. This would require generating the expected outputs for all the generated inputs, which is an inherently difficult task. Never-theless, this ability is crucial for the usage of the automated test case generations in real software projects. However, it should be noted that, in many cases, it is possible to detect the incorrect behavior of an application even without the known correct outputs. An obvious example is when the application crashes, but there can also be limitations of the outputs, which can be used for incorrectness checking (e.g., the calculated volume of a cube cannot be negative).

Another issue, which is often discussed (e.g., in [3]) is related to the combinatorial explosion. Consider a unit test of a method with several parameters where various combinations of the parameters should be considered. Even when the parameters can be grouped into several discrete classes, the number of all the possible combinations grows very fast with the growing number of parameters and classes. This problem is even more pronounced in higher-level tests, when multiple methods are executed during one higher-level functionality testing. Various settings and running environments of the tested application only worsen this problem. Hence, even in tools, which are used in real projects, such as EvoSuite or Randoop [4], the number of generated test cases can be very high, which leads to long running times. This partially limits the usability of automated testing. Nevertheless, the problem can be mitigated by employing efficient test case selection in

This work was supported by Institutional support for long-term strategic development of research organizations.

order to generate and run the test cases, which provide the highest expected code coverage and/or have the highest expected error detection rate. The increasing power of contemporary computers is also helpful, as running a huge number of tests is more and more feasible.

The last issue, we would like to mention, is the validation of the automated test-generating methods themselves. Several different approaches for the evaluation of the automated test-generating methods can be found in the existing literature. From the practical usability of the methods in real projects point of view, there are two most important questions – how realistic the methods are and how well they perform in finding different types of realistic errors.

There are many different approaches, which can be considered automated test case generation. However, a common feature is the generation of the data for the test cases. Ultimately, the test data decide the program branching and can be used on any testing level, from the unit tests to the tests focused on the behavior of the entire application. The test data are also mostly independent on any specific technology, such as programming language or paradigm.

This paper is a survey of existing literature of the last two decades that deals with automated test data generation or with tests based on it. This survey is not a systematic literature review and it does not try to answer specific scientific questions formulated in advance. Its purpose is to map and categorize the existing methods and to summarize their common features. Such a survey can be useful for any teams developing their methods for test data generation as it can be a starting point for the exploration of related work.

The remainder of this paper is structured as follows. Related surveys are discussed in Section II. The selection of the papers for this survey is described in Section III. The existing methods for test data generation are discussed in Section IV. Their common features and trends are described in Section V. Threats to validity are described in Section VI. The conclusions and the future work are in Section VII.

II. Related Work

There are multiple studies, which survey the existing testing approaches. Our survey is intended to complement them from the automated test data generation point of view.

A. *Existing Methods Studies*

Ref. [5] summarizes the methods for test generation based on control flow analysis, automatic random data generation, and program execution analysis and/or the methods designed to produce tests, which maximizes the code coverage. The majority of the methods described in this survey is designed to deal only with simple program constructions and are often based on the models of the program instead of real programs. This is quite understandable, since the survey is rather old (from 1999). Nevertheless methods based on the same principles repeat again and again in more modern papers, only the methods or at least the examples, on which the methods are demonstrated, are usually more complex. For example, a more recent orchestrated survey [6] is focused on adaptive random testing among other methods.

A thorough review in [7] focuses on the papers dealing with search-based test case generation. The review makes it obvious that there is a constant increase in the number of testing-related publications between 1995 and 2007. The main focus of the review is the quality of the verification of the test generation methods. It is concluded that there is a lack of a standardized rigorous method to perform, asses, and compare the individual methods. Moreover, in many papers, there is even not enough empirical data to perform any comparison. It is also pointed out that, while many methods can achieve relatively high code coverage, it is not clear, whether the tests covering the code are able to find errors in the code. Another survey focused on search-based test case generation can be found in [8].

The search-based testing with an emphasis on mutation-based methods is also the theme of the survey in [9]. The methods described in papers published between the year 1996 and 2014 are based on genetic algorithms, ant colony optimization, simulated annealing, or hill climbing. The survey discusses also the relations and development of the methods in multiple papers. There are several conclusions. One is that the above-mentioned meta-heuristics significantly reduce the number of generated test cases without negative effects on the code coverage. Another is that the automated test generation methods are not designed for the concurrency problems. The last conclusion is that the comparability of the automated methods is difficult, similarly to [7].

The review in [10] focuses on the dynamic symbolic execution. There are twelve tools, which are compared based on various features, such as the number of publications dedicated to each tool, the utilized method for automated test generation, and the environment, in which the tool can be used. The ability of the tools to detect errors in the software is not among the investigated features. This feature is investigated in [11], which is focused on the methods utilizing aspect-oriented programming (namely Wrasp, Aspectra, Raspect, and EAT). One of the conclusions is that the structural evolutionary testing (EAT) shows the most promising results but at the cost of greater effort compared to random testing.

The short survey in [12] focuses on papers dealing with test data generation. It discusses various types of data generation from their architecture and usage points of view. The advantages and disadvantages of the methods as well as the best practices are discussed.

Although the majority of the surveys described above are focused on a technology or a set of technologies, there are also surveys focused on a specific type of software. An example is a systematic literature review [13], which deals with automated functional testing of mobile applications. Another example is a study [14], which discusses application of several different techniques for verification of flight software in Jet Propulsion Laboratory.

B. Practical Usability Studies

There are also studies, which focus on the usage of the automated testing methods in real projects, such as [15]. This study is not focused on published papers, but rather describes how the testing methods are used in real software projects and how the automated testing methods would improve the situation. The study has a bit darker tone than the studies mentioned in Section II.A as it points out that there is a lot of additional effort necessary when a promising method described in a paper should be used in a real industry project.

The study described in [16] is focused on the comparison of existing tools for automated test generation, such as Randoop, AutoTest, AnalitiX, Jtest, and so on. This study describes how the comparison of different methods for automated test generation should look like – precisely the aspect, which was mentioned as missing in [7] and [9]. In [16], a complex benchmark consisting of over 30 cases is described, which enables to empirically determine whether the automated test generation methods are able to uncover specified conditions. The results from this benchmark can be used for comparison of the methods. Although this benchmark is a good basis for the comparison of the automated test generation methods, it still utilizes synthetic cases, not real software [16].

An unorthodox practical study is the Java Unit Testing Tool Contest, which is held annually and its results are reported at various conferences (e.g., in [17] or [18]). The contest is intended for test generation tools designed for Java. Their ability to find errors in programs is tested using a benchmark consisting of real-life classes taken from various open-source GitHub projects. The contesting tools are evaluated based on the code coverage and mutation score [17], [18].

III. Survey Description

This paper is an intermediate result of our exploratory work to create a substance for a systematic literature review, which is the main aim of our current and future work (see Section VII). Although this intermediate result is only a (non-systematic) survey, the collection of the primary studies was performed in a rigorous manner described in following subsections, as the collected papers will also form part of the basis for our future systematic literature review.

A. Papers Searching

As the sources of the papers, we used the IEEE Xplore[1] library, which includes full texts of a large number of technology-related papers from both conferences and journals and the ScienceDirect[2] library, which includes papers from a large number of technology-related journals. Due to the institutional subscription, we have access to the majority of the full texts of the papers contained in both libraries, which is essential for the survey. Both libraries enable basic and advanced searching, but the available filters are quite different. For this reason, we used different settings for each library to obtain manageable numbers of relevant results. We made several attempts with various filters and search strings before we reached the final settings for both libraries.

The final search string for the IEEE Xplore library was "automated test data generating". It was used together with two filters. The year of publication had to be from 2000 to 2022 and the publication topic had to be "Program Testing". Using this setting, 461 results were obtained. The final string for the ScienceDirect was "automated test data generating program testing". It was used with three filters. Similarly to IEEE Xplore, the year of publication had to be from 2000 to 2022. Additionally, the subject area had to be "Computer Science" and the title of the paper had to contain "test data". Using this setting, 58 results were obtained. The searching in both databases was performed in April 2023.

B. Papers Filtering

From the search results, only the papers focused on the issues of automated test data generation for software testing, were selected. In first round, the selection was performed based on the titles. In second round, the selection was performed based on the abstracts, but only from the papers, which passed the first round. After the second round, there were 179 papers left (see Table I). The full texts were downloaded and investigated only for the 179 papers, which passed the second selection round. From these papers, some were eliminated from further processing, because, despite the promising title and abstract, the theme of the paper was outside the scope of this survey. Of the remaining papers, only 67 were included into the study, because they best represent the current trends in test data generation.

It should be noted that many of the obtained papers were already processed during our preliminary work with different search strings and filter settings in 2022. Hence, only the newest papers and papers not obtained previously due to different search settings of the libraries had to be processed. This enabled us to finish the paper in a relatively short time after the final search was performed.

C. Aims of the Survey

As this survey is intended to serve as a starting point for the exploration of related work for research teams dealing with automated test data generation, the aims of the survey can be summarized as follows:

- To categorize existing automated test data generation methods (see Section IV).
- To summarize and discuss common features of the methods (including their verification, implementation availability, testing level, and target platform) and observable trends (see Section V).

TABLE I SUMMARY OF THE NUMBERS OF SELECTED PAPERS

Library	Search results count	Selected papers count

IV. Existing Methods in Literature

The categorization of the surveyed automated test data generation methods was performed based on the primary technology used for the test data generation. This categorization enables the readers to focus mainly on the papers related to the technology of their interest. It is also consistent with the existing surveys, as they are often focused on a relatively narrow set of technologies (see Section II). The papers of individual categories are discussed in following subsections.

A. Pseudorandom Generation-based Methods

The most basic approach, how to obtain test data, is to generate them using pseudorandom generators. Though the basic method can give relatively good results (e.g., code coverage) for number inputs, its usage for a more complex (and valid) data, such as specific strings or objects is difficult. Nevertheless, pseudorandom number generation is often combined with other approaches. In [19], the stochastic process models of the objects and their random initiation is used together with random method invocation.

In [20], the pseudorandom generating is combined with the constraint solving for the generation of test data for relational database schemas. The testing of object-relational mapping (ORM) based on the pseudorandom generation and formal models is described in [21]. In [22], data description using XML and regular expressions is used together with pseudorandom generating to generate invalid and atypical testing inputs for robustness testing.

B. Control-Flow-based Methods

The control-flow-based methods create control-flow graphs of the tested program using, for example, the static analysis. From these graphs, the tests are generated. A common aim is to achieve a high code coverage, which can be observed for example in [23], [24], or [25].

The method described in [24] is rather basic. It generates input data for the tested program in order to ensure the execution of all branches of the program. The number of generated test cases is limited by the elimination of already explored paths in the control-flow diagram. However, the method is limited to the numerical inputs only. A similar limitation can be also observed in [23].

The control-flow-based methods are often used for web applications. The method described in [25] is designed for the testing of the frontend of web-based applications. It analyzes the content and structure of the investigated website, creates the possible paths of the user, and generates the input testing data for the web forms in order to ensure path coverage. In [26], a method for the generation of test data for testing REST APIs is described. The connected control flow graphs are traversed in order to find patterns of variable usage to produce usable variable values. Another example of the usage for the web application can be found in [27].

The control-flow-based methods are also quite often combined (among other technologies) with the pseudorandom generation of the input data. In [28], stochastic hill climbing is used for the finding the probabilistic distribution. This distribution is then used for the generation of the pseudorandom input testing data. The combination of control-flow diagrams and pseudorandom data generation can be found also in [29].

C. Specification-based Methods

The specification-based methods utilize a form of the specification of the investigated software to generate the test cases. This approach is tempting, as it should compare the actual behavior of the software with the expected behavior given by its specification. The existing methods utilize the UML models (e.g., in [30], [31], [32], or [33]), specification of use cases (e.g., in [31], [34], [35], or [36]), or contracts (e.g., in [37]). Program states description is utilized in [38].

In [30], tests of the entire system are generated from the UML use case and state diagrams. From these diagrams, a usage model is created, which is then used as the basis for the tests. In [32], the activity diagram, the sequence diagram, and the system testing graphs are used to create a combination graph, which is then explored using a modified Depth-First Search (DFS) to generate expected test cases. The contracts in [37] are used similarly to the use case diagrams in [30]. They are transformed into models describing the expected behavior of the investigated program. From this form, the executable test cases are created.

The method described in [35] utilizes textual use case specifications for the generation of acceptance tests. The method is based on natural language processing (NLP) and constraints solving. In [36], the use cases are used to generate a control flow graph and a NLP table, which are, in turn, used for test case generation. The method described in [39] is designed for process-driven applications. The method utilizes analysis of the application and the specification of tests to generate test codes.

D. Program Execution Analysis Methods

The methods based on the program execution analysis utilize the observation of the application behavior in order to generate test cases. There are two main approaches – the approaches based on the instrumentation and on the dynamic symbolic execution (also known as concolic testing).

First approach is based on instrumentation of the tested application in order to enable a simple observation of its behavior. Examples include wrappers around tested functions or methods (e.g., in [40]) or probes near important points of the program, such as control structures (e.g., in [41]), usage of augmented virtual machines (e.g., LLVM [42]), or usage of runtime instrumentation (e.g., in [43]).

Second approach is used for example in [44], [45], [46], [47], [48], or [49]. A dynamic symbolic execution is used in [45] to observe the behavior of the tested application. This observation is used for checking whether new randomly generated input data lead to better path coverage than already stored paths. In [48], the dynamic symbolic execution works with additional attributes enabling to check the efficiency of the paths produced based on the random input data. It is also possible to check whether the expected boundary values described by the contracts are observed. In [50], the dynamic symbolic execution is used for the testing of C++ Qt Framework classes. A source code preprocessing phase is used to find constructors of Qt classes parameters. A similar approach is used in [51], but for C++ templates.

In [52], automated guided symbolic execution combined with constraint solving is used to avoid exploring useless paths in the program. The method is used for system vulnerability detection. In [44], preprocessing of enterprise applications to enable usage of existing symbolic execution tools for their testing is described. In [53], the tested program is transformed into a set of constraints, which are then solved using a symbolic reasoning engine. So, the approach resembles the dynamic symbolic execution. The evaluation of the CREST concolic testing tool's ability to find real-life errors in real embedded applications is described in [54]. In [43], a concolic test generation tool is combined with the automatic generation of test cases from a formal description of the program (e.g., database table definitions, process-flow diagrams, etc.).

E. Data-Description-based Methods

In some papers, the described methods are not focused on a program, but rather on the specification of the input testing data. This approach is quite common in relation to the increasing number of web-based applications and with the necessity to test their text-based APIs. The frequently used description formats include the Web Services Definition Language (WSDL) used for example in [55], [56], and [57] or the JavaScript Object Notation (JSON) used for example in [58]. XML Schema Definition (XSD) is used in [59].

An interesting comparison is described in [57] where a realistic WSDL-based data set is compared to a fully random data set. The conclusion is that the utilization of realistic data leads to a higher code coverage. In [53], a method for generating complex interconnected data from a WSDL specification is described. The method enables to generate both valid and invalid input data. In [60], a method for the preparation of the test data for web forms utilizes an ontology and types of the fields of the web form. In [61], existing data and rules for their converting were used for testing a data warehouse.

A quite different approach is used in [62]. It uses static analysis of existing tests for mining of literals, which can be suitable as input values in generated tests in a specific domain. Yet another different approach is described in [63]. There, the test cases are generated from inputs specification in natural language. Natural language processing (NLP) and key phrases detection are employed for this purpose.

F. Search-based Methods

A common aim of the search-based methods is to provide high code coverage with a relatively low number of generated test cases. These methods typically do not rely on the knowledge of the program structure, but rather employ various search meta-heuristics to find efficient input test data. Regardless of the utilized meta-heuristic, there must be a way to evaluate the solutions found by the heuristic. Hence, these methods are combined for example with models of the tested program behavior, such as the control flow [64] and event flow [65], or with the program instrumentation [66].

The commonly used meta-heuristics include genetic algorithms, which are employed, for example, in [67], [68], [69], [70], [71], or [72], ant colony optimization (e.g., in [73]), or particle swarm optimization (e.g., in [74] or [75]). A genetic algorithm is used for test data generation for unit testing of Java programs in [67]. In [76], a genetic algorithm is combined with grammar-based fuzzing to generate highly structured testing input data. In [77], a genetic algorithm is combined with random search and database instrumentation to generate test data for SQL queries testing. In [78], a genetic algorithm, an evolutionary algorithm, and an alternating variable method combined with an Object Constraint Language (OCL) description of constraints are investigated.

In [73], the ant colony optimization is employed to achieve higher branch coverage with a relatively small set of testing data. The method is based on the simulation of the pheromone path and is reported to provide better branch coverage than a standard genetic algorithm or particle swarm optimization. In [74], the particle swarm optimization is combined with formal specifications (written in SOFL) and mutation testing. Improved particle swarm optimization is also employed together with predicate functions and path similarity calculation in [75] for test case generation. An unspecified meta-heuristic is employed in [79] together with constraint solving of manually added constraints.

G. Machine-Learning-based Methods

The methods based on machine learning usually utilize artificial neural networks (ANNs) for the test data generation. In [80], a neural network is used for black-box testing of the graphical user interface (GUI) of Android applications. The input of the neural network is a set of screenshots of the tested application. In [81], generative adversarial networks are employed for automated test data generation. A neural network for test generation, which uses the execution trace of the program as an input, is employed in [82]. In [83], the dataset for the neural networks training for source code vulnerability detection is prepared using a mutation approach.

In [84], two approaches for test oracle generation are described. One is based on an artificial neural network and the second is based on data mining from decision trees. The advantages and limitations of both approaches are discussed. In [85], no artificial neural network is used. Instead, random forest, which is a generalization of tree-based classification, is employed for predictive mutation testing.

V. Common Features of Existing Methods

Regardless of the technology utilized by the methods described in Section IV, there are common features and issues of these methods discussed in following subsections.

A. Methods Verification

The lack of verification possibilities or of standard ways how to compare various methods is mentioned in several works (e.g., in [7] or [9]). Based on the investigated papers, it can be concluded that an objective comparison and assessment of the methods cannot be done by using the text of the papers only. Simply, there is not enough information and the provided examples and technologies are quite often vastly different. Some papers (e.g., [29]) contain only a very general description of the verification or testing of the proposed method. Some papers (e.g., [33]) contain no testing at all and focus solely on the description of the proposed method.

Nevertheless, some papers provide means for assessing the quality of the described methods, which are "above average". For example, in [38], [49], [61], or [78], very thorough descriptions of the evaluation process of the proposed methods can be found. It is reported that the evaluation process includes tests performed on realistic programs with actual errors found by the methods. This is in contrast with the majority of the paper, in which the methods are often demonstrated on quite simplified examples (e.g., in [67] or [75]).

B. Implementation Availability

It would be beneficial if the implementations of the methods described in individual papers were available for download and further trials. If this is not possible, a complete data set with data supporting the quality of the described method would be also quite informative. However, from the investigated papers, the majority does not enable to perform a replication study without a reimplementation of the methods from the description in the paper. Of the 67 primary studies referred in this survey, there were only 15 studies with direct links to tools with implementation of the described methods.

From the available tools, 11 tools are provided in the form of GitHub repositories (see Table II) and the remaining 4 tools have dedicated websites. The website of the CREST [54] also contains a link to the GitHub repository along with a downloadable `.zip` file. The website of the CATG [43] contains downloadable `.jar` files. The method described in [72] is implemented in the DCRTT, which appears to be a commercial product, as we were unable to find direct download links on the website. Finally, the website of the SDG [79] contains downloadable `.zip` file. As of May 21 2023, all the links are functional. The available tools are summarized in Table II.

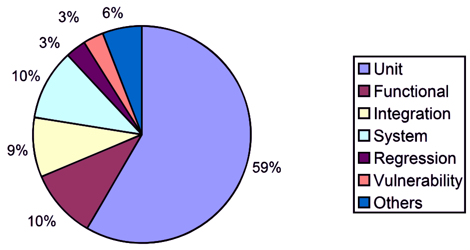

Fig. 1 Percentage of individual testing levels in primary studies

C. Testing Level

As it was stated in Section I, the automated test case generation methods exist for various testing levels. From the primary studies referred in this survey, the vast majority (specifically 39 papers) was focused on unit testing (see Fig. 1), for example [19], [23], [27], [59], or [69]. One of the possible reasons could be that the methods are often demonstrated on quite simple and/or short examples (see Section V.B). Short examples correspond well to unit tests, which usually deal with relatively short part of the source code with limited functionality.

As can be observed in Fig. 1, there were 6 testing levels, which were represented by more than one primary study (including the unit testing). There were papers focused on functional testing (7 papers, e.g., [20], [34], or [80]), integration testing (6 papers, e.g., [26] or [43]), system testing (7 papers, e.g., [25], [29], or [49]), regression testing (2 papers – [39] and [77]), and vulnerability testing (2 papers – [52] and [83]). There were also 4 other testing levels, each represented by a single primary study (4 papers, e.g., [22] or [64]). These papers/methods are grouped as "others" in Fig. 1 and 2.

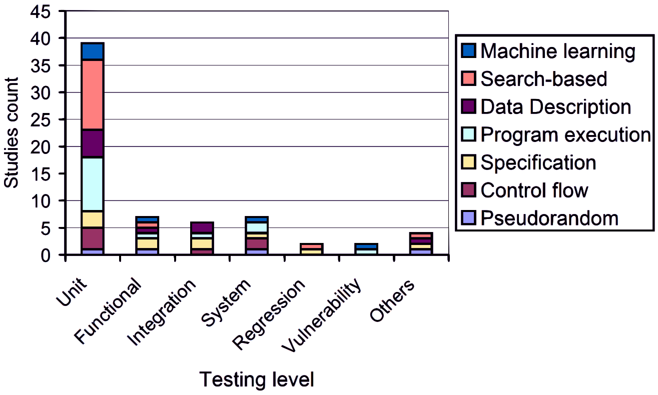

Fig. 2 Main utilized technologies for individual testing levels

In Fig. 2, the portions of the main utilized technologies of the methods for the individual testing levels are depicted. For the unit testing, there are comparatively high numbers of search-based methods (12 papers, e.g., [79], [81], or [84]) and program execution analysis methods (10 papers, e.g., [44], [48], or [51]). Together, they make up more than half of the primary studies focused on unit testing. For other testing levels, the methods are distributed relatively uniformly, but the numbers are too low to draw any further conclusions.

D. Target Platform

The methods described in primary studies are designed for a specific platform, for example for a specific programming language or a specific domain, such as web applications or databases. The methods can be also sufficiently general to be utilizable for multiple platforms. Such general methods usually do not use source code for the generations of the tests, but rather other forms of descriptions of the application, such as UML diagrams (e.g., [35] or [36]). There were 7 target platforms, which were represented by more than one primary study, including the generally utilizable methods (see Fig. 3). The generally utilizable methods also form just the largest group with 19 papers (e.g., [23] or [39]). The specific target platform with the largest number of papers was Java language (18 papers, e.g., [59] or [81]) followed by C/C++ languages (14 papers, e.g., [28] or [42]). Further groups include C#/.NET platform (2 papers – [48] and [56]), web applications (6 papers, e.g., [26] or [55]), databases (DB – 2 papers – [61] and [77]), and programmable logic controllers (PLCs – 2 papers – [46] and [47]). There were also 4 methods designed for other target platforms, each represented by a single primary study (4 papers, e.g., [64] or [74]). These papers/methods are grouped as “others” in Fig. 3 and 4.

In Fig. 4, the portions of the main utilized technologies of the methods for the individual target platforms are depicted. For the Java language, there are mostly search-based (6 papers, e.g., [76] or [79]) and then the machine-learning-based (3 papers – [80], [84], and [85]) and program execution analysis (3 papers – [43], [44], and [53]) methods. The program execution methods are prominent for the C/C++ programming languages (8 papers, e.g., [41] or [50]) and the data-description-based methods for the web applications (4 papers, e.g., [55] or [60]). The generally utilizable methods are mostly specification- (8 papers, e.g., [30] or [36]) and search-based (6 papers, e.g. [65] or [75]).

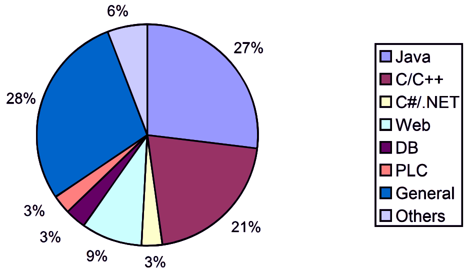

Fig. 3 Percentage of individual target platforms in primary studies

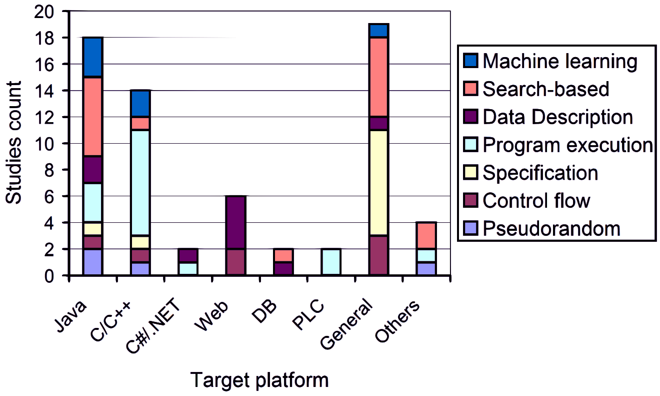

Fig. 4 Main utilized technologies for individual target platforms

E. Observable Trends

Since the time period of the analyzed primary studies is more than two decades (2000 to 2022), there are a few observable trends. Two technologies, which exist for a relatively long time, but are practically used only recently for the test case generation, are natural language processing (e.g., [35] or [36]) and artificial neural networks (e.g., [80] or [81]). Of the primary studies referred in this survey, the oldest study is from 2021 and 2020 for the NLP and the ANNs, respectively. This can be attributed to the relatively recent but significant progress in these fields leading to the practical usability of both technologies.

Another observable trend is the slight increase in the number of studies with direct links to the tools implementing the proposed methods (see Fig. 5). As can be observed in Fig. 5, studies with 11 of 15 available tools were published in 2017 and later. From the primary studies referred in this survey, there was no available tool before 2007.

VI. Threats to Validity

As pointed out in Section I, this survey is not a systematic literature review and does not attempt to answer specific research questions formulated in advance. It also does not attempt to exhaustively list all papers related to the test case or test data generation. Hence, there are papers, which would fit the theme of this survey, but we did not include them. There are several possible reasons:

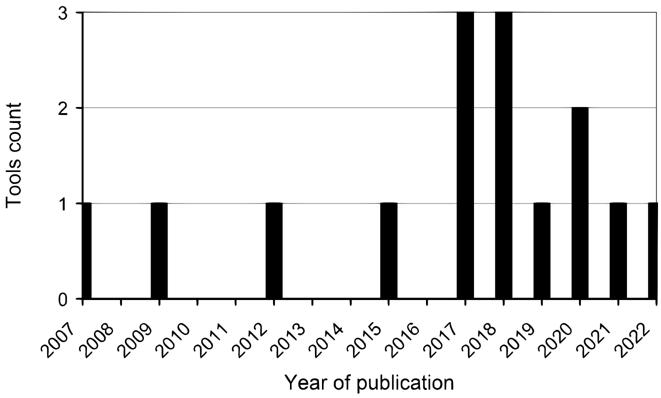

Fig. 5 Number of available tools in individual years

1. The paper was not discovered in the libraries, because it did not pass the utilized filters (see Section III.A).
2. The paper was not present in the two utilized libraries, but may be present in others.
3. The paper was discovered and its full text was read, but because of the similarity to other papers (in the sense of used techniques and/or their combinations), it was not included into the survey.

For the reasons described above, the reader should have in mind that this survey is not exhaustive in any sense, but tries to summarize the approaches and technologies currently in use in the field of automated test data generation.

VII. Conclusion and Future Work

In this paper, the existing literature that deals with test data generation or with tests based on test data generation was summarized. The commonly used approaches were discussed and their common issues and features were described including a few observable trends.

The collected primary studies, which this (non-systematic) survey summarizes, will be used as part of the basis for our future systematic literature review that will cover the theme of this survey, but will add specific research questions and formalization of the entire review process.

Another branch of our current and future work is the creation of a benchmark for the test data generation methods. Such a benchmark would allow us to objectively compare the ability of the methods to find known realistic errors. For this purpose, we are currently developing the Testing Applications Generator (TAG) [86]. This tool is intended to generate applications with selected introduced errors of various types. It enables to introduce errors on the method level meaning that each method can have several different implementations with various introduced errors. The resulting generated application is a general Java application with few limitations and with a structure of the entire project (not only source codes, but also libraries, additional files, and folder structure). The common types of errors should be also obtained during our future research. The tool will be used to create a set of several applications (with several versions each) with multiple introduced errors. This set will serve as the benchmark for automated test generation methods.

***Abstract*—The aim of the study at hand is to configure and evaluate a GPT-3 chatbot which is resistant to faulty input prompts and sensitive to the emotional setting of a sales dialogue. Design Science Research Methodology by Peffers et al. [46] was applied and evaluated with qualitative interviews in two conditions, that is, short and long language input. Results show that the chatbot was overall able to mimic human-like sales conversations. Some deviant behavior could be observed, especially in the short input condition, revealing more verbiage and insistent questions for purchase by the chatbot.**

I. Introduction

TEXT-BASED conversational agents, namely chatbots, have become increasingly popular in customer service, healthcare or businesses [1], [70]. A chatbot is a program based on artificial intelligence and natural languages processing (NLP) designed to communicate with humans [18]. It is however not only important how efficient and accurate the output of a chatbot is, but also that the input is interpreted correctly [36]. One quality measure of chatbots is robustness towards faulty input [48], [64], [44], [38]. This study looks further into the business domain by using a chatbot in the context of a sales dialogue. A sales dialogue is a dynamic communication process between a buyer and a seller which relies on identifying the buyer's needs such that a sale can be successfully carried out [52]. The chatbot employed here is based on GPT-3 from OpenAI [41], [30].

In contrast to traditional chatbots, which operate on predefined states and rules or match an input towards a predefined answer [18], generative models produce a given input word by word into an output such that the dialogue appears to be more human-like and does not rely on pre-defined answers. However, grammatical errors could occur depending on the available amount of training data and huge amounts of training data play a decisive role as the main requirement in generative models [67], [2], [50]. As the name suggests GPT-3 is based on a pre-trained model, which allows usage in a variety of contexts [41].

There are cases of misbehavior of chatbots reported in the media, which are a consequence of faulty inputs in the training data [69]. This indicates that the input for a chatbot could influence the conversation and possibly change the behavior of the chatbot altogether.

This study aims to further examine the linguistic input of a chatbot in the context of a sales dialogue. The chatbot could react towards faulty input and substantially decrease the quality of the ongoing dialogue by upsetting potential customers. Depending on how the input is interpreted by the chatbot, the emotional setting of the dialogue is likely to change. As a working hypothesis for this study, we like to raise the following question *How can a GPT-3 chatbot be designed and developed such that it is resistant to faulty input prompts and sensitive to the emotional setting in the context of a sales dialogue?*

We decided to restrict the sales dialogue towards buying smartphones. Statistics show that approximately 68.25 million people in Germany were smartphone users in 2022, equivalent to a smartphone penetration of 81.9% in 2022 [40]. Therefore, subjects of this study have likely been engaged in selecting an appropriate smartphone in their past.

Furthermore, we wanted to include the aspect of negotiation in our dialogue setting because negotiation requires enhanced communicative skills and recognizing abstract patterns [25], which would result in a more complex and human-like dialogue.

Literature research revealed that chatbots in the domain of sales have already been investigated. Lee [24] discusses four e-commerce chatbot usage cases in the process of a purchase and concluded that these chatbots have improved the convenience of customers' shopping, ordering, and payment experiences.

Balakrishnan and Dwivedi [3] generally discuss AI-powered digital assistants in conversational commerce, a term emphasized by Mayer and Harrison [33] and introduced by Messina [35]. Conversational commerce is buying activity of a customer interacting with a digital assistant. Balakrishnan and Dwivedi [3] conclude that anthropomorphism in digital assistants is crucial for creating a positive attitude and purchase intention. Therefore, it is beneficial if the chatbot mimics a human-like dialogue [3].

In order to make the chatbot more human-like, we named it "Melissa".

The following chapter explains the theoretical background of a sales dialogue. The chapter on Methods and Design Science Research Cycle gives a concise description how Design Science [46] was applied to the case of the chatbot, by also considering the affordance theory [13], [39]. An affordance is defined as a possibility for goal-oriented action afforded to specified user groups by technical objects [39], [32]. We performed evaluation by conducting interviews based on a questionnaire. In the fourth chapter, we will explain our results obtained during the interviews based on previously defined design principles [46]. Finally, in the last chapter, we discuss our results and outline possible limitations as well as an outlook towards further possible research.

II. Theoretical Background

Based on Lewis' AIDA model [58], an acronym for attention, interest, desire, and action, a sales dialogue can be perceived as a specific domain characterized by a more or less rigid sequence of customized events, vocabularies, and a clear understanding of objectives of the sales situation, i. e. satisfaction of a concrete consumer need that is compensated usually with some sort of monetary means. In our study we assume a buyer's market, in which the salesperson has an inherent interest in customer orientation and satisfaction. Staff will try to create a pleasant atmosphere built on positive emotional states of the respective client based on the assumptions that successful sales agents create trust and sympathy [51], [63], [22], [59], [31], [17]. Indeed, besides how a situation is conceived, a necessary condition is the availability of the desired product and a profound knowledge of all aspects of it (design, handling, prices, pros and cons of the product as well as user benefit). We set forth that the psychological principles of a sales dialogue also apply to the virtual world.

Since the planned scenery of human-CA-interaction was thought to be sales dialogues on mobile phones, the first step in our theoretical engagement was to look into what is known about sales dialogues among humans in general and how humans behave in a sales process as well as which psychological variables play a role in their behavior. The first thought to note is that sales dialogues follow a fairly strict pattern [65], [10] that may be broken down to more general phases like the opening, analysis of needs, product presentation, and closing. Each of the phases requires a different set of communicative skills and strategies [22]. There are also some sensible guidelines and tactics that were developed in practice, gained substantial relevance there and finally found their way to model building and theories [47]. These practical guides elaborate on similar stages and define more granular subcategories. In addition, these can be presented as flow diagrams, which qualify particularly for software implementation.

Yet the theory behind the four stages in sales dialogues is well founded [17]. Whereas the opening consists of codified communication (e. g. greetings, salutations) setting the tone for the rest of the dialogue, the analysis of needs is more analytical, partly based on a variety of indicators and general logic, but it also comprises the evaluation and processing of idiosyncratic information specific to a client. This stage is claimed to be the most challenging for sales in the analogous world [22] and it is plausible to assume this for chatbots as well [28]. Price estimates and price expectations are part of this stage. This information is often sensitive and dependent on the situation, should not be directly asked (anchoring). The product presentation is a more or less skillful derivation from the second phase. If knowledge on a wide selection of products is available (in structured and machine-readable form), effective algorithmic solutions exist for mapping needs to specific products. Again, a positive closing is important for the sensation, yet due to a rather codified situation, there are little new challenges for chatbots. Simply put, the vast majority of the scientific literature and practical marketers take as a basis some kind of models that comprise at least four main stages such as opening, need analysis, product presentation and closing. Need analysis is the most crucial part of a successful sales dialogue.

Research has also shown that chatbots which reveal empathic behavior while communicating with the users are perceived in a positive way and increased the trustworthiness towards the chatbot [20]. Agents which showed human-like behavior had a higher acceptance rate [6]. The emotional states, such as sympathy, joy, allegiance, but also anger or shame, are the decisive variables to create trust and a positive connection to the situation [51], [63]. It is also established that the kind of product is an important variable and as such has to be considered [22]. It is argued that walk-in customers have to be approached differently, i. e. with positive emotions, to foster ad hoc decisions. And, it is clear that the higher the involvement in the product (be it for status, prestige, price, or practicalities) more rational arguments need to be taken into account. However, this line of research should be embedded in the overall decision-making process of humans. There are hardly any decisions free of emotions, but they are justified by ex-post rational arguments long after the decision is subconsciously made [66], [19]. These seemingly conflicting claims from business studies and psychology can be brought together on the common denominator of solving cognitive dissonances [11], [16].

What remains from the theoretical convergence is that the role of rationality is largely overestimated; emotions predominate the center stage of action [56], [57], [31]. Following this logic, it is important to integrate respective variables in any scientific study on consumer decision and behavior. In dialogues emotions come to the fore as linguistic input. So, it should be possible to use language as a carrier of emotions to manipulate the reaction of a chatbot and, vice versa, analyze how the chatbot uses phrases that appeal to the relationship level [54], [26], [53].

Emanating from these findings, it bears a lot of plausibility to use chatbots in sales processes which build trust in the user to increase the likelihood of a sales success. So far, there is mainly research on what chatbots say, but little research on how they say it, yet the research on the role of emotions is gaining ground [14], [21], [28], [1]. Still these overviews clearly show that the interplay of emotional settings and its relation to how and what is really said [23] more research needs to be done. In particular, the interaction at the interface to machine communication with a new generation of chatbots and the integration of the relationship level is largely undiscovered.

III. Methods and Design Science Research cycle

A. Design science research methodology

We chose the design science research methodology (DSRM) by Peffers et al. [46] as this approach is a commonly accepted framework for research in the field of design science. The framework consists of six activities as shown in Figure 1. The first step is the identification of the problem and the formulation of the study's motivation. Based on the identified problem a solution and the artifact should be developed. The identified problem leads to the second step which contains the definition of the objectives which serve as a foundation for the solution. The authors state that "the objectives can be quantitative [...] or qualitative" [46], p. 55. We decided to conduct exploratory research with the intent to gather qualitative data, therefore we defined design requirements, design principles and design features which served as objectives and were analyzed in a later step of our study. The third activity is the design and development which focuses on the creation of an artifact, which is designing the architecture of a text-based conversational agent and creating it in a purchase context. In the fourth step, the demonstration, the artifact is used to solve parts of the problem, for instance by conducting case studies or experiments. In our study we performed usability tests with users with subsequent interviews to gather qualitative data for the next step. The evaluation of this data takes place in the fifth step of the framework. Our aim of this activity was to evaluate and compare the results from the interviews of the usability tests with the design principles we defined at the beginning of our study. The final step of the DSRM is the communication which involves the presentation of the study [46].

The described steps are normally performed sequentially, but generally the process can be started with any of the first four steps and move outward. Nevertheless, we decided to follow the standard procedure, starting with step one. Technical problems during the demonstration phase made it necessary to iterate back to the design and development step to make technical adjustments in the chatbot before continuing with the demonstration phase. The flexibility of the DSRM allowed us this procedure which is one reason we chose this process model as a foundation.

B. Design Requirements, design principles, design features

1) Design Requirements: Design requirements play a crucial role in the development of information systems. They are essential for the identification of the actions or processes that should be supported by the system [15]. In the beginning, we were concerned with the natural limitations of human beings. Making mistakes is normal. However, it can lead to inaccurate or incomplete information, especially in situations such as consultations. We want to address this problem with our first requirement, which we have defined as follows: *DR1: The CA should be robust of input errors.* Minimizing human error and maximizing domain expertise is one of the great potentials of chatbots. Especially in critical areas such as healthcare, this competence could lead to greater trust. In order to do this, the chatbot needs to have access to a comprehensive and verified body of knowledge. In addition, it should be able to understand the input correctly, even if it contains errors in grammar or spelling [4]. Another important aspect we recognized was the emotional connection between the chatbot and the user. Such a connection can lead to a higher level of well-being. In addition, it can make people feel valued if the chatbot is both competent and friendly [37]. So the second requirement is as follows: *DR2: The CA should communicate with consideration of emotional context.* As human agents are increasingly being replaced by chatbots, it is important that their communication mimics human-to-human interaction. Anthropomorphism therefore plays an important role in chatbot research. This human-likeness can help increase the acceptance of a system [29]. People enjoy communicating with chatbots using natural language understanding. Human-like chatbots can also act as a substitute for friendship and affection, helping to prevent loneliness in today's connected world [68]. These points lead to our third requirement: *DR3: The CA should communicate in a natural language.* The requirements that follow are based on the phases of a sales call, as defined by the SPIN Selling sales method, for example [47]. It is essential for a chatbot to have an understanding to whom it is communicating with. In today's business world, this classification of users is of particular importance for the marketing strategies of large companies. Through analysis of input and the use of targeted questions, users can be grouped into segments that can be targeted effectively [49]. An appropriate greeting from the chatbot should be provided to start the conversation. Therefore, our fourth requirement is: *DR4: The CA should be able to greet the user and classify the user based on personal criteria.* Another crucial point is that a chatbot should be capable of understanding the wishes of the conversation partner and respond to their needs. Communicating information should be of high quality and be in line with the needs of the other person [68]. For this reason, we have formulated the following requirement: *DR5: The CA should identify and respect the wishes of the customer.* In line with the third phase of the SPIN model [47], a chatbot should be able to demonstrate how it can help the user. However, this requires the provision of an optimal fact-based solution that fully aligns with the input [68], [61], [34].

Thus, we have formulated the following requirement: *DR6: The CA should provide an optimal solution of fact-based questions and requested information.* It is important for chatbots to have a high level of human-likeness in order to enhance the users experience. This is particularly important when users are negotiating with the chatbot, as they should feel positive and

the chatbot should be willing to compromise [37]. Interaction in computer-assisted meetings can be positively influenced by facilitators which, for instance, aims to create a positive environment and a good relationship and manages negative emotions [8]. So, the seventh requirement is as follows: *DR7: The CA should evoke a good feeling while negotiating with the user.* Similar to identifying the user's wishes in design requirement 5, the chatbot should be able to recognize when the user is convinced to buy the product [37]. This has a high marketing value, similar to the classification in Design Requirement 4, as appropriate accessories can be offered before the purchase is carried out [68], [27]. Furthermore, research has shown that text-based conversational agents have limitations in identifying users' intents [12]. Therefore, we have formulated our final requirement as follows: *DR8: The CA should know when the user is convinced to buy the suggested product.*

2) Principles and Features: According to Gregor et al. [15], design principles in the field of information systems are generally structured into three categories. In the first category the principles refer to the user's activities with focusing on the user's behavior, while the principles of the second category emphasize the role of the artifact. The third category combines the first two categories and therefore consists of principles of user activity and the artifact. As suggested by the authors we phrased our design principles as follows: "'In order to allow users to do A, the system should have feature X"' [15]. By using the third version of principles, we combine the design principles and design features into one statement, addressing the user as well as the artifact, a GPT-3 chatbot. While the first part of the statement refers to the principle itself, based on research, the second part is the desired feature of the chatbot. We defined six design principles and four related features based on the design requirements.

The first principle refers to the possibility to use the chatbot as an information retrieval tool [55]. According to Shawar and Atwell [55], the potential that chatbots can be used to retrieve information has been found in the field of education, where research has shown that the outputs given by the chatbot have similarities with replies generated by Google and can therefore be a source of information. Nevertheless, students preferred the chatbot's answers because they were more detailed and specific while Google results mainly consisted of a high number of links. The first principle was phrased as follows:

DP1: For the customer to allow the retrieval of information about a product, the chatbot should use GPT-3 to process and create natural language text and the chatbot should process a conversation in a purchase context.

The second principle refers to the human-like interaction between the customer and the chatbot. Research has shown that users prefer a human-like interaction with aspects of perceiving a personality, establishing a relationship with the user and the importance of asking and answering questions, good conversational habits and the usage of appropriate grammar and spelling. These traits have been shown to be important to users and is therefore of high importance in the design and development of a chatbot [38]. Especially in a purchase context we consider a human-like interaction to be essential since the chatbot is intended to replace a human salesperson and should therefore have similar character traits. The second principle has therefore been defined as follows:

DP2: To allow a human-like interaction between the customer and the chatbot in a purchasing process, the chatbot should use GPT-3 to process and create natural language text related to the purchase context and to use conversational cues to provide a convincing and satisfying interaction.

The third principle is based on the assumption that in computer-assisted conversations a facilitator is needed that "creates and reinforces an open, positive and participative environment" [8]. In a purchase process where a human salesperson is involed, the human would have to role of a facilitator, with the intention to create a positive environment such that the purchasing process can be facilitated. These attributes should be transferred to the chatbot. The following principle therefore aims at a positive emotional atmosphere during the purchase dialogue:

DP3: To allow a positive emotional atmosphere for the users, the chatbot should use conversational cues and provide a convincing and satisfying interaction and use words and phrases connotating positive emotions.

The fourth principle refers to the finding that one of the most prevalent emotions in customer service is anger [9]. Assuming that in our purchase context negative emotions like anger could occur, too, it is of importance to consider how the chatbot should react to these situations. These emotions should either be ignored or transformed into positive emotions. Hence, our fourth design principle is the following:

DP4: To allow transformation or ignoring inputs connotated with negative emotions, the chatbot should use words and phrases connotating positive emotions.

The fifth principle considers the fact that users prefer a chatbot that respects the flow of a conversation [7]. In a human sales dialogue, fast answers and a good communication flow are traits which are important to potential buyers and should therefore be considered in the design and development of a chatbot:

DP5: To allow a communication flow, the chatbot should use GPT-3 to process and create purchase-context related text in natural language

Another important element is the extent to which the chatbot interprets the user's wishes and needs. For a full service experience the users appreciate a chatbot that understands their requests and interprets them correctly in order to achieve the desired action [12].

DP6: To analyze what the user truly wants the chatbot should use GPT-3 to process and create purchase-context related text in natural language and use conversational cues and provide a convincing and satisfying interaction.

3) Implementation: The third step of the DSRM process model is, as described above, the design and development phase. Using Python and a simple Python UI framework called Tkinter, we created a standalone chat window for the final implementation. This allowed for unlimited response time as the user's input, including chat history, continued to be sent to the OpenAI API for processing. We used the text-davinci-003 model from OpenAI for this implementation [41].

C. Participants and Study Design

During the fourth phase, the demonstration phase, the usability tests, and interviews took place. The study participants were all potential users of a smartphone and had no to little experience with chatbots. They were both female and male, aged between 20 and 65, with different occupational and study backgrounds. They all had very good proficiency in German as strong communication skills were essential for the study. The first three interviews served as pre-tests which led to the realization that technical adjustments in the chatbot were necessary. Afterwards, nine persons participated in the usability tests and interviews. All participants were informed about the content of the study, the privacy guidelines, and the terms of their participation. They all participated voluntarily, and data collection was anonymous. The usability testing had a duration of between 10 – 20 minutes, followed by an interview of duration of approximately 10 – 20 minutes. The participants task was to buy a smartphone via chat. They were asked to imagine having a budget of 500 € and were told that 15 % discount were possible. In reality, a discount of only 5 % was given. This approach was chosen in order to frustrate the user and to provoke negative input to test the chatbot's reaction. Furthermore, one group was asked to enter long input, while the other group was asked to enter short input. There was no time limit set, a researcher was available for questions. After purchasing a smartphone or canceling the purchase process, the interview was conducted. Due to the exploratory nature of the study, we chose to conduct semi-structured interviews to allow new questions and insights during the interviews. For each design principles three to four questions were prepared in advance based on the principles described above. For DP1, referring to the retrieval of information, one question was, for instance: “How did the salesperson help you to answer your questions about the product?”, for DP2, the human-like interaction, questions were phrased like: "‘Was there a situation in which the salesperson approached you on a relationship level?"’. An example question for DP3, the positive atmosphere, was: "‘Did you trust the salesperson? Why/why not?"’. DP4 referred to the negative emotions, therefore we asked, for instance, about the discount they did or did not get: "‘If you got less than 15 % discount: how did you feel?"’. DP5 aimed to gather information about the communication flow, one question was: "‘How did you perceive the communication flow? Did the salesperson answer quickly or slowly?"’. Regarding DP6, the user's needs, one question was, for instance: "‘What could the salesperson have done or say to show that they understand your needs and wishes?"’. Similar questions were asked, all with purpose to receive meaningful answers. Therefore, the questions were phrased open-ended. The chat logs of the conversations were saved after the conversation, and the interviews were recorded, transcribed and served as a foundation for the next phase of the process.

D. Analysis

The next step, in accordance to the DSRM process model, was the evaluation and analysis of the collected data. Interviews were conducted in German, but analysis was done in English. In the following text, we translated the interview quotes from German to English.

IV. Results

This chapter reveals the results of a qualitative interview for each of the identified design principles. These are presented from DP1 through DP6 without implying any importance of order. As described in the chapter on methods, the design principles were used as a foil to generate questions, whose evaluations would provide us with knowledge in how far the design principles are met or what is still missing. A standard way to operationalize the mapping of the interview answers to the questions is by using codes. Codes in this understanding are the realizations or parameters of the set of questions (variables) representing the design principles. It is important to note that the interview answers were analyzed using these codes and with respect to the condition ("‘long"’ versus "‘short"’). DP1 aims at the retrieval of information about a product by the customer from a chatbot. It implies that a chatbot should reveal the following qualities (codes): appropriate length of reply, fit of reply, give correct product features, and make reasonable price suggestions (price sensitivity). Referring to the length of the agent's reply, the interviewees confirmed a generally appropriate to excellent ability. In the short condition, several interviewees indicated that keeping on asking for purchase the presented product made it unnecessarily lengthy and annoying. In the long input condition, the agent seems to be more dissipated. Heavy use of verbiage and more set phrases are reported there. This coincides with the main result from the actual fit of the agent's reply, which turned out to be independent of the condition. In both conditions, the fit of the answers concerning the technical details of a product are consistently high. Yet, the same applies to the peculiarity of jargon usage that is perceived as marketing talk. Interestingly according to the respective subjects, they confirmed not to be dissatisfied by the overuse of verbiage. Rather they had expected it and thus accepted the agent's behavior. The questions on product features aim at two dimensions. First the bot retrieved relevant product features of a requested brand. Second, the retrieval task was reversed: from a set of features, the bot made a suggestion for a product. The interview answers (and the chat scripts) show that the chatbot also made suggestions of a new feature that was likely to be relevant to the subject from what was mentioned previously, i.e., the agent used logic correctly. More specifically, the respective chat revealed that the subject wanted a superior camera. Now, the agent might have learned that pictures need a lot of storage and therefore suggested having a mobile with more memory. The conversational agent also explicitly communicated this interrelation. However, at another instance on battery performance, any argumentation could be given although the subject insisted, and the logic was subjectively perceived as contradictory. To sum up, an effect of the condition could not be seen. And the feature retrieval was restricted to a rather limited set of popular features that were suggested without acquiring knowledge of the customer needs. Even though the conversational agent was set up to grant discounts of only up to five percent, it violated the allowance, which could not be foreseen in the development phase. Still, this gave us the opportunity during the evaluation to learn how a potential client would perceive the chat bot's price sensitivity. There was a clear effect on the input. In the short condition, the chatbot followed the specification and stuck to the five percent limit. Low discounts were not explicitly reported as a reason for dissatisfaction, but the criticism of the chat bot's performance was harsh in these cases. The exception to this claim is twofold, which is documented in two answers. One subject mentioned to be happy because a "free" mobile cover was promised. The other subject felt acknowledged because the chatbot did an exceptionally good job in considering the very needs of the subject. The second design principle (DP2) is supposed to allow a human-like interaction between the customer and the chatbot in a purchasing process. Human interaction takes place in two spheres: how something is communicated (relationship aspects) and what is said (factual level). These two spheres were circumscribed in the codes of interpersonal cooperation and rational misunderstanding. There is no clearly documented example for the latter except for two short passages that could also be found in a typical human conversation. In the short condition and due to a typo, a subject requested "Has the display got 122 Hertz?" and the agents responded with "Yes, the display has got 120 Hertz." In the long condition, one interviewee expressed some discomfort on a discount for a used device, which turned out to be a misunderstanding. Interpersonal cooperation occurred more clearly in the long condition. Here the chatbot made phrasal assertions implying emotional understanding (e.g., "I understand", "Ah, I didn't know that" chatbot: "No problem"). In addition, the investigator could observe some correct logic. When a subject asserted to be a student or directly claimed to have little money available, the bot suggested a more drastic student discount or correctly recommended cheaper brands, even second hand offers. The third design principle addresses the positive emotional atmosphere for the users of a conversational agent. For reasons of plausibility, the chat bot should be polite and trustworthy. It also has been shown that competence is positively correlated to a positive emotional atmosphere in sales contexts. Consequently, as a fourth code, we initially wanted to know about the emotional state of the customer and how it changed. While coding the interviews, we realized that the answers to these questions were unsatisfactory. The emotional state was claimed to be neutral throughout all subjects and there was no indicator of any emotional shift before and after the chat. Again, we decided to leave this item out of the analysis.

The agent's politeness was perceived as positive independent of the input condition. When the subjects had the feeling of a particularly engaged answer or that their particular needs were considered as opposed to the mere general claim, the interviewees received extra praise. Answers from DP1 could also be considered here and construed towards impoliteness, i.e., initially asking for purchasing the recommended product is often conceived as impolite. Whereas this is even clearer, when only a little discount was provided. The perceived competence on technical details was evaluated as high. There seemed to be a correlation: Lower discounts coincide with lower perceived competence even if the retrieval of technical information as shown in DP1 was evaluated as high throughout. Again, strong positive feedback was given if a subject experienced a feeling of acknowledgement and considered needs. The questions on trustworthiness confirmed an established phenomenon. Trust is subconsciously connected to competence. Factual competence as defined here is giving the appropriate information on a product (see DP1). That means that a chatbot that was evaluated as competent, was also considered trustworthy. The interesting part here was that two subjects admitted that they cannot prove if the given information was correct, but the way it was presented obviously resulted in a transfer of competency. Trustworthiness was also reported for the case that the chatbot was perceived as a neutral informant who is not trying to sell a particular product. DP4 aims at handling input connotated with negative emotions. Since the chatbot was unexpectedly robust, which we observed during our first testing with a variety of input prompts, we already suspected that DP4 was already satisfied. In order to measure DP4 such that a human-like communication flow could be maintained, we decided to measure DP4 indirectly by telling subjects that they would be able to negotiate up to a total of 15% discount for any desired product. However, the chatbot was programmed in such a way that only 5% discount were given. We hoped that we could provoke the subjects to enter input connotated with negative emotions. Unexpectedly, several discount bugs occurred during our pre-tests, resulting in the chatbot giving a much larger discount than 15%. During our evaluation, we could not particularly observe negative input prompts but only negative emotions the subjects expressed to the interviewer. DP5 is how communication flow with the chatbot is perceived and allowing language deviations of users. Most subjects described positive feelings towards communication flow independent of the input condition , for example: "Generally, I would say that I am very satisfied because of the details of the answers" Many subjects entered informal language as input for which the chatbot was able to proper respond. Also, some subjects explicitly preferred the chatbot over a real human seller independent of the input condition because of fast and detailed answers provided by the chatbot in comparison to delayed and potentially inaccurate information which would be given in a store by a human seller as indicated by the subject's personal experience. Furthermore, some subjects stated that they had less emotional inhibition during negotiation for better discounts because they thought during the sales dialogue that they were likely chatting with a chatbot instead of a real human. On the other hand, as mentioned before, subjects in the short input condition noticed a rigid behavior of the chatbot, in particular that the chatbot would ask multiple times and at an early stage during the sales dialog if the subject would want to buy the product. As a result, negative emotions were provoked, p.e.: "Regarding communication flow there was always such a question at the end. So, the conversation was actually always going towards if I want to buy something. And I have asked, if I what is your recommendation, it continued this way, so it was then always answered this way, just to sell something again". Some subjects in the long input condition indicated that the communication may feel unnatural due to delays, p.e.: "There were some delays, but that was not really bothersome" A subject noticed delays in communication flow. Another subject criticized generic questions of the chatbot and that input was forgotten: "Rather less, because I thought that she did not sickly ask further inquiry but always just e.g. "Do you like this or that?" DP6 aims at the user's needs. Some subjects explicitly said that the chatbot understands what they want and that the chatbot gave a good consultation for the product, independent of the input condition: "I have had the feeling, that he wanted to know what I want and wanted to offer me the suiting smartphone and I did not have the feeling that he does not understand what I want or what is important to me" or "Nope, so she has always looked what wishes I have and has chosen the product then based on that and let me chose. The camera, the battery time and the design was important to me". On the other hand, some subjects, independent of the input condition, noted a lack of empathy, in particular, one subject reported that his desires for the product were not considered. Other subjects mentioned that the conversation was obviously going towards buying the product, as mentioned above. Few subjects, independent of input condition, explicitly indicated that they trusted the chatbot which is, as mentioned above, connected to perceived competence of the chatbot which could have contributed to the perception that the subjects' needs were satisfied. One subject reported a misunderstanding during the sales dialogue which resulted in the chatbot shifting attention away from the topic: "At the very beginning I have said, that I do not want Samsung any more, there he offered me exactly these Samsung devices, that confused me for a short time". Noteworthy, this subject had the short input condition which could have promoted the misunderstanding due to lack of information.

V. Discussion

There are two basic lessons learned from the interviews. First, monotonously asking to buy a product without considering the progress of a sales dialogue, that is in the very beginning of the chat, rather induces resentment as satisfaction. It is perceived as not very human. The longer a dialogue lasts, the more this effect disappears. This is especially apparent in the short condition, i.e., the user makes very concise requests, where the conversational agent tends to use more verbiage and set constructions. Second, considering needs seems to be the key quality in the overall perception of the conversational agent. If so, even unjust treatment (less discount than others get) is forgiven. Otherwise, a low discount coincides with low competency perception. If the client has good reason to assume her or his needs are taken into consideration and a comprehensible suggestion including the price, the above discomfort effect is also not reported.

As revealed in the chapter on the theoretical background, customers find it inappropriate to be asked to buy right away and even more striking, strong discomfort is felt if the same question is repeatedly asked. During extensive pretesting, the chatbot did not show this behavior. However, it is undeniable when the interviews were carried out. This leads to the assumption that the configuration option of GPT-3 has some influence on the bot's selling behavior. If this logic holds, the typical stages of a sales dialogue as put forward in the theoretical background above, could be added to the algorithmic set up of GPT-3 and the chat bot could follow the phases of sales dialogue. This would add immense value to the authenticity of a virtual salesperson and, above all, would avoid the risk of impoliteness, which often leads to closing the dialogue or even changing the web store altogether.

The experiment and interview on the short condition hint at another capability of the GPT-3 conversational agent that might not have been explicitly designed. The chat bot seems to converge on similar length of answers or put differently, the agent has learned an appropriate mean average of answers. If this length is not reached, the bot may find it more adequate to fill its response with questions or marketing verbiage.

Reformulated as a rule: if the mean length of answer is not reached, use the remaining length to follow your purchasing goal, i.e., in its simplest form, ask a question to purchase. In case this behavior was learned from deep nets, it certainly did not include a significant amount of material on sales conversations. Unfortunately, there is little known about the algorithmic specification and to which extent rule-based adjustments can be made. As a set of configuration variables such as the temperature scroll bar suggest, adjustment is indeed feasible beyond what is configured in the prompt option. So, one possibility is to postpone direct questions of purchase to the moment in which the conversation is established. This is not meant to say that the bot may not ask questions to figure out the needs of the client, which is highly appreciated. In addition, some more variation of the purchasing question would give it a much more human and familiar appearance.

The interview results showed that some subjects appreciated the chatbot's ability to make correct inferences such as that a good camera calls for more memory. Avoiding a hasty conversion on this presumption, we would like to offer an alternative mechanism more in line with recent technologies of neural nets and big data processing. Characteristic to sales are strategies of up-selling and cross-selling that can almost always be encountered in real life conversations between sales agents and customers. There is also evidence in the chat logs that covers for mobile phones (cross-selling) or more performance, i.e., more recent versions of mobile phones are dominantly mentioned (up-selling), are actively engaged. Instead of presuming logical inference, which may indeed appear as such, it could as well be learned behavior since this should be predominantly available. So really it is a side effect of learning that turns out to have a very positive impact on customer satisfaction. The same would apply to the assumed logic reported in DP2, when requesting more discount for being a student. Yet, the strategy changed to down-selling; it still parallels sales dialogues in the real world.

There is one answer categorized to DP1 that was perceived to be a "wrong" claim by the subject. Despite the fact that this answer could also be included in DP2 (rational misunderstandings) or even DP3 (trustworthiness), it illustrates the problem of context and relation, which occurs as well in the analogous world with the difference that it is likely to be interpreted in favor of the agent. The answer goes as follows:

"This waaas.. how is it called… this happened once for the cheaper price of a mobile for 699€. I asked, "Is this really low-priced?" and the answers went "Yes! It is very low-priced!" (laughs) Ehm… or also regarding the conditions in … in the production of another mobile, there it was wrong, too, then."

What we can observe from the answer is that it circles around the question of what is expensive and thus it is about a relative truth. This can be in relation to the imagination of the subject or relative to other brands. Without context, "wrong" answers are restricted to the interpretation. Indeed, to circumvent this misunderstanding the conversational agent could make this clear by adding something like "compared to the other brands, it is low-priced". Another alternative is that the bot has determined the expectation of the subject and could then suggest a cheaper model. Still, one must admit, with reference to the answer script, that the subject's claim is decontextualized. The logic of the agent to set the price in relation to other products is comprehensible and would probably be experienced with human sales agents alike.

DP5 considers the perception of communication flow during the entire sales dialogue. Most subjects felt a positive communication flow by expressing satisfaction. towards our questions. Our results indicate that some subjects would prefer the chatbot over a human seller. The subjects justified this by outlining the detailed and fast answers of the chatbot which contributed towards a positive communication flow.

This insight was unexpected since we thought that humans would prefer to chat with a real human instead of an artificial intelligence. Our results indicate that the presence of a human might not be necessary to maintain a positive emotional atmosphere during a sales dialogue, a key aspect of a successful sales dialogue [62], [63], [22], [45], [60].

DP5 also covered the handling of language deviations for users. Misunderstanding was only reported by a minority of subjects and in particular those with short input condition. In most cases, the chatbot was able to proper respond to informal language which also contained a few spelling and grammatical errors. Hence, DP5 is likely to be satisfied, although deviant behavior was observed which could be improved by further improving the implementation settings and restrictions of the chatbot e.g., it could be implemented that the chatbot would not ask if a customer would want to buy the product multiple times. A good communication flow serves as a basis for a successful dialogue making it less likely of endangering a positive emotional atmosphere.

The results of DP6 are ambiguous. Some subjects had the impression that the chatbot understands their desires towards the discussed products while other subjects stated the opposite, in particular, because of generic answers of the chatbot. Since that was observed independent of the input condition, further attempts towards satisfying DP6 should focus on altering the implementation settings of the chatbot.

Noteworthy, the short input condition could have resulted in misunderstandings due to a lack of information in the prompts. Identifying the buyer's needs is a core concept of a sales dialogue [52]. As mentioned before, it is connected to perceived competence. Therefore, DP6 is crucial for a successful sales dialogue and our ambiguous results indicate that further research towards DP6 is needed.

VI. Conclusion

The results show that the GPT-3 chatbot has the potential to perform a human-like sales dialogue, although, we observed relevant deviant behavior of the chatbot. In the short input condition, the chatbot generated more verbiage and quickly asked for purchase, which was perceived as annoying and not human-like. An important aspect for the subjects was to be felt understood in their desires towards buying a product. If the chatbot could meet their expectations, it did not matter if the discount was lower than announced. In contrast, if subjects felt not understood and got a discount lower than promised, they concluded that the chatbot would lack competence. Most subjects were satisfied in terms of communication flow. Surprisingly, subjects explicitly said that they would prefer the chatbot over a human seller because of the chatbot's abilities to be able to respond quickly, while simultaneously giving detailed fact-based answers to the subjects' questions about smartphones.

Because of GPT-3's generative nature, the output could be unexpected and varying, which would be in favor of a human-like conversation but could also cause problems of misunderstanding or false information of a product. As discussed above, a scenario with explicitly telling subjects to enter insult prompts could facilitate evaluating and thereby confirming DP4. Since our evaluation was qualitative by conducting interviews, general conclusions on how the chatbot influences the outcome of a sales dialogue could not be drawn. Further research would be needed to confirm our assumptions. Our research question did not aim towards implementation of the chatbot in a real company. However, we want to mention that actual implementation of a GPT-3 chatbot could be challenging, especially because GPT-3 is generative and may provide false payment information or misleading company information during a dialogue which are hard to detect. We recommend using GPT-3 chatbots only to provide information about a desired product and the actual purchase and payment transmission should be handled separately.

In order to improve the emotional atmosphere of the sales dialogue, the phases of a sales dialogue as mentioned above should be considered during the implementation of the chatbot [65], [22], [47]. The observed preference of a chatbot over a real human seller could pave the way for further research, in particular to decide whether a chatbot could even be better than a human in specific sales scenarios. Furthermore, the novel chatbot of OpenAI, ChatGPT, was released recently, which is especially designed for dialogue and currently using the newest GPT-4 engine [42], [41], [43], [30].

Further research could aim at investigating our research question with ChatGPT instead of GPT-3, although ChatGPT is currently at an early stage and support for developers is not fully implemented yet, making it susceptible to a variety of unexpected problems during implementation [42]. Another possibility would be to further investigate other sales dialogue scenarios with ChatGPT [42]. As mentioned in the introduction, many chatbots are already being used in customer service, healthcare, or businesses [1], [70]. Anthropomorphism of digital assistants involved in a purchasing process is crucial [3]. Hence, the chatbot has the potential to mimic a human-like conversation in the context of a sales dialogue. The above-mentioned deviant behavior could likely be fixed in further research iterations. Overall, our findings support the usage of GPT-3 based chatbots in the domain of sales.

VII. Acknowledgments

This paper originated from our work in the project module "Project Information Systems, Socio-Technical Systems Design" which was a joint offer by the Chair of Information Systems, Socio-Technical Systems Design at Universität Hamburg, the Chair of Digital Transformation and Information Systems at Universität des Saarlandes and the Chair of Business Information Systems, esp. Intelligent Systems and Services at Technische Universität Dresden. The topic and approach of this paper was suggested by the supervisors of the project module.

***Abstract*—As cyber-attacks become more and more sophisticated, sharing information that helps organizations design and implement efficient defense measures, is of critical importance. Such information can be shared using any service available, such as plain-old mailing lists, forums, etc. More mature systems use standards that facilitate the structural and semantic organization of information about cyber threats, which enables both automated processing and interpretation of such info, such as indexing, cross-referencing, updating, and more. However, even systems sharing cyber-attack info are themselves vulnerable, not only to typical and easily detectable attacks such as DoS, but also to content poisoning. Implementing such systems using decentralized architectures such as Blockchain, could overcome many deficits of centralized cyber-threat-info sharing systems. This paper presents the specification, design and implementation of such a decentralized system using two popular standards for cyber threat intelligence sharing, namely STIX for representing and TAXII for sharing such info using a REST API. The system, implemented on Hyperledger Fabric, faces the challenge of adhering to standards designed for a centralized world, and offering a transparent way for implementing all the backend, on a Blockchain.**

***Index Terms*— Blockchain, Cyber Threat Intelligence, Cyber defense, TAXII**

I. Introduction

IN THE field of cybersecurity, attackers and defenders are in a constant battle to outdo each other. Obtaining data about attackers' methods, tools, targeted vulnerabilities etc., support defenders in predicting attack targets and patterns, which is critical to proactively adjusting defenses, developing awareness and even preventing future attacks. Cybersecurity threat intelligence is the process of collecting appropriate cybersecurity data, evaluating it in the general context of its source and reliability, and analyzing it with methodical and structured techniques by specialized personnel, in the context of each organization. Collecting Cybersecurity Threat Intelligence (CTI) is a cyclical continuous process that employs several techniques, such as automation to extract only relevant information from data sources, human intervention by experts to understand and analyze information about threats and attack patterns, as well as integration with existing cybersecurity systems [1]. Considering that CTI is of great value, it is itself critical and must be trusted and dependable. To support this process and facilitate secure CTI exchange, two standards have been introduced: Structured Threat Information Expression (STIX) is a language and serialization format used to represent CTI data elements [2]; Trusted Automated Exchange of Intelligence Information (TAXII) is an application protocol for securely exchanging CTI over HTTPS. TAXII defines a RESTful API (a set of web services and message exchange services) and a set of requirements for TAXII Clients and Servers [3]. Even though it is expected CTI-sharing services to be offered over high-security infrastructures, it remains true that centralized implementations of such services, whose security is based on traditional centralized concepts, suffer themselves from vulnerabilities inherent to all centralized systems. Motivated by the challenge to further improve the security of CTI-sharing services, in this paper we investigate the benefits of providing CTI over a decentralized Blockchain infrastructure. We propose an architecture of a Threat Intelligence sharing service that implements the STIX/TAXII standards over a private permissioned Blockchain running on the Hyperledger Fabric network, instead of a centralized client-server model, to exploit the advantages of decentralized peer-to-peer trust models. Using a private Blockchain network such as Hyperledger Fabric can provide several advantages in a cybersecurity application as critical as sharing CTI. It can improve confidentiality by ensuring that only parties authorized by their trusted peers have access to the data; it also improves integrity by providing a tamper-proof record of all CTI producing and consuming transactions, availability by ensuring that time-critical access to CTI data does not depend on the availability of a central by-definition-trusted service, as well as non-repudiation by eliminating the possibility of denial of executed actions finally, it enhances auditability by providing a complete and transparent record of all in- and outbound CTI exchange transactions. We also present an implementation of the STIX/TAXII on Hyperledger Fabric and discuss observed advantages, issues and assumptions.

II. RELATED WORK

Aiming to support collaboration against threats, and in-line with EU legislation on information security, researchers have created a threat sharing system [12] using Hyperledger Fabric; the primary focus was towards addressing authorization concerns related to threat information. Authorization is accomplished using the native STIX traffic light protocol [13]. In other works [14], a threat sharing application was developed, motivated by the security properties offered by private blockchain and Hyperledger Fabric. The application was integrated with an SDN (Software-Defined Networking) Controller to exploit the synergy of threat intelligence and automation. Its primary objective was to enable seamless collaboration among organizations during distributed denial of service attacks and blacklist potentially malicious IP addresses during the flood, based on collective threat intelligence. In their study [15], the authors developed a CTI sharing platform tailored to the requirements of real-time threat intelligence in electrical power and energy systems. The platform comprised a generalized publish-subscribe middleware, which communicated with a Hyperledger Fabric network. Subsequently, the research was expanded [16] to tackle privacy concerns stipulated by GDPR (General Data Protection Regulation) and the performance overhead of storing large volumes of data on-chain. To accommodate this known issue in all Blockchains, they only stored the hash values of STIX objects on the Fabric Network, while storing the actual data on a separate database. Furthermore, the authors conducted both quantitative and qualitative analysis of the network's performance concerning various types of attacks. This work, although focused on threats in Energy systems, which is undoubtedly a critical domain, highlights the significance of strengthening cybersecurity and the growing interest in the development of advanced threat info sharing systems, leveraging technologies like Hyperledger Fabric and private permissioned Blockchains.

III. CTI SHARING ON BLOCKCHAINS: REQUIREMENTS, CHALLENGES AND ADVANTAGES

Cyber Threat Intelligence is a challenging field, particularly in the context of multi-party collaboration, which clearly makes a lot of sense for both corporate and public sector cyber defense. Considering that CTI itself needs to be trusted and protected from malicious infections and alterations, the sharing of CTI among multiple organizations requires overcoming several challenges; the heterogeneity of data sources, the trustworthiness of data, the timely delivery of information, the need for privacy and confidentiality, as well as the availability of data even without network connections, are some of these challenges. Moreover, the accuracy and relevance of CTI are crucial for proactive defense against cyber threats, and is also very critical to be left upon centralized services, vulnerable or even malicious themselves. It is not uncommon CTI to shared within networks that, even if they are private, they still engage a centralized trust model. Therefore, establishing a zero-trust framework for collecting, analyzing, and sharing CTI among multiple parties is worth investigating. This framework should address both the technical and operational challenges of CTI sharing, while ensuring the protection of sensitive information and privacy, even from entities which are normally taken for trusted. Although standardization itself is a significant aspect of designing and developing information systems, this paper does not discuss the advantages of standardizing CTI sharing using STIX and TAXII. The focus is on the investigation of the benefits of utilizing a blockchain system to improve the security of organizations that are willing or are already a part of a Cyber Threat Intelligence (CTI) sharing network.

As several technology options for satisfying the above requirements may exist, in the sequel we will discuss the security properties that acted as selection criteria for a blockchain platform and how they are implemented using the Hyperledger Fabric mechanism.

- Organization level privacy: The TAXII standard requires confidentiality in STIX object collections, ensuring that only authorized organizations have read access to them. We address this requirement by utilizing private data collections on Hyperledger Fabric where actual transaction data is stored only in the nodes of organizations that have the required access, while others only receive metadata and hashes for the transaction [4].
- Organization level access control: The TAXII standard restricts the ability to write data to authorized organizations only, which is also satisfied by the Private Data Collections mechanism of Hyperledger Fabric [4]. However, within a conventional centralized client-server implementation of a TAXII Server, one single hosting organization has complete write authorization on all data stored in the database; this alone can be a deal-breaker for the participation of critical-mission strategic organizations (e.g. defense and civil protection bodies) in CTI sharing networks.
- Data Integrity: The TAXII standard does not impose a strong requirement or mechanism for verifying the integrity of the data, as this is out-of-scope of the standard. Nevertheless, it is considered necessary for any application in the field of cyber se-

curity to have a mechanism for data integrity verification. One can argue that organizations participating in a CTI sharing network generally rely on the information provided by other peers of the network, as they share a common goal; still, data integrity checks must be performed, since data tampering on the TAXII Server by malicious actors may lead to infected security information reaching all CTI consumers; thus, the integrity of shared CTI data constitutes a central point of failure. Being a central element of the nature of the Blockchain philosophy, this requirement is satisfied by all blockchain ecosystems, as data integrity needs to be verified and signed by all peers holding the information. [5]

- High Availability: For a CTI sharing application, it is crucial to ensure high availability. However, managing the TAXII Server, even within a single corporate network protected by firewalls, employing replicas etc, the single logical TAXII server is also a single point of failure. Malicious actors can launch various types of denial-of-service attacks that could render the server non-functional during critical times, such as attack campaign timeframes. Hyperledger Fabric offers a solution to this challenge by enabling organizations to manage multiple peers that provide redundancy of data and services at the organizational level, while still satisfying the data control and integrity requirements. The nodes of all organizations that participate in the network maintain a copy of the distributed ledger at all times [5]. This ensures that access of other peers to CTI can be provided, even if all nodes of one organization become for any reason unavailable.
- Non Repudiation and Auditability: Injection of incorrect or even malicious cybersecurity information from one member to the CTI sharing network, can have catastrophic implications for other members. In such a case, in centralized systems governed by one single entity, it cannot be guaranteed that the information producer will be charged for its erroneous or malicious activities so as to be rendered responsible. However, the TAXII Server administrator(s) should not be able to take any action that protect any peer from taking the responsibility of its mistakes or malicious activities. The inherent feature of decentralized transaction write-only transaction ledgers been maintained by all Blockchain nodes of all organizations, typically satisfies the non-repudiation and auditability requirement.

Beyond the security properties achieved by migrating from a client server model to a blockchain platform there are significant platform specific advantages in Hyperledger Fabric compared to other blockchain networks.

- Hyperledger Fabric is a permissioned blockchain network. Compared to public blockchain networks such as Ethereum access of new members is strictly controlled and must be first approved by other participants [6]. We believe that this model serves better the purpose of threat intelligence sharing.
- Hyperledger Fabric offers feature-rich ways of interacting with the network using the Fabric SDK using general purpose programming languages and is designed with organization level decentralization in mind while public blockchains are designed for censorship resistance first. While these concepts mays seem similar at first, they are different.

As a conclusion, it is apparent that the development of a multiparty CTI sharing application on Hyperledger Fabric can potentially resolve several issues inherent in the traditional client-server model.

The primary challenge encountered by this paper is the commitment to adhere strictly to a STIX/TAXII standards implementation on a blockchain ecosystem. As these standards were originally designed to function on a RESTful API, the challenge arises from the need to translate them into an equivalent decentralized version. This means that to comply with the standard, HTTP requests must be used, and a REST API server must be integrated into the blockchain network. As mentioned above, all collaborating organizations will participate in the Blockchain network, each with at least one node; clients coming from each organization will be connected to their organization's node(s), as shown in Figure 1 below.

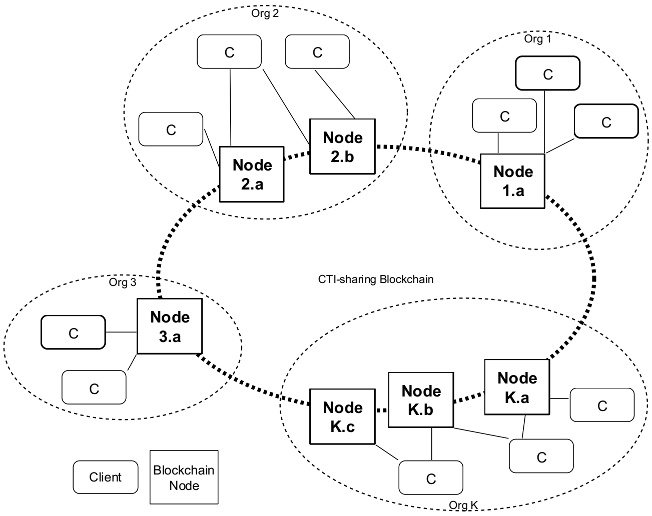

Figure 1. A Blockchain architecture for CTI sharing.

To address this, we need to enhance Hyperledger Fabric with a REST API server that acts as an intermediary to forward requests from the organization's clients to the blockchain network. This is not a bypass to the decentralized nature of the network, considering that it only acts as a relay or secondary client to the blockchain network; furthermore, in this architecture Hyperledger Fabric is decentralized only in the organization level, in contrast with Ethereum or other public blockchains that provide user level decentralization. The nature of this application allows organization-level decentralization, although user-level decentralization can still be possible in specific environments and applications.

Regarding the adherence to the STIX standard, a validator has been developed to verify STIX compliance; implemented as a proof of concept, it currently operates on the API server and is intended to be deployed as Fabric chaincode. This task was comparatively less challenging than integrating the TAXII server into the network, due to two reasons: Firstly, Fabric's data layer is based on a key-value store [7] (either LevelDB or CouchDB) that is inherently similar to JSON objects. Secondly, the validator can be tested off-chain and then effortlessly moved on-chain as it requires minimal or no additional blockchain-metadata to function properly. The work described in this paper encountered a final difficulty in selecting a scope for the API specification to design, implement, and document [8]. The TAXII standard is highly extensible [8], which made it challenging to identify the essential features that offer the basic functionality of threat intelligence sharing and facilitate system management, especially in scenarios involving multiple parties. The process of designing and implementing REST API endpoints that comply with the TAXII standard has been fully documented at various levels, using UML diagrams.

IV. System Design

As we mentioned above, the basic TAXII specification consists of a series of REST API endpoints [8]. The first step in order to design the system is to select a subset use cases to implement at the REST API level. These endpoints are divided into two categories, those that facilitate interaction with the blockchain that are completely custom, and those that provide the functionality required by the TAXII server standard; the API consumers should observe behavior identical to their client/server equivalent. This is shown as a use-case diagram in Figure 2.

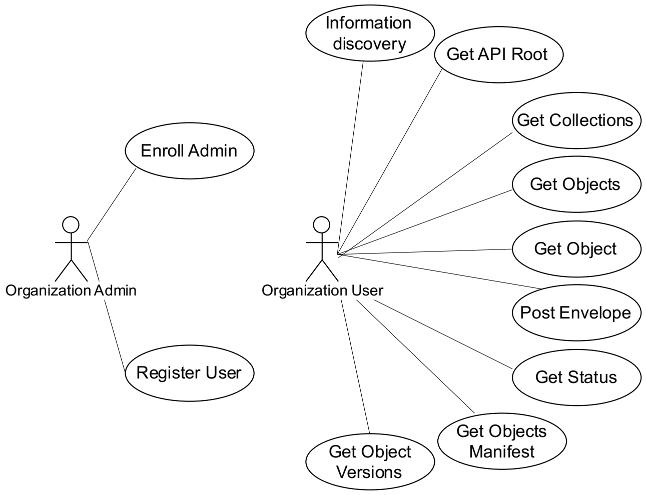

Figure 2. Roles and access to services offered.

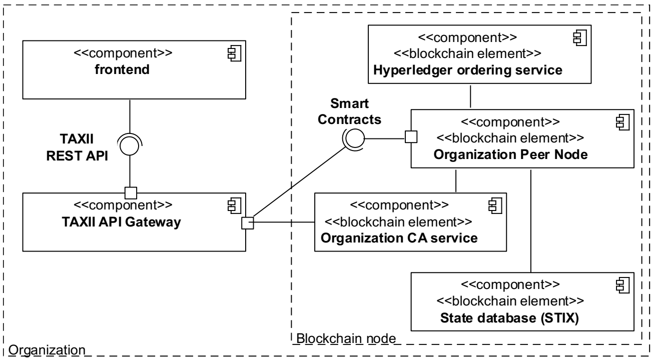
In summary, based on the use case diagram, organization administrators are responsible for enrolling and registering users on the fabric-network [9]. Organization users can interact with every endpoint specified by the TAXII standard, with one critical exception: the ability to delete a STIX object from a collection. This is because blockchain transactions result in an immutable record of assets being transferred from nodes - CTI producers to other nodes. Thus, the best approach is to restrict access to assets beforehand using private data collections and access control. Once an asset reaches an organization's blockchain, it cannot be removed; this is a required behavior that allows the identification of the origin of false CTI coming from compromised or malevolent organizations.

The next step is to create an architecture containing an overview of the software components needed to implement the required functionalities. The UML component diagram below represents these components as containers or processes that live inside an organization's node; further details about their physical deployment will be discussed later. It is important to emphasize that this architecture needs to be implemented inside every single organization participating in the CTI-sharing Blockchain. Therefore, organizations may implement customized versions of this architecture in their production systems, such as fewer or more peer nodes, as discussed earlier; another parameter is whether one organization will be participating in the ordering service or not. Without compromising the principles of the proposed decentralized approach, we assume that every organization implements an identical infrastructure to standardize and simplify aspects of the blockchain layer that will be presented. Such an architecture is shown in Figure 3 below.



<<component>> frontend
TAXII REST API
<<component>> TAXII API Gateway

Organization

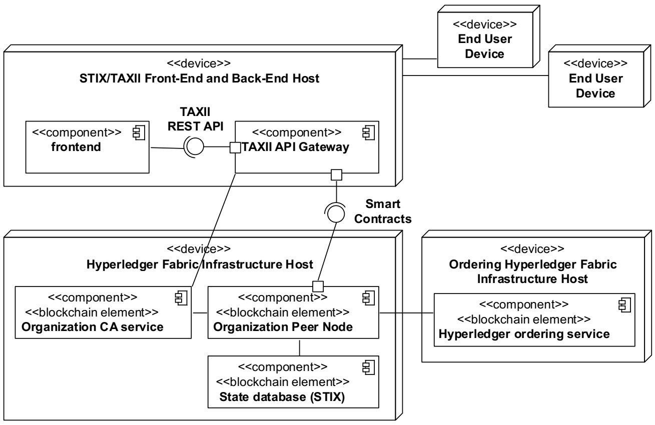
Figure 3. Component-level architecture of Blockchain nodes in organizations.

In the sequel we briefly discuss the system architecture shown in the above UML component diagram. The frontend component can be any implementation of a UI using typical web technologies (Apache, js), or a custom smart client that provides services such as event triggering upon incoming CTI etc.. In both cases, the frontend consumes the TAXII Rest API. The frontend needs not to be aware that the TAXII API offering is really based on a decentralized application. This allows even third-party TAXII clients to be used.

The Organization API Gateway is responsible for three main tasks: First, it validates the compliance of incoming requests with the TAXII standard, by checking HTTP headers, methods, and body parameters. It rejects any input that does not conform with the TAXII standard, without any further interaction with the blockchain backend. Second, it provides user authentication and authorization, by utilizing the organization's certification service(s). The API Gateway receives a token from the client and checks the organization's database for a corresponding certificate stored on behalf of this client. If the certificate exists, it is retrieved, and the request is relayed to the network with that certificate. If an authentication error occurs, the user is informed accordingly.

The third and most important function of the API Gateway is to submit to the blockchain-based backend, transactions on behalf of the organization's clients. These are the core of the TAXII server as they implement the main application business logic and ensure threat intelligence sharing functionality that benefits from the immutability of the blockchain. It is important to note that the transactions are not being run on the API Gateway itself: instead, they are submitted to the Hyperledger Fabric network to be executed on the Blockchain. The results are then received and forwarded to the actual clients. Further discussion on the smarts contracts will follow in the next section.

Consistent to the diagram of the software components, we present a UML deployment diagram to show the assignment of components to execution nodes. This deployment, shown in Figure 4, refers to a specific organization, and seems reasonable enough for production, as it physically isolates the REST API, the Fabric Infrastructure and the ordering service which are in fact very different in business functions.



<<device>> End User Device

<<component>> <<blockchain element>> Organization Peer Node
<<component>> <<blockchain element>> State database (STIX)
<<device>> Ordering Hyperledger Fabric Infrastructure Host
<<component>> <<blockchain element>> Hyperledger ordering service

Figure 4. Deployment of the CTI Blockchain architecture.

Notably, a possible option for deploying the system is to combine the REST API and the fabric organization infrastructure into a single physical host. This approach may be beneficial for smaller organizations that want to conserve resources. However, it is advised to deploy the ordering nodes in separate physical hosts to improve security and performance. Furthermore, as mentioned earlier, it is possible that each organization maintains more than one blockchain node and ordering service, as shown in Figure 5 below.

V. TECHNICAL IMPLEMENTATION

The main components that implement the blockchain are the peer nodes, which are the fundamental building blocks of the Hyperledger Fabric. These nodes serve two essential functions that comprise the blockchain network: ledger and transaction management. In the context of this paper, it is important to note that the peers serve as the hosting component for chaincode, which is a collection of smart contracts that are the main mechanism for interacting with the network [10]. Each peer node implements a number of smart contracts as shown in the UML class diagram in Figure 6 below.

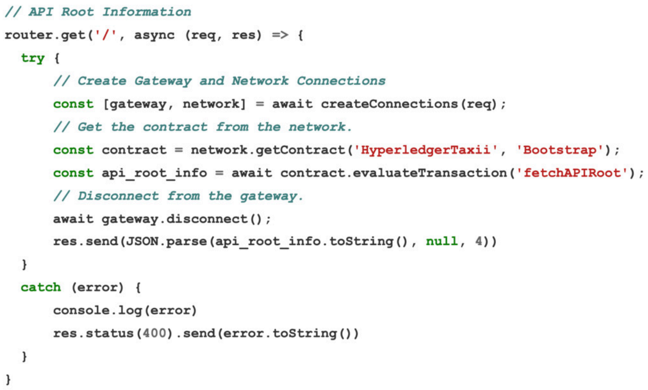
Figure 6. Smartc contracts implemented in peer nodes.

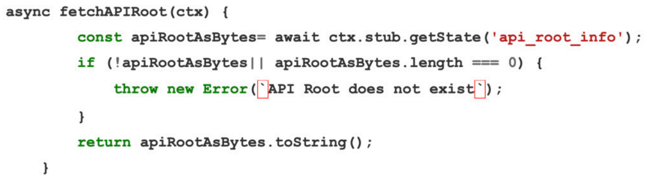
The diagram depicts a chaincode called Hyperledger TAXII Chaincode, which is installed on the file system of the organization's peer node. This chaincode implements three smart contracts: bootstrap, data_contract, and collection. The bootstrap and data_contract contracts are standard patterns used to initialize the ledger and perform some administrative tasks that are later removed in production. It is the collection contract that handles the core application logic of the TAXII server and is responsible for every task related to TAXII terminology, from API Root information to STIX object reads and writes. In Figure 7 below we list an example of the most basic REST API call in javascript code at HTTP server detail:



```
// API Root Information
router.get('/', async (req, res) => {
  try {
      // Create Gateway and Network Connections
      const [gateway, network] = await createConnections(req);
      // Get the contract from the network.
      const contract = network.getContract('HyperledgerTaxii', 'Bootstrap');
      const api_root_info = await contract.evaluateTransaction('fetchAPIRoot');
      // Disconnect from the gateway.
      await gateway.disconnect();
      res.send(JSON.parse(api_root_info.toString(), null, 4))
  }
  catch (error) {
      console.log(error)
      res.status(400).send(error.toString())
  }
}
```

Figure 7. JS code to implement a typical API call.

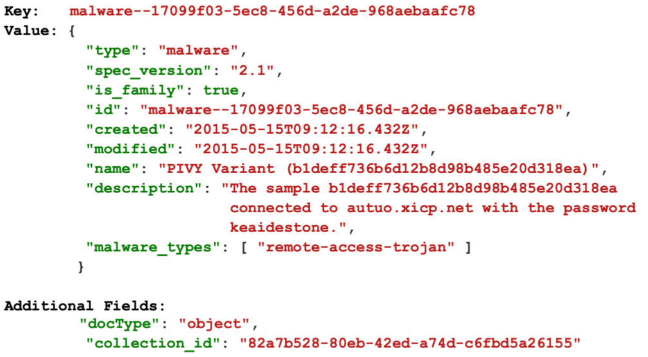
And at smart contract transaction level:



```
async fetchAPIRoot(ctx) {
        const apiRootAsBytes= await ctx.stub.getState('api_root_info');
        if (!apiRootAsBytes|| apiRootAsBytes.length === 0) {
             throw new Error(`API Root does not exist`);
        }
        return apiRootAsBytes.toString();
   }
```

Figure 8. JS code to implement a transaction.

The remaining three components to implement an instance of the system are the state database, certificate authority node, and ordering service. For the purposes of this work, the certificate authority node and ordering service remain unaltered from their default roles in Fabric. The state database serves as a cache for the current key-value pairs, known as the world state, in Hyperledger Fabric [7]. Past values are stored in the ledger. The state database was changed from Hyperledger's default levelDB, to couchDB for rich querying support and improved performance and management. It also stores certificates for organization users and CTI compliant data in STIX language [11] where a key of **<ObjectType>-<ID>** or **<ID>** format is used to quickly retrieve the STIX payload along with a custom field **<docType>**. In some cases a **<collection_id>** field is added and then stripped away before displaying to the user to identify the collection an object belongs to. These are standard best practices provided by fabric code examples. An object of type malware is stored inside the world state database in the format shown in Figure 9



```
Key:   malware--17099f03-5ec8-456d-a2de-968aebaafc78
Value: {
         "type": "malware",
         "spec_version": "2.1",
         "is_family": true,
         "id": "malware--17099f03-5ec8-456d-a2de-968aebaafc78",
         "created": "2015-05-15T09:12:16.432Z",

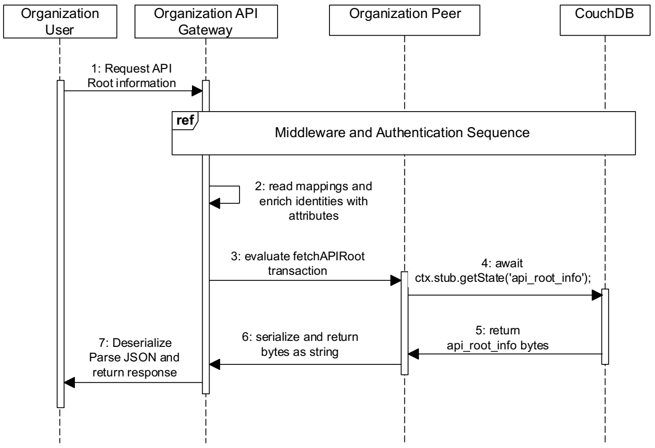
                         keaidestone.",
         "malware_types": [ "remote-access-trojan" ]
        }

Additional Fields:
        "docType": "object",
         "collection_id": "82a7b528-80eb-42ed-a74d-c6fbd5a26155"
```

Figure 9. JSON representation for a STIX "malware" object.

The data flow within the system initiates with the API consumers who are permitted to access the system either via a web browser or by directly making requests to the REST API. The REST API server carries out authentication checks to verify the user's authorization to participate in the blockchain network. After the authentication is confirmed, the API server retrieves the user certificate and functions as a client of the blockchain network, submitting transactions on behalf of the user. In Figure 10 we demonstrate the UML sequence diagram that corresponds to GET API Root endpoint code above.



Organization User
Organization API Gateway
Organization Peer
CouchDB
1: Request API Root information
ref
Middleware and Authentication Sequence
2: read mappings and enrich identities with attributes
3: evaluate fetchAPIRoot transaction
4: await ctx.stub.getState('api_root_info');
5: return api_root_info bytes
6: serialize and return bytes as string
7: Deserialize Parse JSON and return response

Figure 10. A sequence diagram for the "GET API Root" endpoint.

In certain cases, an endpoint might require the submission of multiple transactions. However, submitting multiple transactions is not a recommended practice due to the potential inconsistencies and interruptions that may occur during the code execution. A more effective approach is to map each

REST API endpoint directly to a distinct Hyperledger Fabric transaction. This ensures that the transaction is not only clearly defined but can also be further expanded into subtransactions as necessary. It is important to note, however, that the implementation of this principle is out of scope of this work, as it serves as a proof of concept.

VI. Conclusion

We introduce an architecture for implementing a decentralized Threat Intelligence sharing system utilizing the STIX/TAXII standard, over a Hyperledger Fabric network. The proposed system leverages blockchain technology to enhance security in existing threat sharing systems and standards. By implementing a private permissioned blockchain network like Hyperledger Fabric, the proposed system provides a range of advantages such as improved confidentiality, integrity, availability, non-repudiation, and auditability. The blockchain network ensures that only authorized parties have access to data, maintains a tamper-proof record of all transactions, guarantees that data is always accessible, prevents the denial of service, and provides a transparent and complete immutable record of all transactions. The proposed system uses a decentralized architecture, in which several components work together to provide seamless threat intelligence sharing functionality. These components include the front-end, organization API gateway, peer nodes, state database, certificate authority node, and ordering service. The decentralized architecture is designed to ensure that decentralization does not hinder the system's overall functionality. The proposed system employs REST APIs to facilitate end-users', including third-party TAXII clients interaction with the system, and smart contracts to execute transactions on the blockchain network. The results of this research demonstrate the feasibility and effectiveness of the proposed architecture for threat intelligence sharing systems.

Some future improvements to the functionality, security and performance of the overall system are as follows:

- More robust authentication scheme: In the context of security applications, the basic TAXII standard authentication method that employs the Authentication Basic scheme poses potential risks due to its simplicity. To mitigate these risks, we suggest as a future improvement using a more secure authentication scheme that combines Basic Authentication with Multi Factor Authentication to generate a new certificate. This approach significantly reduces the risk of unauthorized access, especially in cases where an attacker has the enrollmentID and enrollmentSecret elements. Using certificates instead of enrollmentID/enrollmentSecret pairs offers two significant advantages: it minimizes user credential exposure over the channel, even if encrypted with TLS, and the credentials are short-lived, which means they can be easily revoked through the Certificate Authority (CA) authority node if exposed to a malicious actor.
- Writing the STIX validator on chain: One way to ensure a common data format is to validate the STIX data using the validator before storing it in the TAXII Server. Currently, this validation is performed at the API Gateway level and at a basic level. However, this approach may allow organizations to deviate from the STIX standard after processing the Gateway code, which is off-chain. To address this, data validation can be performed at the peer nodes of the Hyperledger Fabric through Chaincode transactions, for more multi-party trust. This would solve the problem of organizations agreeing on a common data validation logic as the code would be common and visible to all. Additionally, the Fabric Chaincode Lifecycle process can change this code at any time in a manner that is agreed upon and approved by all organizations.
- Implementing voting functionality: In CTI systems, the anonymous exchange of threat intelligence often includes a reputation mechanism to incentivize sharing sensitive data with other analysts. However, in our proposed system, which is designed for smaller to medium-sized consortiums, such a mechanism is not necessary since it is not open to the public. However, a voting and/or ban mechanism implemented on the Blockchain may still be useful if the network grows beyond a certain size, to further prevent malicious activities such as data poisoning.

***Abstract*—We present the results of experiments on minimizing the model size for the text-based Open Vocabulary Keyword Spotting task. The main goal is to perform inference on devices with limited computing power, such as mobile phones. Our solution is based on the acoustic model architecture adopted from the automatic speech recognition task. We extend the acoustic model with a simple yet powerful language model, which improves recognition results without impacting latency and memory footprint. We also present a method to improve the recognition rate of rare keywords based on the recordings generated by a text-to-speech system. Evaluations using a public testset prove that our solution can achieve a true positive rate in the range of 73%–86%, with a false positive rate below 24%. The model size is only 3.2 MB, and the real-time factor measured on contemporary mobile phones is 0.05.**

I. Introduction

MACHINE learning techniques are being developed nowadays in two distinct directions. In some applications, model sizes are constantly growing to support the increasing number of domains. This is especially visible in the case of large language models (LLM), in which the number of trainable parameters reaches hundreds of billions. Those models require tremendous amounts of computing power for inference. However, there is also a trend pushing the boundaries in the opposite direction by minimizing the model sizes. In this case, the models are designed for very specific tasks and they are most commonly deployed on devices with a limited amount of computing power, such as mobile phones or home appliances.

A good example of such a specific task is keyword spotting in an audio stream. This task aims to detect all occurrences of the given keywords in audio data provided either in streaming or non-streaming mode. Systems that solve keyword-spotting tasks are usually deployed on users' devices. Therefore, they need to have low latency and a small memory footprint. In the most basic case, the models are fitted to support detecting only a fixed number of keywords (e.g., wake words in contemporary voice assistants such as "OK Google", "Alexa", "Hey Siri" or "Hi Bixby"). Such models can be minimized well, even to sizes below 100 kB. However, users of voice assistants often request the possibility to customize the keywords, which introduces an open-vocabulary Keyword Spotting (KWS) problem. In this case, the model needs to be much larger to support the recognition of potentially arbitrary keywords.

In this paper, we present our solution to the KWS task for the non-streaming mode. It is based on the acoustic model (AM) architecture used in automatic speech recognition (ASR). However, to fit the entire system (model and engine) on the mobile device, we strongly reduced neural network layer sizes and applied post-training weights quantization. As expected, the baseline model performance was far from satisfactory. Therefore, we applied hypothesis re-scoring with a simple language model (LM). We also explored the idea of using recordings generated by a text-to-speech (TTS) model to improve performance on rare keywords not known during AM training. It should be noted that both improvements can be used independently of each other and can be applied to any type of AM.

The rest of this paper is organized as follows. In Section II, we discuss previous solutions to the KWS problem. In Section III, we present different parts of the model architecture: AM in Section III-A; LM together with the algorithm of its construction in Section III-B; keyword classifier, which makes the final decision is described in Section III-C; and extension of this module to multiple keywords is explained in Section III-D. All the variants of our solutions discussed in this paper were evaluated. Results of those experiments are presented in Section IV. Finally, we summarize this paper in Section V and provide a selection of possible future research directions in Section VI.

II. Related work

KWS can be split into two types: query-by-text (QbyT) and query-by-example (QbyE). In QbyT the keyword is provided by text, while in QbyE one or more “enrollment” audio recordings are provided during the initialization phase. Both types of KWS were considered before.

A thorough review of QbyT solutions can be found in [1]. It should be noted that currently, the most popular testset used to evaluate such solutions is a subset of Google Speech Commands (GSC) [2]. It is a public dataset developed for training and evaluating models designed for simple command recognition. It is also used for the KWS task. GSC contains a small number of keywords, hence it is more suited for classification problems with a fixed number of classes rather than open-vocabulary tasks.

Solutions designed for open-vocabulary QbyT evolved similarly to the ASR models. There was a long phase of solutions based on the hidden Markov model (HMM) – Gaussian mixture model (GMM) architecture [3], [4]. Later the GMM component was replaced by deep neural networks (DNN) [5], [6]. Finally, with the advent of sequence-to-sequence architectures to speech processing, ideas such as connectionist temporal classification (CTC) [7] and attention mechanism [8] became standard solutions in KWS as well.

Present-day solutions to open-vocabulary KWS can be based simply on CTC. In [9], the model contains three long short-term memory (LSTM) layers and the output is at the character level. The keyword is detected once the negative log posterior is below a predefined threshold. LSTM-CTC architecture is also used in [10]. However, in this case, the model operates at the phonetic level. The keyword is represented by one or more phone sequences. During the inference phase, those variants are compared with the hypothesis using minimum edit distance. The decision threshold is estimated for each keyword separately based on the training data and the lexicon.

The connection between KWS and ASR can be also limited to the training phase. In [11], the model is trained using CTC in a multi-task approach with ASR and KWS outputs. During inference, only the KWS output is used. Such an approach is intended to improve the model's ability to generalize and improve the performance in acoustically challenging conditions. The solution presented in [12] is based on an audio encoder network and a convolutional classifier. The encoder network is trained using the ASR task. The classifier network uses filters computed by a keyword encoder. The keyword encoder is a bidirectional LSTM (BiLSTM) layer processing the text keyword provided by the user.

Some solutions are based on the attention mechanism. An ASR model composed of five LSTM layers is used in [13]. The model is trained with CTC loss but has an additional keyword encoder and attention network which is used to direct the prediction network towards the keyword of interest. One of the models presented in this paper employs a phoneme level n-gram LM, which improves the model's performance. An attention-based model is presented in [14]. However, this is one of many solutions with a fixed-size output layer, hence supporting new keywords requires retraining the model.

Another approach to supporting open vocabulary is the on-the-fly adaptation of the model during the initialization phase. In [15] an embedding model is pre-trained on a large number of classes. A classification layer for specific keywords is added on top of the embedding model and adapted using only a handful of samples. Such classification layers can be independent of each other and use the same embedding model, since in the adaptation phase only the last layer is modified. A similar solution based on a few-shot transfer learning is described in [16]. It should be noted that usually KWS solutions are deployed on devices with limited resources, hence performing any type of model adaptation might be troublesome.

Many QbyE solutions are also based on the concepts used in the ASR. In [17] the ASR model with CTC is applied to enrollment phase recordings. N-best phonetic level keyword labels are stored together with their log probabilities in the keyword model. During the inference phase, each audio is processed with a similar ASR model. For each keyword from the keyword model log probability is computed and added to the final score. The keyword is detected if the score is above a certain pre-determined threshold. Similarly in [18] a small-footprint ASR model based on CTC is employed. In the enrollment phase, phonetic level posteriorgrams obtained from the model are used to build a finite-state transducer graph (FST) that models the keywords. In the inference phase, the audio is processed with the ASR model, and the output is scored using the keyword model FST. Finally, the score is compared with the threshold, which is chosen automatically based on the enrollment recordings and negative samples generated by rearranging each enrollment waveform. Since both of those solutions operate on the phonetic level rather than directly on the acoustic level, they can be treated as converting the QbyE task to QbyT.

QbyE can be also approached on the acoustic level. In [19], [20], [21], [22] audio embeddings are computed for both enrollment and inference phase recordings. Distance between those vectors is computed using different metrics and compared to a predefined threshold.

III. Model architecture

The main assumption in the KWS task is that the keyword might be any phrase, most likely not known during model training. This means the model architecture cannot be based on a classifier with a fixed-size softmax-type output layer. A more elaborate solution is necessary for this problem. Fig. 1 provides a general overview of our solution. We decided to adopt the AM architecture developed for the ASR task. To gain high accuracy, AMs usually contain hundreds of millions of trainable parameters. However, since KWS is simpler than speech recognition, we decided to leverage knowledge distillation to minimize the model size, but still keep the capability of dealing with large or open vocabulary, which is the base of

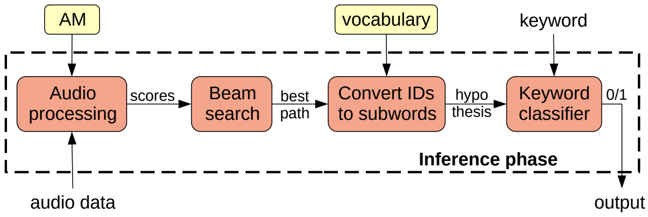

Fig. 1. Overview of the baseline solution.

ASR. Our solution employs AM in a standard way to generate frame level subwords. This is followed by a beam search to create the best path, which is converted to the final hypothesis using model vocabulary. The last step consists of keyword classification, which compares the hypothesis with the given keyword to make a final binary decision: whether a keyword is present in the recording or not.

A. Acoustic model architecture and training

The AM used in our solution is based on monotonic chunkwise attention (MoChA) [23]. It is a sequence-to-sequence model split into encoder and decoder parts, both composed of recurrent neural layers (RNN). The encoder computes embedding vectors for each frame in the audio stream. The attention-based decoder combines and transforms those embeddings into a series of subwords that will constitute the hypothesis. The MoChA used in our decoder is a modification of soft attention, designed to address the issue of real-time (online) processing. It consists of two attention layers. The first layer uses hard monotonic attention for each frame to determine whether the second layer needs to be run. The second layer uses soft attention over a small sequence (“chunk”) of frame embeddings to compute the context vector. Each chunk comprises the current frame and several frames preceding it. The chunk length is a model hyperparameter.

To compress the model, we use a knowledge distillation approach, in which a small student model is trained to mimic a large teacher model [24]. Both models are based on MoChA architecture but differed in the sizes of the selected layers.

The teacher model encoder consists of six BiLSTM layers with 512 units for each direction with 0.3 dropout. To reduce the time domain size, max-pooling layers are used after each of the three initial BiLSTM layers. The decoder consists of one unidirectional LSTM layer with 1000 units, an embedding layer of size 621, and a readout layer of size 1000. The decoder also contains two attention layers of size 512 each. Chunk size two is used for chunkwise attention. The teacher model has 50.1 million trainable parameters (34.2 million in the encoder and 15.9 million in the decoder). It was trained jointly with CTC loss and categorical cross-entropy loss [25]. The CTC was used with the encoder output to encourage the model to learn monotonic alignments. We used 0.1 label smoothing of the output softmax distribution.

The student model has the same architecture as the teacher model but with reduced layer sizes. Each of the BiLSTM encoder layers has 124 units for each direction with 0.3 dropout. The decoder comprises an LSTM layer with 256 units, an embedding layer of size 156, a readout layer of size 256, and two attention layers of size 124 each. The student model includes a total of 3.1 million trainable parameters (2.0 million in the encoder and 1.1 million in the decoder).

The input to both models consists of 40-dimensional power-mels computed over a period of $25\,\mathrm{ms}$ with a $10\,\mathrm{ms}$ step. During training and inference, we applied cepstral mean and variance normalization, which were computed over all training samples. The model’s output consists of 500 subwords obtained using the method described in [26]. It uses the adaptation of byte pair encoding (BPE) to word segmentation to generate a compact symbol vocabulary of variable-length subword units. The vocabulary was generated from all the transcriptions contained in the training and testing sets. 500 was chosen as the vocabulary length since this size keeps the output model layer small and allows for more accurate recognition of rare or out-of-vocabulary words. Four special subwords were added to the vocabulary: `<s>` (beginning of a sentence), `</s>` (end of a sentence), `<unk>` (non-speech events or characters not included in the Latin alphabet) and `<blank>` (required for CTC training).

The teacher model was trained for 23 epochs with a learning rate equal to 1×10^{-4} in the first epoch. The learning rate was reduced by a factor of 0.95 after every 10 consecutive validation steps without change. Validation was done every 5000 steps. During training, we added randomly selected room impulse response (RIR) and mixed the data with a randomly selected noise signal with a ratio between -2 and $12\,\mathrm{dB}$. RIR dataset contains simulations of distances from one to five meters and reverberation time between $0.2\,\mathrm{s}$–$0.9\,\mathrm{s}$. Noise data consisted of both internal noise dataset and AudioSet [27]. The internal noise data contained audio from various environments and is similar to MUSAN [28]. Moreover, the features were augmented with SpecAugment [29] by masking one frequency block of size eight and one time-domain block of size 50.

The student’s total loss was the weighted sum of distillation loss and categorical cross-entropy loss with weights of 0.4 and 0.6, respectively. During knowledge distillation, we used temperature two to make teacher predictions softer. The student model was trained for 22 epochs with a learning rate equal to 4×10^{-4} in the first epoch. The same learning rate scheduler and parameters were utilized during student model training as for the teacher model. We observed accuracy degradation while using SpecAugment during student model training; therefore, we skipped this type of augmentation.

Both models were trained on generic ASR datasets. We used LibriSpeech [30] (all training splits, $960\,\mathrm{h}$), $1779\,\mathrm{h}$ of English Mozilla Common Voice [31] (version 7.0, excluding sentences selected for testing). Additionally, we used $4\,\mathrm{h}$ of audio data not containing speech (silence or quiet noise). The sampling rate of all audio data was $16\,\mathrm{kHz}$. During training, we used greedy decoding, while in the inference phase, we applied the beam search algorithm with a beam size equal to four.

To further minimize student model size, we applied post-training 8-bit quantization. This step reduced the model size

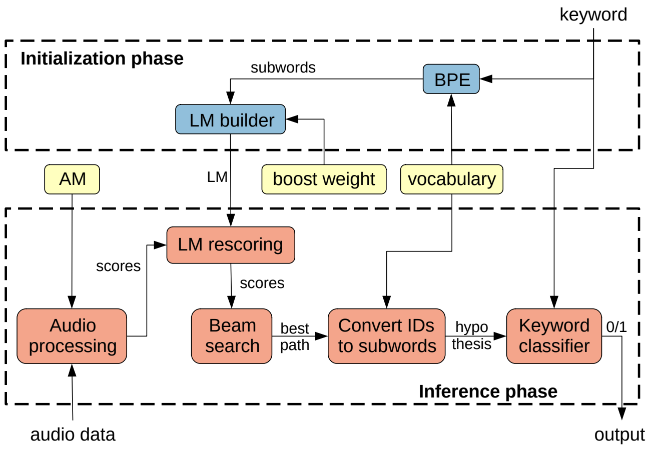

Fig. 2. Overview of the solution with static LM.

from 13 MB to 3.2 MB. This model achieved the following word error rates (WER): 16.0 on LibriSpeech test-clean and 30.9 on LibriSpeech test-other.

B. Language model architecture and initialization

LM can be used to modify scores generated by AM. This process is known as re-scoring. We decided to use a very simple 1-gram LM, where the model is a vector of the same length as the AM output layer size. Such a type of LM introduces only a minor additional memory footprint and a small increase in latency. With this kind of LM, re-scoring consists of element-wise multiplication of the scores returned by the AM and the LM vector. It is the initialization of weights that is the key to a LM of this type. This step should be performed only once for each novel keyword; hence it does not influence latency during the inference phase.

We decided to use a very simple initialization method which we called Static LM. In this method, LM weights are initialized only with two values: one and *boost* weight which is treated as a model hyper-parameter. A general overview of the Static LM method is shown in Fig. 2. The BPE algorithm is applied to the keyword with the same vocabulary as used to convert the AM scores to obtain the hypothesis. Subwords included in the keyword are assigned a *boost* weight, and all the remaining subwords are assigned 1. Note that setting *boost* weight to 1 will not change AM scores and setting *boost* weight to values smaller than 1 will decrease the probability of recognizing the keyword.

C. Keyword classifier

Generating an ASR-based hypothesis is only the first step in the KWS solution. Based on this hypothesis, it is necessary to decide whether the recording contains the required keyword or not. The pseudocode of the procedure we employed for this purpose is presented in Algorithm 1. Note that the recording which is processed by the AM might contain more speech data than just the keyword. To remedy this issue, we calculate the keyword length as the number of words and compare it with all the subsequences of the hypothesis of the same word length. We calculate the character level normalized Levenshtein distance between each such subsequence and the keyword. If the distance is smaller than a predefined threshold, the true value is returned by the system (keyword detected) and the false value is returned otherwise (keyword not detected).

Algorithm 1 Keyword classifier algorithm

```
Input: $keyword$ – custom keyword
Input: $hyp$ – hypothesis returned by AM
Input: $t$ – recognition threshold
$l \leftarrow len(keyword)$ {number of words in keyword}
for $s \in \{sub : sub$ is substring of $hyp \wedge len(sub) = l\}$ do
    if $dist(keyword, s) \leq t$ then
        return $true$
    end if
end for
return $false$
```

D. Multi-keyword classifier

In the generic text-based KWS task, the keyword is provided by the text. However, often additional audio data can be leveraged to improve recognition rates. This can be done for example by requesting the user to provide a spoken version of the keyword. Since such an approach requires additional action from the user, we decided to pursue an automatic solution. An overview of this method is presented in Fig. 3. We employ the TTS system to generate synthetic recordings representing the spoken version of the keyword. The number of those recordings depends on the TTS solution and can also be set as a parameter of the system. Each of those recordings is processed by the AM, followed by the beam search algorithm to generate a hypothesis. The original keyword is appended to the hypothesis list and duplicates are removed. This list is treated as containing additional variants of the original keyword and is later used during inference by the keyword classifier.

Algorithm 2 presents the multi-keyword classifier pseudocode. It is the extended version of the keyword classifier described in section III-C. Once more substrings of the hypothesis are selected for comparison, but this time they are compared with each keyword from the list prepared during the initialization phase. As previously, normalized character level Levenshtein distance and a predefined threshold are used to make the final decision.

The main idea behind the multi-keyword classifier is to improve the recognition rate on keywords that are very distinct from the phrases presented to the AM during training (eg. named entities or other non-standard phrases). In such cases, the AM most likely would return an incorrect hypothesis. However, provided those errors are similar across different samples of the same keyword, adding them to the classifier should increase the true positive rate (TPR). Hence this idea can be described as adding additional pronunciation variants

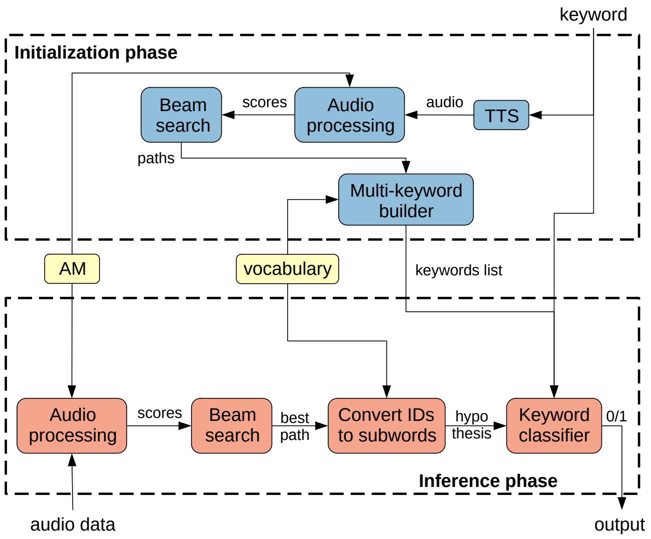

Fig. 3. Overview of the multi-keyword solution.

Algorithm 2 Multi-keyword classifier algorithm

```
Input: $keywords$ – list of custom keywords
Input: $hyp$ – hypothesis returned by AM
Input: $t$ – recognition threshold
for $keyword \in keywords$ do
    $l \leftarrow len(keyword)$ {number of words in keyword}
    for $s \in \{sub : sub$ is substring of $hyp \wedge len(sub) = l\}$ do
        if $dist(keyword, s) \leq t$ then
            return $true$
        end if
    end for
end for
return $false$
```

for the user-entered keywords. Obviously, this procedure might also have negative results. Phrases similar to the keyword, but different from it might be recognized with the same, wrong hypothesis, which would result in an increase in the false positive rate (FPR).

Note that the keywords list used by the multi-keyword classifier can be prepared during the initialization phase; therefore, this step does not influence inference phase latency. The impacts of the multi-keyword approach on memory and latency are linear with respect to the number of TTS recordings used. However, since the multi-keyword solution requires at most one additional string for each TTS recording, the memory footprint is negligible. The same reasoning can be applied to the impact on latency since Levenshtein distance calculation is much faster than ASR decoding.

IV. Experiments Results

A. Evaluation procedure

Our solution was tested with MOCKS 1.0 testset [32] and GSC v2 testset.

Since the AM was trained with English data, we used *en_LS_clean*, *en_LS_other*, and *en_MCV* subsets of MOCKS. Each test case is composed of two audio files and a keyword. One of those files is treated as initialization (enrollment) phase data and the other is treated as inference phase data. However, since our goal is to limit the user's interaction with the device, we skip the initialization phase data in the case of static LM. Furthermore, in the case of a multi-keyword classifier, we replace the initialization phase recording with synthetic data. We will refer to the inference phase data as test audio.

Each of the MOCKS subsets used for evaluation is split into three distinct parts:

- positive test cases – where the test audio contains a given keyword; we will call this part *pos*,
- similar test cases – where the test audio contains a different phrase than the given keyword, but both are close phonetically; we will call this part *sim*,
- different test cases – where the test audio contains a different phrase than the given keyword and the phonetic distance between both is large; we will call this part *dif*.

To present the impact of different hyperparameters on the above-described parts of MOCKS (true positive on *pos* and false positive on *sim* and *dif*), we used recognition accuracy as the main metric.

GSC is not suited for the open-vocabulary version of KWS, since it contains a very limited number of keywords. Nonetheless, we present the evaluation results of our solution on this testset for the sake of comparison with previous works. The most popular metric used with GSC is simply accuracy [33]. The negative test cases should be recognized as either _unknown_ or _silence_ special classes. The former contains words not included in the positive classes and the latter contains silence and non-speech events. Evaluation on GSC is a 12-class classification problem, while our solution is designed for the generic case of open-vocabulary classification. To remedy this issue evaluation for the negative test cases (labeled _unknown_ or _silence_) is performed in the following way:

- In the initialization phase for each positive keyword we prepare an LM and extended keywords list (if the multi-keyword classifier is enabled).
- After audio processing is done, for each positive keyword we perform re-scoring, apply beam search, convert the result to the hypothesis, and finally compute the character level Levenshtein distance between the hypothesis and the given keyword.
- Finally, we find the minimal distance from the previous step. If this distance is less than or equal to the threshold, this sample is counted as a false positive and a true negative otherwise.

We used an internally-developed end-to-end TTS system to generate synthetic recordings for the multi-keyword classifier. The system was composed of a neural AM and a vocoder. The AM mapped sequences of phonemic labels to acoustic features, while the vocoder mapped those features to audio samples. The set of phonemic labels contained language-specific (English) symbols of phonemes, word delimiters, and end-of-sentence marks. However, during synthesis, keywords were stripped of those marks. Acoustic feature vectors were derived from F0 (interpolated in unvoiced regions), mel-spectra, and band-aperiodicity as in the case of the WORLD vocoder [34]. The vocoder architecture was based on [35] and AM was similar to the Tacotron 2 [36] architecture as described in [37], with the use of the mutual information loss (MILoss) function [38]. Audio data included in the LJ speech dataset [39] and Hi-Fi Multi-Speaker English TTS Dataset [40] were used to train the entire system. The vocoder was trained separately for each voice. The AM was trained for 10 k epochs on the entire training data, followed by 450 k epochs of each voice-specific data.

For each keyword in MOCKS and GSC, we generated 10 synthetic recordings. We chose one male and one female voice for the experiments with a multi-keyword classifier based on two synthetic recordings. Two further types of experiments with this type of classifier were performed:

1) using clean audio data;
2) using audio data mixed with background noise and convolved with RIR.

We used the same types of noise and RIR as during AM training.

For confidence interval estimation we used bootstrap resampling of the testsets. Each testset was resampled 200 times with replacement. The trainset and model remained fixed. In order to provide a 95 % confidence interval we calculated the $[2.5, 97.5]$ percentile boundaries.

B. Evaluation results

1) Impact of the boosting weight: For the purpose of testing the impact of the static LM and different *boost* weights, we performed evaluations using values from the set $\{2^n : n \in \{0, 1, \ldots, 11\}\}$. Note that setting the *boost* weight to one means that none of the subword scores will be modified during re-scoring and only the AM scores will be taken into account in beam search. We treat this case as the baseline solution.

Fig. 4, 5 and 6 show acceptance rate in the function of the threshold applied in the keyword classifier for *en_LS_clean*, *en_LS_other* and *en_MCV* respectively.

Let us start the analysis of the results with $boost = 1$. For $threshold \in [0, 0.05]$, in all the testsets acceptance rates in *pos*, *sim* and *dif* are constant. This is due to the fact that all keywords in MOCKS are relatively short (phonetic transcription length $p \leq 16$). As long as the $threshold$ is greater than 0.05, acceptance rates in both *pos* and *sim* are increasing. However, those values in the former subsets grow slower than in the latter subsets. This means that increasing the threshold improves the TPR, but increases the FPR even faster. Values of acceptance rate in *dif* start to increase only with $threshold > 0.4$ since this test set contains test cases that are very different from the given keyword. For such test cases, the AM returns very different hypotheses from the keyword, even if they do not match the proper transcription. Similar

EER IN % FOR DIFFERENT VALUES OF BOOST ON MOCKS, WITHOUT A MULTI-KEYWORD CLASSIFIER.

boost	*en_LS_clean*	*en_LS_other*	*en_MCV*
1	30.05 ± 0.28	37.27 ± 0.26	27.30 ± 0.16
16	16.56 ± 0.24	26.04 ± 0.23	14.46 ± 0.19
32	$\mathbf{15.18 \pm 0.14}$	22.65 ± 0.13	$\mathbf{14.22 \pm 0.10}$
64	19.86 ± 0.11	$\mathbf{20.34 \pm 0.17}$	21.57 ± 0.12

observations also apply to cases with *boost* > 1, except for *dif*, for which the higher the $threshold$, the sooner this function starts to grow. This analysis suggests that it is safe to use $threshold = 0$.

For clarity, Fig. 4, 5 and 6 show evaluation results only for $boost \leq 32$. In Fig. 7 we present evaluation results for all the testsets and *boost* values up to 2048 using $threshold = 0$. It should be noted that for $boost \leq 32$, for all the testsets acceptance rates in *pos* are growing faster than in *sim*. These *boost* values are also accompanied by small acceptance rates in *dif* in all the testsets. However, the larger the *boost* gets, the faster acceptance rates in *sim* grow when compared to *pos*. This is also accompanied by a rapid growth of those rates in *dif*. This observation suggests that there is a limit for *boost* after which static LM brings more harm than benefit.

We use an equal error rate (EER) to estimate the optimal *boost* value. For each testset, FPR is calculated after summing *sim* and *dif* subsets. Fig. 8 shows EER for all the testsets and $boost \leq 128$ (for higher *boost* values EER is growing hence it is omitted). The width of the lines in Fig. 8 represent confidence intervals for EER estimation. It should be noted that the minimal EER values are located at *boost* equal to 32 or 64, depending on the testset. The rapidly growing value of EER for large *boost* is caused by the fact that in those cases FPR is always greater than the false negative rate (FNR). Since there is no point for which FPR and FNR are equal, the largest of those values is chosen as EER. Detailed values of EER for MOCKS can be found in Table I.

Fig. 9 shows the evaluation results for different *boost* values on the GSC testset using $threshold = 0$. Applying static LM improves accuracy from 84.60% for the baseline model to 95.97% at $boost = 32$. For higher *boost* values accuracy drops rapidly. This is due to the fact that with those large *boost* values the keyword subwords are favored during beam search. Therefore the number of negative test cases recognized as keywords grows. Detailed values of accuracy for GSC can be found in Table II.

2) Impact of the multi-keyword classifier: The main motivation for applying a multi-keyword classifier should be the increase in TPR, which ideally would not be accompanied by the increase of FPR. Our experiments show that this is not the case for MOCKS. Fig. 10 shows the evaluation results using *en_LS_clean* for multi-keyword classifiers initialized with 2 and 10 clean TTS recordings. Those results are compared to a single-keyword classifier solution. Furthermore in Table III we present exact evaluation results (acceptance rate) for each English testset in MOCKS. For clarity we limit those results to $boost = 1$ (no LM) and $boost = 32$, since this value gave the highest results as shown in Section IV-B1.

We observed that the improvement in acceptance rate on *pos* was larger than a similar increase on *sim* and *dif* only for small *boost* values. This difference was very small for the multi-keyword classifier initialized with two synthetic recordings. However, with 10 such recordings, the improvement of the acceptance rate on *pos* was almost 2 pp. larger than on *sim*.

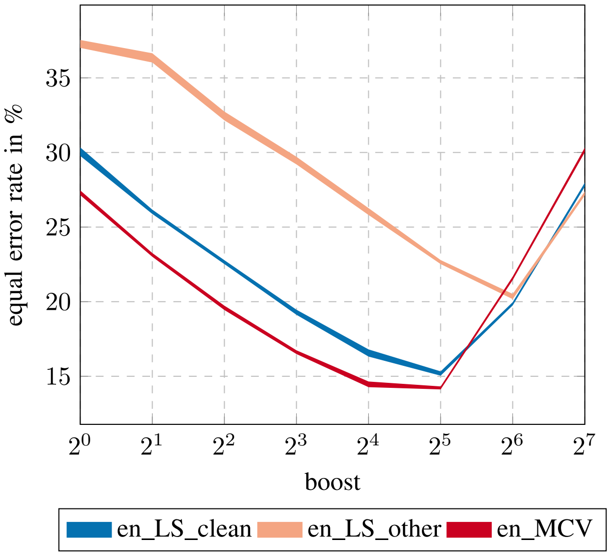

Fig. 8. Boosting results with static LM, without multi-keyword classifier, for MOCKS testset.

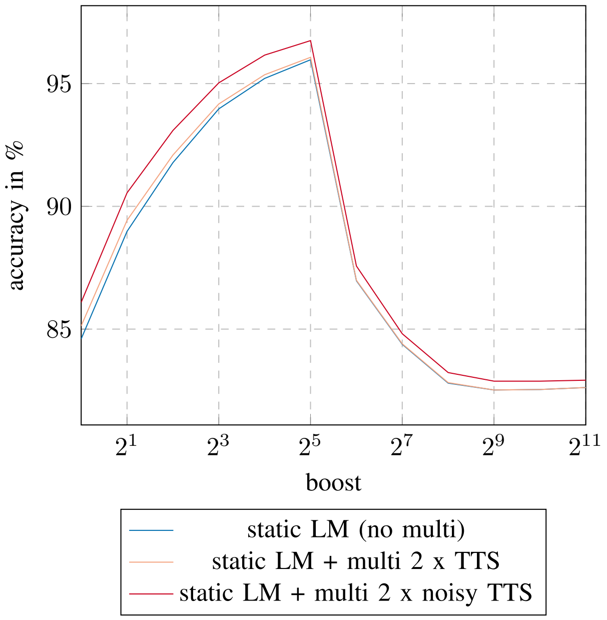

Fig. 9. Boosting results with static LM, with and without multi-keyword classifier, for GSC testset.

As soon as *boost* = 8 multi-keyword classifier introduced a larger increase in acceptance rate on *sim* than on *pos*, which was visible in all testsets. Mixing synthetic recordings with background noise and RIR did not improve the situation. The increase in acceptance rate on *pos* was smaller than on *sim*.

Evaluation results on GSC with a multi-classifier show a similar increase in accuracy (0.78 pp–2.3 pp depending on the *boost*). This improvement seems to be insignificant, nonetheless, it should be noted that it is gained in the range of 85 %–96 %. At this level of accuracy, even a minor increase in this metric means a substantial reduction in the number of errors.

TABLE II
ACCURACY IN % FOR DIFFERENT METHODS ON GSC.

method	accuracy
boost 1 (baseline)	84.60
boost 1 + multi 2 x TTS	85.13
boost 1 + multi 2 x noisy TTS	86.09

boost 32 + multi 2 x TTS	96.07
boost 32 + multi 2 x noisy TTS	**96.75**

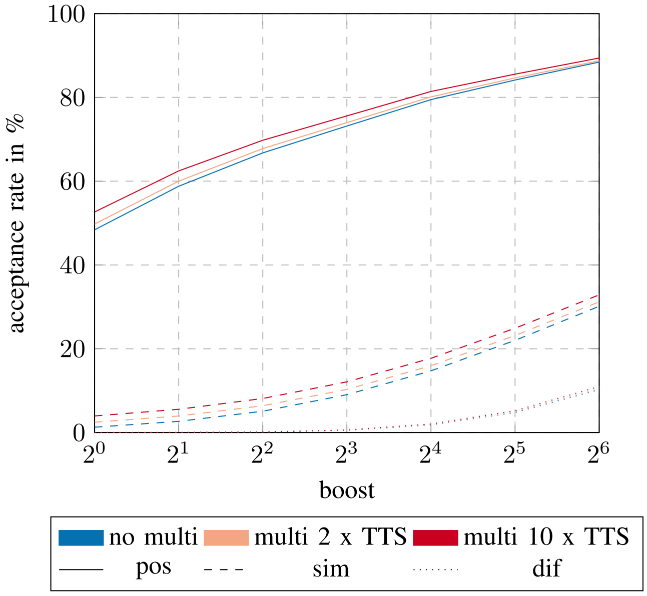

Fig. 10. Boosting results with static LM, with and without multi-keyword classifier, for en_LS_clean testset.

V. Discussion and Conclusions

Two major observations can be drawn from our experiments:

1) The increase of *boost* in static LM improves TPR, however, the larger the *boost* gets, the more dominant the increase of FPR compared to the increase of TPR.
2) The multi-keyword classifier introduces a positive impact on TPR only for very low *boost* values, while for high values of *boost*, however, the increase of FPR is much larger than the increase of TPR.

Using *boost* = 32 seems to be the right choice in general cases since this value resulted in the minimal EER in *en_LS_clean* and *en_MCV* and the largest accuracy in GSC. However, it should be noted that EER was minimal in *en_LS_other* with *boost* = 64, hence there is no universal value for this parameter.

The positive impact of the multi-keyword classifier is especially visible with the increased number of TTS recordings for each keyword. This number can be potentially unbounded, but a rule of thumb suggests using only a small amount (not exceeding 10) of such recordings. This suggestion is based on the observation that the longer the list of additional

TABLE III

keyword variants, the more likely the chance of false positive acceptance of phrases similar to the given keyword.

Evaluation of MOCKS and GSC with a multi-keyword classifier shows that there is a significant difference in both testsets. With MOCKS at $boost = 32$ adding 10 keyword variants increases FPR on *sim* more than TPR on *pos*. On the other hand with GSC at $boost = 32$ and 10 keyword variants we still observe improvement in accuracy. This can be explained by the fact that GSC contains short phrases and the negative samples are very different from the keywords in terms of character level Levenshtein distance. On the contrary, MOCKS contains longer phrases and a subset of negative samples similar to the keywords, hence they are difficult to distinguish. This means that adding additional keyword variants also increases the probability of false acceptance in this subset (*sim*). This analysis also leads to the conclusion that a multi-keyword classifier is an effective solution as long as one does not expect to deal with such challenging negative cases.

It might seem that a solution with accuracy equal to $96.75\,\%$ on GSC is far behind the current leading architecture which was evaluated on this testset and gained $98.37\,\%$ [41]. Still, it should be noted that our solution is designed for a far more complex task. GSC contains a very limited amount of keywords, all very short and distinct from each other. Finally, there are no challenging negative test cases in GSC. On the other hand, our solution is designed for the open-vocabulary case, in which the model needs to deal with keywords that are very similar to each other. Hence the evaluation results on MOCKS are much more informative and the decrease in accuracy on GSC evaluation is the cost paid for much broader generalization.

VI. FUTURE WORK

In the future, we plan to work on methods that automatize the selection of the optimal $boost$ value. Furthermore, setting specific $boost$ values for different keywords might have positive results on evaluation results. Another intriguing research direction is using a combination of clean and noisy TTS recordings as ensembles in the multi-keyword classifier. This way it might be possible to reduce FPR without impacting TPR.

***Abstract*—Time Expanded Networks, built by considering the nodes of a base network over some time space, are powerful tools for the formulation of problems involving synchronization mechanisms. Those mechanisms may for instance be related to the interaction between resource production and consumption or between routing and scheduling. Still, in most cases, deriving algorithms from those formulations is difficult, due to both the size of resulting network structure and the fact that reducing this size through rounding techniques tends to induce uncontrolled error propagation. We address here this algorithmic issue, while proposing a generic decomposition scheme which works by first skipping the temporal dimension of the problem and next expanding resulting projected solution into a full solution of the problem set on the time expanded network.**

I. Introduction

ONE derives a *Time Expanded Network* (TE-Network) $N^{\mathbf{TIME}}$ (see [11]) from a base network $N = (X, A)$ and a time space **TIME**, by considering all the copies (x, t) of the nodes x of N at the different instants t of **TIME**. Then, an arc of $N^{\mathbf{TIME}}$ is either an arc $\big((x, t), (y, t + \delta)\big)$ which corresponds to the time required to traverse an arc (x, y) of N while starting from x at time t, or an arc $\big((x, t), (x, t')\big)$ with $t < t'$, which expresses some kind of standby in x from time t to time t'. It may happen that the traversal time δ depends on t. Note that the time space **TIME** may be either discrete or continuous.

Time Expanded Networks are powerful modeling tools for problems involving synchronization, between for instance resource production and consumption or between routing and scheduling. They are also well-fitted to deal with the time-dependence of a network. They were introduced by Ford and Fulkerson (see [11]) in order to cast such problems into the network flow framework. Some time later, concerns raised by time dependence and synchronization issues motivated the notion of *dynamic network* (see [2], [16]). They next gave rise at the beginning of the 80's to *flow over time* models, where flow values are trajectories, that means functions from a time space **TIME** onto real or integer numbers. Those functions may be subject to constraints like continuity or differentiability, and so the *flow over time* framework is well-fitted to the management of problems involving gas or power production and distribution. Years 1990/2000 also registered applications of these notions to evacuation planning (see [9]). At this time, authors adapted standard algorithms (min-cost flow and max-flow algorithms) and brought insights about the link between TE-Networks and the *flow over time* models (see [13]). They addressed complexity issues and stated some *polynomial approximation scheme* (PTAS) results. In the years 2010, authors came back to the original TE-Network framework. They did it with the purpose of handling multi-commodity flow models (see [1]) like those which may derive from transportation (see [5]) and industrial scheduling problems (see [18], [3]). They tried to take advantage of the improvement of both computers and *Mixed Integer Linear Programming* (MILP) libraries in order to directly implement some transportation models on those libraries (see [6], [17], [21]). They coped with the size issue by trying to adapt standard column generation and branch and cut techniques (see [7]), but faced difficulties as soon as the size of the time space increased. All those contributions suggested that the *Time Expanded Network* might be very efficient to deal with scheduling/routing problems involving synchronization (see [15], [14]) requirement or time dependence features (see [20]) .

Actually, though the TE-Network framework is good for modeling, it often fails in providing efficient algorithms. The fact is not only that the size of the TE-Network $N^{\mathbf{TIME}}$ increases very fast with the size of the time space **TIME**, but also that controlling this size through rounding techniques induces strong error propagation. So our purpose here is to bypass those difficulties by applying a *Project/Expand* decomposition scheme. We first search (*Project* step) for a good projected solution on the base graph N, and next (*Expand* step) turn this projected solution into a full TE-Network solution. We started addressing the *Project* step in a former contribution (see [12]), while setting a *Projected* model provided with *Extended No-Subtour* constraints enhancing its ability to yield full feasible solutions. We are now going to first reinforce this *Projected* model with constraints which guaranty the feasibility of the *Expand* process, and next derive from resulting projected solution a formal bi-level setting of related *Expand* problem. We shall deal with this problem in both an exact way and a heuristic way, by introducing a flexible active sub-network of $N^{\mathbf{TIME}}$ and tuning this sub-network until getting a full TE-Network solution. Though our approach is generic, we shall refer here, for the sake of understanding and with the purpose of testing, to a 2-commodity flow model related to the management of an *item balancing* process (see [8] and [17]).

The paper is organized as follows. In Section 2, we first present our reference TE-Network model, related to some *item balancing* problem, and next the projected model which derives from this TE-Network model. In Section 3 we set the *Expand* problem, characterize its feasibility and reinforce the projected model with constraints which ensure the feasibility of resulting *Expand* problem. In Section 4 we propose a bi-level formulation of this *Expand* problem and in Section 5 we present an exact MILP model together with heuristic algorithms which deal with the *Expand* problem. We conclude by providing some numerical experiments and discussing some open questions.

II. A TE-Network Model for the Item Relocation Problem

We refer here, for the sake of understanding, to a specific *Item Balancing Problem* (IBP). So, we consider here a transit network $N = (X, A)$, together with a *Depot* node (see Figure 1). Every arc is provided with a time value $T_{x,y}$ and a cost value $C_{x,y}$. Also:

- We set $\mathbf{T} = (T_{(x,y)}, (x,y) \in A)$ and $\mathbf{C} = (C_{(x,y)}, (x,y) \in A)$. For any path π from $x \in X$ to $y \in X$, we denote by $L^T(\pi)$ its length in the sense of $\mathbf{T}$. We do the same with $\mathbf{C}$. For any pair of nodes (x,y) we denote by $D^T(x,y)$ the shortest path distance from x to y in the sense of $\mathbf{T}$, and by $D^C(x,y)$ the shortest path distance from x to y in the sense of $\mathbf{C}$.
- Let U be some subset of X. We set $\partial^-_N(U) = \{(x,y) \in A$ such that $x \notin U, y \in U\}$, $\partial^+_N(U) = \{(x,y) \in A$ such that $x \in U, y \notin U\}$, $\partial_N(U) = \partial^-_N(U) \cup \partial^+_N(U)$, and $A(U) = \{(x,y) \in A$ such that $x \in U, y \in U\}$. Clearly, $\partial_N(U)$ means the arcs which allow entering and getting out of U. We simplify these notations in case U is a singleton $\{x\}$ by writing $\partial^-_N(x)$, $\partial^+_N(x)$ and $\partial_N(x)$, instead of $\partial^-_N(\{x\})$, $\partial^+_N(\{x\})$ and $\partial_N(\{x\})$, respectively. Also, we denote by $U \setminus V$ the difference of the sets U and V (i.e., the set $\{u \in U$ such that $u \notin V\}$).

Then our IBP: *Item Balancing Problem* comes as follows: Items are located inside the network and must be relocated, within a *time horizon* $\{0, 1, \ldots, T_{max}\}$, by a fleet of identical carriers with *capacity* Cap. We are provided with an integral *balance* vector $\mathbf{b} = (b_x, x \in X)$ such that $\sum_{x \in X} b_x = 0$: $b_x > 0$ means that x is in *excess* and that b_x items must leave x; $b_x < 0$ means that x is in *deficit* and that b_x items must arrive to x. The *Item Balancing Problem* (IBP) consists in scheduling those transfers, while minimizing a hybrid cost $\alpha \cdot c_1 + \beta \cdot c_2 + \gamma \cdot c_3$, where c_1 is the number of active carriers, c_2 is their running cost in the sense of $\mathbf{C}$, c_3 is the time spent by items while moving inside the carriers, and α, β, γ are scaling coefficients. An important feature of the problem is that we allow *preemption*, which means that the carriers may exchange items, making synchronization become an issue.

Example 1 Consider the network $N = (X, A)$ of Figure 1. It shows two carrier routes $\Gamma^1 = (Depot, v, x, y, Depot)$ and $\Gamma^2 = (Depot, w, x, z, Depot)$ linked together by a transfer from Γ^1 to Γ^2 at node x. We check $c_1 = 2$, $c_2 = 10$, and $c_3 = 32$.

A. A Time-expanded 2-commodity Flow Model for the IBP Problem

In order to cast this IBP problem into the TE-Network framework (see [8]), we first derive from the network $N = (X, A)$ its *time expansion* $N^{Tmax} = (X^{Tmax}, A^{Tmax})$ according to $Tmax$. The node set X^{Tmax} is the set of all pairs (x,t), $x \in X$, $t \in \{0, 1, \ldots, Tmax\}$, augmented with two distinguished nodes: $source$ and $sink$. The arcs $a \in A^{Tmax}$, together with their *carrier cost* $\hat{C}_a$, and their *item cost* $\hat{I}_a$, come as follows:

- *input-arcs* $a = \big(source, (x, 0)\big)$, $x \in X$, with $\hat{I}_a = 0$ and $\hat{C}_a = 0$;
- *output-arcs* $a = \big((x, Tmax), sink\big)$, $x \in X$, with $\hat{I}_a = \hat{C}_a = 0$;
- *waiting-arcs* $a = \big((x,t), (x, t+1)\big)$, $x \in X$, $t \in \{0, \ldots, Tmax - 1\}$, with $\hat{I}_a = \hat{C}_a = 0$;
- *active-arcs* $a = \big((x,t), (y, t + T_{(x,y)})\big)$, $(x,y) \in A$, $t \in \{0, \ldots, Tmax - T_{(x,y)}\}$, with $\hat{I}_a = \gamma \cdot T_{(x,y)}$ and $\hat{C}_a = \beta \cdot C_{(x,y)}$;
- *backward-arc* $a = (sink, source)$, with $\hat{I}_a = 0$ and $\hat{C}_a = \alpha$.

In order to formalize our IBP problem as a 2-commodity flow model on this network $N^{Tmax} = (X^{Tmax}, A^{Tmax})$, we introduce integral 2 flow vectors $\mathbf{H}$ and $\mathbf{h}$, both indexed on the arc set of N^{Tmax}. The first one is going to describe the way the carriers move inside the transit network: for any active-arc $a = \big((x,t), (y, t + T_{(x,y)})\big)$, H_a will mean the number of carriers which traverse the arcs (x,y) of the transit network between time t and time $t + T_{(x,y)}$. The second one will describe the moves of the items: for any active-arc $a = \big((x,t), (y, t + T_{(x,y)})\big)$, H_a will mean the number of items which traverse the arcs (x,y) of the transit network between time t and time $t + T_{(x,y)}$. The value H_a on the *backward-arc* will provide us with the number of carriers involved into the process. The values H_a and h_a on a *waiting-arc* $a = \big((x,t), (x, t+1)\big)$ are going to respectively provide us with the number of carriers and items waiting on node x between time t and time $t+1$. By proceeding this way, we get:

TE-Network IBP Model. *Compute two nonnegative integral A^{Tmax}-indexed vectors $\mathbf{H}$ and $\mathbf{h}$ (for carriers and items, respectively) such that:*

- **H** *and* **h** *satisfy flow conservation at any node of* N^{Tmax}; (E1)
- *for any active-arc* $a = \big((x,t),(y,t+T_{(x,y)})\big)$: $h_a \leq Cap \cdot H_a$; (E2)
- *for any input-arc* $a = \big(source,(x,0)\big)$, $x \neq Depot$: $H_a = 0$; $h_a = \max(b_x, 0)$; (E3)
- *for any output-arc* $a = \big((y, Tmax), sink\big)$, $y \neq Depot$: $H_a = 0$; $h_a = \max(-b_y, 0)$; (E4)
- *the global cost* $Cost(H,h) = \sum_{a \in A^{Tmax}} \big(H_a \cdot \hat{C}_a + h_a \cdot \hat{I}_a\big)$ *is minimized.*

Constraints (E1) express the circulation of carriers and items. Constraints (E2) mean that any item move is supported by some carrier. Constraints (E3) and (E4) characterize initial and final states: carriers start and end at $Depot$, while any node ends as *neutral*.

Example 2: Fig. 2 shows the TEN $N^{Tmax} = (X^{Tmax}, A^{Tmax})$ deriving from network $N = (X, A)$ of Fig. 1 and $T_{max} = 6$. It turns the solution of Example 1 into a full solution (**H**, **h**). Tour Γ^1 gives rise to a path $\{source, (Depot, 0), (v, 1), (x, 3), (y, 4), (Depot, 5), (Depot, 6), sink\}$. Tour Γ^2 gives rise to a path $\{source, (Depot, 0), (w, 1), (x, 2), (x, 3), (z, 5), (Depot, 6), sink\}$. The value of **h** on the arc $(x, 2), (x, 3)$ shows the way the 5 items transported by carrier 2 wait on node x before splitting themselves along the arc (x, y) and (x, z).

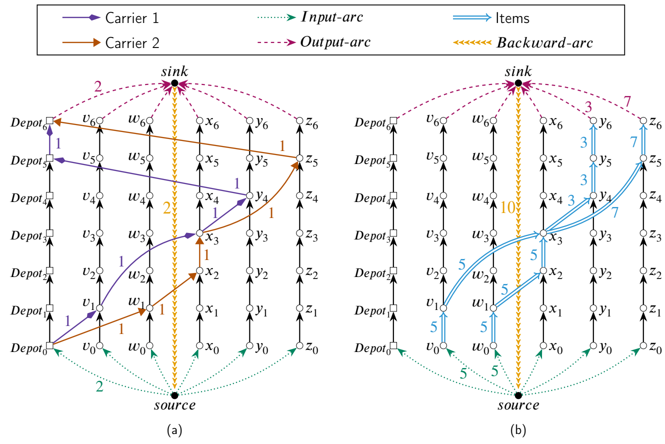

Fig. 2. The routes and schedules as a TE-Network 2-commodity flow: (a) Carrier flow vector **H**. (b) Item flow vector **h**.

As it is formulated, we understand that this **TE-Network IBP Model** is going to be difficult to handle. Its size grows fast with value T_{max}. We might try to control this size by rounding the values t. For instance, instead of measuring the time in minutes, we could try to round it to 15 minutes packages. But if traversing an arc requires 3 minutes, then rounding will mean either canceling this traversal time, or multiplying it by 5. In both case, we guess that the propagation of resulting errors will be difficult to manage. So we are going to implement a *Project and Expand* scheme, which means that we are going to first skip the temporal dimension of our problem (*Project* step) and restrict ourselves to the identification of the arcs followed by the carriers and the items, and next perform an *Expand* step in order to schedule those arcs and get a full solution of our problem.

B. The Projected IBP Model

Given a feasible solution (**H**, **h**) of above **TE-Network IBP** Model. We define the *projection* **F** of **H** on the network N by setting, for any arc (x, y) of N:

$$F_{(x,y)} = \sum_{t=0}^{Tmax} H_{(x,t),(y,t+T_{(x,y)})}.$$

We define the same way the *projection* **f** of **h**. Clearly, the meaning of those projected vectors is that we want to simplify our problem while skipping its temporal dimension. They are going to provide us with a kind of signature of the routes followed respectively by the carriers and the items on the transit network, without taking care neither of the order according to which they run along the arcs of this transit network nor of the timestamps telling when they do it. Of course, we expect that computing those projected vectors **F** and **f** will be easier than computing **F** and **f**. In order to perform this computation, we must characterize those vectors.

We see that **F** and **f** must be such that:

- **F** satisfies flow conservation at any vertex of X; (E5.1)
- for any node x of N: $\sum_{a \in \partial^+_N(x)} f_a - \sum_{a \in \partial^-_N(x)} f_a = b_x$; (E5.2)
- for any arc a of N: $f_a \leq Cap \cdot F_a$; (E6)

According to this, carrier riding cost c_2 and item riding time c_3 come as follows:

- carrier riding cost $c_2 = \beta \cdot \big(\sum_{a \in A} C_a \cdot F_a\big)$; (E7.1)
- items riding time $c_3 = \gamma \cdot \big(\sum_{a \in A} T_a \cdot f_a\big)$. (E7.2)

Still, this formulation is not enough in order to efficiently characterize **F** and **f**. First, (E5.1)-(E7.2) fail in estimating the carrier number $c_1 = H_{(sink, source)}$. In order to make our projected model provide a good estimation of the carrier number, we proceed as follows:

Approximating the carrier number: We first notice as in [12] that the quantity $\sum_{a \in A} T_a \cdot F_a$ means the global time that carriers spend running inside N, waiting times being excluded. Since the whole process must last no more than $Tmax$ time units, it requires at least $\left\lceil \frac{\left(\sum_{a \in A} T_a \cdot F_a\right)}{Tmax} \right\rceil$ carriers. Thus, (**F**, **f**) should minimize the *projected cost*:

$$PCost(\mathbf{F}, \mathbf{f}) = \alpha \cdot \frac{\left(\sum_{a \in A} T_a \cdot F_a\right)}{Tmax} + \beta \cdot \big(\sum_{a \in A} C_a \cdot F_a\big) + \gamma \cdot \big(\sum_{a \in A} T_a \cdot f_a\big).$$

Next, we notice that constraints (E5.1) and (E5.2) do not forbid subtours. In order to forbid subtours, we proceed in an augmented way:

The *Extended No-Subtour* Constraint: Given a subset $U \subset X \setminus \{Depot\}$. The time that carriers spend moving at the border or inside U, is equal to $\sum_{a \in \partial_N(U) \cup A(U)} T_a \cdot F_a$. For each carrier q, this time cannot exceed $Tmax$. If Q denotes the number of carriers involved into an IBP solution, then we see that $Q \cdot Tmax \geq \sum_{a \in \partial_N(U) \cup A(U)} T_a \cdot F_a$. Since $\sum_{a \in \partial_N^-(U)} F_a \geq Q$, we deduce that the following *Extended No-Subtour* inequality should hold:

$$Tmax \cdot \left(\sum_{a \in \partial_N^-(U)} F_a \right) \geq \sum_{a \in \partial_N(U) \cup A(U)} T_a \cdot F_a. \quad \text{(E8)}$$

This leads us to set the following *projected* problem about the search for $\mathbf{F}$ and $\mathbf{f}$:

PIBP: *Projected Item Balancing* Problem
$\{$*Compute on the network $N = (X, A)$ two nonnegative integral vectors A-indexed* $\mathbf{F}$ *and* $\mathbf{f}$ *such that:*

- $\mathbf{F}$ *satisfies flow conservation at any node of X;* (E5.1)
- *for any node $x \in X$, $\sum_{a \in \partial_N^-(x)} f_a - \sum_{a \in \partial_N^+(x)} f_a = b_x$;* (E5.2)
- *for any arc $a \in A$, $f_a \leq Cap \cdot F_a$;* (E6)
- *for any $U \subseteq X \setminus \{Depot\}$: $Tmax \cdot \left(\sum_{a \in \partial_N^-(U)} F_a \right)$ $\geq \sum_{a \in \partial_N(U) \cup A(U)} T_a \cdot F_a$;* (E8)
- *Minimize $PCost(\mathbf{F}, \mathbf{f}) = \alpha \cdot \frac{\sum_{a \in A} T_a \cdot F_a}{Tmax} + \beta \cdot \left(\sum_{a \in A} C_a \cdot F_a \right) + \gamma \cdot \left(\sum_{a \in A} T_a \cdot f_a \right)$.* (E9)$\}$

We proved in [12], that the *Extended No-Subtour* constraints may be separated in polynomial time. A consequence is that this projected problem may be efficiently solved while using a MILP library and implementing a Branch and Cut process.

III. The Expand Issue

So we come now to the *Expand* step. That means that we suppose that we have been computing ($\mathbf{F}$, $\mathbf{f}$) as above and that we want to derive ($\mathbf{H}$, $\mathbf{h}$) in a satisfactory way. First, we notice that, in many cases, there will not exist ($\mathbf{H}$, $\mathbf{h}$) whose projection is equal to ($\mathbf{F}$, $\mathbf{f}$). Figure 3 shows that a PIBP solution ($\mathbf{F}$, $\mathbf{f}$) may not be the projection of any feasible IBP TE-Network solution ($\mathbf{H}$, $\mathbf{h}$): The carrier must follow the route $(Depot, y, x, z, y, Depot)$ and will never be able to transport that way any item from z to x.

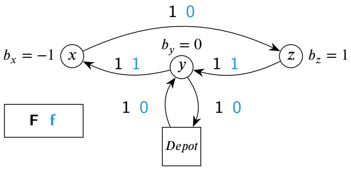

Fig. 3. A solution of PIBP which cannot be expanded.

So we must put some flexibility while setting our *Expand* issue. Namely, we should set it as follows: How can we derive from ($\mathbf{F}$, $\mathbf{f}$) a good full IBP solution ($\mathbf{H}$, $\mathbf{h}$)? In a more generic way, how can we efficiently deal with a TE-Network model while applying the following resolution scheme?

***Project/Expand* Decomposition Scheme.**

1) Solve a projected version of the problem which skips the temporal dimension.
2) Turn (*expand*) resulting solution ($\mathbf{F}$, $\mathbf{f}$) into a *"good"* solution ($\mathbf{H}$, $\mathbf{h}$) of the original problem, while restricting ourselves to a reduced representation of related TE-Network.

One feels that there are several ways to interpret above *expand* part of the process. Intuition would suggest to search for ($\mathbf{H}$, $\mathbf{h}$) such that ($\mathbf{F}$, $\mathbf{f}$) is the projection of ($\mathbf{H}$, $\mathbf{h}$). Such a setting is NP-Hard (see [8]). But the true problem is that both above example and numerical experiments show that such a setting is too strong and most often does not admit any feasible solution. So what we decide in the present case is to formalize step 2 while only requiring $\mathbf{f}$ to be the projection of $\mathbf{h}$. So we set the **Expand** problem as follows:

***Expand* Problem EXPAND(f).** $\{$*Compute a feasible IBP solution* ($\mathbf{H}$, $\mathbf{h}$) *such that:*

- *The projection of* $\mathbf{h}$ *on the transit network N is equal to* $\mathbf{f}$;
- *The cost value $Cost(\mathbf{H}, \mathbf{h})$ is the smallest possible.*$\}$

This **Expand** problem is difficult. One may check that EXPAND(f) contains both the **TSP**: *Traveling Salesman Problem* and the standard **Pick up and Delivery** problem. It is far more general, since we may by no way identify the arcs which support f with requests and must take care of the precedence relations implicitly related to those arcs. Above example of Figure 3 shows that part of our problem consists in determining in which order the arcs supporting $\mathbf{f}$ must be visited.

Before going further towards the design of algorithmic solution for this *Expand* problem, we must address the issue related to its feasibility: Can we characterize the conditions which will make this **Expand** problem admit a feasible solution? The answer is positive, and checking it is going to provide us with a reinforcement of the *Projected* model of Section II, that means with a way to compute ($\mathbf{F}$, $\mathbf{f}$) which will guaranty this feasibility.

Checking the Feasibility of EXPAND(f): Enhancing the PIBP model.
We just told that a too strong setting of the *Expand* issue could lead to unfeasible situations. So a natural question comes about the feasibility of above EXPAND(f problem. In order to deal with it, let us introduce the following notion of *feasible path*. A *feasible path* is a path that an item may follow while moving from an *excess* node to a *deficit* one, taking into account that the carrier which transports it must be able to move from the *Depot* node to the start-node of this path and next from the end-node of this path until the *Depot* node, within the time horizon $\{0, 1, \ldots, T_{max}\}$. Clearly, flow vector $\mathbf{f}$ should be such that all items may follow feasible paths. We formalize this by saying that:

- A *feasible path* of N is any path π from $x \in X^+$ to $y \in X^-$ whose length $L^T(\pi)$ in the sense of the time is such that: $D^T(Depot, x) + L^T(\pi) + D^T(y, Depot) \leq Tmax$. We denote by $\mathbf{f}^\pi$ related $\{0, 1\}$ flow vector and by Π^{FP} the set of feasible paths.
- Vector $\mathbf{f}$ is *feasible-path-decomposable* iff it can be written: $\mathbf{f} = \sum_{\pi \in \Pi^{FP}} \lambda_\pi \; \mathbf{f}^\pi$, with $\lambda_\pi \geq 0$.

Since any item in node $x \in X^+$ must be transported to some vertex $y \in X^-$ along a feasible path, we get that $\mathbf{f}$ must feasible-path-decomposable. But checking that $\mathbf{f}$ is feasible-path-decomposable is just a matter of solving a rational linear program, and characterizing the feasibility of this linear program may be done by using Duality Theory. More precisely, we define a *Path Feasibility* vector as any Π^{FP}-indexed vector $\mathbf{w} = (w_\pi, \pi \in \Pi^{FP})$ such that:

For any feasible path π, we have $\sum_{a \in \pi} w_a \geq 0$.

This allows to state:

Theorem 1: EXPAND(**f**) *is feasible iff, for any Path Feasibility vector* $\mathbf{w}$*, we have:* $\sum_{a \in A} f_a \cdot w_a \geq 0$.

Sketch of the Proof: Linear Programming Duality makes that (E10) holds iff **f** is feasible-path-decomposable. This property is clearly necessary in order to allow the existence of **H** and **h**. We get sufficiency by considering such a decomposition of **f** and assigning to any item its own feasible path and a carrier which transports it along this feasible path. We explicitly build this way flow vectors **H** and **h**. **EndProof**

So we reinforce our **PIBP** model by imposing vector **f** to be feasible-path-decomposable:

For any *Path Feasibility* vector **w**: $\sum_{a \in A} f_a \cdot w_a \geq 0$. (E10)

Theorem 2: *(E10) can be separated in polynomial time.*

Sketch of the Proof: Every time we are provided with a flow vector **f** (rational or integral) we search for a *feasible-path* decomposition of **f**. This means solving some linear program with respect to some current collection Λ of feasible paths. In case of failure, then we apply duality and generate another feasible path, until we succeed or we get a *Path Feasibility* vector which contradicts (E10). The time-polynomiality of this separation process derives from the time-polynomiality of Rational Linear Programming. **EndProof**

It comes that the **PIBP** model reinforced by (E10) may be efficiently handled through Branch-and-Cut.

IV. A Bi-Level Decomposition Scheme for the Expand Problem

The purpose of this section is to show the way the **Expand** problem man be decomposed in a way which will allow us in next section V to implement both exact and heuristic algorithms. The main idea behind this decomposition scheme is that the quality of final solution (**H**, **h**) is mostly determined by the way items are routed. Intuitively, that means that we should first expand flow vector **f**, and next try to *cover* it by a carrier flow **H** according to the following 2-step approach:

1st step: *Expand* item flow **f** into an item flow **h** on the TE-Network N^{Tmax}, while relying on a specific $Split(N,$ **f**) network. This network is going to split those arcs and nodes of network N which are supporting **f** (in practice, it will mean few arcs and nodes) according to item packages likely to be carried by the same carriers. This will allow us to make appear the feasible paths followed by the items when moving from an excess node to a deficit nodes. Providing *ad hoc* time values to the nodes exploded this way will yield item flow vector **h**.

2nd step: Once **h** has been fixed, extend **h** into a good (best) solution IBP (**H**, **h**), while solving a Min-Cost Flow problem on the *active* part of a specific $Carrier(N,$ **f**) network. Network $Carrier(N,$ **f**) is going to extend above mentioned network $Split(N,$ **f**) in order to make appear the possible moves performed by the carriers. Related *active* part will be made of the arcs which are consistent with the time values related to vector **h**.

Linking 1st step and 2nd step: The quality of the resulting solution deeply depends not only on the route followed by the items, but also on the time values of the vertices related to **h** in N^{Tmax}. We shall delay, as long as possible, the instantiation of those time values while relying on a flexibility device which will take the form of a collection Λ of arcs common to both $Split(N,$ **f**) and $Carrier(N,$ **f**). This device will identify the moves that carriers and items are allowed to perform when switching from an arc of N supporting items to another one. This arc collection Λ will become the master object of a bi-level *Split/Carrier* decomposition scheme.

A. The Networks Split(N, f) and $Carrier(N, f)$

The Network $Split(N,$ **f**).

The purpose of the network $Split(N,$ **f**) is to help us in describing the way items traverse any vertex x of the network N, and so the trajectories followed by the items when moving from the excess nodes to the deficit ones. So we build it while relying on the arcs of network N which support non null **f** and exploding the nodes involved into those arcs in order to make appear the routes followed by the items.

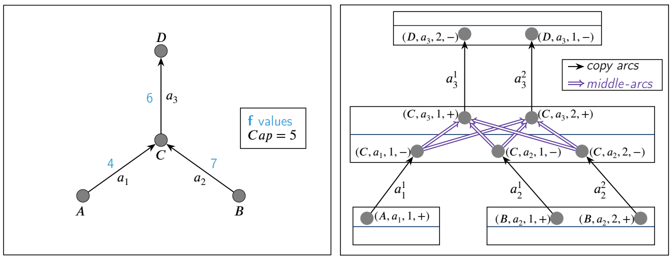
Nodes of $Split(N,$ **f**): With any arc $a = (x, y) \in A$ such that $f_a \geq 1$, we associate $\lceil \frac{f_a}{Cap} \rceil$ *copy-arcs* $a^m, m = 1, \ldots, \lceil \frac{f_a}{Cap} \rceil$, with respective origin $p = (x, a, m, +)$ and respective destination $q = (y, a, m, -)$. We denote by $Copy(a)$ the set of those arcs $a^m, m = 1, \ldots, \lceil \frac{f_a}{Cap} \rceil$. At the same time we create those copy-arcs, we also create *copy-nodes* $p = (x, a, m, +)$ and $q = (y, a, m, -)$, which respectively correspond to the carriers who leave x with a non-null load and to the carriers who arrive into y with a non-null load. Resulting node set X^* becomes the node set of $Split(N,$ **f**). We denote by $Copy(A)$ the set of all those copy-arcs. For any node $p = (y, a, m, \varepsilon)$ of X^*, we set $x(p) = y$ and $\varepsilon(p) = \varepsilon$. Also, for any node y of N, we set:

- $X^*(y) = \{p \in X^* \text{ such that } x(p) = y\}$;
- $X^*Plus(y) = \{p \in X^* \text{ such that } x(p) = y$ and $\varepsilon(p) = +\}$;
- $X^*Minus(y) = \{p \in X^* \text{ such that } x(p) = y$ and $\varepsilon(p) = -\}$.

Arcs of $Split(N,$ **f**): We complete the arc collection $\{a^m$, $a = (x, y)$, such that $f_a \geq 1$, $m = 1, \ldots, \lceil \frac{f_a}{Cap} \rceil\}$ by *middle-arcs* which, for any node x of N, connect copy-nodes $(x, a, m, -)$ (with a arriving into x), $m = 1, \ldots, \lceil \frac{f_a}{Cap} \rceil$ to copy-nodes $(x, a', m', +)$ (with a' starting from x) $m' = 1, \ldots, \lceil \frac{f_a}{Cap} \rceil$. We denote by $Middle$ the set of all middle-arcs created that way, and, for any node x of N, we denote by $Middle(x)$ the set of all middle-arcs u whose origin may be written $(x, a, m, -)$. $Middle(x)$ defines a complete bipartite graph on the nodes of $X^*(x)$. For any vertex $p = (x, a, m, +)$, we denote by $MiddleIn(p)$ the set of middle-arcs u with destination p, and for any vertex $q = (x, a, m, -)$, we denote by $MiddleOut(q)$ the set of middle-arcs u with origin q. We also set:

- $CopyIn(y) =$ $\{a \in Copy(A)$ with destination in $X^*Minus(y)\}$;
- $CopyOut(y) =$ $\{a \in Copy(A)$ with origin in $X^*Plus(y)\}$.

We denote by $Split(N, \mathbf{f})$ the resulting network, that one may check to be acyclic. This construction is illustrated in Figure 4.



(a)

(b)

Fig. 4. Building the $Split(N, \mathbf{f})$ Network

The network $Carrier(N, \mathbf{f})$.
This network is going to help us in computing the carrier routes, in such a way that those carrier routes *cover* the item routes. So, it will contain exactly the same nodes as the network $Split(N, \mathbf{f})$, but two additional nodes *source* and *sink*. Its arcs will express all the ways a carrier may move from an arc supporting items to another one while following a shortest path in N i the sense of vector $\mathbf{C}$. Depending on the time values assigned to its nodes, those arcs will be allowed or not to support non null carriers flow values. It comes that this network will behave as a flexible reduced version of N^{Tmax}.

Nodes of $Carrier(N, \mathbf{f})$: They are all nodes of $Split(N, \mathbf{f})$, augmented with two nodes $source$ and $sink$. We denote by $V(Carrier)$ the node set of $Carrier(N, \mathbf{f})$.

Arcs of $Carrier(N, \mathbf{f})$: They are the arcs of $Split(N, \mathbf{f})$ augmented with:

- one *back* arc $u = (sink, source)$, provided with cost $Q_u = \alpha$;
- any *in* arc $u = \big(source, p = (x, a, m, +)\big)$, $p \in X^*$, provided with a cost Q_u equal to the cost of a time-minimal path (in the sense of cost matrix $\mathbf{C}$) from $Depot$ to x;
- any *out* arc $u = (p = (x, a, m, -), sink)$, $p \in X^*$, provided with a cost Q_u equal to the cost of a time-minimal path from x to $Depot$;
- any *transverse* arc $u = \big(p = (x, a, m, -),\ q = (y, a', m', +)\big)$, with $p, q \in X^*$, provided with a cost Q_u equal to the cost of a time-minimal path from x to y.

We denote by $A(Carrier)$ the arc set of the network $Carrier(N, \mathbf{f})$.

B. The Split/Carrier Decomposition Scheme

The way item flow values f_a, $a \in \partial_N^-(x)$ arriving into a node x distribute themselves into values $f_{a'}$, $a' \in \partial_N^+(x)$ leaving x while moving through x, is going to be described by two integral vectors $\mathbf{z} = \big(z_u,\ u = \big((x, a, m, -), (x, a', m', +)\big) \in Middle\big)$, and $\mathbf{z}^* = \big(z^*_{a^m},\ a^m \in Copy(A)\big)$. Those two vectors will provide us with an *expanded* vector $\mathbf{h}$ once we assign time values t_p to the nodes p of the $Split(N, \mathbf{f})$. On the other side, the routes followed by the carriers are going to be described by a $\{0, 1\}$-valued flow vector $\mathbf{Z}$ defined on the arcs of the network $Carrier(N, \mathbf{f})$. In order to link those vectors $\mathbf{z}$, $\mathbf{z}^*$, $\mathbf{t}$, and $\mathbf{Z}$ together we need a *mediator* object. This *mediator* object is going to be here a collection Λ of arcs in $A(Carrier)$, providing us with the *transverse* arcs and the *middle* arcs supporting the item and carrier moves. It will induce the following constraints:

- on the time vector $\mathbf{t} = (t_p, p \in V(Carrier))$: for every arc (p, q) in Λ, $t_q \geq t_p + D^T(x(p), x(q))$, which means that any carrier or item move along an arc of the network $Carrier(N, \mathbf{f})$ requires a time at least equal to the length of the path in N which is related to such an arc;
- on the $\mathbf{z}$ vector: for every *middle-arc* $u = (p, q)$ which is not in Λ, $z_u = 0$;
- on the flow vector $\mathbf{Z}$ representing the carrier routes on the network $Carrier(N, \mathbf{f})$: for every *transverse* arc $u = (p, q)$ which is not in Λ, $Z_u = 0$.

More precisely, once Λ has been determined, we get that vector $\mathbf{t}$ must satisfy the following linear constraint system CTIME(Λ), with underlying totally unimodular constraint matrix.

CTIME(Λ) constraint system on $\mathbf{t} = (t_p,\ p \in X^* \cup \{source, sink\})$:

- $t_{source} = 0$; (E11)
- $t_{sink} \leq Tmax$; (E12)
- *For any in arc* $u = \big(source, p = (x, a, m, +)\big)$, $p \in X^*$: $t_p \geq D^T(Depot, x)$; (E13)
- *For any out arc* $u = \big(p = (x, a, m, +), sink\big)$, $p \in X^*$: $Tmax \geq D^T(x, Depot)$; (E13-1)
- *For any copy arc* $u = \big(p = (x, a, m, +), q = (y, a, m, -)\big)$, $a = (x, y) \in A$ *such that* $f_a \neq 0$: $t_q \geq t_p + D^T(x, y)$; (E13-2)
- *For any arc* (p, q) *in* Λ: $t_q \geq t_p + D^T(x(p), x(q))$. (E13-3)

As for vectors ($\mathbf{z}$, $\mathbf{z}^*$), they must express the way items move from any arc a support of $\mathbf{f}$ in N and with destination x to another one with origin x. More precisely:

- $\mathbf{z}$ is going to express, for any node x of network N, the way items arriving along a copy-arc a^m into a copy-node $q = (y, a, m, -)$ are going to distribute themselves among the copy-arcs $a'^{m'}$ leaving x. Clearly, the feasibility of this distribution process will impose Λ to contain enough arcs of $Middle(x)$.

- $\mathbf{z}^*$ is going to express, for any arc a of network N, the way item flow values f_a distribute themselves among the copy-arcs related to a.

This yields the following linear constraint system Split(N, **f**, Λ), with underlying totally unimodular matrix and whose feasibility depends on Λ:

Split(N, f, Λ) constraint system on vectors z, z*:

- *For any copy-arc* a^m: $z^*_{a^m} \leq Cap$. (E14)
- *For any copy-node* $q = (y, a, m, -)$: $z^*_{a^m} \leq \sum_{u \in MiddleOut(q)} z_u$. (E15)
- *For any copy-node* $p = (x, a, m, +)$: $z^*_{a^m} \geq \sum_{u \in MiddleIn(p)} z_u$. (E16)
- *For any node x of N*: $\sum_{v \in CopyIn(x)} z^*_u = \sum_{u \in Middle(x)} z_u + \max(-b_x, 0)$. (E17)
- *For any node x of N*: $\sum_{v \in CopyOut(x)} z^*_u = \sum_{u \in Middle(x)} z_u + \max(b_x, 0)$. (E18)
- *For any middle-arc* $u \notin \Lambda$: $z_u = 0$. (E19)

Finally, the flow vector **Z** with indexation on the arcs of $Carrier(N, \mathbf{f})$ and which is going to provide us with the arcs and paths followed by the carriers, should be a solution of the following Min-Cost Flow model Carrier(N, **f**, Λ).

Carrier(N, f, Λ) constraint system on vector **Z**:

- **Z** *satisfies flow conservation.* (E20)
- *For any arc u in Copy(A)*: $Z_u = 1$. (E21)
- *For any transverse or middle arc* $u \notin \Lambda$: $Z_u = 0$. (E22)
- *Cost value* $\sum_{u \in A(Covering)} Q_u Z_u$ *is minimal.* (E23)

We may now reformulate the **Expand** Problem as the following bilevel ([19]) setting.

***Split/Carrier* Reformulation of the Expand Problem.** *Compute $\Lambda \subseteq A(Carrier)$ restricted to middle and transverse arcs, such that:*

- CTIME(Λ) *admits a feasible solution;*
- Split(N, **f**, Λ) *admits a feasible solution* (**z**, **z***)*;*
- *The optimal value* $\sum_{u \in A(Carrier)} Q_u Z_u$ *of* Carrier(N, **f**, Λ) *is minimal.*

It may happens that above *Split/Carrier* model does not admit any feasible solution, while the **Expand** Problem is feasible. In such a case, we say that **f** is *Split/Carrier* {inconsistent. Figure 5 displays an example of such a situation:path A, B, C, D is not a feasible path and so **f** must be decomposed into 2 feasible paths, while the Split(N, **f**, Λ) model would allow only 1 feasible path. However, numerical experiments will show that it happens very scarcely.

Still, we may state:

Theorem 4.1: *Any feasible solution of above Split/Carrier model is a feasible solution of EXPAND(f), with same cost.*

Sketch of the Proof: It comes through an algorithmic construction of (**H**, **h**) from arc collection Λ. Time vector **t** obtained through resolution of CTIME(Λ) allows us to embed the nodes of the network $Carrier(N, \mathbf{f})$ into the time expanded network $N^{Tmax} = (X^{Tmax}, A^{Tmax})$. Then we derive **h** from a solution (**z**, **z***) of Split(N, **f**, Λ) and we derive **H** from a solution **Z** of Carrier(N, **f**, Λ). **EndProof**

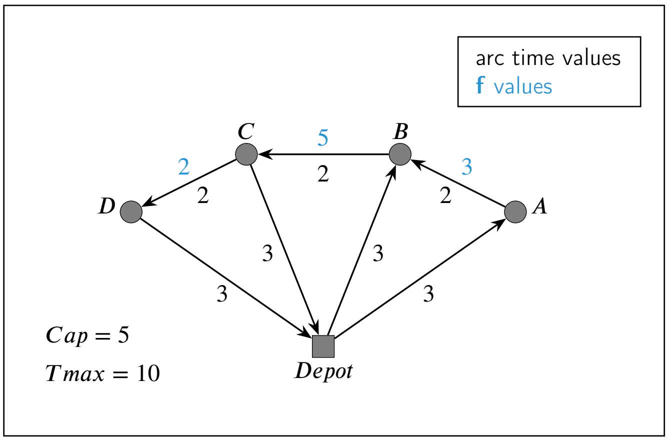


Fig. 5. *Split/Carrier* Inconsistent Flow Vector **f**)

V. Algorithmic Handling the *Split/Carrier* Decomposition Scheme

The *Split/Carrier* decomposition scheme involves, as its master object, a collection Λ of arcs of the $Carrier(N, \mathbf{f})$ network. Constraints of Split(N, **f**, Λ) are transportation constraints set on a bipartite graph. Carrier(N, **f**, Λ) is a Min-Cost Flow model while CTIME(Λ) is about the computation of the largest path in an acyclic graph ([4]). It comes that those 3 sub-problems may be viewed as *easy* and that we may rely either on Carrier(N, **f**, Λ) duality or on the largest paths which arise from the resolution of CTIME(Λ) in order to drive the master object Λ. We are going to describe here the ways we implemented this idea.

A. An Exact MILP Resolution

We turn previous *Split/Carrier* decomposition scheme into an Expand(N, **f**) MILP model. We do it by considering vectors **Z**, **z**, **z*** and **t** as in above Section IV, introducing an additional vector $\mathbf{X}^\Lambda$ with indexation on the *middle* and *transverse* arcs of the $Carrier(N, \mathbf{f})$ network, and merging the programs CTIME(Λ), Split(N, **f**, Λ and Carrier(N, **f**, Λ) into a unique one, according to the following modifications:

- (E13-3) is replaced by: For any *transverse* or *middle* arc $u = (p, q)$: $t_q \geq t_p + D^T(x(p), x(q))$.
- (E19) is replaced by: For any*middle* arc u: $z_u \leq X^\Lambda_u$.
- (E20) is replaced by: For any *transverse* or *middle* arc u: $Z_u \leq X^\Lambda_u$.

B. A Greedy Dual_Carrier Algorithm

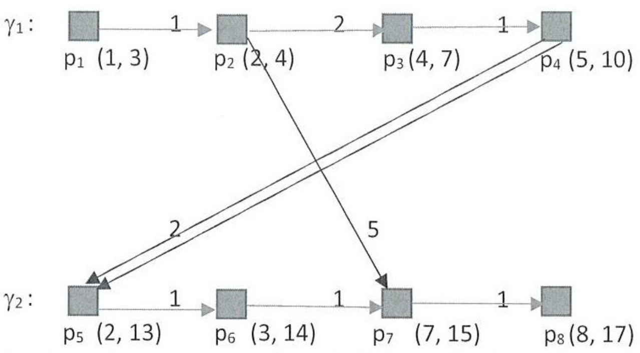
This algorithm works in a greedy way, while making increase the arc collection Λ. We first initialize Λ in such a way that the constraint system Split(N, **f**, Λ) admits a solution. We do it by removing constraint (E19), and defining Λ as the set of *middle* arcs which support non null **z** values. Then, at every iteration of the main loop of the greedy process, we are provided with some current arc collection Λ, and we use a feasible solution **t** of CTIME(Λ) in order to set a version of the min-cost flow model which replace (E22) by:

For any (*transverse* or *middle*) arc (p, q) such that:
$t_q < t_p + D^T(x(p), x(q))$, we have $Z_u = 0$. (E32-1)
This may be summarized as follows:

- 1st step: Solve the Split(N, **f**, Λ) while considering only constraints (E14)-(E18). Derive vectors $\mathbf{z}^*$ and **z** and ℓ, and initialize Λ with the arcs of the network $Carrier(N, \mathbf{f})$ which support $\mathbf{z}^*$ and **z**.
- 2nd step: While Not $Stop$ do:
  1) Get a feasible solution **t** of CTIME(Λ;
  2) Solve the Carrier(N, **f**, Λ) Min-Cost Flow model modified by replacing (E22) by (E22-1);
  3) Search for an arc (p, q) whose insertion into Λ makes related dual solution become infeasible and maintains the feasibility of CTIME(Λ). If $Success(Search)$ then insert this arc into Λ else $Stop$.

C. A Greedy Path_Concatenate Algorithm

Once again, we make the collection Λ increase, while using the CTIME(Λ) constraint system in order to deduce, at any iteration of the main loop, which arc (p, q), with $p = (x_1, a_1, m_1, -)$ and $q = (x_2, a_2, m_2, +)$ has to be inserted in Λ.



Arc (p2, p7) means a *transfer* path, followed by items from p2 to p7, with **T**-Length 5.
Arc (p4, p8) is candidate for insertion into Λ, with **T**-Length 2
Time windows after insertion: p5 (12, 13); p6 (13, 14);
p7 (14, 15); p8 (15, 17)
Notice that arc (p8, p4) is not eligible for insertion into L.

Fig. 6. *Concatenating 2 carrier paths γ_1 and γ_2)*

More specifically, we first solve Split(N,**f**, Λ) obtained while removing constraint (E19) and initialize collection Λ with the *middle* arcs which support non null **z** values. Then we compute some feasible solution **t** of CTIME(Λ), set $\Lambda(\mathbf{t}) = \{(p, q) \in A(Carrier) : t_q \geq t_p + D^T(x(p, x(q)))\}$, and solve the Carrier($N$, **f**, $\Lambda(\mathbf{t})$) Min-Cost Flow problem. This provides us with an initial solution **H**, as well as with a collection Γ of paths that the carriers follows between the first time they load some item and the last time they unload an item.

Next we proceed iteratively, while trying at every iteration to concatenate two paths γ_1 and γ_2 of Γ into a unique one as in ([10]), so that a same carrier can follow those two paths and go back to $Depot$ without violating the time horizon constraint (see Figure 6). We do it, while relying on constraint propagation, in such a way that resulting path is the shortest possible in the **C** sense.

More precisely, we proceed in two steps:

- **Initialization**: Solve Split(N, **f**, Λ) with $\Lambda = \emptyset$ and derive vectors **z**, $\mathbf{z}^*$ which will remain unchanged during all the process. Initialize Λ with the arcs of $Carrier(N, \mathbf{f})$ which correspond to non-zero **z** values. Compute some feasible solution **t** of CTIME(Λ), set $\Lambda(\mathbf{t}) = \{(p, q) \in A(Carrier) : t_q \geq t_p + D^T(x(p, x(q)))\}$, and solve resulting Carrier(N, **f**, $\Lambda(\mathbf{t})$) Min-Cost Flow problem. Derive an initial solution **H**, as well as a collection Γ of paths that the carriers follow between the first time they load some item and the last time they unload an item. Propagate current constraints of CTIME(Λ) and get, for any node $p = (z, a, m, \varepsilon) \in X^*$ a time window $[Inf_p, Sup_p]$, with $Sup_p \geq T_{max} - D^T(x, Depot)$ and $Inf_p \leq D^T(Depot, x)$.
- **Main Loop**: It works as follows:
  1) Denote by $StartCarrier$ the set of all nodes $p_1 = (x_1, a_1, m_1, +)$ which are the start nodes of the paths of current collection Γ and by $EndCarrier$ the set of all nodes $p_2 = (x_2, a_2, m_2, -)$ which are the end node of the paths of current collection Γ.
  2) Select $p_2 = (x_2, a_2, m_2, -) \in EndCarrier$ and $p_1 = (x_1, a_1, m_1, +) \in StartCarrier$ such that $Inf_{p_2} + T_{max} - Sup_{p_1}$ does not exceed T_{max}, which also means $Inf_{p_2} \leq Sup_{p_1}$, and such that $Sup_{p_1} - Inf_{p_2}$ is largest possible. If $Fail(Select)$ then $Stop$ else keep on with 3) and 4).
  3) Insert arc (p_2, p_1) into Λ. Update the time windows induced by the constraint system CTIME(Λ) and compute some feasible solution **t** of CTIME(Λ).
  4) Set $\Lambda(\mathbf{t}) = \{(p, q) \in A(Carrier) : t_q \geq t_p + D^T(x(p, x(q)))\}$ and solve the Carrier(N, **f**, $\Lambda(\mathbf{t})$) Min-Cost Flow problem. Update accordingly the best solution **H** ever found.

  Stop occurs at instruction 2), when it is not possible to find a new arc (p_1, p_2) to insert into collection Λ.

D. Numerical Tests

According to this, we perform several numerical experiments, whose purpose is 3-sided:

1) Evaluating the error induced by the projection step, that means the gap between the value of the projected **PIBP** model and the value of the full TE-Network model.
2) Evaluating the error induced by the 2-step *Project and Expand* process, with respect to a theoretical value which would be obtained by solving in an exact way the full TE-Network **IBP** model.
3) Evaluating the ability of both heuristics *Dual_Carrier* and *Path_Concatenate* to compute in a short time an

efficient solution, with respect to the value obtained from application of a MILP library to the exact model Expand(N, **f**).

Technical Context: We run those experiments on a computer with a 2.3GHz Intel Core i5 processor and 16GB RAM, while using the C++ language (compiled with *Apple Clang 10*) and the CPLEX12.10 MILP library.

Instances: No standardized benchmarks exist for the generic IBP. So we built instances as follows: the node set X is a set of n points inside a 100×100 grid, the set of arcs A consists of m arcs generated randomly, the time matrix **T**= $(T_{(x,y)}, (x,y) \in A)$ corresponds to the rounded Euclidean Distance and the cost matrix **C**= $(C_a, a \in A)$ to the Manhattan Distance. Each node x but *Depot* is assigned to a b_x value in $\{-10, \dots, 10\}$, the capacity Cap is chosen in $\{2, 5, 10, 20\}$, and the time horizon limit $Tmax$ is a product $\lambda \cdot (\max_{(x,y) \in A} T_{(x,y)})$ when choosing $\lambda \in \{4, 5, 6, 8, 9\}$. The scaling coefficients α, β, γ are chosen in such a way that the values of cost components $\alpha \cdot$ *number of carriers*, $\beta \cdot$ *carrier riding cost* and $\gamma \cdot$ *items riding time* become comparable.

Outputs. Table I involves 15 instances and displays:

- Values n, m, respectively the number of vertices and arcs of the base network N.
- Values Cap, $Tmax$, respectively the carrier capacity and the time horizon value.
- Values **G1**, **V1**, respectively the optimal value of the projected model and related carrier number.
- Values **G**,**V**, respectively an upper bound value of the full TE-Network IRP model computed by the CPLEX library in no more than 1 h (this relatively short time limit is due to the fact that we use a personal computer), and related carrier number.

Table II involves the same instances as table I and displays:

- Values **GDC**,**VDC**, **TDC**, respectively the value computed by the *Dual_Carrier* Algorithm, related carrier number and related running time (in seconds).
- Values **GPC**,**VPC**, **TPC**, respectively the value computed by the *Path_Concatenate* Algorithm, related carrier number and related running time (in seconds).
- Values **GL**,**VL**, respectively the optimal value computed of the exact MILP Expand(N, **f**) model (computed through CPLEX Library) and related carrier number.
- Missing values are indicated by a hyphen symbol -, and correspond to PIBP solutions **f** for which the Expand(N, **f**) MILP is unfeasible.

Comments: The *Path_Concatenate* heuristic finds feasible IBP solutions for most instances but only 1, which happens not to be *Split/Carrier* consistent. Also, by comparing values **GDC** and **GPC**, **TDC** and **TPC**, **VDC** and **VPC**, we see that most of the time the solutions found by the *Path_Concatenate* heuristic have lower costs, involve fewer vehicles, and have required lower running times than the solutions computed by the *Dual_Carrier* Algorithm. Finally, comparing values **G**, **GL**, **V** and **VL** shows us that the *Project/Expand* decomposition scheme yields a very good approximation of the optimal value of the TE-Network IBP model. By the way, we notice an instance (instance 12) which really puts the MILP solver in trouble. Examining this instance makes appear that it is very tight, and admits few efficient feasible solutions. Moreover, related vehicle number coefficient α is rather large. So we feel that it was difficult for the MILP solver to turn rational solution into feasible integral solutions.

VI. CONCLUSION

We just presented a *Project/Expand* decomposition scheme for the handling of 2-commodity flow problems set on TE-

Networks and involving a coupling constraint. We focused here on the *Expand* issue, and proposed approaches based on the implicit management of the TE-Network.

Still, some issues remain open. One of them is the time dependency, when the state of the network evolves over time. Another one is about dynamicity and robustness since routing decisions are usually taken in a dynamic way and must cope with some uncertainty.

***Abstract*—Nowadays, organizations must invest strategically in information technology (IT) and choose the right digital initiatives to maximize their benefit. Nevertheless, Chief Information Officers still struggle to communicate IT costs and demonstrate the business value of IT. The goal of this paper is to support their effective communication. In focus groups, we analyzed how different stakeholders perceive IT costs and the business value of IT as the basis of communication. We identified 16 success factors to establish effective communication. Hence, this paper enables a better understanding of the perception and the operationalization of effective communication.**

Index Terms— **Effective Communication, Perception, Success Factors, IT Costs, IT Business Value, Business-IT Alignment, COBIT.**

I. Introduction

FOR DECADES, organizations face pressure to operate efficiently and manage resources and spendings strategically and in times of inflation and war this pressure even increases [1]. To remain competitive and mitigate security risks, those organizations raise their expenditures in information technology (IT) [2] and strive to choose the right digital initiatives [3]. Therefore, they require strategic cost management [4] and successful communication about IT costs and the benefit they generate through their IT investments [5]. However, for 63% of 166 interviewed Chief Information Officers (CIOs), it is still a challenge to communicate this business value of IT [6], which is also confirmed by other studies [7] [8]. Similarly, decision-makers struggle to foster transparent cost discussions [8]. This is why in this paper we aim to understand how IT costs and the business value of IT are perceived and communicated effectively.

Effective communication describes the "bidirectional exchange" [9] of information resulting in common grounds [10]. The foundation of effective communication and the premise to achieve business value from IT is the alignment between business and IT department [11]. Researchers extensively investigate the success factors for business-IT alignment (BITA) and the resulting impacts of better communication on their relationship [12–14]. This relationship also influences the effective communication of IT cost and the business value of IT itself [15–17]. Besides BITA, studies highlight further aspects of business value communication such as common language [15] or appropriate methods and metrics [16]. Furthermore, the perception of the stakeholders plays a decisive role in communication [18]. However, research does not examine the perception of IT costs and business value in connection with their successful communication in detail. Furthermore, a comprehensive overview of success factors for communication following an established framework [15] that supports the operationalization of conceptual models [19] is missing. Our study aims to fill these research gaps: we conduct focus group interviews to get practical insights and generate an overview using the established governance framework *COBIT* [20]. Thereby, we contribute to scientific research by shedding light on the current perception of IT cost and business value of IT and their communication. Furthermore, we present the success factors and support the operationalization of effective communication. Additionally, this study has practical implications: practitioners can use the results to recognize symptoms of non-constructive communication in their organizations and to gain awareness on how to develop an effective communication of cost and IT business value.

This paper is structured as follows: First, we introduce our theoretical foundation related to the communication between business and IT department. We thereby focus on enterprise governance of IT, business-IT alignment, and aspects of cost and value communication. We then show our research method, which comprises focus groups followed by a qualitative analysis. Finally, we present our findings, discuss them, and draw a conclusion.

II. Theoretical background for the communication between business and IT

Collaboration between business and IT department is the baseline for achieving IT business value [21]. The basic elements for this collaboration are structures, processes, and relational mechanisms defined and implemented as enterprise governance of IT (EGIT) [22]. Business-IT Alignment (BITA) thereby acts as a “mediating mechanism” between EGIT and IT business value [22]. It builds the base for effective communication between the business and IT departments [23]. The conceptual model in Fig. 1 presents this relationship. In the following, we describe the mentioned three elements for effective communication. In this paper, we refer to effective communication as “bidirectional exchange” [9] of the interlocutors to develop a “similar representation” [10] of the conversation content.

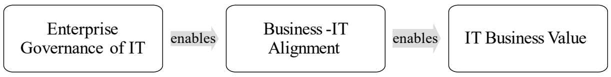

Fig. 1. EGIT-Alignment-Value Conceptual Model following [22]

A. Enterprise Governance of IT

A successful EGIT leads to better controllability of IT and consequently to greater business impact [24]. In order to achieve this successful governance, research intensively investigates determinants leading to an “integrated model of IT governance success and its impact” [25]: success factors analyzed in this context are e.g. the understanding of the IT value chain, top management commitment, IT’s business orientation, and the persuasiveness of communication. To establish successful governance and management of IT, the *Information Systems Audit & Control Association* (ISACA) presents COBIT as a “good-practice framework” with guidelines for organizations [19]. Following the core model of the most recent ***C**ontrol **OB**jectives for **I**nformation and Related **T**echnology 2019* framework, organizations should establish a governance system built from several components [22]: (1) Organizational Structures, (2) Processes, (3) People, Skills, and Competencies, (4) Information, (5) Culture, Ethics, and Behavior, (6) Services, Infrastructure, Applications, (7) Principles, Policies, and Frameworks. Those components lead to a comprehensive and functioning governance system and influence effective IT management [20]. Therefore, earlier studies apply the components to ensure comprehensiveness [8] or use the COBIT framework to transfer the practical functioning to a conceptual framework [19]. COBIT highlights that open and transparent communication about performance enables establishing trust and “a good relationship between IT and enterprise” [20]. It thereby recommends organizations involving and aligning all relevant stakeholders from business and IT departments to overcome communication gaps [20].

B. Business-IT Alignment

The alignment between business units and IT departments is a construct that has been intensively studied for several decades [26] [27]. An established model to describe this relationship between business and IT [28] is the Strategic Alignment Model (SAM) presented by [11]: thus, alignment is based on the strategic fit between external and internal domains as well as the functional integration between business and IT domains. This leads to multivariate relationships between business and IT, always considering the linkage of three of those four domains as presented in Fig. 2. The first perspective *Strategy Execution* (1) is the most common alignment perspective. In this case, the business strategy operates as a driver for organizational decisions and then influences the design of the IT infrastructure. Alignment through *Technology Transformation* (2) also originates from the business strategy followed by an appropriate IT strategy. This then leads to the required IT infrastructure and processes. The third and fourth perspectives are driven by the IT strategy. For the *Competitive Potential* (3) perspective, emerging IT capabilities lead to new strategic orientations of the business such as new products and services. Their implementation follows through the adaption of the operational business processes. The *Service Level* (4) perspective describes how IT builds up infrastructure and processes to then better support business operations.

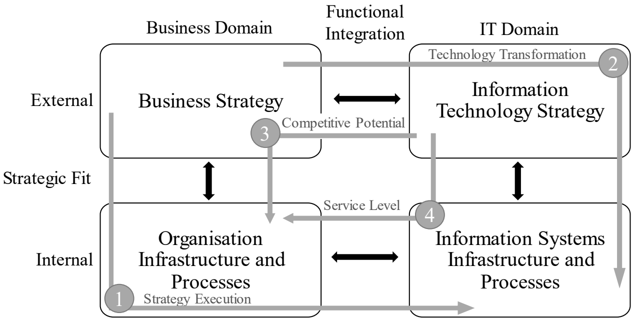

Fig. 2. Strategic Alignment Model following [11]

The alignment between business and IT is a communication and understanding-intensive continuous process [12] [11]. It is not a final state but rather described as “dynamic and evolutionary” [29]. To improve BITA, organizations need to consider six criteria including governance, partnership, scope and architecture, skills, value measurement as well as communication [29]. Depending on the maturity level of the alignment, the communication between business units and IT departments can be optimized and ideally lead to informal and pervasive communication [29]. Various enablers and inhibitors influence the maturity level of BITA and thereby also the effectiveness of communication and value measurement [14]. A literature review on such critical success factors of BITA presents those factors in three dimensions [13]: the human, the social, and the intellectual dimension. Success factors in the human dimension are IT skills & knowledge of business executives and vice versa as well as top management commitment, leadership skills of IT executives, and technical skills & knowledge of IT employees. The social dimension refers to a shared understanding of business

& IT executives, mutual trust & respect between business & IT executives, as well as business-IT partnership. On the intellectual dimension the alignment of business & IT strategy, goals & plans, as well as IT success, are critical for BITA. Those success factors indirectly influence effective communication regarding the costs and value of IT, since earlier studies highlight BITA itself an important factor for their effective communication [15].

C. IT Costs and Business Value of IT

In organizational communication of IT costs and business value, a shared perception often remains that "IT costs too much" [30]. Therefore, executives strive to determine the impact that IT has on the business. To measure this IT performance, research proposes diverse catalogs of key performance indicators (KPIs) [15]. For a variety of those KPIs, e.g. return on investment (ROI) [21], IT costs build the foundation [16]. Therefore, researchers develop conceptual frameworks to enable executives measuring the IT performance and thereby considering all IT-related costs as valid calculation basis [31]. They emphasize that not only the direct expenditures for development and implementation but also a variety of indirect costs related to human and organizational factors also count as IT costs [32]. However, organizations often still lack a clear understanding of the term "IT costs" and CIOs therefore face the challenge to transform non-constructive discussions about IT costs into a discussion about the business value contributed by IT investments [8]. "IT business value" is a concept that has been discussed in literature since the uprising of IT [33]. In line with former studies, we follow the understanding that IT business value is "measured by performance metrics on dimensions that stakeholders find important" [16]. As the perception of the stakeholders plays a decisive role in communication [18], they first need to have a common understanding of cost and value to achieve effective communication [16]. We address this current perception of the stakeholders in our first research question (RQ): *(1) What is the perception of business and IT stakeholders of "IT costs" and "IT business value"?*

Besides BITA and the common perception and understanding of the terms [16], further aspects influence the communication of IT costs and business value [15]. Transparency on IT cost information and the awareness of IT cost and cost drivers are a baseline to communicate IT costs and demonstrate the value of IT [8]. From this cost information, KPIs formulated in business language are an important factor for the effective communication of IT business value [16]. Furthermore, [29] mentions metric portfolios and dashboards to visualize value in communication. Business-IT structures that evaluate IT investments together also count as a success factor [34]. The value communication throughout the organization should then be audience-oriented using different channels [23]. To summarize relevant aspects of value communication, [15] conduct a literature review and investigate how to conceptualize value communication: They present different categories, e.g. transparency, understanding, collaboration, methods, transparent communication, and common language. However, research shows that especially establishing a common language and implementing collaboration on an equal footing is still difficult [8]. Therefore, CIOs still face the challenges of implementing successful communication [5] and demonstrating the business value of IT investments in their organizations [8]. They miss practicable success factors that operationalize the successful communication between business and IT on IT costs and IT business value. This gap leads to our second RQ: *(2) What factors do organizations need to consider for implementing an effective communication of IT costs and business value?*

III. Methodology

We follow the research method of focus groups because it enables academics to study specific topics in groups using focused interviews with a determined direction [35]. Earlier studies in IS make use of focus groups to evaluate design science artifacts [36], to develop a research agenda based on issues of merger & acquisition [37] or to identify factors related to the choice of students to study IT [38]. In small groups with an optimal size of 5 to 8 participants, specific topics may be studied in depth [39]. The direct feedback and the group interaction challenge interviewees' views and can inspire them to new ways of thinking which provide researchers with an in-depth view and innovative ideas [35]. It, therefore, enables researchers to get a wide variety of opinions or perceptions concerning an issue, behavior, or practice and thereby uncover factors that influence those opinions [39]. This is why focus groups support the aim of our study to understand the perception of IT costs and IT business value and get a broad view of the success factors of their communication. We divide our focus group study into two phases [37]: first, the planning phase, including the participant selection [39], and second, the sessions and the analysis.

A. Planning and Participant Selection

In order to achieve our research goal, we chose a single-category design for our focus groups and developed questions to guide the facilitation of the discussion [39]. The questions were open-ended to motivate participants to answer according to their specific situation [39]. The guiding questions are:

- What are we talking about when we talk about IT costs? Which costs belong to the total IT costs?
- What are we talking about when we talk about IT value? What is IT value for you?
- How do you communicate IT costs and the business value of IT within your organization?
- What are the challenges in those discussions?
- What is required to effectively communicate IT costs and IT business value in organizations?

To discuss these questions, we included a broad spectrum of people coming from different industries to cover a variety of perspectives. As a decisive criterion for the selection of the focus group participants, we specified that each of them must have a relevant responsibility and expertise in the communication of IT costs and IT business value. We followed the recommendation by [39] of 5 to 8 participants per focus group.

All participants were already part of the network of the research team. Table I provides an overview of the participants in the two focus groups.

TABLE I. PARTICIPANTS OF THE FOCUS GROUP SESSIONS

ID	Function	Industry (#Employees (EMP))
FG1-1	Head of IT Governance	Transportation (30.000 EMP)
FG1-2	CIO	Service Industry (600 EMP)
FG1-3	CIO	Electronics Manufacturing (1.000 EMP)
FG1-4	CIO	Pharmaceutical Industry (78.500 EMP)
FG1-5	CIO Office	Insurance (3.000 EMP)
FG1-6	Head of Value Mgmt.	Energy (91.000 EMP)
FG1-7	CIO	Infrastructure (1.000 EMP)
FG1-8	IT Controller	Energy and Agriculture (22.300 EMP)
FG2-1	Head of IT Governance	Transportation (2.700 EMP)
FG2-2	IT Controlling	Insurance (3.000 EMP)
FG2-3	IT Controlling	Retail (35.000 EMP)
FG2-4	Controlling	Electronics Manufacturing (1.000 EMP)
FG2-5	Controlling	Banking (2.500 EMP)
FG2-6	Controlling	Electronics Manufacturing (1.000 EMP)
FG2-7	IT Portfolio Management	Energy (91.000 EMP)
FG2-8	IT Controlling	Transportation (30.000 EMP)

B. Focus Group Sessions and Data Analysis

The focus group sessions were executed in September and October 2022. We facilitated the focus groups following the leading questions. We audio-recorded the sessions and took field notes during the discussions. We then conducted qualitative coding [40] across the group results to answer our research questions. The resulted figures for RQ1 were rediscussed in a second session with the focus groups. The coded factors for effective communication to respond to RQ2 were reviewed and adjusted in two further iterations by the research team, consisting of three researchers. We further applied selective coding to assign the 16 identified success factors to the COBIT components as displayed in earlier research [8]. Through the alignment of the factors to the categories, we ensure a holistic approach and the link to an existing framework [41] [8]. Following earlier research on success factors [42] [43], we chose the Ishikawa diagram to visualize the relationship between the identified factors. It further allows structuring the problem and the determining factors [43].

IV. FINDINGS

In the following, we outline our findings from the focus group sessions and thereby answer our research questions. To do so, we present the perception of IT costs and value and describe the factors for effective communication of IT costs and IT business value.

A. The perception of IT costs and IT business value

In this subsection, we describe the results for our first research question: *What is the perception of business and IT stakeholders of "IT costs" and "IT business value"?* We start with the perception of IT costs followed by IT business value.

IT cost perception

The interpretation of IT costs varies among the participants of the focus groups, ranging from *only the costs allocated to the IT department* to *all input factors related to information technology independent of the place of origin*. But even if they perceive all input factors related to IT as IT costs, shadow IT and new technologies such as Low Code Development Platforms, which are largely based in the business, are difficult to identify and capture. One interviewee therefore says that in their organization they estimate a proportion of IT costs for shadow IT to calculate the overall IT costs and proceed with their allocation to the business units (FG1-5). The participants further mention that product IT and operations IT are mainly neglected in their organizations' understanding and consequently management of IT costs. The perception of IT costs often differs from the employees in IT departments to business departments: while the IT department distinguishes between service development and operations or project implementation and management, business departments mainly realize total project or service costs. Furthermore, business stakeholders focus on charged costs such as managed workplace, IT management or overhead fees, service packages, or application licenses. One participant outlines that due to regular exchange and a clear corporate guideline concerning the definition of IT costs, stakeholders in his organization achieve a consensus on how to proceed with IT cost management even if their personal perception differs (FG1-2).

In collaboration with the participants, we develop a layer model on different perceptions of IT costs. Fig. 3 presents these different distinctions and levels of detail.

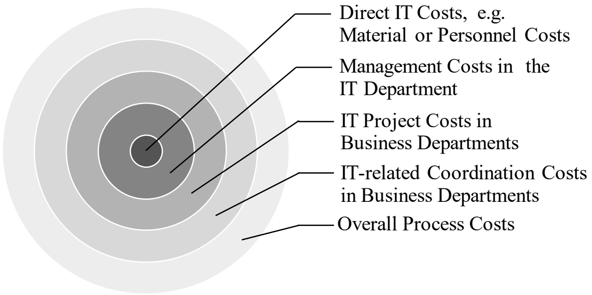

Fig. 3. Layers of IT cost perception

Direct IT costs related to activities assigned to the IT department are displayed in the first layer. With this commonly agreed inner layer, the focus group participants follow definitions of direct costs propagated by [31] and consider costs for the development and operation of hardware and software, personnel costs, external services, and shared services as general IT costs. The next layer comprises *management costs in the IT department*. They include the planning functions of IT, such as governance or enterprise architecture management, which only indirectly contribute to value creation. Most participants perceive these overhead costs as part of the overall IT costs that are "charged to the business units as overhead fee (FG2-1)". However, *IT project costs* that arise within *business departments* are often no longer fully attributed to IT costs. Those costs, displayed in the third layer, are related to activities such as process definition or testing within the business departments. The fourth layer comprises *IT-related coordination costs in business departments*. They primarily include the time spent by business departments on IT tasks such as training, key user activities, or committees for process and project portfolio coordination. Most focus group participants perceive these costs as IT costs but highlight, that they are only partially or not at all accounted as IT costs in their organizations. The consideration of *overall process costs* is only occasionally used for highly automated processes. However, the "effort of a holistic end-to-end consideration of all IT costs in a process does often not pay off" (FG1-3). Therefore, the interviews show that organizations rarely apply an integral approach such as activity-based costing and thereby perceive all costs related to IT throughout a whole process as IT costs.

IT business value perception

During the group interviews on perception, the participants acknowledge that measuring and presenting the business value of IT is a significant challenge. For most of them, the term "business value of IT" refers to the contribution of IT activities to the overall value of a company and perceived by the business. However, this perception varies between the stakeholders in the companies: especially the top management often only perceives value as financial benefits of IT. Therefore, the initial categorization of IT business value perception follows two dimensions: monetary and non-monetary. Typically, the monetary value contribution of IT is measured through revenue. The non-monetary value contribution, by contrast, is reflected by other features: the focus can be on enhancing business capabilities. Likewise, the added value can lie in the optimization of existing processes or capabilities. The external perception of customers or partners regarding new business fields or security risks can also determine the non-monetary added value of IT.

The collaboration between business and IT can also determine different perceptions of the business value of IT. The dimensions discussed in the focus group sessions relate to the SAM model and its alignment perspectives [11] displayed in Fig. 4: In terms of strategy execution (1), IT's added value lies in maintaining operational capability and sustaining the business. IT is an integral part of the business. It provides basic services and meets technical requirements to keep operations running. The alignment between business and IT, following the technology transformation perspective (2), ensures the business value of IT through the IT support for strategic differentiation. Here, the IT department functions as a strategic sparring partner in the development and implementation of the business strategy. IT builds strategic competencies and thereby supports the strategic differentiation of the organization. The participants mention IT's value through the provision of data, which enables better decisions to be made, e.g., for predictive maintenance or risk modeling. Besides that, IT can deliver value by enabling the growth of new business areas or the repositioning of the strategic product market combination through innovation. This can be achieved through an alignment on the competitive potential perspective (3) within SAM. Finally, with alignment on a service level perspective (4), IT's value lies in continuous improvement. The focus groups perceive this perspective of the business value of IT in the development of tools and processes that enable automation and process optimization. Here, the IT department builds new IT capabilities and through them offers opportunities to reduce costs and increase efficiency and effectiveness, as well as to support business capabilities.

B. Factors for Successful Communication

Next, we consider the findings that answer our second research question: *(2) What factors do organizations need to consider for implementing an effective communication of IT costs and business value?* Our findings show that organizations need to take into account various factors to operationalize a effective communication of IT costs and the business value of IT. The Ishikawa diagram in Fig. 5 illustrates those factors. In the following, we outline and describe the identified factors based on the seven components of the COBIT 2019 framework.

Organizational Structure

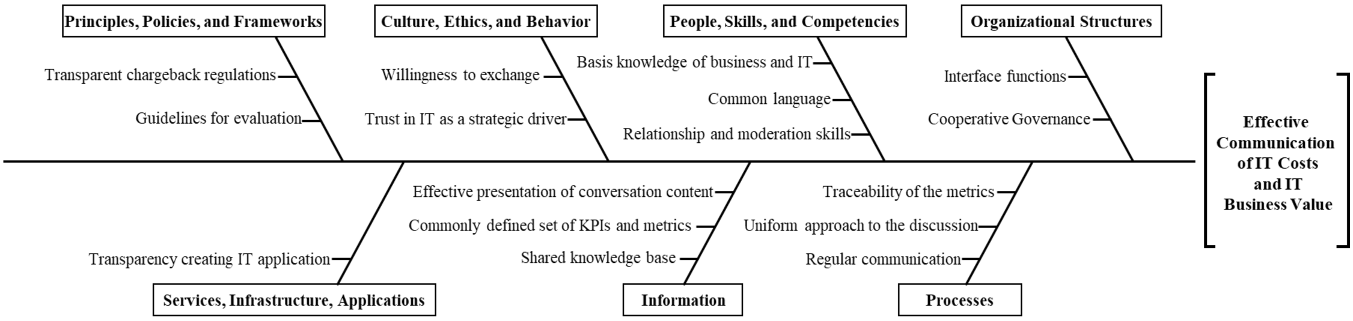
COBIT 2019 presents organizational structures as "key-decision making entities in organizations" [20]. For the effective communication of IT costs and business value, organizations require interface functions and cooperative governance as structural elements:

- **Interface functions:** establish key functions for the dialogue between the business and IT department.
- **Cooperative governance:** ensure responsibility and decision competencies of both business and IT communication part.

For the focus group, an important success factor are interface functions that communicate information on IT cost and business value between the IT department and the business. A key function should be situated within the IT department. However, a collaboration also requires a determined counterpart on the business side to become the "voice of IT within the business" (FG1-1). Those interface functions further request responsibilities for decision-making. Decisions then should be taken in cooperation to foster involvement and commitment on both sides. This cooperative governance enables a strategic discussion on IT investments and final metrics and leads to effective communication of the business value of IT. Additionally, top management should be involved in strategic discussions through boards and commit to decisions.

Processes

The component processes describes "activities to achieve certain objectives and [...] overall IT-related goals" [20]. Effective communication requires activities such as regular dialogues and a uniform approach to the discussion between



Principles, Policies, and Frameworks
Transparent chargeback regulations
Guidelines for evaluation
Culture, Ethics, and Behavior
Willingness to exchange
Trust in IT as a strategic driver
People, Skills, and Competencies
Basis knowledge of business and IT
Common language
Relationship and moderation skills
Organizational Structures
Interface functions
Cooperative Governance
Effective Communication of IT Costs and IT Business Value
Effective presentation of conversation content
Commonly defined set of KPIs and metrics
Shared knowledge base
Traceability of the metrics
Uniform approach to the discussion
Regular communication
Transparency creating IT application
Services, Infrastructure, Applications
Information
Processes

Fig. 5. Success Factors for Effective Communication of IT Costs and IT Business Value

business and IT. Furthermore, the tracking activity of metrics and committed tasks accounts for a success factor.

- **Regular communication:** establish a dialogue format between business and IT counterparts for regular communication.
- **Uniform approach to the discussion:** foster a defined approach to the evaluation and discussion of value.
- **Traceability of the metrics:** track the defined metrics and ensure commitments and consistency.

The participants stress the regularity of communication. They, therefore, propose a dialogue format to discuss the strategic use of IT and occurring costs. This dialogue should be integrated into the annual planning processes to ensure that the topics are incorporated into the budget plan. The frequency may vary depending on the business requirements. Secondly, a uniform approach to this discussion is crucial as it enables comparability and fairness. Furthermore, uniformity in the evaluation of IT investments ensures a clear methodology and transparency for all stakeholders. The participants highlight procedures such as the calculation and evaluation of business cases that require a consistent procedure. Finally, tracking the metrics and the communicated commitments is another important factor. It includes measuring business improvement against the business case and maintaining the business cases to demonstrate value over time. This requires not only a process responsible, but also all parties involved should have assigned tasks and be accountable for them. The liability of the stakeholders to those tasks then increases with a clear tracking activity.

People, skills, and competencies

Effective communication of IT cost and business value involve people with skills and competencies "for good decisions, execution of corrective action and successful completion of all activities" [20]. According to the focus groups, communication about IT costs and value often fails due to a lack of knowledge and know-how, both in the business and in the IT department, as well as a lack of efficiency in implementation. The involved stakeholders, therefore, require a basic knowledge of the business and IT domain, the competency to communicate about the costs and value associated with IT, as well as soft skills that enable effective communication and problem-solving.

- **Basic knowledge of business and IT:** build knowledge in business and IT departments to understand the specialization of the conversation partner.
- **Common language:** establish the competency to develop a common language to communicate IT costs and IT business value.
- **Relationship and moderation skills:** ensure effective communication tailored to the target group through relationship and moderation skills.

The development of knowledge is relevant for the interlocutors. Business employees require technical knowledge and awareness of challenges. They should understand the processes and workings of the IT department. Furthermore, they need skills to describe their requirements concerning IT or the problems and deficiencies they experience. IT employees, in contrast, need business knowledge about the capabilities and processes as well as methodical know-how on cost accounting. Furthermore, both conversation partners should establish a common language. This competency not only includes the common definition of IT costs and value but particularly understanding where the value of IT can be realized in the respective business units and for the whole organization. Business and IT counterparts should understand how to generate value and what drives the thereby occurring IT costs. For this conversation, soft skills are essential to build trust and communicate audience-oriented. The IT counterpart should "take a pragmatic approach and build a relationship through honesty" (FG1-3). Thereby, a "structured way of moderation" (FG2-8) strengthens the credibility and leads to an efficient conversation.

Information

The COBIT 2019 framework states that information is omnipresent throughout any organization [20]. The effective communication of IT costs and business value requires information to build a shared knowledge base. Additional success factors are a commonly defined set of KPIs and metrics and the effective presentation of the conversation content.

- **Shared knowledge base:** report basic information necessary to understand counterparts and find common ground.
- **Commonly defined set of KPIs and metrics:** agree on a set of metrics to measure IT performance quantitatively and qualitatively.

- **Effective presentation of conversation content:** visualize the information on IT cost and business value of IT appropriate for the respective stakeholders.

For the focus group participants, a shared knowledge base enables effective communication. It relates to a structured approach beginning with the alignment of the IT strategy with business objectives and financial constraints. This information leads to a common understanding in all interlocutors of how IT can contribute to the business and the complexity that may hamper the contribution of IT to business objectives. The focus of communication should be on the impact of IT use instead of purely cost-based discussions. This involves asking questions such as where IT can deliver value, what the costs are, and how they can be optimized, highlighting the strategic significance of IT. To communicate this business value, the stakeholders should come up with an agreed set of KPIs and metrics to measure IT performance. However, defining and implementing these KPIs is often a challenge. The participants, therefore, see an important factor in defining the KPIs in cooperation between business and IT. Moreover, they propose to use business capabilities as a baseline and to develop metrics that capture IT's contribution, both in terms of euro value and soft factors. Lastly, successful communication of IT cost and value requires an effective presentation. This entails the creation of a management-ready consolidation of the outcomes adapted to the communication standards of the organization. One participant also mentions a "portfolio visualization that enables better understanding in the business and that allows stakeholders to measure progress through the agreed targets" (FG1-6).

Culture, ethics, and behavior

The factors concerning culture, ethics, and behavior "are often underestimated" [20], however, for the focus groups, corporate culture plays an essential role in the effective communication of IT costs and business value of IT. They highlight the willingness to exchange information as well as the trust in IT to deliver value and drive the business strategically:

- **Willingness to exchange:** foster acceptance of IT as a discussion partner and the commitment to exchange information.
- **Trust in IT as a strategic driver:** foster awareness of the qualitative value proposition of IT instead of rather number-driven management.

The participants mention that they often face a "transparent wall" (FG2-5) between business and IT that hinders effective communication and the perception of the business value of IT. The commitment to exchange at all levels and the acceptance of the IT department as a "discussion partner at eye level" (FG1-1) counts as a success factor. Business and IT should commit together to savings and their consequences because a "successful exchange is also about putting the same intentions – the overall success of the company – in the center of attention" (FG2-7). Thereby, especially business employees should trust that IT may drive business development strategically. A shared worldview on the strategic importance of IT then enables effective communication with a common understanding and acceptance of possible value contribution of IT. The interlocutors should accept that besides the quantitative performance measures, IT's contribution may also be qualitative. The success of communication, therefore, requires a cultural shift from numbers-driven management to the acceptance of qualitative arguments, also on the business side.

Services, infrastructure, and applications

For the support of processing and management in organizations with information technology, COBIT 2019 mentions services, infrastructure, and applications [20]. Also, effective communication necessitates technology support to create transparency.

- **Transparency creating IT application:** provide technical support for illustration of IT costs and metrics as well as tracking mechanisms for communicated targets.

For the participants, transparency of IT costs is crucial for honest communication. Therefore, IT applications are required to integrate cost information of different databases and illustrate relevant numbers. The communication of business value should then be supported by applications comparing actual and target figures as well as the budget plan and the actual project portfolio. This enables comparability and traceability of IT investments and their generated impact.

Principles, policies, and frameworks

For "practical guidance for day-to-day management" [20], organizations apply principles, policies, and frameworks. The participants mention tense discussions in day-to-day management about cost allocation and service delivery. They, therefore, highlight practical guidance through transparent chargeback regulations and guidelines for IT investment evaluation as success factors in communication.

- **Transparent chargeback regulations:** set up agreed rules for the allocation of IT costs.
- **Guidelines for evaluation:** set up transparent guidelines for decision-making and if required business case calculation for IT investments.

A prerequisite for the setup of cost allocation rules is a comprehensible service offer of IT. Then business requires transparency on what they will be charged for. Preselected chargeback regulations foster the acceptance of IT costs in the business. Thereby, the participants mention that e.g. in the case of cost allocation with planned prices, the decision on how these allocated costs are compared with the actual amounts at the end of the fiscal year should be announced transparently (true up or true down). Furthermore, organizations need clear guidelines on how to decide on IT investments and if business case calculation is valuable. If a business case is required there should be clear calculation specifications and evaluation mechanisms. The participants however stress that not for every decision a business case is needed, especially if "projects are business critical or legally necessary" (FG1-6).

V. Discussion

The findings show that the perception of IT costs and business value differs among the stakeholders. In the following, we discuss the significance of these differing perceptions and their relevance to communication. Furthermore, we examine the identified success factors, compare them to previous research and outline how they can contribute to more effective communication.

A. Differing perceptions of IT costs and business value of IT

The costs of IT "appear more tangible in nature" [31] than the value and therefore are "often perceived to be easier to estimate" [31]. The findings stress that business and IT departments however rely on different understandings of IT costs. This lack of a clear definition and a common understanding hampers transparency and leads to difficulties in cost management [8]. The developed layer model visualizes the complexity and multidimensional nature of IT costs for the participants. It stresses that the stakeholders generally agree on the core IT costs, referred to as *direct IT costs* [31], and the *management cost in the IT department*. However, indirect costs, i.e., the outer layers, are often not treated or perceived as IT costs within organizations. We identified those "human and organizational factors" [31], especially outside the IT department. In a detailed study, [32] present various characteristics of indirect costs and emphasize the importance of recognizing these costs as IT costs to enable a holistic evaluation. Therefore, the perception of what IT costs are and to what extent they should be included in metric calculations must follow a clear process and be "determined by a clear cost structure" (FG2-3). Besides, a lack of standardization also leads to challenges in comparing IT costs externally [8]. One focus group participant also mentions that "benchmarks, therefore, create false expectations" (FG1-3) as comparison with other companies is very difficult. The layer model displays those different possibilities of perception and creates awareness of the multifaceted complexity of IT cost. Therefore, it builds a basis for a common understanding of how to define IT costs within the organization as a basis for performance metrics and how to compare them beyond.

The inconsistent perception of IT costs and resulting difficulties in IT evaluation hampers the communication of value. Especially if the "business value of IT is equated with revenue and the non-monetary contribution of IT is not acknowledged" (FG2-2). One common contrast, also highlighted by the participants is the differentiation between monetary and non-monetary contribution: business cases are calculated to express the monetary contribution in comparison to IT costs. The non-monetary contribution of IT, however, is challenging to communicate and "misunderstandings about the definition of value can lead to feelings that value was not delivered" [34]. Alignment between business and IT is therefore indispensable for their mutual understanding and the perception of value [29]. To highlight this, we align the different perceptions of value in Fig. 4 to the SAM and thereby display that the value contribution of IT and its perception differs related to the alignment perspective. The participants stress that IT is mainly perceived as an enabler, sustaining the business. This follows the most common alignment perspective [11] Strategy Execution (1). However, if business and IT foster alignment on different perspectives, it can also improve the perceived value contribution of IT [22]. The results show that IT therefore should take the initiative and empower also the other perspectives to amplify value contribution and perception in the business.

B. Communication as the basis of perception and vice versa

The findings show that organizations with regular exchange and clear definitions struggle less to adopt a shared perception of IT costs and business value. An earlier study investigates how executives achieve consensus on the perception of business value and identifies communication as one supportive factor for this consensus [9]. The focus groups highlight that a lack of constructive communication between business and IT departments leads to "accusations that the IT department is too expensive" (FG1-1). This sentiment reinforces a previous study mentioning that communication shortfall results in different perceptions and limited comprehensibility of expectations on the business side [33]. Also, non-constructive discussions about the costs and value contribution of IT provoke cultural differences [33] [44]. The participant describes this as a lack of trust in the IT department and in IT to be a strategic driver for the business. For this, the ability to develop a "common language is indispensable" (FG1-6). This common language should ideally be expressed in business terms to ensure consistent perception across stakeholders [16]. Thus, our findings stress that for a shared perception of IT costs and business value, business and IT require effective communication.

Effective communication of IT costs and business value, however, also necessitates a shared understanding of the relevant topics. The stakeholders' perception, therefore, is decisive so that both sender and receiver within a bidirectional exchange feel satisfied and consider the communication effective [18]. Several identified success factors foster the development of this "similar representation in the interlocutors" [10]: Besides the ability to develop a **common language**, the skill to have a **basic knowledge** about the domain of the interlocutor supports a common ground in the conversation. For this also the given information should serve as a **shared knowledge basis**. The **effective presentation of the conversation content** then assists communication through visualization. In conclusion, shared perception and understanding are necessary for effective communication, and establishing these requires active efforts from all participants. The interdependence of perception and communication reinforces that besides the common language, a shared knowledge base, and effective presentation, regularity is decisive for effective communication of IT costs and business value. The success factor of **regular communication** supports this required continuous communication process.

C. Success Factors for communication

The effective communication of IT costs and business value is based on successful governance and alignment [22]. Our findings support this interrelation by addressing the success factors mentioned in the EGIT and BITA literature: Especially the factors identified in the categories *people, skills, and competencies* as well as *culture, ethics, and behavior* incorporate the success factors of EGIT and BITA mentioned in the theoretical background section. The outlined cultural aspects include factors such as mutual trust and respect [14], business-IT partnership [14], or IT's business orientation [25]. Success factors identified in the category people, skills, and competencies comprise BITA prerequisites such as various skills and knowledge of both business and IT executives [13] as well as the understanding of the IT value chain and persuasiveness of communication [25] required for EGIT success. Our study indicates that the effective communication of IT costs and business value requires further aspects. Therefore, organizations necessitate successful EGIT as a basis and need to drive BITA as a continuous process [12] but additionally, they should consider specific factors for the communication of IT costs and business value of IT.

Earlier studies in the business value context already mention shortfalls in communicating IT costs and business value and highlight relevant aspects for effective communication [15]. The developed factors in our study are in line with these factors of previous studies: e.g. the required **interface function** represents "business-IT structures to recognize and evaluate opportunities" [34]. The processual factor of **regular communication** mentions regular collaboration [15] and a **uniform approach to the discussion** includes "a clearly defined portfolio value management process" [34]. Earlier studies further establish metric portfolios [15][16] as a prerequisite for effective measurement and communication of business value or balanced dashboards to "demonstrate the value" [29]. In this study factors related to information such as a **commonly defined set of KPIs and metrics** and the **effective presentation of conversation content** include those aspects. This close connection with individual aspects investigated in other studies validates our findings. In contrast to these individual mentions of success factors in previous research, our study develops a comprehensive overview. It thereby includes not only existing aspects but expands them including factors in the category of *principles, policies, and frameworks* neglected in previous studies. The developed overview of success factors, therefore, provides an extension of existing literature as well as a focused, summarized view aligned with the factors for business value communication identified in earlier studies.

The mapping of relevant success factors onto the COBIT 2019 framework provides an overview from different perspectives. With the seven components, referred to as "enablers" [22] in earlier COBIT versions, our categorization enables the implementation leading to successful IT management [19]. However, as organizations face difficulties in the implementation of effective communication [5, 6, 8], they require in addition to the aforementioned success factors further practical guidance for the operationalization of effective communication. Research could, therefore, propose a detailed design of **regular communication** based on the other identified factors. As outlined, the main focus thereby needs to be on the unified understanding and perception. Earlier studies emphasize the importance of a common language [15] based on "terms that the business understands" [29]. In addition, proven approaches to communication plans [15] [16] should be considered. With the success factors presented, we provide a basis for future research on the operationalization of effective communication between the business and IT department regarding IT costs and the business value of IT.

VI. Conclusion

Increasing inflation and security risks urge organizations to manage IT costs effectively and efficiently. Thereby, the communication of IT costs and the impact generated through IT is crucial to remain competitive and to strategically plan investments. However, CIOs face challenges to create a common understanding of IT costs and the business value of IT and furthermore, effectively communicate them. A current view on the perception as well as a holistic overview of success factors to operationalize effective communication does not yet exist in academia. Therefore, the goal of this publication is to identify how business and IT stakeholders perceive IT costs and IT business value. With this understanding, we further aim to give an overview of the success factors that organizations need to consider for the effective communication of costs and business value of IT. To reach this goal, we conduct a focus group study and discuss the findings. In summary, the investigation of the perception shows that it differs between the stakeholders for IT costs as well as for the business value of IT. We conclude that to create a common understanding in organizations, they require communication about the perception and a common ground to discuss IT costs and IT business value. The result of the mapping to the seven COBIT components ensures a holistic perspective and enables transparency on the 16 identified factors for successful communication. It thereby offers a structured representation as a basis for the operationalization of effective communication between the business and IT department about IT costs and IT business value. Furthermore, the paper highlights that this interchange is based on the stakeholder's competency to communicate in a common language. This common language then should enable the transparent demonstration of the value of IT for the organization.

This paper makes a theoretical contribution by providing an insight into the current perception and communication of IT costs and business value of IT, and thus by identifying the relevant factors to operationalize an effective communication. Moreover, practice gains awareness about possible reasons for non-constructive IT cost communication and guidelines on how to turn it into effective communication with a focus on the business value of IT.

However, the study itself has limitations. First, the focus groups were conducted only with organizations situated in Germany. We mitigated these limitations by including participants with diverse backgrounds and from different industries and company sizes. Although we cover as broad a spectrum as possible with these participants, further focus groups around the world could enrich our research findings and add even more validity. Second, the study does not distinguish the perceptions and success factors by company size or industry which could provide a more differentiated view. Focus group design concentrating on organization sizes or industries would enable comparison and stakeholder-specific success factor analysis. Third, the study lacks proof that the identified success factors facilitate the operationalization of IT cost and value communication. To overcome this limitation, researchers could in the next step provide a case study implementing the success factors and evaluating whether considering these factors leads to more positive perception and successful communication. Furthermore, future research should seek to conceptualize how communication of IT costs and business value should look like considering the identified success factors.

***Abstract*—This paper present results, which reveal that approaches obtained for scheduling problems with learning effects can be successfully used to improve the quality of machine learning methods. It is illustrated by modelling some aspects of Q-learning agents as scheduling problems with the learning effect, and constructing sequencing and dispatching algorithms, which take into account the existence of learning. Their application to determine the sequence of tasks processed by Q-learning agents can visibly speed up their convergence to an optimal strategy. Furthermore, we show that a dispatch of tasks according to the longest processing time algorithm for parallel computing can be replaced by a more efficient procedure, if agents can learn. The numerical analysis reveals that our approach is efficient, robust and only marginally dependents on a learning model and an accurate approximation of task processing times.**

I. Introduction

THE LEARNING effect takes place in typical human activity environments or in automatized manufacturing, where a human support for machines is needed during activities such as operating, controlling, setup, cleaning, maintaining, failure removal, etc. It was also observed that performances (objectives) of an industrial system can be essentially improved if the learning ability is utilized (see [1]). It can be done by determining the sequence of processed jobs, which takes into consideration not only the given objectives, but also the presence of learning, i.e., decreasing processing times/costs of jobs. Thereby, time/cost objectives (e.g., the maximum completion time) can be additionally improved (in a specified range) by the sequence (schedule) of jobs (e.g., [2], [3], [4]). In other words, additional benefits from learning can be gained. It is worth highlighting this scheduling approach does not interfere a system nor require any changes of its structure. Therefore, it is a significant advantage, which makes this non-invasive method universal and applicable to improve (optimize) different systems, where learning is present and a sequence of processed jobs can be (at least partially) controlled.

Although scheduling problems with the learning effect have attracted particular attention in research society (e.g., [1], [5], [6], [7], but surprisingly, there was no attempt to apply them to enhance machine learning algorithms, except our idea. However, from the perspective of the discussed utilization of learning by scheduling, there is no difference if the reduction in time or cost required to process a job is the result of human learning or machine learning. Thereby, the mentioned additional benefits from learning can be also gained for dynamically changing systems, which use machine learning. Such illustrative example will be shown in this paper.

Machine learning methods or intelligent agents ([8]) very often act like human, especially in the context of adaptation, self-improvement and autonomous learning, which is present not only during training stages, but first and foremost during their regular exploitation (working stages). In particular, it refers to reinforcement learning algorithms (RL), where an autonomous agent can learn to choose actions in an environment to achieve its goals (see [9], [10]). Such behavior results in robustness and high (increasing) efficiency of these approaches, thereby they have attracted particular attention in different domains (e.g., [11]).

Although there are lots of studies devoted to this group of algorithms, they usually focus on improving them in fields such as learning policies, representation of states, exploration and exploitation strategies and others (e.g., [9], [10]). However, there is lack of research on methods that are able to additionally increase the efficiency of RL by the utilization of its learning ability, without interfering a structure of an algorithm. Therefore, as the preliminary result in this domain, we will show that the speed of convergence of RL can be visibly improved by processing tasks according to a schedule that takes into account the existence of learning (an iterative improvement). It is depicted on the example of finding the shortest path in 2D mesh topology environment by RL. We choose Q-learning based algorithm, which is comprehensible and representative, since the considered relations also hold for other techniques, e.g., temporal difference learning (TD), state-action-reward-state-action (SARSA) (for more details see [10]).

In this paper, we model some aspects of Q-learning as scheduling problems with the learning effect. On this basis, the efficiency of the algorithm can be improved if tasks are processed according to a given sequence following from the analysis of scheduling problems. Furthermore, we show that a dispatch of tasks according to the longest processing time (LPT) algorithm (see [12]) for parallel computing can be replaced by a more efficient strategy, if agents can learn. Our approach does not interfere a structure of machine learning methods and its computation overhead is negligible. It is showed to be efficient, robust and only marginally dependents on a learning model and an accurate approximation of values of task processing times. It is especially crucial for the application of reinforcement learning methods in varying environments, where they should adapt quickly, whereas deterministic algorithms cannot be used. Therefore, the contribution of this paper is not to make new better learning agents, but to reveal that approaches obtained for scheduling problems with learning effects can be successfully used to improve the quality of machine learning methods. The presented promising preliminary results open new perspectives for the application of scheduling theory.

The remainder of this paper is organized as follows. The illustrative application of the reinforcement learning is given in the next section, which includes the formal definition of the shortest path problem and the Q-learning algorithm dedicated to solve it. Next, the considered issue is expressed as scheduling on parallel processors with the learning effect and on this basis scheduling (dispatching) algorithms are proposed. Their application to enhance the Q-learning algorithm is analysed numerically. Finally, the last section concludes the paper.

II. Reinforcement learning

In this section, we will describe an environment, which is used to illustrate and analyse the application of the algorithms constructed for scheduling with the learning effect to improve the efficiency of reinforcement learning methods.

A. The shortest path problem

The shortest path problem is well known and its deterministic cases can be solved *inter alia* by Dijkstra's algorithm or A* search. However, it also constitutes an excellent environment for comprehensive analysis of various other methods also with learning effects (see [13]). It will be used for a similar purpose in this paper.

There is given a graph $G = (V, E)$, where V is the set of vertices (nodes) and E is the set of edges (links). Each edge (u, w) has an associated length (weight) $l(u, w)$, where $u, w \in V$; G is undirected, thereby $l(u, w) = l(w, u)$. We consider the 2D mesh topology, interconnecting in a grid fashion, where each node has at most four neighbors, thus, the following notation can be used to describe nodes: $V' = \{(x_u, y_u) : 1 \leq x_u \leq X \wedge 1 \leq y_u \leq Y, u \in V\}$ and X and Y are the number of vertical and horizontal nodes in the mesh, respectively; such mesh is called $X \times Y$ size. The objective is to find the shortest path (SP) between each of n source nodes from the set $S = \{s_1, \ldots, s_n\} \subset V$ to one destination node $d \in V$ ("hot spot").

B. Q-learning

In this section, we will briefly describe a reinforcement learning algorithm that is based on a typical Q-learning method (see [10], [14]). For mode details concerning similar applications of Q-learning see [15] or [16]. The discussed algorithm is a model free reinforcement learning technique, which was chosen for the purpose of this paper, since it is transparent for analysis and the idea behind our approach can be clearly illustrated. Its behaviour will be depicted on the example of solving in an adaptive manner the shortest path problem. On this basis, we will show that properties obtained for a scheduling problem with the learning effect can be applied to improve the efficiency of Q-learning.

In the considered approach, the Q-learning agent on the basis of the current node (say u) and the state-action function Q chooses the next node (say w), subsequently it receives the reward depending on the distance between these nodes. This process is repeated until the destination node (say d) is reached. The Q-function is represented by a set $\{Q_1, \ldots, Q_u, \ldots Q_{|V|}\}$ of $|V|$ tables, further called Q-tables. The quality of a state-action function (table) $Q_u(d, w)$ defined for each node $u \in V$ is the total expected discounted reward received by selecting (in node u) the next node w on the way to the destination node d. Using the RL nomenclature, the state is represented by the pair $[u, d]$, whereas w is the action taken in this state.

The determination of a next node and the update of the Q-function for each current node $u \in V$ proceed according to the following steps:

1) The next node w is determined according to a greedy strategy that always chooses a node with the highest Q-value, i.e.,
$$w = \arg \max_{w' \in \mathcal{N}(u)} \{Q_u(d, w')\},$$
where u is the current node, d is the destination node and $\mathcal{N}(u)$ is the set of neighbor nodes of u. The greedy strategy is simple and transparent, but together with the optimistic initialization of Q-tables with zeros and the application of negative rewards, it still drives exploration.
2) The Q-value for node u is updated according to the following rule:
$$\begin{aligned} Q_u(d, w) &= (1 - \alpha)Q_u(d, w) + r(u, w) \\ &+ \gamma \max_{a'}\{Q_w(d, a')\}, \end{aligned}$$
where $\alpha \in [0, 1]$ is a learning rate, $\gamma \in [0, 1]$ is a discount factor, $r(u, w) = r(w, u) = -l(u, w)$ is the reward equal to the negative value of the length between nodes u and w and $\max_{a'}\{Q_w(d, a')\}$ is the best expected Q-value in node w to reach the destination node d. In a typical Q-learning implementation, terms $[r(u, w) + \gamma \max_{a'}\{Q_w(d, a')\}]$ are multiplied by α. Although it is omitted in the presented approach to avoid potential deadlocks, Q-values is convergent (since $r < 0$).
3) To improve learning the forward update of Q-value of node w is proceeded:
$$\begin{aligned} Q_w(d, u) &= (1 - \alpha)Q_w(d, u) + r(u, w) \\ &+ \gamma \max_{a' \in \mathcal{N}(u)}\{Q_u(d, a')\}. \end{aligned}$$

The above procedure is applied starting from the source node $s_j \in S$ until the destination node d is reached (i.e., starting u is equal to s_j). It is repeated for the given pair (s_j, d) until the same value of the path is obtained for the given number of succeeding iterations (denoted by $TerminateCondition$). This process of finding the shortest path for (s_j, d) will be called task j; for convenience, we will also use the following notation $j \in S \equiv s_j \in S$. Since in the considered example, the destination node d is the same for all tasks, then it does not need to be implemented a part of a state.

It can be observed that the application of distributed or parallel computing can improve efficiency of algorithms and it is commonly used nowadays, therefore, we present a parallel version of the considered approach. Thus, a set $A = \{A_1, \ldots, A_m\}$ of m Q-learning agents are applied. Each agent A_i calculates the shortest paths for the source nodes (tasks) from the set $S_i \subset S$, where S_i are disjoint sets such that $S_1 \cup \ldots \cup S_m = S$. Due to relatively long latency access to shared Q-tables (caused by mutexes, communication, etc.) in reference to very fast calculation times of the Q-values, each agent has its own set of Q-tables. The formal description of the Q-learning agent is given by Algorithm 1.

The objective of the Q-learning agents is not only to find the shortest paths for all given nodes, but to minimize the time of finding them. Let t_j be the processing time of task j, i.e., time of calculating the shortest path from the source node s_j to the destination node d, whereas $C(A_i) = \sum_{j \in S_i} t_j$ be the calculation time taken by Q-learning agent A_i to find shortest paths for all nodes from the related set S_i, i.e., to process tasks from this set. Thus, the time objective is expressed as the minimization of calculation time of the shortest paths for all source nodes (processing of all tasks), which is the maximum calculation time $t_{\max}$ among all Q-learning agents: $t_{\max} = \max_{i=1,\ldots,m}\{C(A_i)\}$.

Since there are multiple agents, then the calculations are distributed among them, i.e., the set S of source nodes (tasks) is partitioned into subsets $\{S_1, \ldots, S_i, \ldots, S_m\}$, which are assigned to related agents $\{A_1, \ldots, A_i, \ldots, A_m\}$. Thus, an assignment algorithm has an essential impact on the minimization of the objective value $t_{\max}$. To construct such methods, which are efficient, we will express the considered problem as scheduling on identical parallel processors. On the basis of its properties, we will propose scheduling algorithms, which will be applied to handle calculations (tasks) by Q-learning agents (i.e., to determine the assignment of calculations and their processing sequences).

Furthermore, we will show that calculations can be speeded up (i.e., $t_{\max}$ can be further minimized) if the allocation algorithms takes into consideration not only the potential time required to find a solution, but also learning (an iterative improvement), which is an inner nature of Q-learning.

III. Scheduling with learning effects

At first, we will present the general concept how the time minimization of finding the shortest paths by the Q-learning agents can be perceived as scheduling on parallel identical processors or in other words parallel machine scheduling. Next, the related scheduling problem will be formally defined.

Algorithm 1 Q-learning agent A_i

```
Determine the set of the source nodes $S_i \subseteq S$
    and their processing sequence
Initialize $Q-tables$: $\{Q_1, \ldots, Q_{|V|}\}$
for each $s_j \in S_i$ do
    $distance := \infty$
    $distance^* := \infty$
    $distance_{prev} := \infty$
    $counter := 0$
    $s := s_j$
    while $counter < TerminateCondition$ do
        $distance := 0$
        $counter := counter + 1$
        $u := s$
        while $u \neq d$ do
            $w := \arg\max_{w' \in \mathcal{N}(u)}\{Q_u(d, w')\}$
            $distance := distance + l(u, w)$
            $r(u, w) := -l(u, w)$,  $r(w, u) := -l(w, u)$
            $Q_u(d, w) := (1 - \alpha)Q_u(d, w) + r(u, w)$
                        $+\gamma \max_{w' \in \mathcal{N}(w)}\{Q_w(d, w')\}$
            if $w \neq d$ then
                $Q_w(d, u) := (1 - \alpha)Q_w(d, u) + r(w, u)$
                        $+\gamma \max_{u' \in \mathcal{N}(u)}\{Q_u(d, u')\}$
            end if
            $u := w$
        end while
        if $distance < distance^*$ then
            $distance* := distance$
        end if
        if $distance \neq distance_{prev}$ then
            $counter := 0$
        end if
        $distance_{prev} := distance$
    end while
end for
$\{Q_1, \ldots, Q_{|V|}\}$ are the $Q-tables$ containing strategy
    to find the shortest paths for
    the considered pairs $(s_j, d)$, $s_j \in S_i$
```

Each Q-learning agent can be represented in a scheduling problem by a processor, i.e., $A_i \equiv P_i$, whereas a task (say j) that is finding the shortest path (such that $TerminateCondition$ is true) from a source node (say $s_j \in S$) to the destination node d by a Q-learning agent is called a job (also j).

The processing time t_j of task j, i.e., the time required to find (calculate) the shortest path (s_j, d), can depend on the number of nodes from a source node to the destination node (including). Hence, we model it by the processing time p_j of job j, which is given as follows:

$$p_j = |x_d - x_{s_j}| + |y_d - y_{s_j}|, \qquad \forall s_j \in S. \tag{1}$$

Note that p_j is not an exact value of the real processing time t_j required to find the related shortest path, but it only models this parameter in scheduling domain, i.e., it should reflect the relations such that $t_j < t_k$ implies $p_j < p_k$.

For a better comprehension, we will analyse the following computational example.

Example 1

Let us verify the accuracy of model (1) for the following settings generated from the uniform distribution: graph $G(V, E)$ of size 100×100, lengths of edges $l(u, w) \in \{1, \ldots, 5\}$, where $(u, w) \in E$, 100 random source nodes $s_j = (x_{s_j}, y_{s_j})$, where $x_{s_j} \in \{2, \ldots, 99\}$, $y_{s_j} \in \{2, \ldots, 99\}$, and destination node $d = (x_d, y_d) = (99, 99)$. On this basis, we ran implemented Q-learning algorithm and measured (in milliseconds) the time of finding the shortest path by a single agent from a source node s_j to the destination node d, i.e., processing time t_j of task j. Such analysis was done for each source node $s_j \in S$, but to measure relevant times t_j, Q-tables were cleared before processing each task. Thus, each of them was processed as the only task by a Q-learning agent. We refer each measured t_j to the modelled value – the job processing time p_j – obtained according to (1). The result of this analysis is shown in Figure 1, where related pairs (p_j, t_j) are presented according to the non-decreasing order of p_j. It can be seen that there are some bias such that $t_j < t_k$ not always refers to $p_j < p_k$, but the general tendency holds as required (and expected).

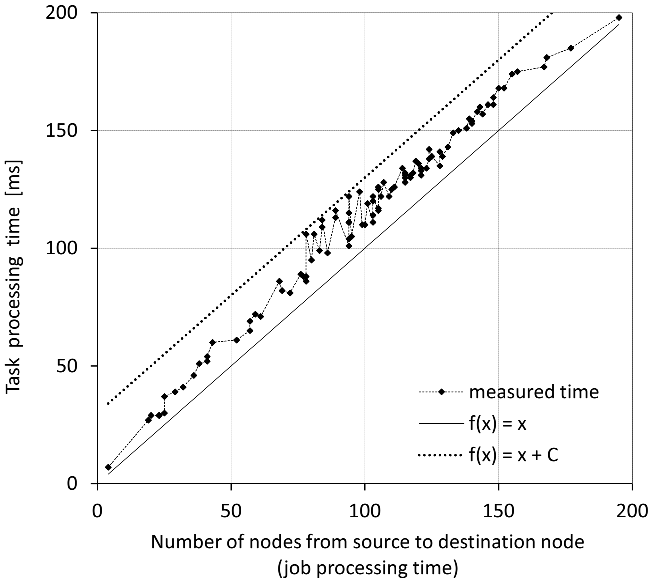

Fig. 1: Relations between measured task processing times t_j and modelled job processing times p_j

It can be seen in Figure 1 that model p_j approximates measured times t_j (in a constant range) if an agent processes only one task. However, due to the learning ability of an agent, the time required to perform a task decreases with the number of previously processed tasks. Let us consider the following example.

Example 2

Given a task related with node $s_1 = (x_{s_1}, y_{s_1}) = (2, 2)$, for which its processing times are measured (in milliseconds) depending on the number of previously processed tasks. Namely, an agent performs tasks from the following groups (1), $(2, 1)$, $(2, 3, 1)$, ..., $(2, 3, \ldots, 100, 1)$ such that $j = 1$ is always processed as the last and Q-tables are cleared before a next group is processed. Other settings are the same as in the earlier example. The result of the analysis is shown in Figure 2, which illustrates a learning curve of an agent, which is similar to learning curves observed in industrial systems (see [17], [18]). The model of decreasing task processing times (learning curve) will be proposed subsequently.

On the basis of the above observations, let us define formally the related scheduling problem. There are given a set $J = \{1, \ldots, n\}$ of n jobs that model tasks S and a set $P = \{P_1, \ldots, P_m\}$ of m identical processors referring to Q-learning agents $\{A_1, \ldots, A_m\}$. Each processor is continuously available and can process at most one job at a time. Once it begins processing a job it continues until this job is finished and there are no precedence constraints between jobs. Each job j is characterized by the processing time $\tilde{p}_j(v_i)$ dependent on the number of previously processed jobs v_i by processor P_i. It models a variable task processing time (see Figure 2), which depends (due to learning) on the number v_i of previously processed tasks by agent A_i. In general, it can be describe by the following:

$$\tilde{p}_j(v_i) = p_j \cdot f(v_i), \tag{2}$$

where p_j is the normal processing time of job j defined as the job processing time of a job without influence of learning, which is calculated on the basis of source and destination nodes related with a task and given by (1); it models a processing time of a task, which is processed by an agent as the first one, i.e., without influence of learning (see Figure 1). Moreover, a function $f(v_i)$ is a learning curve that describes decreasing processing times dependent on the number of processed jobs v_i (see Figure 2).

Note that the only assumption concerning f is that the function is non-increasing for the considered scheduling model, but it is only a model, which does not have to precisely describe the decreasing task processing times. Nevertheless, we will show that even such imprecise and general model (following (1) and (2)) is sufficient to derive properties, which allow us construct a task assignment algorithm that improves Q-learning.

The schedule of jobs can be unambiguously defined by their sequences $\pi = \{\pi_1, \ldots, \pi_i, \ldots, \pi_m\}$, where π_i denotes the sequence of jobs on P_i and $\pi_i(k)$ is the index of the kth job in π_i for $i = 1, \ldots, m$. Moreover, n_i is the number of jobs assigned to P_i, i.e., the cardinality of π_i. Note that π_i refers to the sequence of tasks from set S_i assigned to be processed by agent A_i. For each job $\pi_i(k)$, we can determine its completion

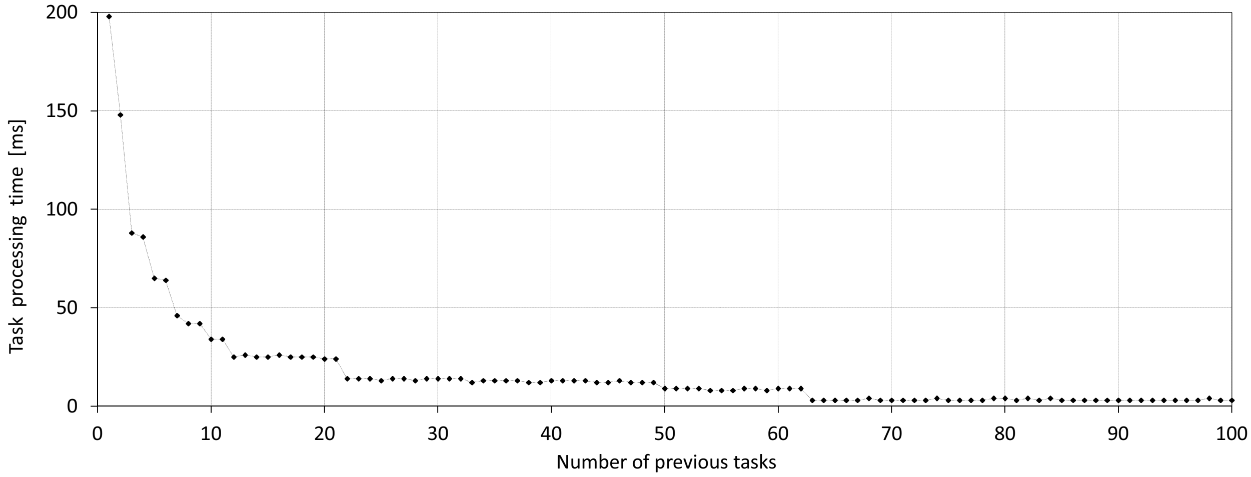

Fig. 2: A measured task processing time depending on the number of previously processed tasks

time $C^{(i)}_{\pi_i(k)}$ on processor P_i:

$$C^{(i)}_{\pi_i(k)} = \sum_{k=1}^{n_i} \tilde{p}_{\pi_i(k)}(k). \quad (3)$$

On this basis $C^{(i)}_{\pi_i(n_i)}$ models the calculation time $C(A_i)$ taken by Q-learning agent A_i to find shortest paths for all nodes from the related set S_i, i.e., to process tasks from this set. Since the objective of Q-learning agents is to minimize the time of finding all shortest paths $t_{\max}$, then the criterion value (we use a similar symbol) for the scheduling problem is defined by $C_{\max}(\pi) = \max_{i=1,\ldots,m}\{C^{(i)}_{\pi_i(n_i)}\}$.

Formally, the objective is to find such a schedule $\pi^* = \{\pi^*_1, \ldots, \pi^*_m\}$ of jobs (i.e., assignment of jobs to processors and their sequences) that minimizes the maximum completion time (makespan):

$$\pi^* \triangleq \text{minarg}_{\pi\in\Pi}\left\{\max_{i=1,\ldots,m}\left\{C^{(i)}_{\pi_i(n_i)}\right\}\right\}, \quad (4)$$

where Π is the set of all schedules π.

For convenience and to keep an elegant description of the considered problem we will use the three field notation scheme $X \mid Y \mid Z$ (see [19]), where X describes the processor environment, Y describes job characteristics and constraints and Z represents the minimization objectives. According to this notation the scheduling problem with model (2) will be denoted as $Pm|LE|C_{\max}$, whereas its case with constant job processing times ($\tilde{p}_j(v_i) = p_j \ \forall(j, v_i)$) will be denoted by $Pm||C_{\max}$.

On the basis of the formulated scheduling problem, we will propose algorithms that determine the assignment of tasks to agents and their processing sequences.

IV. Job scheduling algorithms

In this section, we focus on the job scheduling problem with the learning effect. The considered criterion is the minimization of the maximum job completion time (makespan). In the classical version of this problem $Pm||C_{\max}$, the job processing times are constant, thereby their sequence does not affect the criterion value, and thus, the objective is to find the allocation of jobs to the processors to minimize the makespan.

Let us analyse job assignment (dispatching) algorithms for the problem $Pm||C_{\max}$. One of the primary and efficient methods is a list scheduling, which assigns jobs to the first available processor according to an order defined by a list (see [12]). If the sequence of jobs on the list is random, then the worst case of the algorithm (further denoted by RND) is $\frac{C_{\max}(RND)}{C^*_{\max}} = 2 - \frac{1}{m}$ and its computational complexity is $O(nm)$ (see [20], [12]), where $C^*_{\max}$ denotes an optimal criterion value. However, its efficiency can be improved if jobs are assigned according to their longest processing times (LPT), then its worst case is $\frac{C_{\max}(LPT)}{C^*_{\max}} \le \frac{4}{3} - \frac{1}{3m}$, whereas its computational complexity is $O(n\log n + mn)$ (see [12]).

Note that RND can be straightforwardly applied to the problem of finding shortest paths by Q-learning agents without any definition of a scheduling problem nor any model of task processing times. It only assigns each task to the first available agent. On the other hand, the application of LPT requires a model of task processing times, which has to be sufficient only to determine the non-decreasing relation between tasks during the assignment process.

However, unlike a typical approaches to parallel computations, we will reveal that in case of learning algorithms (such as Q-learning), not only the assignment of tasks is important, but their processing sequences by an agent seem to be essential. It will be shown on the basis of the formulated scheduling problem with learning. At first, we will provide a property for a single processor case $1|LE|C_{\max}$ (referring to one Q-learning agent), which holds for the problem with different learning models (e.g., [5], [6], [7]).

Property 1: The problem $1|LE|C_{\max}$ can be solved optimally by scheduling jobs according to their shortest normal processing times p_j (SNPT rule).

If job processing times are constant, then the sequence of jobs is immaterial for the makespan minimization on a single processor $1||C_{\max}$. However, following Property 1, it is no longer valid if job processing times can vary. This is a premise for a more efficient processing of tasks by a Q-learning agent, which will be analysed numerically in the next section. Furthermore, it can be easily extend to a scheduling on parallel processors (tasks processed by multiple agents).

Property 2: There exists an optimal solution to the considered problem $Pm|LE|C_{\max}$ such that jobs on each processor are scheduled according to their shortest normal processing times p_j (SNPT).

Based on Property 2, we propose a list scheduling algorithm, where jobs on the list are sequenced according to their shortest processing times (further denoted by SNPT). Such conclusion is not only opposite to the popular and efficient LPT algorithm often used for parallel computing ([12]), but it does not follow from any other combined analysis on machine learning algorithms and parallel computing.

It is worth noticing that our theoretical analysis showed that SNPT rule overwhelms LPT in the domain of scheduling problems with the learning effect. It is completely against the existing approaches to dispatch tasks for parallel learning algorithms according to LPT or RND (randomly).

Recall that a job is equivalent to a task, thereby a schedule π for jobs (obtained on the basis of LPT, RND or SNPT) straightforwardly determines the assignments (dispatching) of tasks to Q-learning agent and their processing sequences by each agent.

V. Numerical analysis

In this section, we will use scheduling algorithms LPT, RND and SNPT in the domain of the Q-learning and the shortest path problem. Namely, we will analyse how Q-learning agents can improve their efficiency (running times) if they process tasks according to sequences determined by the application of scheduling algorithms LPT, RND and SNPT. In other words, we run implemented Q-learning agents and measure (in milliseconds) the real time of finding the shortest paths depending on different sequences of processed tasks (i.e., LPT, RND, SNPT).[1] The impact of scheduling algorithms on running times of Q-learning is analysed for the following settings.

2D-mesh (environment):

- mesh (graph) size $X \times Y$: 100×100,
- lengths (weights) of links between nodes $l(u, w)$: generated from the uniform distribution over the integers in the following ranges of values $\{1, \ldots, 5\}$ and $\{1, \ldots, 100\}$, where $u, w \in V$,
- destination node d ("hot spot"): $(x_d, y_d) = (X-1, Y-1)$,
- size $|S|$ of the set S of source nodes (number of tasks): 1000, 2000 and 4000,
- source node coordinates (x_{s_j}, y_{s_j}): $x_{s_j} \in \{2, \ldots, X-1\}$, $y_{s_j} \in \{2, \ldots, Y-1\}$, $s_j \in V$, where $j = 1, \ldots, |S|$.

Q-learning (agent):

- $m \in \{1, 2, 10, 20\}$ agents, $\alpha = 0.9$, $\gamma = 0.9$, $TerminateCondition = 5$,
- the applied Q-learning always provided optimal solution (the shortest path) for the considered settings, which was verified by Dijkstra's algorithm.

Job scheduling algorithms:

- $m \in \{1, 2, 10, 20\}$ processors,
- job processing times (the model of task processing times) $p_j = |x_d - x_{s_j}| + |y_d - y_{s_j}|$ for $j = 1, \ldots, |S|$,
- algorithms LPT, RND, SNPT.

For each combination of the defined mesh parameters, a set I_Q of random instances (replications) were generated, where its cardinality is equal to $|I_Q| = 100$. On their basis, the impact of scheduling algorithms on running times of Q-learning is evaluated (as percentage speed up δ) in reference to the running times obtained with LPT as follows for each instance I

$$\delta(TS(I)) = \frac{t_{\max}(LPT(I)) - t_{\max}(TS(I))}{t_{\max}(TS(I))} \times 100\%,$$

where $TS \in \{LPT, RND, SNPT\}$ and $t_{\max}(TS(I))$ is the measured (in milliseconds) maximum calculation time (running time) among all Q-learning agents (equivalent to the makespan) that processed tasks according to the applied task scheduling algorithm TS for the instance $I \in I_Q$.

Thus, for each instance I, the running times (in milliseconds) of finding the shortest paths by Q-learning agents are measured, which processed tasks according to LPT, RND and SNPT, respectively. The results concerning mean, minimum, and maximum speed up δ (in percents) and running times $t_{\max}$ (in milliseconds) of Q-learning are given in Table I, where the related are calculated for each set I_Q of instances as follows: $\delta(TS, min) = \min_{I \in I_Q}\{\delta(TS(I))\}$, $\delta(TS, max) = \max_{I \in I_Q}\{\delta(TS(I))\}$, $\delta(TS, mean) = \sum_{I \in I_Q} \delta(TS(I))/|I_Q|$, and $t_{\max}(TS, min) = \min_{I \in I_Q}\{t_{\max}(TS(I))\}$, $t_{\max}(TS, max) = \max_{I \in I_Q}\{t_{\max}(TS(I))\}$, $t_{\max}(TS, mean) = \sum_{I \in I_Q} t_{\max}(TS(I))/|I_Q|$. Note that the higher value of δ then better, whereas it is oppositive for $t_{\max}$. Moreover, only mean values of δ and $t_{\max}$ are correlated, whereas min and max are informative. For a better comprehension, let us consider the first row of Table I for minimum values of RND. We have the minimum speed up $\delta = -2\%$ and minimum running time $t_{\max} = 204$ ms of Q-learning. However, -2% does not refers to 204, it only means that there was a running time of Q-learning using RND for which the minimum speed up comparing to the approach using LPT was -2%, i.e., LTP caused a result 2% faster than RND. On the other hand, minimum $t_{\max} = 204$ means that the smallest running time of Q-learning using RND was 204 ms.

In the previous studies on machine learning, a sequence of processing tasks has not been taken into account as an

[1] Q-learning and scheduling algorithms were coded in C++ and simulations were run on PC, CPU Intel® Core™i7-2600K 3.40 GHz and 8GB RAM.

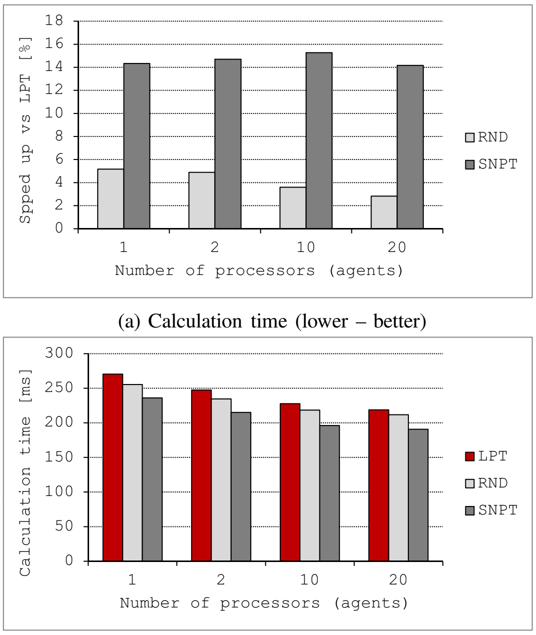
approach of speeding up these methods (in particular Q-learning). Similarly for computing them in parallel, it might be expected that the most efficient among task assignment (scheduling) algorithms is LPT, next RND and SNPT is the worst, or more likely that the differences in running times of machine learning methods are negligible for different sequences of processed tasks. However, the numerical analysis following our theoretical research reveals that it does not have to be so (in fact it is completely opposite to the popular approach).

It can be seen in Table I that a proper sequence of processed tasks (see SNPT) can significantly speed up Q-learning (even 22% and not less than 8%). The running times of Q-learning $t_{\max}(LPT)$ using LPT are 204–342 ms depending on the number of tasks n and agents m, whereas the impact of values of lengths (weights) $l(u,w)$ is negligible. Similar relations hold for RND and SNPT. The best running times are obtained for Q-learning that processed tasks according to SNPT, which is consistent with the theoretical results. It can be seen that SNPT always speeds up Q-learning, i.e., 11–18% (mean), but at least 8–15% (min) and even 14–22% (max); see also Figure 5. For RND, we have speed up about 2–6% (mean) and 7–12% (max), whereas its minimum speed up of RND in reference to LPT is -3–1% (min), where the negative values mean that for some cases LPT is slightly better.

Let us analyse running times of a single agent and multiple agents. For $m = 1$ and $n = 500$, we have the following average running times $t_{\max}(LPT) = 225$ ms, $t_{\max}(RND) = 213$ ms, $t_{\max}(SNPT) = 192$ ms, thereby SNPT is about 30 ms and 20 ms faster than LPT and RND, respectively. Thus, SNPT is visible better not only than LPT, but also than random sequence. It shows that our approach can significantly speed up Q-learning even for a single agent. On the other hand, for $m = 20$ and $n = 4000$ for which LPT should be (according to other studies) an efficient task assignment method for parallel computing, the mean running times are as follows: $t_{\max}(LPT) = 219$ ms, $t_{\max}(RND) = 211$ ms, $t_{\max}(SNPT) = 188$ ms. Once again, LPT is the worst and a random sequence is better, but they are overwhelmed by SNPT for all analysed instances. It can be seen that the proposed approach is robust, it is slightly affected by the number of agents (Figure 3) or tasks (Figure 4). Moreover, the mean speed up is over 15% in reference event to LPT (well known to be very good algorithm for such cases).



(a) Calculation time (lower – better)

(b) Speed-up vs LPT (higher – better)

Fig. 3: Mean calculation times and speed-ups of algorithms for different numbers of processors (agents); following Table I

Finally, the time required by considered scheduling algorithms (in particular SNPT) to determine sequences of processed tasks does not exceed 1 ms (even for greater instances $n = 4000$ and $m = 20$), which is negligible. Hence application of our approach significantly speeds up Q-learning (about 15%) without additional effort, it does not interfere Q-learning structure nor cause time overhead. It is especially crucial for varying environments, where Q-learning should adapt quickly. Thus, it can be used in a similar way for other related machine learning methods.

VI. Conclusions

Following dependencies observed in production and manufacturing systems related with a human factor (learning), we modelled relations, which occur between tasks processed by machine learning algorithms. Namely, we presented preliminary results, which revealed that approaches obtained for scheduling problems with learning effects (known from production and manufacturing) can be successfully used to improve the quality of machine learning methods. It was illustrated by modelling some aspects of Q-learning as scheduling problems with the learning effect. The previous studies on machine learning had not taken into consideration that the existence of learning can be utilized and bring additional benefits. On the basis of our approach, we claimed that the efficiency of Q-learning algorithms can be improved (running times) if tasks are processed according to a given sequence. Furthermore, we showed that for a parallelized Q-learning an assignment of tasks by SNPT is significantly more efficient than LPT, which is somehow in opposition to an intuition following from the previous studies on the sole LPT rule without the presence of learning (e.g., [12], [21]). The numerical analysis revealed that the dependency between running times and applied task processing (scheduling) algorithm is not incidental, but it is a rule.

Thus, our approach is efficient and robust, since it does not depend on a learning curve model nor accurate values of the normal job (task) processing times, but requires only their non-decreasing relation. In the same time, it does not interfere a structure of machine learning methods and its computation overhead is negligible. On the other hand, it is also the main limitation of the presented approach, since the SNPT rule cannot gain additional optimization benefits from knowing the exact model of learning curves describing the reduction of task processing times.

Our future research will focus on the application of our approach to other machine learning methods as well as on the analysis of different criteria, thereby development of other efficient algorithms.

***Abstract*—Large-scale computation (LSC) systems are often performed in distributed environments where message passing is the key to orchestrating computations. In this paper, we present a new message queue concept developed within the context of an LSC system (BalticLSC). The concept consists in proposing a multi-queue, where queues are grouped into families. A queue family can be used to distribute messages of the same kind to multiple computation modules distributed between various nodes. Such message families can be synchronised to implement a mechanism for initiating computation jobs based on multiple data inputs. Moreover, the proposed multi-queue has built-in mechanisms for controlling message sequences in applications where complex data set splitting is necessary. The presented multi-queue concept was successfully implemented and applied in a working LSC system.**

I. Introduction

LARGE-SCALE computations (LSC) are often performed in a distributed environment. Several computation nodes can be linked together to execute resource-consuming tasks. One of the main issues is the management of data flow between these nodes [1]. The goal is to reduce data transfer overheads and maximise the speed of computations. In a data flow-driven approach to LSC, computation applications are divided into computation steps, with data flowing as messages between these steps. An example of such a system is the BalticLSC platform [18], [13] (www.balticlsc.eu). It is a low-code computation environment created as part of a project intended to facilitate easier access to LSC. It performs computations in the form of Docker-based computation modules that are orchestrated according to applications defined in a dedicated graphical language called CAL (Computation Application Language) [19]. CAL revolves around the flow of data. The specific sequence of execution for computation modules is defined by specifying paths through which data flows between them. This creates the need for means to schedule starting of computation jobs according to data availability and to propagate that data between modules as defined by a CAL application. Other examples of systems where computations are driven by flowing data and that use graphical languages are WS-PGRADE [7], [6] and Flowbster [8]. Also, other Scientific Workflow Systems use this kind of approach [11].

Figure 1 shows an example application written in CAL. This application consists of three computation modules (the boxes) communicating through 6 data flows (the arrows). The application has two inputs (“Videos” and “Subtitles”) and one output (“Films”). In this example, the inputs and the output are sequences of folders containing appropriate files. Module “A” is a File Synchroniser type. It accepts two folders and, using certain naming conventions, produces two synchronous sequences of files (here: a video file matched with a subtitle file). The video file is processed by module “B” which is a Video Converter. Finally, module “C” (a VS Mixer) mixes the processed video file with the subtitle file received directly from module “A”. Individual files resulting from module “C” are then placed in appropriate folders at the output.

The flow of data between computation modules in Figure 1 is shown through additional tokens besides data flows. The numbers in circles relate to the specific flows (numbered 1 to 6 to denote the six flows). The numbers in rectangles denote sequence numbers. As we can notice, these sequence numbers can be stacked. For instance, token “1” with sequence number “0” (T1-S0) denotes a token message representing the first folder with video files on the “Videos” input. In case more folders are placed on the input, additional token messages (T1-S1, T1-S2, ...) are produced (not shown in the figure). Token number “3” necessitates a stack of two sequence numbers (e.g. T3-S0-S0, T3-S0-S1, ...). The top element corresponds to the source folder (cf. T1-S0), and the bottom element represents the number in the sequence of files in that folder. Note that these sequence numbers have to be maintained throughout computations. In our example, each instance of module “C” has to receive tokens with appropriate sequence stacks. For instance, token message T5-S0-S1 has to be matched with token message T4-S0-S1.

As in the example above, the message-passing system operates on sequences of token messages. It is thus natural to implement it using queues. However, according to our best knowledge, no existing solution could offer out-of-the-box all the functionality required to schedule jobs controlled by multiple data passing between the jobs. General-purpose queue systems are heavy-weight and offer extensive functionality for instantiating multiple queues. However, they do not provide mechanisms for task scheduling based on many synchronised queues. After analysing the available options, we have decided

This work was partially funded by the InterReg BSR Programme, grant no. #075

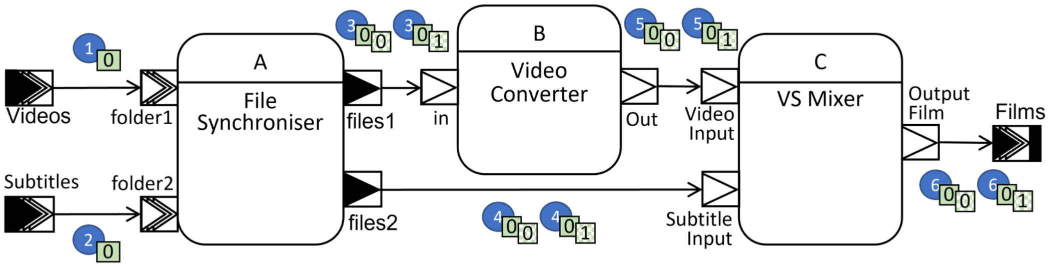

Fig. 1. Example application in CAL with sample tokens

to develop our own lightweight queue system, suitable for the CAL execution environment. In this paper, we present the details of our queue system and its application as part of a computation orchestration system within the BalticLSC environment.

II. Related work

There are two main approaches to performing distributed computations – orchestration and choreography [14], [16]. This follows two global trends of deploying workflows or composite micro-services. In the first approach, an external entity manages the flow of computations. BalticLSC and WS-PGRADE are examples here. In the second approach, this flow is realized by each participating computation element that fulfils its role that is known in advance. Flowbster is an example here.

The usage of FIFO queues is especially important for choreographed computations where they are intensively used. This includes managing the initiation of jobs in the proper order (either directly [9] or as part of more complex mechanisms [12]) and ensuring the exchange of messages between them. Especially relevant in the context of this paper is the usage of systems consisting of multiple queues (multi-queues) for task scheduling [2], [10], [5], [20], [22], [15]. Since such systems use queues to schedule tasks, they operate by scheduling computation steps, not data flows. For example, Li et al. [10] propose a system for scheduling read-write tasks for a distributed database system. Their solution is based on a multi-queue feature built into the Cassandra database system.

Generally, using queues provides two main advantages. Firstly, the responsibility to deliver messages falls on the queues, without the need to implement any additional mechanisms on the side of the message senders. Secondly, queues create separation in time between sending and receiving messages. Senders can send messages to yet non-existent recipients. Moreover, they can finish working before the recipients even start.

When describing a queue, we distinguish two roles of entities interacting with it - producers supplying messages to the queue and recipients interested in receiving these messages. Most queues utilize the publish-subscribe pattern. In this pattern, recipients declare to a queue their interest in messages of a given type. When a message fulfilling appropriate criteria arrives from a producer, all interested recipients are notified. The delivery of messages to recipients is generally done in one of two ways. Either a queue sends messages to its recipients (the push method), or recipients ask a queue for the messages and fetch them themselves (the pull method).

There are also a few additional issues that queues need to address, especially in the case of the push method. Messages can get lost because communication between queues and their recipients is never flawless. This necessitates repeating messages to guarantee their delivery. On the other hand, this can cause occurrences of unwanted duplicated messages. As a result, striving to ensure guaranteed delivery or lack of duplicates leads to hindering one of these features. Repeating undelivered messages could also change the order of messages, that is – the order in which messages reach the recipients can be different than the order in which they arrive from the producers. It is especially problematic when messages are delivered to multiple recipients simultaneously.

There are many systems implementing message distribution using queues [23], [21], but two of them found very wide usage – RabbitMQ [17] and Apache Kafka [3]. RabitMQ is an implementation of an extension to the AMQP protocol [24]. It supports delivering messages through both the push and the pull methods. However, the former is not recommended in most cases. Message distribution in RabbitMQ is oriented around the concept of exchanges. Exchanges define how messages are distributed between queues (which are related to particular recipients). RabbitMQ supports several types of exchanges, which allow directing messages to particular queues (direct exchange), duplicating messages to groups of queues (fanout exchange), distributing messages according to predefined topics (topic exchange) or checking for more complex patterns in message headers (header exchanges). The most commonly used publish-subscribe pattern is typically realized using topic exchanges through recipients subscribing to particular topics. To provide messages to recipients using the push method reliably, RabitMQ introduces a special mechanism for the acknowledgement of received messages by the recipients. It works based on the same principles as the mechanism for acknowledging receiving messages from the producers by the queue system. The idea was introduced to avoid confirming message delivery through the transaction system. Even if more reliable, this was considered as inconvenient for more trivial cases. Its existence also allows more subtle options used

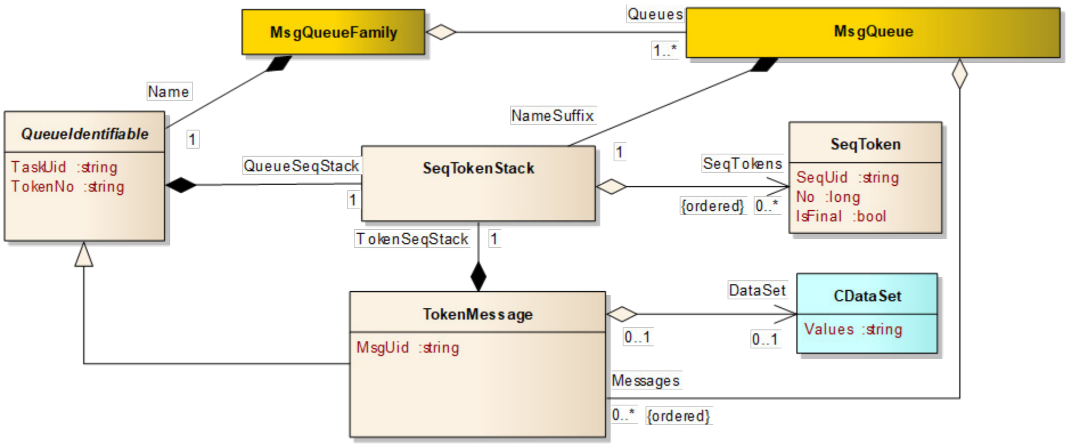

Fig. 2. Multiqueue metamodel

in managing the distribution of messages, like defining the prefetch count – the maximum number of unacknowledged messages that can be sent to a given recipient.

In the case of Apache Kafka [25], [4], queues are organized by topics to which particular recipients can subscribe. Each topic can also be further divided into partitions containing messages for a given recipient. Message delivery is then done by the pull method. This means that particular subscribers need to request messages that are of interest to them, typically as a part of a so-called pull loop. Kafka by default does not delete messages after they are delivered, and there is a possibility to access them again when needed. Accessing messages is done by means of an offset – the particular position in the sequence of messages that indicates which of them were already received. This particular setup obviously makes any message acknowledgement from the recipient obsolete. Thus, Kafka supports only the acknowledgement of message delivery to producers. However, particular client implementations can simulate an acknowledgement mechanism to manage the offset.

III. Multi-queue concept

As mentioned in the introduction, the orchestration of jobs in systems like BalticLSC is based on data flowing between these jobs. This makes message passing extremely important and imposes additional requirements. First, we need to ensure a reliable exchange of messages, as in every distributed system. In addition, our solution needs to allow representing and checking orchestration information attached to the messages. This information can be used to direct messages to appropriate queues.

Figure 2 shows the data structure of our multi-queue in the form of a UML model (a meta-model). The exchange of data between computation modules is handled by "token messages" (see the "TokenMessage" class), and such messages are managed by our multi-queue. Each token message contains a reference that points to a specific data set (see the "CDataSet" class). Data sets can contain data directly or can hold information about accessing data held in a storage system. Each token message is assigned properties that identify its position in the data flow within an instance of a specific application. This is reflected by two attributes specialised by the "TokenMessage" class from the "QueueIdentifiable" class. The "TaskUid" attribute refers to a specific task or – in other words – an instance of an application being executed within the BalticLSC system. The "TokenNo" attribute refers to the particular token number assigned to a specific data flow within the respective application (e.g. tokens 1-6 in Figure 1).

Token messages contain additional information about their sequence numbers. In fact, each token message contains a stack ("SeqTokenStack) of sequence numbers ("SeqToken"). This stack is divided into the "QueueSeqStack" and the "TokenSeqStack". The first stack corresponds to the specific queue to which this message is designated, while the second stack corresponds to a specific sequence of tokens produced by computation modules. These stacks ensure proper processing in applications where data can change its "granularity" (e.g. from folders to files). In such cases, we need to split larger data sets into many smaller pieces to be processed individually (e.g. in parallel). On the other hand, we might need to merge many smaller pieces into a final, larger data set. At the same time, we need to manage these various sequences so that relations between and within these sequences are preserved.

The token message stacks ("SeqTokenStack") allow keeping track of dependencies between data items and thus enable proper distribution of computations between computation jobs. The general rule is that a new level of the stack is added when a data set (file, folder) is split into smaller elements. On the other hand, when several data items are merged, one level of the stack is removed. Note that in some cases, two or more stack levels can be added or removed, depending on particular processing (e.g. processing of a two-dimensional data matrix). Moreover, it can be noted that sequence tokens contain sequence numbers ("No" in the "SeqToken" class). This is necessary due to the possible parallel processing of token messages. In case of delays in the processing of tokens, their order has to be maintained regardless of individual processing times. Moreover, we need a flag denoting the last token in a sequence (“IsFinal”).

The queue system that handles token messages consists of two elements. The top-level element is the Message Queue Family (“MsgQueueFamily”), which contains individual Message Queues (“MsgQueue”). The role of the queue family is to handle messages associated with a single data flow (see Figure 1 again). The individual queues handle messages directed to specific computation module instances (jobs) deployed in different distributed computation nodes. Queues are identified by token sequence stacks similar to the token messages that they contain. The identification (“Name”) of a message queue family contains two main values describing a token (TaskUid, TokenNo). This is appended with a token sequences stack (“QueueSeqStack”) to form the full identifier of a queue family. The message queues contain the suffix part (“NameSuffix”) of the token sequence stack, identifying the particular jobs to which tokens should be sent. As we can notice, the main assumption is that individual queues contain token messages that are meant to be processed by the same computation modules. Thus, these token messages point to the same type of data. The assignment of messages to queues is done in two steps. First, we assign them to a message queue family and then – to a particular queue.

Token messages in each of the queues contain full token sequence stacks. In addition to the stack defined in the queue family and its queues, the token sequence stack in a message contains additional levels defining the sequence of tokens sent to the particular job. As a result, before putting a token message to a specific queue, we need to construct a token sequence stack consisting of two parts. The first part identifies the queue (and its family), and the other part contains indexing data that will be forwarded to the recipient (job) to help in internal processing.

In practice, the relationships indicated by the elements of each “SeqTokenStack” serve two purposes. Firstly they ensure that jobs that should process corresponding groups of data from different queues will receive correct data items. Secondly, when computations are distributed between separate machines, related data will be grouped together to reduce unnecessary data transfer. It is also worth mentioning that there is an exception to these rules. This is for so-called “simple” modules, i.e. those that process only one token message from a single queue at a time. In the case of such queues, there is no need to use SeqTokenStack elements for either of the two mentioned purposes, at least at the individual level. However, to maintain consistency in handling queues, we still use “SeqTokenStack” to identify such queues.

An example of a queue family is shown in Figure 3. The outer box represents a family with a task identifier (“Task1”), a token number (“8”) and a token sequence stack (here with one level – “0”). The family contains three queues. Each queue contains a “suffix” for the token sequence stack (“0”, “1” or “2”). In each queue, we have several token messages. As we can see, each message contains the same token number (“8”)

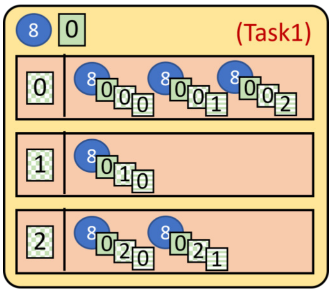

Fig. 3. Example structure of a queue family

and token sequence stack prefix (“0”), which reflects the queue family. Moreover, tokens assigned to each queue in the family have the second levels of their stacks corresponding with their appropriate queue stack suffix. Finally, the third level in the stack reflects the token sequences.

Queues defined according to the presented rules can be used to initiate jobs (instances of computation modules). In general, specific modules require either one or many tokens to be delivered to them from a given queue. For some queues, the arrival of tokens is required to start a job. In other cases, tokens arriving at a queue are passed to a job but are not mandatory to start processing. With our multi-queue, we can easily determine meeting conditions to start jobs. When a new token that matches a given queue in a family arrives, we can check all the queues in queue families assigned to the inputs of a respective computation module. If all the corresponding queues contain tokens, the condition for a new processing job is met. We can then either start a new instance of a computation module or use an instance that is currently idle.

Apart from this additional functionality, our queues work like traditional FIFO queues. They use the publish-subscribe pattern to deliver tokens to jobs using the push method. An additional non-standard element is the implementation of the acknowledgement mechanism, which has some similarities to that of RabitMQ. When a message is delivered to the queue, it is first stored in it. It then waits for its turn (FIFO) and gets assigned to one of the available recipients. This is done by balancing the number of messages each registered recipient receives. Recipients may reject messages (e.g. have insufficient resources), which results in attempting to send the message to another recipient. If the message is accepted, its status changes accordingly, but it is not removed until the recipient acknowledges the finishing of its processing. There is also a possibility of the recipient sending a negative acknowledgement (processing did not succeed). In this case, the message status is reverted, which causes a repetition of the above process.

IV. Illustrative example

In this example, we use the application presented in the introduction (Figure 1). Each data flow (numbered from 1 to 6) is associated with one or more queue families. Moreover, these families are grouped by computation modules depending on

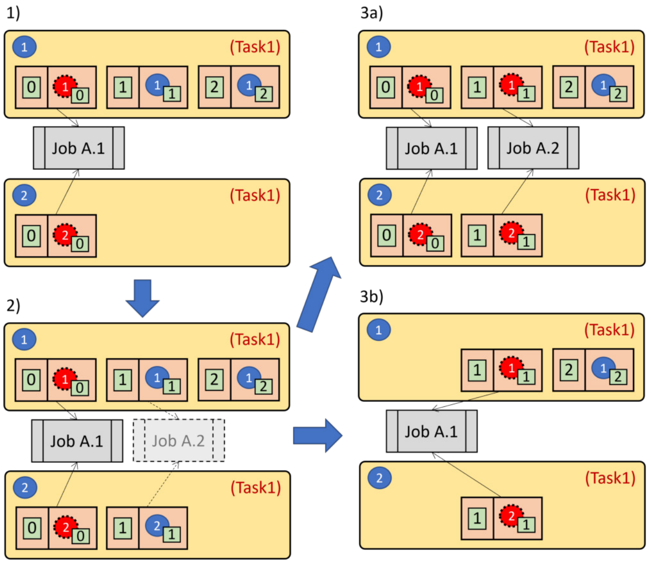

Fig. 4. Queues for tokens 1 and 2

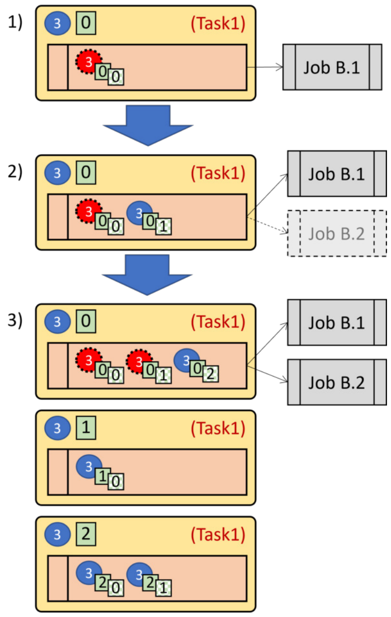

Fig. 5. Queues for token 3

their inputs. These groups can be used to initiate appropriate jobs being instances of the computation modules. We assume that a single task was created from our example application ("Task1"). Obviously, more such tasks can be executed at the same time, and thus more queue families can be created whose identification differs only by the task identifier.

Figure 4 shows queues responsible for providing token messages to instances of module A in our application. The situation shown in step 1) is somewhat advanced in time. We have two queue families (related to tokens "1" and "2"), which already have a few token messages in each of them. We also have one instance of the module (job) running (named "A.1"). It can be noted that each input of module A has been assigned a separate queue family. Moreover, separate queues related to the existing token sequence stacks were created inside the families. At this moment, we have three queues for tokens of type "1" and one queue for tokens of type "2". Note that each of these queues was created with the arrival of an appropriate token message. The name suffixes correspond to the token sequence numbers of these token messages.

When queues 1-0 and 2-0 were created, job A.1 was initiated and assigned to these queues as their recipient. Through this mechanism, the job is guaranteed to get the related pair of token messages. In the situation shown in step 1), we already have job A.1 running and processing the pair of token messages denoted with the sequence number "0" in their token sequence stacks. The queues marked these messages as delivered but did not delete them, as the job did not acknowledge finishing their processing. We have also two additional messages in the first queue family that haven't been delivered yet.

In step 2), a new message is inserted into the second queue family which results in creating an appropriate queue (2-1). With this arrival, we have a new pair of matching token messages (1-1 and 2-1). This creates a condition to create a new job. Depending on the decision of the job broker module, this can lead to one of two situations shown as 3a) and 3b) in Figure 4. In the first situation, a new instance of the computation module A was started ("A.2"). This instance has immediately subscribed to the two related queues. The appropriate messages were then delivered and marked as being processed. In the second situation, a new instance of module A was not created. The job broker waited until instance A.1 finished its previous processing. Only then could the instance subscribe to queues 1-1 and 2-1. This is followed by delivering the new pair of token messages to A.1 and marking them as being processed. Note that the second situation can occur in the situation of limited resources. If we cannot create a new instance of module A, we must wait for an existing instance to finish its current job.

Figure 5 presents queues that serve to provide messages from instances of module A to instances of module B. Note that module B is a simple module – it has only one single-token input. Thus, the incoming messages do not need to be grouped. However, we need to preserve the grouping made for module A at the start of the application. In step 1) we create a new queue family when a message arrives from one of the jobs being instances of module A. We note that this message has a stack with two layers. The first layer corresponds to the sequence numbering preserved from the tokens messages for token no. "1". This reflects a series of folders placed on the application input "Videos". The second layer contains a new sequence (a sub-sequence), corresponding to messages created from one instance of module A. These messages reflect individual files present in a given folder.

The first queue family is identified by the token number

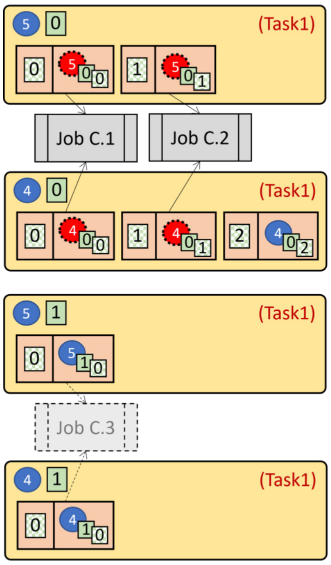

Fig. 6. Queues for tokens 4 and 5

and the top-level sequence number (here: 3-0). It has one default queue that does not need any additional identification. In Figure 5, we can see that the queue already has one job (B.1) assigned as its recipient and the first token message (3-0-0) is already being processed by this job. In step 2), another message in the sequence (3-0-1) is delivered to the queue. This creates an occasion to start another job of type "B" (assuming that job B.1 still processes token 3-0-0). Such a new job (here: B.2) would subscribe to the queue the same way as job B.1. In this case, further token messages can be processed by two jobs.

Step 3) in Figure 5 shows the configuration of queues after several other messages for token "3" arrive. As we can see, further queue families were created. These families reflect the token message sequence arriving at module A. For each such token message (1-0, 1-1, 1-2), we create a separate queue family (3-0, 3-1, 3-2). The reason for applying such a mechanism is to facilitate the distribution of computations. Each of the queues can be assigned to a different computation node potentially located in different geographical locations. In such a case, e.g. jobs for queue 3-0 will obviously not be able to process token messages in queue 3-1. On the other hand, if both queues are assigned to a single node, it is fairly easy to assign a job to both queues as their recipient.

Figure 6 presents queues that handle messages coming from instances of modules A and B and sent to instances of module C. The situation is to some extent similar to the previous ones, so we present only one "snapshot" of the queues. The main difference is the existence of many queues in queue families with split token sequence stacks. This split is caused to facilitate the distribution of jobs. Queue families are assigned to specific computation nodes, and individual queues in these families are assigned to specific computation module instances.

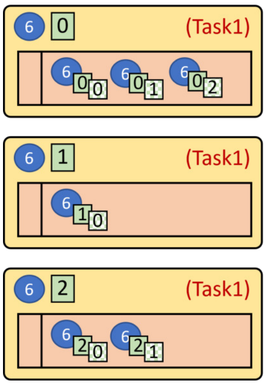

Fig. 7. Queues for token 6

In our example, we have two jobs already created based on two sets of token messages (5-0-0 with 4-0-0 and 5-0-1 with 4-0-1). These two jobs are running on one computation node. Another job (C.3) starts based on messages 5-1-0 and 4-1-0. This job can potentially be started on a different computation node.

Finally, Figure 7 shows queues containing token messages with the final results of the application. Here we can see three queue families created for a single token ("6"). These families correspond to the initial token message sequence shown in Figure 4. For instance, queue family 6-0 corresponds to tokens 1-0 and 2-0 sent initially to queues "1" and "2". As we remember, these initial tokens reflected folders with video and subtitle files. At this final stage, the results should also be grouped into folders according to the CAL application (see the output "Films" in Figure 1). Messages assigned to each of the queues in Figure 7 reflect individual files with the resulting films. Queues reflect folders into which these files should be sent. These output folders will contain films created from videos and subtitles contained in synchronised input folders.

Note that the application can be easily extended with further modules. In such a case, the queues for token "6" could be exactly the same (depending on how we exactly extend our application). In such a hypothetical case, the first arrival of a token message will create an occasion to start a new job, to which all messages from the given queue would be sent. It has to be stressed that our multi-queue mechanisms allow for the fully automatic creation of queues, as in the presented example. The execution engine can create queues based on the definition of the application in CAL and the arrival of consecutive token messages. In the next section, we present the implementation of these mechanisms.

V. Multi-queue implementation

The BalticLSC system consists of several components that cooperate to orchestrate jobs in a distributed computation environment. An extract of the BalticLSC logical architectural model (see https://www.balticlsc.eu/model/) is shown in Figure 8. The multi-queue mechanisms presented in this paper are

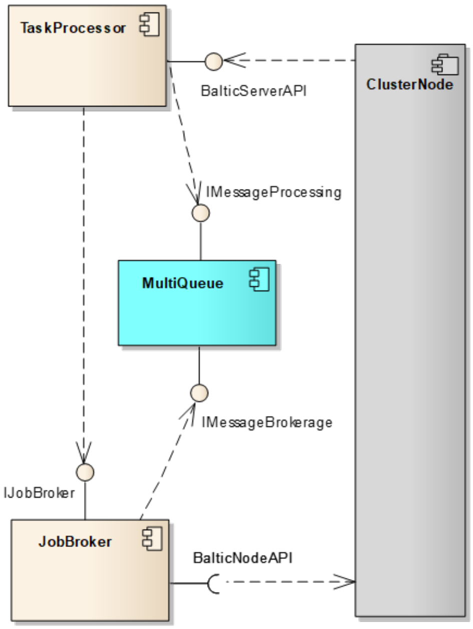

Fig. 8. Multi-queue usage in a computation system

implemented within a separate component – “MultiQueue”. This component works in cooperation with the middleware responsible for orchestrating computations. As we can see in Figure 8, this middleware contains two components that work as intermediaries between the multi-queue system and the actual computation modules.

The “TaskProcessor” component is responsible for invoking most of the presented multi-queue mechanisms. It receives token messages from computation modules through the BalticServerAPI. It then appends them with all the necessary information (including the sequence stacks) and inserts them into the multi-queue. It also checks all the conditions for starting new computation module instances. When a condition is met, it passes an appropriate command to the “JobBroker” component. This component is responsible for the actual initiation of new module instances, which includes making decisions regarding job balancing and sensing these jobs to specific computation nodes. It also registers these new instances in the queues, allowing appropriate tokens to be transmitted.

To communicate with the multi-queue, the Task Processor uses the IMessageProcessing interface, and the Job Broker uses the IMessageBrokerage interface. The details of these interfaces are shown in Figure 9. The first of the interfaces groups operations to enqueue new token messages, acknowledge the finishing of their processing and check the status of tokens in specific queues. For managerial purposes, there is also the possibility to create queue families. Finally, there is the possibility of forming a tree-like structure from the queues by defining queue predecessors. This additional mechanism is used by an automatic queue-cleaning mechanism. This ensures that empty queues will not be deleted as long as preceding queues have unacknowledged tokens left. The IMessageBrokerage interface contains an additional method that allows registering new recipients for specified queues. Figure 9 also shows the IQueueConsumer interface that should be implemented by a computation module. This simple interface allows module instances to receive messages.

Fig. 9. Interfaces of the multi-queue implementation

Operation of the TaskProcessor component when processing a token message is presented in Figure 10. The whole process is initiated by invoking the PutTokenMessage method in reaction to the incoming token message. First, the method checks if there is the need to start a so-called job batch. This feature of the BalticLSC system allows for grouping of jobs so that they would be computed on the same computation nodes making data transfer more efficient (see CAL specifications [19]). Starting of job batches is similar to starting of jobs. The TaskProcessor needs to check all the queues related to the inputs of all jobs that are also inputs of the particular job batch. For this, it calls the CheckQueue operation which returns the number of messages in a given queue. Presence of at least one message in all the input queues required to start the job batch results in calling the ActivateJobBatch operation of the JobBroker component. Obviously, if the job batch is already activated, there is no need to perform queue checks and activate it again.

A similar approach is used to activate the specific job related to the processed token. Again, the procedure includes checking of all the required input queues. Note that the queue for the processed token message does not need to be checked. Instead, the message is enqueued after all the necessary checks are done.

Details of the multi-queue implementation are shown in Figure 11. The MultiQueue class is responsible for the functioning of the MultiQueue component and implements its provided interfaces. It runs a thread (the “Run” operation) that periodically sends tokens to consumers registered with the various queues. Message distribution is performed through handles to queue families grouped by task identifiers. These queue families are implemented by the MsgQueueFamily

class, which groups queues with a common ‘name’. This name is formed using the same data structure (“QueueIdentifiable”) as in the original data model (Figure 2). The queue family class has various operations that allow to enqueue and acknowledge messages, distribute them to the registered consumers, and check queue statuses.

As expected, the MsgQueueFamily class contains the MsgQueue class. This class holds the actual queue contents, i.e. the messages. It also contains the name suffix in the form of a token sequence stack and has handles to the queue consumers. Operations of this class are typical for a queue and do not necessitate a detailed explanation.

To illustrate the usage of our multiqueue within the BalticLSC system we will use the CAL program fragment presented in Figure 12. The main module in this fragment is the “ImgChannelJoin” module. It has three input pins and one output pin. The three inputs are connected with certain processing modules, where one of them is shown in the figure. The input pins are associated with appropriate tokens (np. 3, 9 and 10). In the figure, we can see three tokens arriving, each of them having the same sequence number (0) and thus causing initiation of a new job instance for the “ImgChannelJoin” module.

In Figure 13 we can see a fragment of execution log for the situation in Figure 12. The log contains information about processing of a single token message arriving at one of the inputs of the “joiner” module. The first entry in the log denotes the arrival of the message at the Task Processor component (see also Figure 8). As we can see, the message is related to Token number 3. It is the first in a sequence of messages for this Token, and thus contains the index number 0 on its sequence stack (see the ‘seq_stack’ section).

Fig. 11. Code structure of the multi-queue implementation

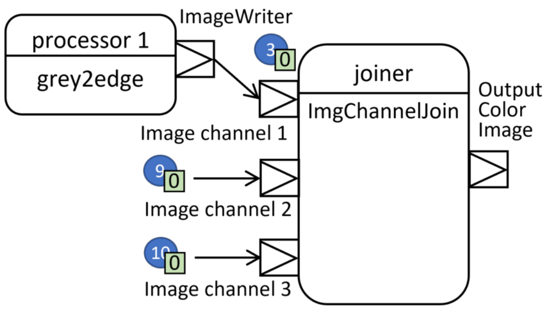

Fig. 12. CAL program fragment to illustrate queue module usage

Immediately after receiving the message, the Task Processor performs a sequence of checks to determine if the incoming message would trigger a new job instance (see the "Check-Queue" operation). In our case, three queues are checked – the ones related to the three inputs of the "joiner" module, including the queue for the incoming message. As we can see, the Task Processor requests checking queues for Tokens 3, 9 and 10 with the sequence index 0.

In the presented situation, queues "9.0" and "10.0" already had messages in them. This means that arrival of the message to the queue "3.0" should trigger a new job instance. The log in Figure 13 thus contains information about creating a new job message. This new message contains information about the queues for input tokens and about the output token. It also determines technical details of the module to be executed by the runtime. Some of these details (image file, configuration file) are shown in the figure but other are omitted as not relevant here. Note that the information about the module to be executed are determined by the Task Processor based on information compiled from the appropriate CAL program.

The new job message is passed to the "JobBroker" component through the "IJobBroker" interface (see again Figure 8). The broker then selects an appropriate computation node for execution of the job and sends the job message to this node. Note that job brokerage algorithm is out of scope of this paper. After determining the job's executing module at the computation node, the broker registers it in all the relevant queues through the "IMessageBrokerage" interface. Finally, the Task Processor inserts the incoming token message into the multi-queue using the "Enqueue" operation of the "IMessageProcessing" interface (see Figure 9). This finishes processing of the token message by the Task Processor. This is signalled by the last entry in the presented log. Further steps involve the computation node that accesses the queues according to the description in the previous sections.

By examining the log in Figure 13 we can also determine the efficiency of the queue system. Each entry contains information about its time with the precision of tenths of milliseconds. As we can see, it took the engine around a millisecond to process the message – put it into the queue module, check

Fig. 13. CAL program execution log fragment

associated queues and create a job message. This time is negligible in relation to the time used for computations which usually takes minutes, hours or even days. It thus can be argued that such message processing times allow for significant scalability of the system. Even with a single instance of the runtime engine, many parallel tasks could be processed without noticeable delays related to message processing. If needed, this could be further improved by adding additional runtime engine instances running on several machines. Note that determining detailed performance characteristics of our solution are subject to future work.

An important additional feature worth noting as facilitated by the existence of queue families is "queue garbage collection". Each queue has information about its successors, and each queue family has information about its predecessors. This allows the multi-queue to keep track of queues that are not used and will not be used in the future (within the current application instance). The garbage collector mechanism traverses queues and queue families to determine all the relations for a given queue and based on an appropriate algorithm removes "dead" queues. Discussion on the details of this mechanism is out of the scope of this paper.

VI. Conclusion

The presented multi-queue concept was validated in a fully operational distributed computation system. It has proven to be effective means of orchestrating computations with diverse configurations of data sets, flowing between instances of computation modules. The users of the BalticLSC system have developed various computation applications with different configurations of data flows. Examining of computation logs from the system acknowledges the effectiveness of message distribution by the queue system. Message handling times are short (in the scale of milliseconds) and thus negligible within the whole computation process.

The characteristics of our multi-queues facilitate the simultaneous delivery of multiple token messages to many instances of the same computation module running on different computation nodes. It also allowed the implementation of a job initiation mechanism that is based on the availability of data transmitted through complex data processing paths. At the same time, the implementation of our multi-queue system is quite simple and results in a lightweight queue component that can be used in similar contexts.

***Abstract*— The paper proposes a new way to access semi-permanent services in ad-hoc and mesh networking in the context of the Internet of Things and the Internet of Services. The solution is based on address-free communication, with individual addresses of the nodes replaced by a semantic description of their functionality. The mesh network is accessible from outside using the classic RESTful approach and needs no centralized catalog to maintain at-the-moment available services. Instead, entry gateways are responsible for mapping incoming REST-compliant communication to internal mesh messaging, and the mesh nodes individually decide how to react to particular messages. Installing each new or replaced node or monitoring the node status is unnecessary. Automatic communication among the nodes is possible without human intervention, including both runtime and the registration phase.**

Bluetooth mesh topology network was chosen as the implementation base. Transmission in the network occurs in a broadcast mode, in which one network node sends information that is then received and interpreted by all other nodes. Selected devices equipped with alternative communication modules of a different type, in particular, connected to the home WiFi network, can be used as input/output gateways for outside communication.

***Index Terms*—address-free networking, zero-configuration networking, P2P broadcasting networks, BLE mesh, ad-hoc networks, RESTful approach.**

I. Introduction

Recently we have observed a boom in the client-server architecture. The RESTful approach needs special attention among multiple protocols and strategies used to implement a client-server system [1, 2]. This is an architectural style based on standard HTTP requests, and URL addressing. The key entity for a REST-compliant system is the so-called ‘resource’. A REST resource is a well-defined part of server functionality, being a building block for the set of servers’ services. A resource could be a pointer to a file, a server-side script, a database entry, etc. Each resource is uniquely identified by means of an URL address [3], composed of the scheme identifier, domain name, port number, a local path to a file/script, and a set of parameters composing a query**.**

The RESTful approach is an efficient tool for implementing a fixed, well-defined network. On the contrary, recently, we have observed the growing importance of ad-hoc [4] and dynamic networking, especially in the context of vehicular and road networks [5], not to say about classical sensor networks [6] and MANETs [7, 8]. The research in the domain of ad-hoc networking recently concentrated on mobility, energy savings, and routing [9], especially under specific circumstances (such as underwater acoustic connections [10], also evolving into an interesting concept of a digital twin [11]. Recently, a new approach to distributing network functionality, namely the fog [12], has become popular, concentrating some resources (nodes, computation power, memory, etc.) close to the most needed places in order to provide real-time reaction.

For ad-hoc networking, nothing is fixed – neither the set of services/nodes nor the information contents. Especially, ad-hoc networking strongly limits fixed ways of addressing network services (resources) by their location and name, leading to the concept of address-free networking [13], which is well known but somehow abandoned recently. Thus, using classical URLs in the ad-hoc system is disputable unless the server-side is fixed and only the clients are connected incidentally. As a consequence, server-side architecture for ad-hoc applications is usually replaced by a mesh. A mesh network [14] is a local area network topology in which the nodes connect directly, dynamically, and non-hierarchically with as many other nodes as possible and cooperate with one another to route data efficiently. A mesh node is not characterized by a permanent identification (e.g., an address); moreover, such a node may suddenly vanish from the network structure or convert to another node due to network evolution, such as the one provoked by the mobility of nodes, amount of available energy, problems with radio transmission, etc. A popular example of a mesh network is BLE (Bluetooth Low Energy) Mesh proposal [15, 16], with several implementations [17] and sub-standards/extensions [18], also related to security and privacy [19], and interoperability [20], addressed to not only classical computers, tablets, or smartphones, but also IoT (Internet of Things) devices based on (among others) Espressif, STM, and Nordic Semiconductor processors with built-in BLE unit.

A question arises if it is possible to apply the RESTful approach with its persistent services, which is very efficient and thus popular in fixed/stable networking, to mesh networking? At first view, the answer is 'no'. Indeed, if we cannot identify a node for a longer time, we cannot establish a client-server connection to ask for a service. However, the above question may be converted to another one: is it possible to address REST-compliant persistent resources in a dynamic way, not using fixed URLs but mapping external REST calls to internal mesh messages of particular format and semantics? Thus, persistent addressing of the resources is to be replaced by a persistent (i.e., stable) description of their functionality. Later on, this fixed description may be used for individual selection of the nodes fulfilling certain criteria. The selection may be performed by the nodes – each node, based on its own declared functionality, accepts or refuses the incoming requests.

In the paper, we propose such an extension to provide RESTful information exchange for a mesh network, especially for BLE Mesh. The idea is to treat a mesh network as a set of REST resources of a given functionality, to be identified not by their URL addresses but by means of their characteristics and possibilities. From the outside, the mesh network is seen as a REST server with specific functionality. Internally, the nodes composing the dynamic network react individually to fulfill incoming REST requests. The node's reaction depends on the individual characteristic of this node, in particular, its type being a counterpart of the REST resource name and the REST query.

The remainder of the paper is organized as follows. Section 2 overviews the motivation for using semi-persistent services in ad-hoc interactions. Section 3 describes a generic approach to mapping REST calls to mesh functionality and the reasons for particular network topology and organization. Sections 4 and 5 describe a sample implementation of kitchenware equipment based on our approach. Next, we include a comparison with similar work, and finally, we provide some conclusions and directions for future work.

II. Specificity of Mesh and Ad-Hoc Networking

If we speak about ad-hoc networking, at first view, we think that every activity is undertaken incidentally: ad-hoc place and time, situation, context, etc. However, that is not the whole truth. There is one element that is fixed – the user. We do not change our needs and expectations just because we are, by coincidence, in an unknown situation. On the contrary, we try to act in a "usual" way, according to our past experience and customs. One may say that we stay with our needs, fixed, as long as it is possible, and we try to act "as usual" even if the case is extraordinary.

Thus, an idea arose to propose a new sort of services for an ad-hoc environment. The goal is to use a service in the same (or at least very similar) way, regardless of place and time. Such services are semi-persistent. In such a way, from the point of view of a user, they are the same everywhere, appearing for this user in the form the user expects. However, from the technical point of view, the services are independent entities, implemented individually and possibly adjusted to the place (conditions) where they work.

In an ad-hoc environment, the users do not know the specificity of the place they are currently in, particularly the set of nodes and their identifiers (addresses, services, and their entry points). However, they know the place's overall character (such as a home, a shop, a bus stop, etc.), and they expect some well-known services accessible at this place. For example, they expect hot water to be prepared in the kitchen or a bus going to a specific destination at the bus stop. Please note that location-specific services are usually well-defined and common for all places of the same type and purpose.

With a classical approach, such as a typical REST application, getting consistent services at many unrelated and unsynchronized places is almost impossible. For example, one cannot expect the same IP address and naming convention for network nodes. Moreover, an installation phase is needed to create some "entry points" for the services, such as installation and configuration of a specific application, catalog of available services and their status, etc. It is unrealistic to expect each place to follow the same rules of addressing and parameterizing, not to say about the security (user identification, access codes, passwords, etc.). As a consequence, we usually deal with one fixed application per place.

This paper proposes a different approach to preparing and accessing such semi-persistent services. We assume that a definition of the semantics of the services is fixed and shared by all the ad-hoc accessible places. Such a semantic description is also known for end-user devices, usually smartphones. Each time a user is at an unknown, ad-hoc place/situation, the description is used to formulate a request, to be disseminated across all the ad-hoc network nodes. If a node (or a set of nodes) "understands" the request, then this node undertakes particular action related to the semantic description, trying to fulfill the request. The network is "silent," and no activity is performed if no single node can provide the service.

Please note that the node should individually choose the "implementation" of the requested service. Only the node knows in detail the specificity of the place, which is unknown to the user. So, the user may only formulate a generic request (such as "turn on some light here"), but how the request would be served (such as "switch on ceiling lamps to 50%") depends on the possibilities and strategy of the place.

As it may be seen, the idea of accessing semi-persistent service in an ad-hoc manner is the following: "try it, and if you are lucky, the service is there for you; otherwise, try a different way or give up". Such experiments are to be undertaken at any unknown (not previously visited, or changed for some reasons) ad-hoc place; however, they are quite natural and intuitive for humans. Moreover, these experiments somehow bypass the installation phase and need no a'priori catalog of at-the-place services.

Initially, we planned to implement our approach as a home application, namely, a "smart" kitchen. Usually, the kitchenware is (1) not synchronized, such as a kettle does not know about a presence of a radio, and an oven is not informed if a ventilator is here to reduce the smell while cooking, and (2) fixed as for the overall functionality (such as “a kettle” or “a refrigerator”), not necessarily fixed as for models/producers/functionality of specific devices. Even if all the “smart” devices are accessible via the same kind of network (which is, in our case – classic Bluetooth, and recently BLE Mesh), these devices are to be registered in a catalog, and in most cases, the smartphone applications are specific for a given model of a device. Each time a device is broken and changed, the user must update the catalog information or install a different application. Keeping with a single application and ad-hoc access to semi-permanent services would solve these problems, on the condition that the services describe the possibilities of typical devices (in our case – the set of devices of a single producer). As a consequence, each application

- will be useful at any “smart” kitchen, no matter its location,
- no additional security checks are needed (the users are granted to use the devices installed at the place they are currently visiting), and
- no installation and cataloging is needed, as well as no “user manuals” for different models of similar devices.

The semantic description of the at-the-place services covers all the details and frees users to learn detailed functionality (for some “smart” devices, quite complex, and, as previously mentioned, model-specific).

The proposed idea is generic and may be adjusted to many places and situations. The kitchenware application could be extended to any place, not necessarily private, but also public. For example, entering a bus stop, one can experiment with a service providing an actual timetable for the buses traveling to/from this bus stop in a minute. While visiting a shop, users may obtain additional information, e.g., the locations of the goods on the shelves, personalized advertisement, etc. At the school, the services may be related to the current schedule of the lectures (solving the “where is my next lecture” problem, etc.). The generic idea is that: entering an unknown place, the users ask for known services.

III. REST MODIFICATIONS TOWARDS THE USAGE IN MESH NETWORKS

As already mentioned, addressing a REST resource via HTTP calls aims in: providing computer identification (node address), declaring port number, defining a path to an internal entity implementing the REST resource (a file, a script, a database entry, etc.), and providing a query to adjust the resource’s behavior. Suppose we divide the above set into the “external” and “internal” parts. In that case, we may separate the node address and port number (“external” parameters), and the rest to be processed “internally” by the node. Further, we may logically link the “external” part with a gateway to the mesh network as a whole and the internal part with the given mesh functionality (to be, in turn, implemented by a set of mesh nodes). Such a global mapping is presented in Fig. 1.

As already mentioned, it is hard to identify a node in a mesh network permanently. Thus, linking REST resources with any node identifier is not justified. Instead, we propose to attach such a resource with certain well-defined, thus somehow persistent, functionality to be dynamically implemented by a node (or nodes). To clear the idea, we propose to join this functionality with a named type and to provide a map of resource names and their types. Types create a hierarchy, being a direct acyclic graph (DAG), precisely, a tree with a single root. Fig. 2 represents a sample hierarchy of types for typical kitchenware equipment we used for the sample implementation of the proposed approach.

schema
domain
port
path
c
parameters
External part
Internal part

Fig. 1. External and internal parts of URL address

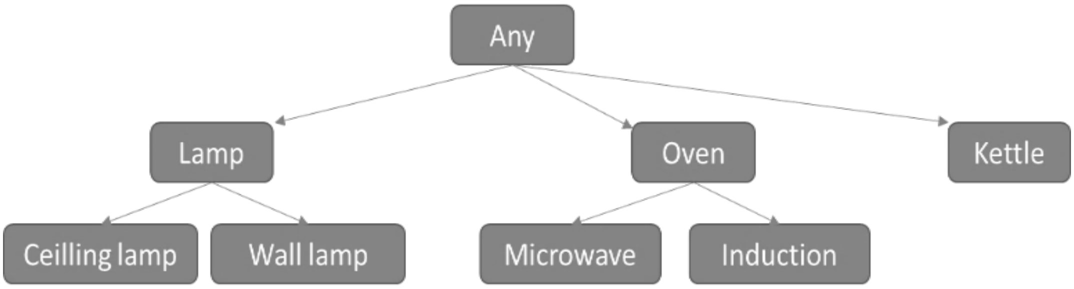

Fig. 2. Sample hierarchy of types of kitchenware equipment

As the types form a DAG hierarchy, they may be specialized or extended, depending on the point of view and the direction of graph analysis. For example, an 'oven' node may group "microwave oven", "gas oven", "induction oven" etc. Please note that all these "ovens" share some functionality, such as "set power to 1000W", and in turn have common functionality with some other electrical devices, such as "run timer". In particular, the root (a device of type "any") could possibly be linked with some generic functionality of any electric device, such as "on", "off", and the above "timer" actions.

According to the REST principle, we specialize some types, such as the above "ovens" share the basic functionality of an oven, and some specific functions of "oven/microwave", "oven/grill", "oven/induction", "oven/induction/plate_NE", etc. Please note that the above naming schema conforms to the REST principle.

The types may also be extended to individual names. For example, a "lamp" can be specialized to a "lamp/ceiling" and a "lamp/wall", sharing exactly the same functionality but differing in, e.g., the place of installation of the physical object the mesh node is connected to. In general, detailed organization and interpretation of the hierarchy depend on the application area and the installation place. As described later in the text, the hierarchy may be reflected by nodes' data, to be processed in a distributed manner – there is no need to represent the hierarchy as a whole by any network node or somewhere in a cloud. Furthermore, last but not least, addressing the primary REST name (such as the "lamp" in the above example) would activate all the devices of the same basic type. If "on" command is sent to all the "lamps", they will be all activated. However, if such a command is sent to "lamp/wall", only this lamp is illuminated.

Note that the above-described mapping shares the basic ideas of object-oriented programming, namely encapsulation, inheritance, and abstraction. Each mesh node may be treated as a singleton, with a well-defined set of "private" variables and functions and a "public" interface. This interface accepts only the "known" (from the node's point of view) incoming messages. As the nodes share the persistent inheritance hierarchy (c.f., Fig. 2), each node may check if the incoming message is of any of the "known" types. In such a way, the node must know both the type (mapped from the REST resource name) and the query (mapped from the REST parameters) to react; however, such a reaction is individual for each node.

As the mesh network structure is dynamic, and we do not provide such functionality as a centralized directory, one cannot apply direct identification of nodes. Thus, unicast transmissions are not possible. Instead, we propose to broadcast all the messages in the "non-responding" way. Each message comes to any node within the radio range. There, a preliminary checking occurs if such a message addresses a type that is linked with the node. If any node's type matches, the node interprets the message according to the query parameters. Appropriate action is undertaken (such as switching the real device linked with the node "on" or "off"). Thus, the nodes may react differently to the same messages. For example, an "alarm" message will close the windows, open the doors, switch on the lights, activate a siren, etc.

As it may be seen, a single broadcasted message may provoke quite complicated behavior of the mesh network, depending on the individual functionality of each network node. On the contrary, some messages are possibly not served once there is no node with certain functionality. For example, if an "oven" device asks for some ventilation, and no node with "a ventilator" type is provided, no air flow is initiated. If, however, at any time, an owner of the network decides to buy a new ventilator, this device will be activated with no changes in the existing network structure and nodes' functionality/hardware/software.

Broadcast messaging limits the way of possible response from the nodes. However, direct responding may be replaced by two succeeding broadcast transmissions. For example, if a device (e.g., a smartphone) is interested in temperature measurement, its node may broadcast a message "get temperature". Thus, each thermometer node reacts by broadcasting the "current temperature" parameterized in the query by the temperature value (Fig. 3). If no "response" broadcast message is observed for a certain period, this means there is no thermometer in the network. On the contrary, if several thermometers exist, they will all send a broadcast transmission with their values. It is up to the caller to get only the first (the highest, the lowest) one or to fetch them all and compute an average value.

IV. System architecture and data flow

We assume that a mesh network is equipped with at least one gateway to any public network (LAN or Internet). The node with the gateway has two network connections (Fig. 4): a public one (such as WiFi or LTE), and a mesh-related one (such as BLE Mesh). The gateway node is responsible for the mapping of incoming REST resources to internal mesh messages representing REST calls and eventually collecting the responses (i.e., reverse broadcast messages coming back within a certain timeout window) from mesh nodes to form an HTTP public response for the external call (c.f., "fridge" node from Fig. 3).

The mapping aims to process the URL address of a REST resource in several steps:

- cutting off the address part and port number,
- mapping resource name to type name,
- passing the incoming query with no changes,
- adding some specific query parameters, such as gateway identifier, the node number of the message sender, etc.,
- encrypting the message using BLE Mesh keys.

The mesh message is sent to any other node in the network (Fig. 5). If the network is big enough, so the relaying is needed, then some nodes may re-send the message to some other nodes. Standard BLE Mesh mechanism is used to relay the messages, and to eliminate incidental message copies in a reasonable time window (usually a second).

Fig. 5. Mapping messages in the gateway node

Each node, after receiving the mesh message, is responsible for (1) unfolding the non-standard characters using the standard *URLdecode()* function, (2) checking the accordance of the type, and (3) if the message type conforms to any type declared for the node, consume the message and start appropriate action(s) addressed to the real-world entity the node is connected with.

Due to the strategy used by BLE Mesh, the messages must be exchanged in the scope of so-called models. Each model is responsible for managing the messages of a certain structure and semantics. A model defines a set of states, state transitions, state bindings, messages, and other associated behavior. Each node must support one or more models, and these model or models define the node's functionality. There are two basic types of BLE Mesh models. Special Interest Group proposes SIG models [21] as a set of well-defined models of fixed functionality (starting from such simple models as Generic ON/OFF, to quite more complicated such as battery-level monitoring). These models are usually implemented as a part of the BLE Mesh library. The second group of models is called vendor models. Vendor models use a slightly different mode of identification of messages (longer identifiers). Thus they are sometimes less efficient. However, these models are not standardized, so in theory, they may represent an arbitrary set of additional services (functions) of the node, prepared by the network designer.

In the next section, we describe our reasonable for proposing the implementation of a certain set of BLE Mesh models, in turn, to implement REST messaging in the mesh network.

V. Implementation issues

As described above, one has to propose a model to exchange the information in the scope of the BLE Mesh network. The model comprises both message syntax (i.e., data length) and semantics (i.e., data type and location in the buffer). We decided to provide two implementations: a new SIG model and a vendor model. The implementation was based on Nordic Semiconductor processors (namely nrf52840) and NS BLE Mesh library, and Espressif processors (ESP-32 WROOM-E, ESP-32 S3) programmed within the IDF framework. In addition, we adapted the Nordic library for BLE Mesh for Android smartphones to administrate/test the network. The adaptation aimed in implementing the same models we designed for BLE Mesh as an extension to Nordic library. Please note that the main reason for choosing ESP-32 and nrf52840 processors was based on the fact they have a built-in BLE unit. Obviously, the solution would work for non-BLE processors such as most of the STM family with external BLE units.

It was soon detected that the choice of implementing the model as a new member of the SIG-model group was not justified. Even if, in theory, such implementation is more efficient due to shorter identifiers, it was soon detected that the library lacks documentation about some programming tricks applied by SIG programmers. For example, fixed tables of semaphores and fixed maps of model identifiers were used and indexed by model identifiers. As a result, the library itself needed to be rewritten and re-compiled. Such an adaptation should be performed every few months as a new library version comes unless SIG agrees to incorporate the model into the set of their models (which has not been planned so far).

Thus, the work concentrated on implementing a vendor model, which was less efficient, however, with no reason to update basic libraries. In contrast to any of the SIG models, the model is based on strings of characters of variable length (textual messaging). Thus, the model is quite generic, which is not the case with the existing models, and the semantic analysis of the message is to be performed at the application level. To this goal, a dedicated interpreter has been designed. Fetching a textual REST request at the input, the interpreter produces a union at the output containing the type identification (a node of the graph of the hierarchy of all types), subtype, and a list of query parameters in the form <name, value>, where "name" is a string of characters, and "value" is a number or a string of characters. "Subtype" needs more explanations. This parameter is a difference between the most-specialized type name within the hierarchy of types and the type identifier used to formulate the REST request. For example, the identifier "kettle/silver" identifies "kettle" as the basic type (as this is the most specialized node in the hierarchy of types addressing "kettle" identification), and "silver" as a subtype. Using subtypes is similar to the usage of individual names of real-world artifacts connected to the mesh nodes. It is up to each node to interpret not only the type name but also the subtype, for example, to distinguish the artifacts of the same type but different meanings or locations (such as "tv/kitchen" and "tv/mainroom"). Please note that type and subtype names conform to the REST approach to resource naming.

Queries are encoded according to the REST standard (so-called URL-encoding schema). The query addresses the detailed functionality of a node and is also interpreted at-the-place, similar to the traditional REST approach. The query elements (names and domains/formats) are not standardized. Instead, it is up to the caller to formulate the query so the mesh nodes can understand it.

Note that our textual BLE Mesh model somehow replaces any previous models. Formulating the types and queries is relatively straightforward in such a way that they are equivalent to any other call. For example, instead of the time-synchronization model, one may apply "any?setTime=12:34:56" message, asking for setting the time at each node ("any" is the root of the hierarchy of all types, cf. Fig. 2).

We also found that sometimes knowledge is needed about the existence of the nodes of a certain type in the network. Returning to one of the previous examples, a "ventilator" should inform all the "ovens" that it is possible to force the airflow, in case it becomes too hot, or a smell is irritating. To this goal, it is enough to periodically broadcast a message stating each node's type and current state. For example, the ventilator could broadcast "any?airFlow=1" informing any other node about its current state. Again, the interpretation of such information depends on each node's needs and capabilities, and the semantics of the query elements needs to be known for all the nodes interested in such information. For the rest of the nodes, such messages will be ignored as pointing to an unknown action to be done, similar to the traditional interpretation of REST requests.

VI. Sample implementation – a kitchenware application

As already mentioned, our implementation targeted "an intelligent kitchen" idea. We took several assumptions to characterize the needs of such specific networking better:

- in general, within a single network, we use one device of a given type, such as a "kettle", a "microwave_oven" etc. It is possible to use subtypes to differentiate several instances (entities of the real world) of the same type, as described in the previous section, if needed. If not parameterized, all devices of the same type react to the incoming message (such as the message "lamp?on=1" will switch on all the lamps in the location);
- we use classical RESTful usage of the mesh network as a whole, via a WiFi gateway implemented in one selected mesh node (in our case – a kettle) and a dedicated Android application connected to the same WiFi network; the Android application is equipped with some extensions to facilitate user interfacing, such as voice analysis/synthesis;
- we apply mapped REST calls (broadcasts) inside the network to control the devices in a predefined manner (any node knew its type and meaning of the query elements);
- there is no centralized directory of network services; however, some devices (especially a smartphone) may specialize in grouping/providing some information about some other devices, if needed;
- we rely on the security and relaying mechanisms from BLE Mesh (in particular, the provisioning of each new node);
- we apply periodic broadcasts of each device's state (message content depending on the device's functionality and type) to enable Android application planning and controlling the kitchen activities as a whole.

As already mentioned, we use a smartphone (Android-based) as a provisioning center and several network nodes based on processors with BLE support, mainly Espressif ESP 32 WROOM-32D/E, ESP-32 S3 (BLE 4.x), and Nordic Semiconductor nrf52840 (BLE 5.x). Selected Espressif nodes also serve as WiFi gateways. These nodes broadcast their IP addresses to all the other nodes. Note that the overall WiFi security is not broken here, as the broadcast messaging is encoded with BLE Mesh keys, and thus it is readable only by the members of the BLE network.

During the tests, we found that the smartphone application based on Nordic Semiconductor's library is insufficient for contacting the device. The library itself is huge, and the application consumes a lot of energy for transmission (both BLE and WiFi connections are active all the time). Thus we apply a mixed mode – the application listens to BLE broadcasts and sends all the requests to the network to any of the available WiFi gateways. Even if strange at the very first view, such a mixed mode was found as quite efficient and easy to implement. The communication mode depends on end-user strategy: WiFi calls are less efficient but more straightforward to implement (standard HTTP calls and REST messaging), BLE messaging needs a separate implementation of the new mesh model, but then the IP address is not necessarily known. The choice should be left to the users.

The above-mentioned application was also used as the main provisioning center for the network. As already noticed, we soon found such a way of provisioning as non-efficient, and we are working now on a new approach to provision the new nodes by any existing node from the network. Once completed, such distributed provisioning will eliminate the need for a smartphone as a network node. This work is not finished yet; it also needs some hardware extensions, such as WPS buttons known from WiFi access points. Once the work is finished, it is to be described in a separate paper. To our best knowledge, no proposal exists for dynamic provisioning within a single mesh network, where any node may act as a provisioner. Please note that we cannot rely on a single predefined provisioner, as this node may be temporarily out-of-network or even gone, thus preventing any new node to join. The above problem is also linked to the so-called "newcomer" problem, i.e., how to find an entry point to access the network for the first time. This problem also needs particular attention; we plan to work on it using intelligent BLE beacons.

Our implementation aimed to design an "intelligent" kitchen. Thus, besides the smartphone as a provisioning center, we linked the mesh nodes with the following kitchenware: a kettle (this device was equipped with a touch screen to serve as a main network node), an induction plate, a ventilator, a lamp, radio with an MP3 player.

The touch screen of the kettle could be converted to act as an interface of any network node to (1) facilitate the user interface (the interface was unified for all the devices regardless of their type, but taking into account their specificity), and (2) limit the costs of the "intelligence" of the devices to a reasonable minimum. We implemented the following automatic messaging:

- the radio automatically increases its volume while the kettle is finishing boiling the water,
- the ventilation is started after 10 minutes of using an induction field with a level greater than 50% of the maximum,

- the kettle sends an alert to the MP3 player when hot water is ready,
- the ventilation is stopped if none of the devices was used (i.e., activated) for the past 30 minutes.

The above functionality may be programmed by the producer of the devices, not necessarily the end-user. This is only a sample set of actions to be performed automatically by the network. Any new device may be incorporated at any time with no changes in the code/variables of any other device. There is no centralized directory of services, global coordinator, "main" node (maybe except the kettle – but only for economic reasons), etc. There is also no need for the "installation" of any new device (except for the provisioning process we plan to improve, as already mentioned).

Please note that our network is neither a classical sensor network nor a MANET one. This is also not quite an ad-hoc network. Even if the nodes may be switched on/off at the temporary base and coincidentally, apart from such switching, they are relatively stable – always at the same place, and usually with the same (fixed) functionality. Some nodes are used frequently, some all the time, some at request, and some rare, but the set is not evolving very often (unless a new device is bought or an old device is broken). Thus, our approach is well-suited to the above circumstances.

VII. Comparison with previous work

While we started the research for similar work to be compared with our proposal, we found that most of the existing proposals concentrated on the "smart home" idea, with an engineer's design of ready-to-market products. Some of these proposals were related to patent applications, demonstrating a growing need to provide such solutions on the market. Although very popular in the scope of client-server architecture and classical applications, we discovered that the REST idea was hardly used for controlling the behavior of home appliances and systems except the proposals based on WiFi traffic (classical REST applications). To our best knowledge, no single proposal exists for using REST like addressing in Bluetooth-based mesh networking. The existing proposals aimed in using specialized, centralized directories of services capable of mapping WiFi calls to Bluetooth direct (paired) communication. Thus, we compared our proposal with similar proposals for efficiently managing "smart" systems and devices used at home, especially in the kitchen.

Known solutions for communication and control of home devices use a centralized home network in which the entire network transmission is supervised by a center, which is most often a specialized router, sometimes a smartphone, or the most advanced, always-on home device, for example, a refrigerator. In a network with such a topology, all data sent over the network must be sent by the central node, and each device must be installed and registered in this node before its first use.

Chinese patent specification CN109218098A [22] discloses a smart home control method, a radio transmission network gateway, and a smart home control system. The gateway is the primary authorization center and the primary point that limits the functionality and capacity of the entire network. It is a typical centralized solution that requires installation in the network and registration of each new device and uses the traditional method of addressing the devices.

Another patent specification CN109088994A [23] discloses a solution in which a smartphone is used to establish a connection with one device equipped with a Bluetooth communication module at a time. The application can transcribe the command given via the graphical or voice interface to the commands sent via Bluetooth to the currently connected home device. The application also acts as a central directory of available devices that must meet very strict requirements as to the type and method of data transmission, which in practice limits the number of such devices only to the list prepared for the purposes of this invention. A severe functional limitation of this system is also that home devices cannot directly exchange any information with each other. The data must be transferred only to and from the smartphone.

The invention described in document CN109981776A [24] concerns a system that solves the problem of the limitations of the classic Bluetooth communication channel, i.e., "exclusive" operation over an established link in this type of transmission. Each device has several Bluetooth transmission modules, the first of which is used to synchronize access to the others. In this way, by establishing connections in the other modules for a while, one can transmit data between any pair of network devices through them. The biggest disadvantage of this solution is the necessity to install many communication modules in each device. A similar solution is depicted in [25].

Document CN111585855A [26] discloses a system that uses a smart wireless router integrated with a WiFi module, an infrared module, a ZigBee module, and a Bluetooth module, which enables address communication with any device available through supported forms of communication. The system does not provide for direct communication between these devices without the use of the above-mentioned router.

Contrary to all the above-presented (and similar) proposals, this paper describes a system and method of communication with intelligent home devices via a network without a central point, in which each device is equally privileged. Automatic communication among the devices is possible without human intervention. In addition, external requests are formatted in a way to replace node addresses with semantic names of functions performed by devices.

The purpose has been achieved with the use of a Bluetooth mesh topology network, in which communication among network components is possible without the need to involve the central unit. In such a network, each network device is equally privileged and can communicate with any other device directly or via any other network component. Selected devices, equipped with alternative communication modules of a different type, in particular, connected to the home WiFi network, can be used as input/output gateways for communication outside the mesh network. Transmission in the network occurs in a broadcast mode, in which one node sends information that is then received by all other nodes.

No device is individually addressed in the proposed solution, so no central directory is needed. Installing each new or replaced device or monitoring the device status is unnecessary. The transmitted signals contain digital information formatted in accordance with the REST software architecture style with respect to the fact that the addresses of devices are to be replaced with semantic names of functions performed by devices. For each device, one can define any set of functions for which that device will be responsible. The naming of the functions corresponds to the REST resources naming.

The proposal responds to the idea “different locations, similar usage”. There is no installation needed, such as when users buy new equipment, these devices are, from the very start, ready to use. Moreover, we detected un unexpected add-on while working with the smart kitchen: a possibility of targeted, personal marketing for non-existing devices. Once a requested functionality is not achieved, any other device (in our case it was the most complicated and advanced one – a kettle) may detect this fact, contact the cloud for a possible solution and broadcast some advices in the local network. As a consequence, the users are informed in JIP (just-in-place) and JIT (just-in-time) manner, thus increasing the probability of taking a decision and buying the missing equipment.

Our semi-persistent services are a response to fixed needs of the users changing places (such as several locations of a single family, or family helper), or changing organization of a mesh at a single place (such as a home or a kitchen) without a need for registration and tracking the current status of the services. Moreover, the same application may be used to control a smart kitchen, and near-by – a home audio-video system.

VIII. CONCLUSIONS

In the paper, we proposed an adaptation of the popular REST approach to BLE Mesh networking and address-free traffic. The idea enables a system and method of communication with home appliances and components of home infrastructure, such as household appliances, audio/video, lighting, heating, and air-conditioning equipment, in order to control these devices in a decentralized manner.

We use double-mode communication with home devices connected via microcontrollers to the BLE Mesh network, and WiFi. Connecting a smartphone or a computer device (e.g., a laptop or a tablet) is also possible. Gateway nodes automatically map REST messaging from WiFi networking to internal BLE messaging, conforming to REST strategy and using a hierarchy of types instead of resource names. The types enable semantic interpretation of the REST messages to be used dynamically for the such variable environment as a mesh network.

Messaging of REST-compliant communication is implemented as a broadcast transmission in the scope of a dedicated vendor model of a BLE Mesh network, implemented for the popular BLE microcontrollers as well as Android smartphones. The model is equipped with an interpreter of the incoming messages based on the semantics of the type (basic part of REST resource name), subtype (additional elements of REST resource name), and REST query complemented with some network-specific parameters. The query is provided as a list of parameters of the "name-value" type, where "name" means a command to activate a function, and "value" is a parameter of such a command. The requested functions specified in the information sent are activated for the real kitchen device associated with a given resource type, and parameterized by the query. Each device is responsible for (1) filtering all the incoming messages by their types and the accordance with the type(s) declared for the device, and (2) interpreting the query parameters. The filtering and the interpretation are programmed in the control code of the devices, and preferably switched on/off by end-users.

The devices associated with the network nodes do not have any information about the other devices on the network, including whether the device is active on the network or not. A message with a command sent by a device to an inactive device on the network does not affect the operation of the device sending the command. In the embodiment of the invention described above, the induction cooktop will not stop cooking if the cooker hood does not turn on. Still, if the cooker hood is active on the network, it will start automatically if needed.

The devices on the network are identified only by the name of the currently assigned resource and the set of functions assigned to that resource. The address or location of the device is not required for communication between devices on the network. The device cooperation can be programmed by placing appropriate REST messages in the device microcontroller code. Replacement of one device model with another will not require reprogramming these microcontrollers, and the network as a whole will work the same despite the changes.

The system is fully implemented and tested for the devices produced by Polish biggest kitchenware manufacturer Amica. It was also a base for a European patent application [27].

As for future work, we plan to extend the proposal to address the problem of the “newcomer”. If the users visit an ad-hoc location for the first time, they are not informed about the possible services to be accessed there. Thus, some experiments are needed to determine which services are available. To minimize the time spent for these experiments, we plan to include a so-called "advertisement channel" and

BLE beaconing [28] to broadcast some information for early detection of the services and their types.

We also plan to apply one of the well-known ontologies of IoT devices to provide some generic services in public places. An obvious candidate for such a service is a thermometer, but also UV-meter and PM-* detectors, to be used primarily to protect people with asthma and similar diseases. So far we concentrated on smart kitchen, but the number of ontologies (as well as the level of their complexity) for this application area is limited. If, however, we plan to extend our approach to some public places and common devices, using such external ontology is a must. Selecting given ontology depends on the application area, but our approach makes it possible to address as many different ontologies as it is needed, by a selection of an "optimal" type hierarchy.

We also plan to optimize the process of validating access to the BLE Mesh network, so-called provisioning [29], aimed at exchanging encryption keys. So far, a dedicated mesh node called a provisioner has been used for this goal. However, this node may be temporarily inaccessible for many reasons, thus preventing new users from entering the network. Thus, we plan to apply the provisioning function to any node and dissipate the necessary information among the other nodes, dynamically voting for the best "candidate" for at-the-moment provisioning.

***Abstract*—The paper introduces a customized approach to handle failures in IEC 61131-3 programmable controllers. The solution assumes the utilization of a virtual machine as a runtime environment to execute control code in an isolated manner. A formal model of the runtime is presented, employing denotational semantics. Subsequently, the model is expanded by incorporating new procedures that enable the handling of runtime exceptions using ST code constructs. This formal model serves as the foundation for implementing the exception infrastructure in the CPDev development environment. The research presented in the paper, driven by industry demands, aims to facilitate the development of more reliable and resilient control systems, capable of effectively dealing with failures.**

I. Introduction

PROGRAMMABLE Logic Controllers (PLC) and Programmable Automation Controllers (PAC) have established their position in the modern world. Their applications are wide-ranging, including industrial production, energy, transportation, and Internet of Things solutions. They control processes, often using advanced algorithms, and are expected to be reliable and operate in real-time mode.

One characteristic that allows for the flexibility of these devices is the ability to program them, where an engineer creates their own control algorithm and places it in the controller. From this perspective, such a controller is versatile as it can be programmatically tailored to specific applications and its functionality can be extended or modified when changes are required in the controlled object.

In some controllers, programming is done using typical languages, most commonly C/C++. However, there are standardized mechanisms and programming solutions specifically designed for control devices. The most significant of these are the international standards IEC 61131-3 [1] and IEC 61499 [2]. Particularly, the former has become a recognized standard adopted by many manufacturers. It allows, among other things, the transfer of program code between devices from different vendors and introduces specialized programming languages such as structured text (ST), instruction list (IL), graphical block diagram (FBD), ladder diagram (LD), and sequential function chart (SFC). The language structures align well with control system programming paradigms. Hence, this article considers a system that complies with the IEC 61131-3 standard.

The stable and predictable operation of PLC and PAC controllers is a feature resulting from their applications, where errors and unexpected reactions can have serious consequences. To minimize the risk of such situations, developers employ various solutions. The mere use of the standard's languages can reduce potential problems, particularly by avoiding programming mechanisms related to manipulating pointers and dynamic memory allocation. Another solution involves constructing an isolated runtime environment for user programs. In such cases, the effects of programmer errors will not propagate beyond that runtime, allowing the device to remain operational and enabling controlled handling of exceptional situations.

One concept for creating such an isolated environment is a virtual machine [3]. In general terms, a virtual machine (referred to as VM) is understood here as a type of processor with its own instruction set and data types, implemented through software on specific hardware platforms. This means that when processing code designed for a VM, appropriate software mechanisms execute it using the native resources of the target platform, such as a specific CPU and memory. The VM processes code, typically referred to as intermediate code, which is generated by a compiler from a source program. The concept of virtual machines has gained prominence in information technology due to the widespread use of platforms such as the Java Runtime Environment [4] and the .NET Framework [5], [6].

Solutions based on virtual machines offer several important advantages. Firstly, the source program and intermediate code are independent of the target hardware platforms. This means that only one compiler for the source language is required, rather than separate cross-compilers for different platforms. Additionally, programs are executed within secure environments with memory protection, preventing potential errors from propagating beyond the designated boundaries.

However, there are also disadvantages to consider. Execution of intermediate code tends to be slower compared to executing native code on the target processor. This is because the instructions and operands of the intermediate language need to be decoded by software, whereas a standard CPU utilizes hardware decoders and pipelining. Consequently, implementing even a simple intermediate instruction requires multiple native instructions.

When designing a virtual machine as a runtime environment prepared to handle error and exceptional situations, several aspects need to be taken into account. The first aspect is the compatibility of the machine's operation with its specification. For this purpose, the authors have proposed a formal model of operations performed by the virtual machine using denotational semantics [7]. This model enables the implementation of these operations in accordance with the assumptions, for example, in languages like C/C++. In this article, the model has been expanded to include functions related to exception handling.

Another task is to supplement the languages of the IEC 61131-3 standard with additional constructs related to exception handling. This is necessary due to the lack of dedicated solutions in the standard. Hence, there is a need to introduce them. The authors take into account the extensions to the ST language available in the CODESYS package but propose their own implementation of these extensions.

II. Programming and runtime environments

The engineering environment CPDev (Control Program Developer) allows to program controllers according to the IEC standard [8]. It consists of ST/IL/FBD/LD/SFC editors, a compiler translating programs to the intermediate code [9] and a VM-based runtime system written in C/C++ [10].

The architecture of the VM is shown in Fig. 1. It includes the following components:

- code and data memories,
- code and data stacks,
- registers and pointers,
- instruction processing module.

The *Instruction processing* module fetches successive instructions from *Code memory* and executes them acquiring values of operands either from *Data* or *Code memory*. Results are stored directly in *Data memory*.

The machine does not utilize an accumulator, however it maintains other registers. The instruction pointer, also known as the program counter, is stored in the *CodeReg* register. VM increments the *CodeReg* register every time after fetching an instruction code or an operand address. The *DataReg* register is used for managing the data base addresses and is set during subprogram calls and returns, including function blocks and functions. This allows the executed code to access variables in different areas of the *Data memory* and handle multiple instances of subprograms. When entering a subprogram, the current values of *CodeReg* and *DataReg* are pushed onto the *Code stack* and *Data stack* respectively. Upon returning, the contents of these registers are popped from the stacks. This stack mechanism enables nested function blocks. Additionally, the machine includes the *Flags* register, which contains status flags that signal errors or unusual situations such as an array index outside the valid range, an unknown instruction code, or a cold start.

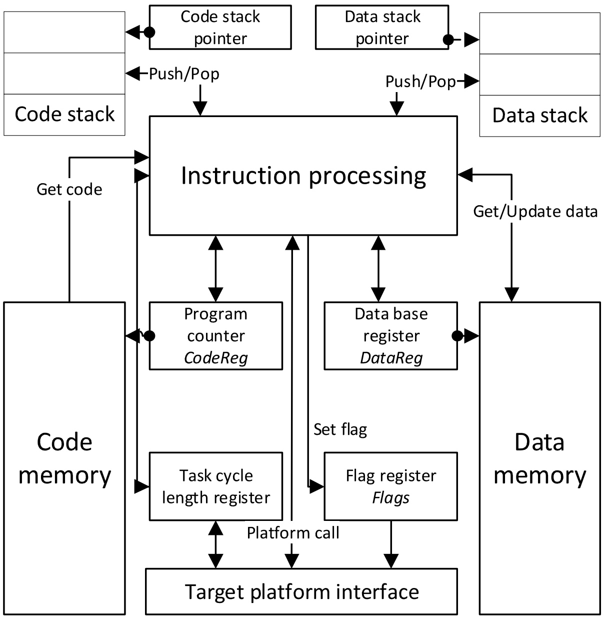

Fig. 1. Architecture of the virtual machine

The virtual machine, as designed specifically for execution of control programs, can handle all IEC 6131-3 data types. The number of bytes required to store each such type in the data memory is given in Table I.

There are two kinds of virtual machine instructions:

- functions,
- system procedures.

Examples of some functions are shown in Table II with decreasing priority. The functions return one value each to be written into the variable being the first operand (as said, an accumulator does not exist in this VM) and may have up to 15 other operands. Note that such order is different than in *Static Single Assignment* of dataflow graphs used in typical compilers [11]. Arithmetic operations are executed in limited ranges, depending on the type. In case of integers the ranges are $(-128,\ 127)$ for SINT, $(-32768,\ 32767)$ for INT, etc.

Contrary to functions, system procedures do not return values or return more than one. Table III shows typical examples. The procedures control program flow, handle memory, call

TABLE I
Data types and number of bytes

Types	Bytes
BOOL, BYTE, SINT, USINT	1
INT, UINT, WORD	2
REAL, DINT, UDINT, DWORD	4
DATE, TIME, TIME_OF_DAY	4
LREAL, LINT, ULINT, LWORD	8
DAY_AND_TIME	8
STRING, WSTRING	var

TABLE II
FUNCTIONS OF THE VIRTUAL MACHINE

Mnemonic	Meaning	Operator
EXPT	Power	**
NEG	Negation	− (unary)
MUL	Multiplication	*
DIV	Division	/
ADD	Addition	+ (arithm.)
SUB	Subtraction	− (arithm.)
CONCAT	String join	+ (text)
GT	Greater	>
GE	Greater or equal	>=
LE	Less or equal	<=
LT	Less	<
EQ	Equal	=
NE	Not equal	<>
AND	Logical and	&

subprograms, etc. From the programmers' viewpoint there is no major difference in using functions or procedures.

TABLE III
SYSTEM PROCEDURES OF THE VIRTUAL MACHINE

Mnemonic	Meaning
JMP	Unconditional jump
JNZ	Conditional jump
JR	Unconditional relative jump
JRN	Conditional relative jump
CALB	Subroutine call
RETURN	Return from subroutine
MEMCP	Copy memory block
MCD	Initialize data
FPAT	Fill memory block
GARD	Copy global memory to local area
GAWR	Copy local memory to global area

To accommodate exception handling, the architecture of the virtual machine needed to be expanded. The modifications mainly revolved around the protected code stack, which will be thoroughly explained in Section IV.

III. Runtime formal model

A formal model has been developed to specify the operation of the virtual machine using denotational semantics [12], [13]. The fundamental aspects of the model were outlined in the previous publication [14]. In this context, we now expand upon the description of the model components. The model consists of various domains that define the states, memory functions, value interpreters, limited range operators, and a universal semantic function that invokes specific functions representing individual instructions.

The domains within the model encompass abstract data types that represent the values processed by different components of the virtual machine (Fig. 1). One such domain, denoted as $BasicTypes$, comprises four sets that correspond to the memory sizes of the basic data types outlined in Table I. Another domain, named $Address$, specifies the size of addresses associated with data or code memory. The domain $Memory$, maps $Address$ to $OneByte$. Both $CodeMemory$ and $DataMemory$ are aliases for the $Memory$ domain. The domain $Stack$ represents a sequence (indicated by *) of $Address$ domains, with $CodeStack$ and $DataStack$ serving as aliases for specific stack types. The other domains are defined similarly.

$$\begin{aligned}
BasicTypes &= OneByte + TwoBytes + \\
&\quad + FourBytes + EightBytes \\
Address &= FourBytes \\
Memory &= Address \to OneByte \\
CodeMemory &= Memory \\
DataMemory &= Memory \\
Stack &= Address^* \\
CodeStack &= Stack \\
DataStack &= Stack \\
CodeReg &= Address \\
DataReg &= Address \\
Flags &= TwoBytes
\end{aligned}$$

Broadly speaking, the goal of program execution is to transition the current state of the computer into a new state. In the context of the virtual machine, the state is represented as a Cartesian product of various domains including memory, stacks, registers, and flags. More specifically, the domain denoted as $State$ can be understood as a collection of tuples $(cm, dm, cs, ds, cr, dr, flg)$, where each element corresponds to a value within its respective domain.

$$\begin{aligned}
State = {} & CodeMemory \times DataMemory \times \\
& \times CodeStack \times DataStack \times \\
& \times CodeReg \times DataReg \times Flags
\end{aligned}$$

The functions presented below model low-level operations executed on memory, stacks and flags.

- Get data from memory
  $$Get1BMem = (Address \times Memory) \to Byte$$
  $$Get2BMem = (Address \times Memory) \to TwoBytes$$
  $Get4BMem$, $Get8BMem$, etc. are defined similarly.
- Get address from memory
  $$GetAddress = (Address \times Memory) \to Address$$
  The function returns the value stored at the given $Address$ in $Memory$ which is another $Address$. Since the VM has no accumulator, it operates directly on addresses, and the function $GetAddress$ is essential for the model. $Address$ domain means $TwoBytes$ or $FourBytes$.
- Memory update
  $$\begin{aligned} Upd1BMem = {} & (Address \times Memory \times \\ & \times OneByte) \to Memory \\ Upd2BMem = {} & (Address \times Memory \times \\ & \times TwoBytes) \to Memory \end{aligned}$$
  Similarly for $Get4BMem$, $Get8BMem$, etc.

- Memory move

$$\begin{aligned} MemMove = (&Address \times Memory \times \\ &\times Address \times Memory \times \\ &\times OneByte) \to Memory \end{aligned}$$

  The source and target $Addresses$ of code or data $Memory$ should be provided. The number of bytes being moved ranges from 0 to 255 ($OneByte$).
- Stack functions

$$Push = (Stack \times Address) \to Stack$$
$$Pop = Stack \to (Address \times Stack)$$

  The functions execute stack operations needed by subprograms. Note that Pop returns a pair, viz. $Address$ and new $Stack$.
- Flag operations

$$\begin{aligned} ClearFlag &= (TwoBytes \times TwoBytes) \to \\ &\to TwoBytes \\ SetFlag &= (TwoBytes \times TwoBytes) \to \\ &\to TwoBytes \end{aligned}$$

  The $Flags$ domain is an alias to $TwoBytes$. The successive $TwoBytes$ above denote actual flags, bits to be set or reset, and new flags.
- Value conversions

$$ByteToWord = OneByte \to TwoBytes$$
$$WordToByte = TwoBytes \to OneByte$$

  For a value without a sign, $ByteToWord$ places zero bits into the more significant byte of $TwoBytes$, otherwise the byte is filled with the sign bit. $WordToByte$ reduces the value by removing the most significant bits.

The following sample functions provide numerical interpretations of $OneByte$, $TwoBytes$ and two other memory chunks.

$$\begin{aligned} BoolOf &= OneByte \to BOOL \\ FromBool &= BOOL \to OneByte \\ IntOf &= TwoBytes \to INT \\ FromInt &= INT \to TwoBytes \\ DIntOf &= FourBytes \to DINT \\ FromDInt &= DINT \to FourBytes \\ LIntOf &= EightBytes \to LINT \\ FromLInt &= LINT \to EightBytes \end{aligned}$$

Other types are interpreted analogously.

The numeric identifiers of VM instructions consist of the identifier of a group `ig` and the identifier `it` of a particular data type or procedure. In this way type-specific instructions or procedures may be selected. For some functions `it` also indicates the number of inputs.

To collectively represent the concept of decoding a group and type, followed by the execution of a specific instruction, a universal function $\mathcal{U}$ has been defined. The algorithm of the function $\mathcal{U}$ is presented in Fig. 2. It is assumed that the code register `cr` initially points to the group identifier `ig` in code memory `cm`. The algorithm starts by fetching `ig` (one byte) and incrementing `cr` to $\mathtt{cr}_1$. Then `it` is acquired and the code register incremented to $\mathtt{cr}_2$. At this moment the state of the VM is described by the tuple $(cm, dm, cs, ds, cr_2, dr, flg)$ involving memories, stacks, registers and flags. For instance, for `ig=04` and `it=02` the DIV function is called with the two operands `op1`, `op2` of type INT, whereas `it=09` means operands of type REAL. The last group `ig=1C` consists of system procedures, including JMP and CALB.

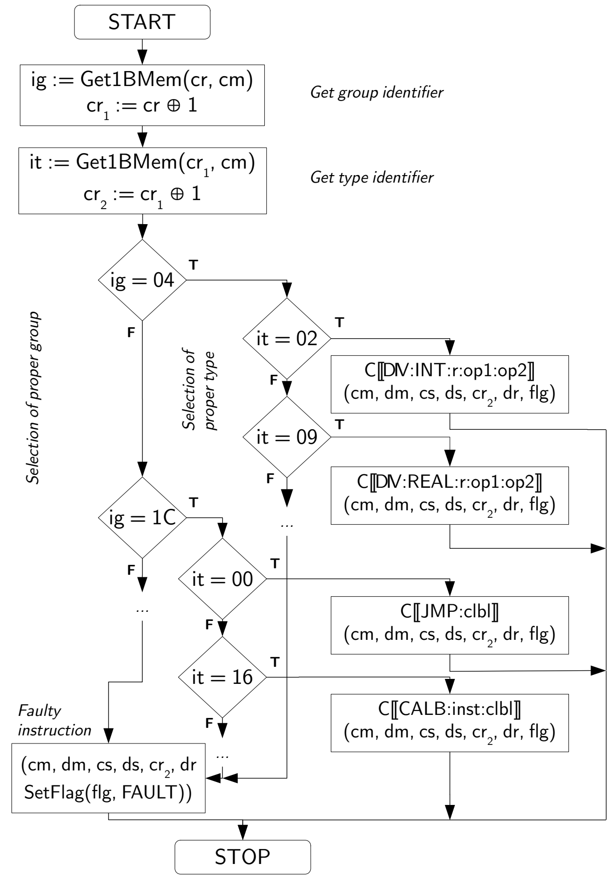

Fig. 2. Algorithm of the universal function $\mathcal{U}$

The semantics of the DIV function for INT-type operands is shown in Listing 1. The function divides two operands of type INT, sv denotes the value of the division. The result of a function execution is stored in the location labeled by the first operand, here denoted by `r`. The updated data memory is the second element of s_1 as the result of invoking $Upd2BMem$. The number stored at $raddr$ is given by $FromInt(sv)$.

The procedure GAWR presented in Listing 2 is used in algorithms involving arrays. This procedure copies elements of an array in local memory to an array in global memory. The arrays may contain elements of any type, including arrays and structures. There are four operands, source `src` and destination `dst` labels, `size` of the elements, and array index `idx`. The values $size$ and idx are addresses to data of type WORD. Since the operand `dst` refers to global memory, its

Listing 1 The semantic equation of the DIV function

$$\begin{array}{r}
\mathcal{C}[\![\texttt{DIV:INT:r:op1:op2}]\!] = \lambda s. \\
(cm, dm, cs, ds, cr, dr, flg) := s \\
r := GetAddress(cr, cm) \\
raddr := dr \oplus r \\
cr_1 := cr \oplus AddressSize \\
op1 := GetAddress(cr_1, cm) \\
op1addr := dr \oplus op1 \\
cr_2 := cr_1 \oplus AddressSize \\
op2 := GetAddress(cr_2, cm) \\
op2addr := dr \oplus op2 \\
cr_3 := cr_2 \oplus AddressSize \\
sv := IntOf(Get2BMem(op1addr, dm)) \div \\
\div\ IntOf(Get2BMem(op2addr, dm)) \\
s_1 := (cm, Upd2BMem(raddr, dm, \\
FromInt(sv)), cs, ds, cr_3, dr, flg) \\
s_1
\end{array}$$

value dst is a direct address (zero dr). The $resultaddr$ is the sum of address dst and the product of $idxval$ and $sizeval$.

Listing 2 The semantic equation of the GAWR procedure

$$\begin{array}{r}
\mathcal{C}[\![\texttt{GAWR:dst:src:size:idx}]\!] = \lambda s. \\
(cm, dm, cs, ds, cr, dr, flg) := s \\
dst := GetAddress(cr, cm) \\
cr_1 := cr \oplus AddressSize \\
src := GetAddress(cr_1, cm) \\
srcaddr := dr \oplus src \\
cr_2 := cr_1 \oplus AddressSize \\
size := GetAddress(cr_2, cm) \\
sizeaddr := dr \oplus size \\
sizeval := WordOf(Get2BMem(\\
sizeaddr, dm)) \\
cr_3 := cr_2 \oplus AddressSize \\
idx := GetAddress(cr_3, cm) \\
idxaddr := dr \oplus idx \\
idxval := WordOf(Get2BMem(\\
idxaddr, dm)) \\
cr_4 := cr_3 \oplus AddressSize \\
resultaddr := dst \oplus idxval \otimes sizeval \\
um := MemMove(dm, resultaddr, dm, \\
srcaddr, sizeval) \\
s_1 := (cm, um, cs, ds, cr_4, dr, flg) \\
s_1
\end{array}$$

It is important to note that the equations provided for the DIV and GAWR procedures do not account for erroneous operands, such as a divisor equal to zero or an array index out of bounds. Consequently, to address these failures and prevent unpredictable behavior, the model had to be extended with an exception mechanism.

IV. Adding exception handling

Exceptions have been introduced to replace a sequence of nested `if-else` instructions when performing compound operations that may fail under certain circumstances. The complex branching of algorithm paths, depicted in Figure 3, can be challenging to analyze and distinguish between the normal execution path and the path taken to handle failures. To address this issue, some programming languages have introduced a `try-catch` construct, which separates the algorithm's main path (protected code) from the failure handling path. This approach allows programmers to focus on the operations that the algorithm needs to perform, while storing the failure handling logic in a separate section of the code.

When a failure occurs, it is reported through an exception, which can take various forms, ranging from a simple value like a number or string to a specifically designed object. The presence of an exception terminates the execution of the remaining instructions within the protected code. Subsequently, the processing of the first `catch` clause begins, but only if it matches the type of the exception object. If the exception does not match the type of the first `catch` clause, the subsequent `catch` clauses will be checked for a match. If no further `catch` clauses are found, the execution switches to the surrounding `try-catch` construct. However, if such a construct is not present, the execution is terminated with an unhandled exception state, preventing further execution.

Therefore, the revised code based on Figure 3 would resemble the examples provided in the code snippet shown in Listing 3. However, it is important to note that such code may overlook certain critical tasks that must be performed even if an exception occurs. To address this concern, the `try-catch` construct has been enhanced with an additional clause called `finally`. The `finally` clause contains the code that is always executed when the control exits the protected section of code, irrespective of whether a matched exception occurs, an unhandled exception is encountered, or no exception occurs at all.

The IEC 61131-3:2013 standard does not include constructs for writing code in an exception-style manner. However, certain manufacturers offer their own extensions to the ST language to support such functionality. For instance, the CODESYS development environment provides the following keywords to indicate protected code:

- `__TRY` – beginning of the protected code,
- `__CATCH` – point where failure path of code begins,
- `__FINALLY` – beginning of mandatory code executed always,
- `__ENDTRY` – end of the protected code.

```
if(oper1())
  if(oper2())
    if(oper3())
     if(oper4())
        return success();
     else return error("oper4");
    else return error("oper3");
  else return error("oper2");
else return error("oper1");
```

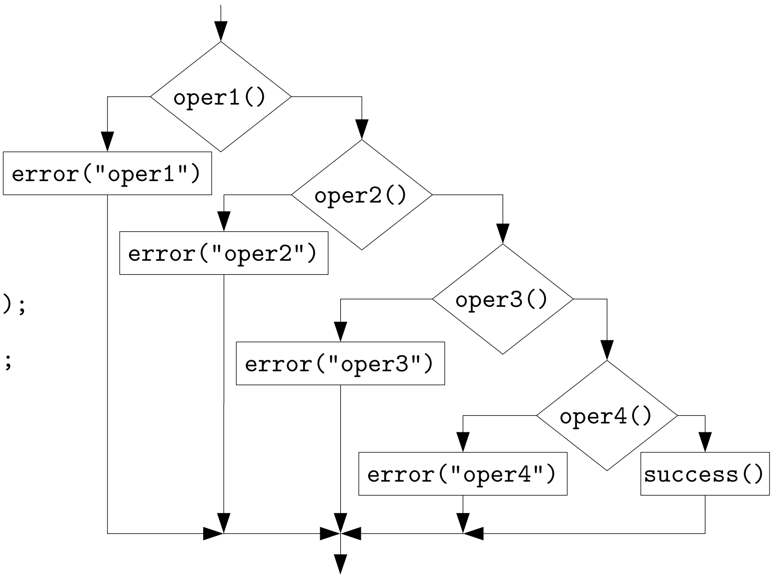

Fig. 3. An example of nested `if` commands and their block diagram

Listing 3 The `try-catch` approach

```
try {
    oper1();
    oper2();
    oper3();
    oper4();
    return success;
} catch(Exception1 e1) { ...
} catch(Exception2 e2) { ...
}
```

TABLE IV
SYSTEM PROCEDURES FOR EXCEPTIONS

Name	Operand	Type
PHPRS	excAddr	:gclabel
	finAddr	:gclabel
	contAddr	:gclabel
RAISE	excObj	:gdlabel
MEXCT	excTyp	:rdlabel
	nxtm	:gclabel
POPRS	—	—
CEXCF	—	—

In our solution, it was decided to use keywords from CODESYS for exception handling for greater compatibility. In addition to the above keywords, __THROW keyword for throwing user-defined exceptions as in the general purpose programming languages (e.g. C++, Java, C#) is added.

To accommodate these language constructs, several changes need to be made to the denotational model of the virtual machine. Firstly, the $State$ tuple needs to be expanded to include two additional components: $ProtStack$ and $ExcObj$. $ProtStack$ represents a stack (Kleene closure) of $ProtEntry$ tuples, which consist of four addresses. To modify the $ProtStack$, the following functions are introduced: $PushProt$, $PopProt$, and $PeekProt$. The $PushProt$ function adds an item to the stack, $PopProt$ removes an item from the stack, and $PeekProt$ returns a copy of the topmost item without modifying the stack. $ExcObj$ is an $Address$ that indicates the location where the exception object has been stored. Since an $Address$ always refers to a memory location, a new flag, EXCOBJ, needs to be introduced in the $Flags$ mask to indicate the presence of the exception object.

$$\begin{aligned}State = {} & CodeMemory \times DataMemory \times \\ & \times CodeStack \times DataStack \times CodeReg \times \\ & \times DataReg \times Flags \times ProtStack \times ExcObj\end{aligned}$$

$$\begin{aligned}ProtStack &= ProtEntry^* \\ ProtEntry &= Address \times Address \times Address \times Address \\ PushProt &= (ProtStack \times ProtEntry) \to ProtStack \\ PopProt &= ProtStack \to (ProtEntry \times ProtStack) \\ PeekProt &= ProtStack \to ProtEntry\end{aligned}$$

In order to handle the __TRY, __CATCH, __FINALLY, __ENDTRY keywords, as well as the additional __THROW, new system procedures are required. These procedures are listed in Table IV.

When encountering the __TRY instruction, the ST language compiler should generate the system procedure PHPRS. The purpose of this procedure is to store the current DPTR context, the address of the first __CATCH instruction, the address of the __FINALLY instruction, and the address of the __ENDTRY instruction on the $ProtStack$. The corresponding denotational model of PHPRS is presented below.

```
$\mathcal{C}[\![\texttt{PHPRS:ea:fa:ca}]\!] = \lambda s.$
  $(cm, dm, cs, ds, cr, dr, flg, ps, eo) := s$
  $dptrCtx := dr$
  $excAddr := GetAddress(cr, cm)$
  $cr_1 := cr \oplus AddressSize$
  $finAddr := GetAddress(cr_1, cm)$
  $cr_2 := cr_1 \oplus AddressSize$
  $contAddr := GetAddress(cr_2, cm)$
  $cr_3 := cr_2 \oplus AddressSize$
  $se := (dptrCtx, excAddr, finAddr, contAddr)$
  $ps_1 := PushProt(ps, se)$
  $s_1 := (cm, dm, cs, ds, cr_3, dr, flg, ps_1, eo)$
  $s_1$
```

When the ST compiler encounters the __CATCH statement, it should generate the system procedure MEXCT. The purpose of this procedure is to detect whether the exception type (excTyp operand) matches the current exception. If the exception type matches, the following instructions will be processed and the exception state will be cleared with a jump to the __FINALLY statement. If the exception type does not match, a jump to the next __CATCH statement is performed. If there are no further __CATCH statements, a jump to the __FINALLY keyword is executed. This behavior can be represented using the following denotational equation:

```
$\mathcal{C}[\![\texttt{MEXT:exct:nxtm}]\!] = \lambda s.$
  $(cm, dm, cs, ds, cr, dr, flg, ps, eo) := s$
  $exct := GetAddress(cr, cm)$
  $cr_1 := cr \oplus AddressSize$
  $nxtm := GetAddress(cr_1, cm)$
  $cr_2 := cr_1 \oplus AddressSize$
  $dext := Get4BMem(dm, dr \oplus exct \oplus typeOffset)$
  $sext := Get4BMem(dm, eo \oplus typeOffset)$
  $dcr :=$ **match** $sext = dext$ **with**
      | **true** $\rightarrow cr_2$
      | **false** $\rightarrow$ **match** $nxtm = -1$ **with**
          | **true** $\rightarrow stk := PeekProt(ps)$
                $(dct, ctch, fin, efn) := stk$
                $fin$
          | **false** $\rightarrow nxtm$
          **end**
      **end**
  $s_1 := (cm, dm, cs, ds, dcr, dr, flg, ps, eo)$
  $s_1$
```

After the last statement of __CATCH, the compiler should generate the system procedure CEXCF, which marks the end of exception handling. The denotational model of CEXCF can be defined as follows:

```
$\mathcal{C}[\![\texttt{CEXCF}]\!] = \lambda s.$
  $(cm, dm, cs, ds, cr, dr, flg, ps, eo) := s$
  $stk := PeekProt(ps)$
  $(dct, ctch, fin, efn) := stk$
  $flg_1 := ClearFlag(flg, F\_EXCPT)$
  $s_1 := (cm, dm, cs, ds, fin, dr, flg_1, ps, 0)$
  $s_1$
```

No special action is needed when the compiler encounters the __FINALLY statement. However, an action is required when the compiler encounters __ENDTRY in the ST input. In this case, the compiler should emit the POPRS system procedure, which can be represented by the following denotational model:

```
$\mathcal{C}[\![\texttt{POPRS}]\!] = \lambda s.$
  $(cm, dm, cs, ds, cr, dr, flg, ps, eo) := s$
  $tf := SetFlag(flg, F\_EXCPT)$
  $(dcr, ddr, nstk) :=$ **match** $tf = flg$ **with**
      | **true** $\rightarrow (ent, stk) := PopProt(ps)$
            $(dct, ctch, fin, efn) := ent$
            $(ctch, dct, stk)$
      | **false** $\rightarrow (ent, stk) := PopProt(ps)$
            $(cr, dr, stk)$
      **end**
  $s_1 := (cm, dm, cs, ds, dcr, ddr, flg, nstk, eo)$
  $s_1$
```

If a programmer wishes to throw their own exception in ST code, they can use the __THROW keyword. In this case, the ST compiler should emit the RAISE system procedure with the exception object. The denotational model of RAISE can be represented as follows:

```
$\mathcal{C}[\![\texttt{RAISE:excObj}]\!] = \lambda s.$
  $(cm, dm, cs, ds, cr, dr, flg, ps, eo) := s$
  $excObj := GetAddress(cr, cm)$
  $eo_1 := dr \oplus excObj$
  $flg_1 := SetFlag(flg, F\_EXCPT)$
  $stk := PeekProt(ps)$
  $(dr_1, ctch, fin, efn) := stk$
  $s_1 := (cm, dm, cs, ds, ctch, dr_1, flg_1, ps, eo_1)$
  $s_1$
```

V. Implementation in CPDev

An exception is reported in the CPDev virtual machine either automatically or manually. The call is invoked internally, when a system exception condition is met during the program execution. It may be also invoked by the programmer by calling the RAISE system procedure to manually trigger the failure path. The automatically generated system exceptions are reported when on of the runtime errors occurs. Selected system exceptions are listed in Table V.

TABLE V
SELECTED SYSTEM EXCEPTIONS

Type	Description
Division by zero	Invalid DIV instruction parameter
Modulo by zero	Invalid MOD instruction operand
Bad array index	Index array access out of bounds
Bad format	Invalid string format during parsing to numeric types (STRING_TO_INT, STRING_TO_WORD, STRING_TO_REAL, etc.)
Cycle overflow	Program execution exceeded the declared cycle time

The corresponding operations performed by th VM have been extended with exception reporting. For example, the semantic description of the DIV function from Listing 1 should be extended which checking for zero divisor as follows:

```
$divisor := IntOf(Get2BMem(op2addr, dm))$
match $divisor$ with
| 0 → $excObj := (cr_3, DIV\_BY\_ZERO\_EXC)$
    $\mathcal{C}[\![\mathtt{RAISE:op}]\!](cm, dm, cs, ds,$
        $cr_3, dr, flg, ps, excObj)$
| _ → $sv := IntOf(Get2BMem(op1addr,$
    $dm)) \div divisor$
    $s_1 := (cm, Upd2BMem(raddr, dm,$
    $FromInt(sv)), cs, ds, cr_3, dr, flg, ps, eo)$
    $s_1$
end
```

Listing 4 shows the DIV instruction utilizing a C macro for division of several numeric types. The function IG_DIV_04 implements the division for all relevant data types (group), thus avoiding repetitions of rather similar code. The function calls the parameterized macrodefinition DIV_TYPE which is common for all types. The value of an operand of a particular TYPE is determined in DIV_TYPE by the function TYPE##Of with given sizeof(TYPE). The code calls an internal function WM_RaiseException in the case when the second operand (divisor) is zero. The division result cmp updates the INT value at raddr (Upd2BMemData also increments the code register). The function IG_DIV_04 recognizes a particular type as the second nibble (half byte) of the type identifier it by masking it & 0x0F. Note that case and break are hidden for switch in the DIV_TYPE definition.

Listing 5 contains a simplified implementation of the GAWR procedure (Sec. III). The check is made if the parameter corresponding to the array index is less than zero. If so, the system exception is raised (EX_ARRAY_IDX).

In the case of an exception, the virtual machine examines the ProtStack. If the stack is empty, no __TRY...__CATCH block has been defined by the programmer. In such a case, the system may perform one of the predefined actions:

- stop execution and go into a fail-safe state (set outputs to safe values)
- perform a cold start of the controller
- perform a warm start
- restart the program cycle.

Listing 6 contains a simple ST code using the exception-related keywords. The program includes a declaration of an array BA indexed from 0 to 10. The protected code between

        }
        return;
}
```

Listing 5 Implementation of the GAWR instruction

```
case VMF_GAWR & 0xFF:
{
  ADDRESS src = GetCodeAddress();
  ADDRESS dst = GetCodeAddress();
  INT idx = getINT(GetCodeAddress());
  BYTE size = getBYTE(GetCodeAddress());

  if (idx < 0)
    WM_RaiseException(EX_ARRAY_IDX);
  else
    memcpy(dst+idx*size, src, size);
}
break;
```

Listing 6 Exception handling in ST code

```
PROGRAM WORKER
  VAR
    BA : ARRAY[0..10] OF INT;
    AI : INT;
    RES, VALUE, SCALE : REAL;
    DIV_EX : DIV_BY_ZERO_EXCEPTION;
    OTHER_EX : ANY_EXCEPTION;
  END_VAR

  __TRY

    BA[AI] := BA[AI] + 1;
    RES := VALUE / SCALE;

  __CATCH(DIV_EX)

    SCALE := 1;
    DIV_EX.ACTION := RESTART_CYCLE;

  __CATCH(OTHER_EX)

    OTHER_EX.ACTION := TERMINATE;

  __ENDTRY

END_PROGRAM
```

__TRY and __CATCH increases the array element at the index pointed by the value of the variable AI. In case of a division by zero exception during the operation, the failure path from __CATCH(DIV_EX) is executed. If any other exception occurs, the next failure path from __CATCH(OTHER_EX) is taken. The exception block restores the AI value to the acceptable value of 0 and instructs the virtual machine to restart the program cycle.

An exception is usually an unexpected behavior, so CPDev IDE provides a set of tools to debug such situations. Figure 4 shows the CPDev Integrated Environment (IDE) running a program in a simulation mode. As one may observe, the exception has occured due to the fact, that the variable AI (array index) has been set to 11, so outside the array bounds. The environment allows to break the execution to examine the cause, to terminate the program completely or to continue with the default action for an exception.

VI. Final remarks

The introduction of exceptions into the control environment based on a virtual machine was driven by industry demands. The presented concepts from a programmer's perspective resemble solutions available in high-level object oriented programming languages like C# or Java. However, in this case, the solution needs to be applied to embedded controllers with limited resources and performance.

To address this, the proposed mechanism for exception handling was designed to minimize the extra operations performed by the CPU. The requirement for additional memory to accommodate the $ProtStack$ is relatively easy to fulfill, even for small devices. It is anticipated that incorporating exception infrastructure supported by a formal model will facilitate the development of more robust and reliable control solutions.

Acknowledgment

***Abstract*—In this paper, we propose a novel approach to distance measurement for rankings, introducing a new metric that exhibits exceptional properties. Our proposed distance metric is defined within the interval of 0 to 1, ensuring a compact and standardized representation. Importantly, we demonstrate that this distance metric satisfies all the essential criteria to be classified as a true metric. By adhering to properties such as non-negativity, identity of indiscernibles, symmetry, and the crucial triangle inequality, our proposed distance metric provides a robust and reliable approach for comparing rankings in a rigorous and mathematically sound manner. Finally, we compare our new metric with distances such as Hamming distance, Canberra distance, Bray-Curtis distance, Euclidean distance, Manhattan distance, and Chebyshev distance. By conducting simple experiments, we assess the performance and advantages of our proposed metric in comparison to these established distance measures. Through these comparisons, we demonstrate the superior properties and capabilities of our new drastic weighted similarity distance for accurately capturing the dissimilarities and similarities between rankings in the decision-making domain.**

I. Introduction

DISTANCE measures are fundamental tools in many areas of data analysis, including machine learning, statistics, data mining, and many more [1], [2]. They quantify the difference or dissimilarity between pairs of objects, like vectors, sets, or more complex structures, providing a quantitative basis for their comparison [3].

A key aspect of distance measures is that they must satisfy certain properties, such as non-negativity (distances are always non-negative), identity of indiscernibles (the distance between an object and itself is zero), symmetry (the distance from A to B is the same as from B to A), and the triangle inequality (the direct distance from A to B is always shorter or equal to the distance from A to B via an intermediary point C) [4].

There are various types of distance measures, including Euclidean [5], Manhattan [6], Chebyshev [7], Hamming [6], Canberra, Bray-Curtis, and many others [8], [9], each with their own characteristics and use-cases. Some measures like Euclidean and Manhattan are primarily used for continuous variables [6], while others like Hamming are used for categorical variables [10]. Some measures are sensitive to the scale and distribution of the data, while others are more robust.

The choice of the appropriate distance measure is highly dependent on the nature of the data and the specific objectives of the analysis [11], [12]. For example, in a scenario where extreme values or outliers are important, a measure such as the Chebyshev distance could be useful as it focuses on the maximum difference in any one dimension. On the other hand, for data that represents rankings or preferences, a measure like Spearman's footrule or the Kendall tau distance might be more appropriate [13].

When comparing rankings in decision-making, distance measures play a vital role. To compare rankings, we need a way to quantify how similar or different two rankings are [14], [15]. That's where distance measures come in. They provide a numeric value representing the dissimilarity between two rankings, with lower values typically indicating greater similarity.

The choice of distance measure can have a significant impact on the comparison. Some measures are more sensitive to the exact order of the rankings, while others, like Spearman's footrule [16], are more focused on the overall similarity. Moreover, some measures are more sensitive to differences at the top of the rankings [17], [18], while others treat all positions equally. Overall, comparing rankings using distance measures can provide valuable insights in decision-making, helping decision-makers understand how different choices, evaluations, or scenarios compare to each other, and aiding in making more informed, data-driven decisions [19].

Rankings and comparisons form an integral part of decision-making processes in diverse fields such as information retrieval, sports [20], elections, and more [21]. However, a significant challenge that persists in these scenarios is quantifying the dissimilarity or distance between different rankings effectively and accurately. Traditional distance measures, while useful, can often fail to capture the nuances and subtleties inherent in the comparison of rankings. To address these limitations and introduce a more robust and versatile solution, the motivation behind this paper emerges.

In this paper, the main contribution is to propose a novel distance metric that is particularly well-suited for ranking comparisons. We aspire to create a metric that not only captures the dissimilarity between rankings accurately but also exhibits essential properties required of a true metric. A key part of our motivation is to ensure that this new measure is defined within the interval of 0 to 1, thus providing a compact and standardized representation that is easy to interpret across diverse scenarios.

The structure of the paper is as follows: In Section II, the necessary groundwork is laid by introducing and defining key distance measures. Section III is dedicated to proposing a novel distance metric, WS_{dra}, along with comprehensive proof of its properties. Section IV then provides a comparative study of this new metric against the traditional measures introduced in Section II. Finally, Section V concludes the paper by summarizing the research findings and their potential implications.

II. Preliminaries

A. Weighed similarity

The Weighted Similarity (WS) measure aims to be sensitive to significant changes in rankings while remaining robust against minor fluctuations. It also offers the advantage of being easy to interpret, with its values falling within a specified range [17].

In designing the WS measure, a key assumption is made that differences in the top rankings are more impactful than those lower down the list. This is intuitive in scenarios where top-ranked items often have more importance, such as in competitive rankings or search results.

The formula to calculate the WS measure is:

$$WS = 1 - \sum_{i=1}^{n} 2^{-x_i} \frac{|x_i - y_i|}{\max\{|1 - x_i|, |N - x_i|\}} \tag{1}$$

In this equation: WS represents the similarity coefficient's value, n is the length of the ranking, and x_i and y_i represent the place in the ranking for the i^{th} element in the respective rankings x and y.

This formula implies that WS calculates the absolute differences in the ranks of each element in two rankings, normalizes them by the maximum possible difference for that element, and then sums the results. This total is subtracted from 1 to convert it into a similarity measure. Thus, a larger WS value indicates a higher similarity between the two rankings, making WS an effective tool for comparing and analyzing rankings [17].

B. Hamming distance

Hamming distance is a metric that measures the difference between two strings of equal length. It counts the number of positions at which the corresponding symbols in the strings differ [6]. The formula for calculating Hamming distance is as follows:

$$d(x, y) = \frac{\sum_{i=1}^{n} \delta(x_i, y_i)}{n} \tag{2}$$

where x_i and y_i represent the symbols at position i in the two strings, and $\delta(x_i, y_i)$ is an indicator function that equals 0 if x_i and y_i are equal, and 1 otherwise. The Hamming distance provides a way to quantify the dissimilarity between two vectors by measuring the number of symbol mismatches [22].

C. Canberra distance

The Canberra distance is a metric used to quantify the dissimilarity between two vectors or points in a multidimensional space. It takes into account both the magnitude and direction of differences between corresponding components of the vectors [23]. The formula for calculating the Canberra distance is as follows:

$$d(x, y) = \sum_{i=1}^{n} \frac{|x_i - y_i|}{|x_i| + |y_i|} \tag{3}$$

where x_i and y_i represent the components at position i in the two vectors. The Canberra distance considers the absolute difference between the components, normalized by the sum of their magnitudes. This normalization accounts for differences in scale and ensures that each component contributes proportionally to the overall distance calculation.

D. Bray-Curtis distance

The Bray-Curtis distance is a metric used to measure the dissimilarity between two vectors or points in a multidimensional space. It considers both the magnitude and direction of differences between corresponding components of the vectors, taking into account their relative proportions [24]. The formula for calculating the Bray-Curtis distance is as follows:

$$d(x, y) = \frac{\sum_{i=1}^{n} |x_i - y_i|}{\sum_{i=1}^{n} |x_i + y_i|} \tag{4}$$

where x_i and y_i represent the components at position i in the two vectors. The Bray-Curtis distance calculates the absolute difference between the components and normalizes it by the sum of their absolute values. This normalization accounts for differences in scale and ensures that each component contributes proportionally to the overall distance calculation.

E. Euclidean distance

The Euclidean distance is a metric used to measure the straight-line distance between two points in a multidimensional space. It calculates the length of the line connecting the two points, taking into account the differences between their corresponding components [6]. The formula for calculating the Euclidean distance is as follows:

$$d(x, y) = \sqrt{\sum_{i=1}^{n} (x_i - y_i)^2} \tag{5}$$

where x_i and y_i represent the components at position i in the two points. The Euclidean distance computes the squared differences between the components, sums them up, and takes the square root of the result. This computation ensures that each component's contribution to the distance calculation is positive and reflects the actual geometric distance between the points.

F. Manhattan distance

The Manhattan distance, also known as the city block distance or L1 distance, is a metric used to measure the distance between two points in a multidimensional space. It calculates the sum of the absolute differences between the corresponding components of the two points [25]. The formula for calculating the Manhattan distance is as follows:

$$d(x, y) = \sum_{i=1}^{n} |x_i - y_i| \tag{6}$$

where x_i and y_i represent the components at position i in the two points. The Manhattan distance measures the distance traveled along the grid-like streets of a city, where movement can only occur in vertical and horizontal directions. It sums up the absolute differences between the components, disregarding their sign.

G. Chebyshev distance

The Chebyshev distance, also known as the maximum value or L_∞ distance, is a metric that measures the dissimilarity between two vectors or points in a multidimensional space. It calculates the maximum difference between the corresponding components of the two vectors [7]. The formula for calculating the Chebyshev distance is as follows:

$$d(x, y) = \max_{i=1}^{n} |x_i - y_i| \tag{7}$$

where x_i and y_i represent the components at position i in the two vectors. The Chebyshev distance provides a measure of the largest difference between any pair of corresponding components in the vectors, which corresponds to the maximum distance in any dimension.

III. A New Proposed Drastic Metric

In the realm of data analytics and decision-making, the concept of distance plays a pivotal role, enabling us to evaluate similarities, disparities, and rank variables effectively. However, traditional distance metrics have their inherent strengths and limitations. To address these shortcomings and propel the field forward, we introduce a novel distance measure based on the WS coefficient.

Our proposed distance metric revolutionizes the notion of distance by adopting a drastic approach. Instead of penalizing discrepancies in ranking, we treat each comparison in the ranking position as a binary attribute, representing a significant or non-significant relationship. This novel perspective eliminates the conventional notion of assigning varying degrees of penalty based on the magnitude of ranking differences. In essence, our approach treats all errors equally, as an error is an error regardless of what is given in analysed position. This drastic approach fosters a fairer assessment of rankings.

Moreover, our new distance measure recognizes the inherent significance disparity across different ranking positions. It assigns greater consequence to the head of the ranking, acknowledging the top positions as more crucial than the lower ones. This acknowledgment aligns with the understanding that errors at the top of the ranking can have more significant implications than errors further down the list. By considering this significance disparity, our distance measure offers a more nuanced and accurate evaluation of rankings.

Crucially, our proposed measure is normalized within the interval from 0 to 1, enabling straightforward interpretation and comparison across diverse contexts. This normalization facilitates intuitive understanding and ensures that the distance measure remains consistent and interpretable regardless of the specific data or application domain.

By embodying these innovative characteristics, our proposed distance measure qualifies as a true metric in the rigorous mathematical sense. Its drastic approach, significance-awareness, and normalized range combine to offer a comprehensive and reliable framework for comparing rankings in various decision-making scenarios. Through empirical evaluations and theoretical analyses, we demonstrate the superiority and practical utility of our proposed distance measure, paving the way for enhanced ranking analysis and informed decision-making in diverse domains.

A. Definition

The new metric, denoted as $WS_{dra}(x, y)$, is defined as follows:

$$WS_{dra}(x, y) = \frac{\sum_{i=1}^{N} 2^{-i} f(x_i, y_i)}{1 - 2^{-N}} \tag{8}$$

The metric operates on two rankings, denoted as x and y, with each ranking consisting of N elements. The key element of this metric is the function $f(x_i, y_i)$, which compares the elements at corresponding positions in the two rankings.

The function $f(x_i, y_i)$ is defined as follows:

$$f(x_i, y_i) = \begin{cases} 0, & \text{if } x_i = y_i \\ 1, & \text{if } x_i \neq y_i \end{cases} \tag{9}$$

In other words, if the elements at position i in the rankings x and y are the same, $f(x_i, y_i)$ is assigned a value of 0. Conversely, if the elements are different, $f(x_i, y_i)$ takes the value of 1.

The $WS_{dra}(x, y)$ metric computes the weighted sum of $f(x_i, y_i)$ values for each position i, using the weights given by the geometric series 2^{-i}. The weights decrease exponentially as i increases, reflecting a decreasing level of importance for elements further down the rankings. The summation of the weighted $f(x_i, y_i)$ values is then divided by the factor $1 - 2^{-N}$ to ensure normalization within the range of 0 to 1.

Overall, this new metric captures the dissimilarities between two rankings by assigning a weight to each pairwise comparison based on the function $f(x_i, y_i)$. It combines these weighted comparisons to provide a comprehensive measure of dissimilarity between the rankings x and y, where a higher value indicates greater dissimilarity. The normalization factor ensures that the metric remains consistent and interpretable across different ranking sizes.

TABLE I
A SIMPLE EXAMPLE OF TWO RANKINGS, I.E., x_i AND y_i.

i	x_i	y_i	$f(x_i, y_i)$	2^{-i}
1	1	3	1	$\frac{1}{2}$
2	2	2	0	$\frac{1}{4}$
3	3	1	1	$\frac{1}{8}$

We demonstrate a short computational example of the newly proposed metric. Consider the example shown in Table I, which illustrates two rankings, denoted as x_i and y_i. Each row in the table corresponds to a position i in the rankings, and we calculate the associated values of $f(x_i, y_i)$ and 2^{-i}. Thus, ranking x_i means the order of alternatives in the form $A_1 > A_2 > A_3$, and ranking y_i in the form $A_3 > A_2 > A_1$. To calculate the $WS_{dra}(x, y)$ value for these rankings, we use the formula (8) and we get the following result:

$$WS_{dra}(x, y) = \frac{\frac{1}{2} \cdot 1 + \frac{1}{4} \cdot 0 + \frac{1}{8} \cdot 1}{1 - \frac{1}{8}} = \frac{\frac{5}{8}}{\frac{7}{8}} = \frac{5}{7}$$

A true metric, also known as a metric space or distance metric, is a mathematical concept used to quantify the distance or similarity between objects within a set. It defines a set of rules or properties that a distance function must satisfy to be considered a true metric [2].

In a true metric, the following properties should hold:

1) Non-negativity: The distance between any two objects is non-negative. It is always equal to or greater than zero.
2) Identity of indiscernibles: The distance between two objects is zero if and only if the objects are identical.
3) Symmetry: The distance between object A and object B is the same as the distance between object B and object A.
4) Triangle inequality: The distance from object A to object B, added to the distance from object B to object C, is always greater than or equal to the distance from object A to object C.

In the following subsections, we will explore each of the presented properties to demonstrate the validity of the proposed measure as a true metric. Our objective is to carefully analyze and evaluate these properties, providing a solid foundation for the metric's credibility. Through a systematic examination, we will investigate the non-negativity, identity of indiscernibles, symmetry, and triangle inequality properties. By establishing the fulfillment of these properties, we aim to establish the proposed metric as a reliable tool for comparing rankings. The goal is to offer a well-founded framework that promotes accurate assessments and meaningful insights for decision-making.

B. Non-negativity

To prove the inequality $\frac{\sum_{i=1}^{N} 2^{-i} f(x_i, y_i)}{1-2^{-N}} \geq 0$ when $f(x_i, y_i)$ can take the values 0, 1, or a combination of 0 and 1, we will consider three different cases.

Case 1: $f(x_i, y_i) = 0$ for all i: When all terms in the summation are multiplied by 0, the numerator becomes zero. The denominator, $1 - 2^{-N}$, is positive since $2^{-N} < 1$ for all positive N. Thus, the inequality holds trivially: $0 \geq 0$.

Case 2: $f(x_i, y_i) = 1$ for all i: In this case, each term in the summation will be equal to 2^{-i} since $f(x_i, y_i)$ is always 1. The numerator then becomes:

$$\sum_{i=1}^{N} 2^{-i} = 2^{-1} + 2^{-2} + \ldots + 2^{-N}$$

This sum is a finite geometric series, and its sum can be calculated as follows:

$$\sum_{i=1}^{N} 2^{-i} = \frac{2^{-1}(1 - 2^{-N})}{1 - 2^{-1}} = \frac{1 - 2^{-N}}{2 - 1} = 1 - 2^{-N}$$

Since $1 - 2^{-N}$ is positive, the numerator is non-negative. The denominator, $1 - 2^{-N}$, is also positive and is equal to the nominative. Therefore, when $f(x_i, y_i) = 1$ for all i, the inequality holds:

$$\frac{\sum_{i=1}^{N} 2^{-i} f(x_i, y_i)}{1 - 2^{-N}} = 1 \geq 0$$

Case 3: $f(x_i, y_i)$ is equal 0 or 1: In this case, the numerator of the expression is a sum of terms, each multiplied by $2^{-i} f(x_i, y_i)$. Since $f(x_i, y_i)$ can be 0 or 1, the product $2^{-i} f(x_i, y_i)$ will be either 0 or 2^{-i}. It means that nominative will be limited to interval:

$$0 \leq \sum_{i=1}^{N} 2^{-i} f(x_i, y_i) < 1$$

Since both 0 and 2^{-i} are non-negative, the numerator is a non-negative number. The denominator, $1 - 2^{-N}$, is positive and it is the biggest possible value of nominative, therefore WS_{dra} will be limited to:

$$0 \leq \frac{\sum_{i=1}^{N} 2^{-i} f(x_i, y_i)}{1 - 2^{-N}} \leq 1$$

Hence, when $f(x_i, y_i)$ takes 0 or 1, the inequality holds:

$$\frac{\sum_{i=1}^{N} 2^{-i} f(x_i, y_i)}{1 - 2^{-N}} \geq 0$$

In all cases, we have shown that the inequality holds. Therefore, we can conclude that $\frac{\sum_{i=1}^{N} 2^{-i} f(x_i, y_i)}{1-2^{-N}} \geq 0$ when $f(x_i, y_i)$ can be equal to 0, 1, or a combination of 0 and 1.

C. Identity of indiscernibles

To prove that only $WS_{dra}(x, x) = 0$ for the given expression $WS_{dra}(x, y) = \frac{\sum_{i=1}^{N} 2^{-i} f(x_i, y_i)}{1-2^{-N}}$, we can substitute x for y in the expression:

$$WS_{dra}(x, x) = \frac{\sum_{i=1}^{N} 2^{-i} f(x_i, x_i)}{1 - 2^{-N}}$$

Now, let's focus on the numerator of the expression. Since $f(x_i, x_i)$ represents the function f evaluated at the same element x_i for both arguments, it will always yield the same result. Therefore, $f(x_i, x_i)$ is a constant for all i. Let's denote this constant as c, such that $f(x_i, x_i) = c$ for all i. Substituting c into the numerator, we have:

$$\sum_{i=1}^{N} 2^{-i} f(x_i, x_i) = \sum_{i=1}^{N} 2^{-i} c = c \sum_{i=1}^{N} 2^{-i}$$

The sum $\sum_{i=1}^{N} 2^{-i}$ is a finite geometric series and can be computed as:

$$\sum_{i=1}^{N} 2^{-i} = \frac{2^{-1}(1-2^{-N})}{1-2^{-1}} = \frac{1-2^{-N}}{2-1} = 1-2^{-N}$$

Now, substituting this value back into the expression, we get:

$$WS(x,x) = \frac{c\sum_{i=1}^{N} 2^{-i}}{1-2^{-N}} = \frac{c(1-2^{-N})}{1-2^{-N}} = c$$

Since c is a constant, it does not depend on the choice of x, and therefore, c is equal to $f(x_i, x_i)$ for any x_i. Since $f(x_i, x_i)$ can take the values of 0 or 1 (according to the given property), we can notice that in this case c is equal 0. Therefore, based on the given expression, we can universally prove that only $WS(x,x) = 0$ and it depends on the specific value of c (i.e., the constant $f(x_i, x_i)$).

D. Symmetry

To prove that $WS_{dra}(x,y) = WS_{dra}(y,x)$ for the expression $WS_{dra}(x,y) = \frac{\sum_{i=1}^{N} 2^{-i} f(x_i,y_i)}{1-2^{-N}}$, we need to show that the weighted sum is symmetric with respect to its arguments. Let's consider the left-hand side $WS_{dra}(x,y)$ and the right-hand side $WS(y,x)$ of the equation separately and compare them.

$$WS_{dra}(x,y) = \frac{\sum_{i=1}^{N} 2^{-i} f(x_i, y_i)}{1-2^{-N}}$$

$$WS_{dra}(y,x) = \frac{\sum_{i=1}^{N} 2^{-i} f(y_i, x_i)}{1-2^{-N}}$$

To show that $WS_{dra}(x,y) = WS_{dra}(y,x)$, we need to demonstrate that the numerator and denominator of both expressions are equal. For each term in the numerator, we have: $f(x_i, y_i)$ in the expression for $WS_{dra}(x,y)$ and $f(y_i, x_i)$ in the expression for $WS_{dra}(y,x)$. Since the order of the arguments is switched between the two expressions, we can see that $f(x_i, y_i) = f(y_i, x_i)$ for each i. Therefore, the numerator of both expressions is identical. The denominator of both expressions is the same: $1-2^{-N}$. Since the numerator and denominator of both $WS_{dra}(x,y)$ and $WS_{dra}(y,x)$ are equal, we can conclude that $WS_{dra}(x,y) = WS_{dra}(y,x)$. Hence, we have proven that the weighted sum expression $WS_{dra}(x,y)$ is symmetric with respect to its arguments, satisfying the property $WS_{dra}(x,y) = WS_{dra}(y,x)$.

TABLE II
ALL POSSIBLE BINARY COMBINATIONS FOR $f(a_i, b_i)$, $f(b_i, c_i)$, $f(a_i, c_i)$ AND THE VALUE X_i OBTAINED AS $f(a_i, b_i) + f(b_i, c_i) - f(a_i, c_i)$.

$f(a_i, b_i)$	$f(b_i, c_i)$	$f(a_i, c_i)$	X_i
0	0	0	0
0	1	1	0
1	0	1	0
1	1	1	1
1	1	0	2

E. Triangle inequality

We'll work with the formula (8) to prove the triangle inequality property:

$$WS_{dra}(a,b) + WS_{dra}(b,c) \geq WS_{dra}(a,c)$$

Let's denote $A = WS_{dra}(a,b)$, $B = WS_{dra}(b,c)$, and $C = WS_{dra}(a,c)$. Substituting these values into the inequality, we have $A + B \geq C$. Now, let's consider the individual terms in the numerator of each expression.

$$WS_{dra}(a,b) : \sum_{i=1}^{N} 2^{-i} f(a_i, b_i)$$

$$WS_{dra}(b,c) : \sum_{i=1}^{N} 2^{-i} f(b_i, c_i)$$

$$WS_{dra}(a,c) : \sum_{i=1}^{N} 2^{-i} f(a_i, c_i)$$

Now, let's examine the numerator term-wise for the three expressions: for each i, 2^{-i} is a non-negative constant; for each term $f(a_i, b_i)$ in $WS_{dra}(a,b)$, $f(b_i, c_i)$ in $WS_{dra}(b,c)$, and $f(a_i, c_i)$ in $WS_{dra}(a,c)$, they can take the values of 0 or 1 according to the formula (9). Now, we can compare the terms between the expressions, where for each term i, we have:

$$2^{-i} f(a_i, b_i) + 2^{-i} f(b_i, c_i) \geq 2^{-i} f(a_i, c_i)$$

This inequality holds because for any given term, either $f(a_i, b_i) = f(a_i, c_i) = 1$ or $f(b_i, c_i) = 0$ (which makes the left-hand side greater than or equal to the right-hand side) or $f(a_i, b_i) = f(b_i, c_i) = 0$ (which makes the left-hand side equal to the right-hand side). The all possible cases are presents in Table II, where $X_i = f(a_i, b_i) + f(b_i, c_i) - f(a_i, c_i)$. Now, summing up these inequalities over all i from 1 to N, we have:

$$^{dra}WS(a,b) + {}^{dra}WS(b,c) \geq {}^{dra}WS(a,c)$$

$$\frac{\sum_{i=1}^{N} 2^{-i} f(a_i, b_i)}{1-2^{-N}} + \frac{\sum_{i=1}^{N} 2^{-i} f(b_i, c_i)}{1-2^{-N}} \geq \frac{\sum_{i=1}^{N} 2^{-i} f(a_i, c_i)}{1-2^{-N}}$$

$$\frac{\sum_{i=1}^{N}(2^{-i} f(a_i, b_i) + 2^{-i} f(b_i, c_i) - 2^{-i} f(a_i, c_i))}{1-2^{-N}} \geq 0$$

TABLE III
THE COMPARED RANKINGS, I.E., x_i AND $y_i^{(j)}$ FOR $j = 1, 2, ..., 7$, WHERE RED COLOR INDICATES THE DIFFERENCES WITH THE ORIGINAL RANKING.

i	x_i	$y_i^{(1)}$	$y_i^{(2)}$	$y_i^{(3)}$	$y_i^{(4)}$	$y_i^{(5)}$	$y_i^{(6)}$	$y_i^{(7)}$
1	1	2	1	1	1	3	4	5
2	2	1	3	2	2	2	2	2
3	3	3	2	4	3	1	3	3
4	4	4	4	3	5	4	1	4
5	5	5	5	5	4	5	5	1

$$\sum_{i=1}^{N} 2^{-i} \left(f(a_i, b_i) + f(b_i, c_i) - f(a_i, c_i) \right) \geq 0$$

$$\sum_{i=1}^{N} 2^{-i} X_i \geq 0$$

Therefore, X_i is always non-negativity, we can conclude that we have proven triangle inequality for WS_{dra} distance.

IV. Comparison and discussion

Table III provides a visual representation of the initial ranking x_i and sample rankings $y_i^{(j)}$ for $j = 1, 2, ..., 7$. The table is designed to compare the considered distance measures with the proposed new measure. In this table, the red color highlights the differences between each example ranking and the initial ranking.

The table consists of nine columns. The first column, labeled i, denotes the position in the rankings. The second column represents the initial ranking, denoted as x_i. The remaining columns, labeled $y_i^{(j)}$, correspond to the examplary rankings for $j = 1, 2, ..., 7$.

Each cell in the table represents the element at position i in the corresponding ranking. The red color is used to indicate any differences between the element in the examplary ranking and the initial ranking. By visually highlighting these differences, the table facilitates a clear comparison between the rankings and serves as a reference for evaluating the performance of different distance measures. Table III provides a useful reference point for understanding the subsequent analyses and discussions related to the comparisons between the considered distance measures and the proposed new measure.

Table IV provides a comprehensive summary of the similarity and distance measures for the previously presented rankings, offering valuable insights for analyzing and comparing the relationships between x_i and each $y_i^{(j)}$. The measures included in the table enable a thorough assessment of the similarities and differences among the rankings.

The table introduces a new proposed distance metric denoted as WS_{dra}, represented in blue font. This novel metric returns distances ranging from 0.5484 to 0.7742. It was developed as an enhancement of the WS coefficient. To ensure consistent information direction, the $1 - WS$ coefficient was introduced, yielding values ranging from 0.2083 to 0.5313. This modification was incorporated into the analysis, as the new distance metric was built upon this coefficient.

In addition to the newly proposed metric, Table IV includes well-known distance measures commonly used for comparison purposes. These measures, namely Hamming, Canberra, Bray-Curtis, Euclidean, Manhattan, and Chebyshev, offer additional perspectives on the dissimilarity between x_i and each $y_i^{(j)}$ ranking.

The Hamming measure, typically employed for comparing categorical data, consistently yields a distance value of 0.4000 for all comparisons. This suggests that all rankings $y_i^{(j)}$ exhibit the same level of distance and similarity with respect to x_i. However, from a decision-making standpoint, it becomes evident that this statement does not hold true, as, for example, ranking $y_i^{(1)}$ is closer to x_i than ranking $y_i^{(2)}$.

The Canberra measure calculates distances ranging from 0.6667 to 1.3333, providing insights into the relative dissimilarity between x_i and the different $y_i^{(j)}$ rankings. This measure considers both the magnitude and direction of differences between the rankings, offering a comprehensive assessment of their dissimilarity.

The Bray-Curtis measure, which evaluates dissimilarity based on the proportions of shared and unique elements, yields distances ranging from 0.0667 to 0.2667. This measure takes into account the presence and absence of specific elements, providing valuable information regarding the relative dissimilarity between the rankings.

Let's delve deeper into the two distinct sets of rankings: $y_i^{(1)}$ to $y_i^{(4)}$, and $y_i^{(1)}$ alongside $y_i^{(5)}$ to $y_i^{(7)}$. What sets these rankings apart is the presence of a singular swap between alternatives, occurring either in adjacent positions or non-adjacent ones.

In the first set of rankings, we begin by examining modifications at the top (or head) of the ranking and gradually proceed towards the bottom (or tail). Ranking tasks inherently pose a significant challenge, as they tend to assign more weight or significance to changes at the beginning of the ranking sequence rather than towards the end. For instance, let's consider a scenario where a company not placed first in the ranking wins a tender—such an event is, of course, wrong, as that company would either won or be removed from the ranking (e.g., due to withdrawal).

By comparing these rankings with the x_i ranking and employing five different distance measurement methods—Hamming, Bray-Curtis, Euclidean, Manhattan, and Chebyshev—we observe that the comparison values for all paired rankings remain constant. The respective constant values assigned to these methods are 0.4, 0.0667, 1.4142, 2.0000, and 1.0000. This indicates that these five measurements may not adequately capture the variability required for decision-making processes, as they remain insensitive to changes in ranking positions, regardless of where those changes occur. Furthermore, when considering the $1 - WS$ ratio and the Canberra distance, both measurements consistently exhibit a decreasing trend in values with each subsequent ranking, $y_i^{(j)}$,

TABLE IV
SUMMARY OF SIMILARITY AND DISTANCE MEASURES FOR x_i AND $y_i^{(j)}$ FOR $j = 1, 2, ..., 7$ RANKINGS.

Measures	$d(x_i, x_i)$	$d(x_i, y_i^{(1)})$	$d(x_i, y_i^{(2)})$	$d(x_i, y_i^{(3)})$	$d(x_i, y_i^{(4)})$	$d(x_i, y_i^{(5)})$	$d(x_i, y_i^{(6)})$	$d(x_i, y_i^{(7)})$
WS_{dra}	0.0000	0.7742	0.3871	0.1935	0.0968	0.6452	0.5806	0.5484
$1 - WS$	0.0000	0.2083	0.1458	0.0833	0.0286	0.3750	0.4375	0.5313
Hamming	0.0000	0.4000	0.4000	0.4000	0.4000	0.4000	0.4000	0.4000
Canberra	0.0000	0.6667	0.4000	0.2857	0.2222	1.0000	1.2000	1.3333
Bray-Curtis	0.0000	0.0667	0.0667	0.0667	0.0667	0.1333	0.2000	0.2667
Euclidean	0.0000	1.4142	1.4142	1.4142	1.4142	2.8284	4.2426	5.6569
Manhattan	0.0000	2.0000	2.0000	2.0000	2.0000	4.0000	6.0000	8.0000
Chebyshev	0.0000	1.0000	1.0000	1.0000	1.0000	2.0000	3.0000	4.0000

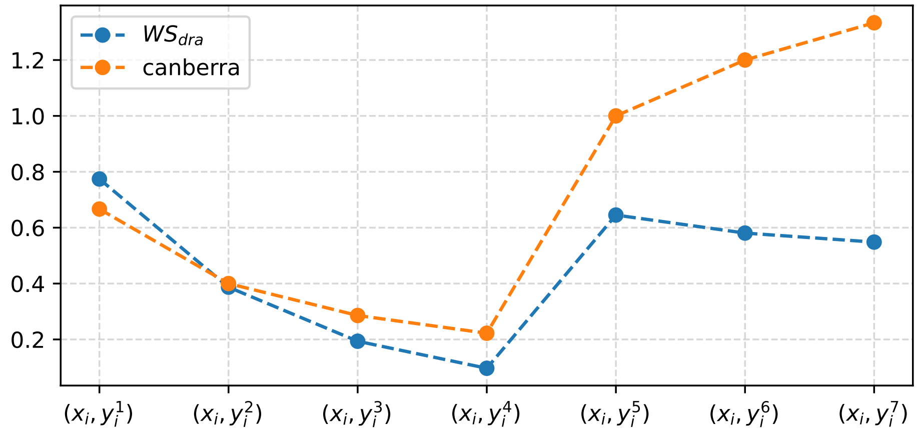

Fig. 1. Comparison of the proposed distance WS_{dra} with the Canberra distance.

where j = 1, 2, 3, 4.

Shifting focus to the second set of rankings, we encounter a scenario where the order of alternatives is swapped, albeit not in adjacent positions. This gives rise to a peculiar situation where the comparison of x_i with $y_i^{(1)}$ results in erroneous rankings at the first and second positions. Similarly, in the comparison of x_i with $y_i^{(5)}$, erroneous rankings occur at the first and third positions, and so on. Intuitively, we would expect a larger distance in the first case, with decreasing values in subsequent comparisons, as errors are initially observed at the first position and then propagate to the further subsequent positions.

However, both the Canberra distance and the $1 - WS$ ratio exhibit counter-intuitive behavior, as their values increase rather than decrease. This contradicts the initial assumption. Moreover, the $1-WS$ ratio cannot be considered a true metric due to its lack of symmetry. The comparison between the results obtained using the WS_{dra} method and the Canberra method is depicted in Fig. 1. The analysis reveals a significant correlation for the first set of alternatives, with a Pearson correlation coefficient of 0.9995. This high correlation indicates a strong agreement between the values obtained from the WS_{dra} method and the Canberra method for this set of rankings.

In the case of the second set of rankings, a similarly strong correlation is observed; however, it possesses a negative nature with a correlation coefficient of -0.9965. This negative correlation suggests an inverse relationship between the values obtained by the WS_{dra} method and the Canberra method for this particular set of rankings.

When considering both sets of rankings collectively, a moderate positive correlation of 0.6995 is observed. This indicates that, overall, there is a consistent relationship between the rankings obtained from the WS_{dra} method and the Canberra method, albeit with a moderate strength of association.

Fig. 1 visually illustrates these correlations, providing a clear understanding of the magnitude and characteristics of the relationship between the WS_{dra} method and the Canberra method for the various sets of rankings. It is important to note that the Canberra distance exceeded the value of 1, which represents the upper limit in the WS_{dra} distance metric.

The WS_{dra} distance metric is based on certain assumptions that contribute to its enhanced reliability and applicability across diverse contexts. Firstly, this metric takes into account the weighted differences between rankings, recognizing that not all changes in rankings hold equal significance. By assigning appropriate weights to these differences, the WS_{dra} metric captures the varying impact of alterations in ranking positions, providing a more accurate assessment of dissimilarity.

Additionally, the WS_{dra} metric adheres to the fundamental principle that "an error is an error." It acknowledges that any deviation or discrepancy between rankings, regardless of its location or magnitude, should be considered as an error. By treating all errors equally, the WS_{dra} metric ensures a fair and unbiased evaluation of dissimilarity, promoting a more reliable comparison between rankings.

Consequently, these examples demonstrate that the distance metric WS_{dra} provides greater reliability, as it considers the weighted differences between rankings, adhering to the principle that "an error is an error." It is important to note that the value of this metric is normalized within the range of 0 to 1, ensuring its applicability across diverse contexts.

V. Conclusion

In this paper, we introduced a new distance metric for the comparison of rankings, demonstrating its effectiveness and advantages over well-established distance measures. This novel measure, which we term the drastic WS distance, conforms to all necessary properties of a true metric and exhibits a unique capability to capture nuances in the ranking structure.

The drastic distance metric provides a compact, standardized representation within the 0 to 1 interval, making it easy to interpret across a broad spectrum of applications. Importantly, it holds the crucial properties of non-negativity, identity of indiscernibles, symmetry, and the triangle inequality. This compliance ensures that our proposed distance metric offers a mathematically sound and reliable framework for comparing rankings, further enhancing its credibility.

By conducting comparative experiments, we illustrated the superior performance of our new drastic distance metric against established measures such as Hamming, Canberra, Bray-Curtis, Euclidean, Manhattan, and Chebyshev distances. The results showcased the new metric's enhanced sensitivity and ability to accurately quantify dissimilarities between rankings, making it a potent tool in the decision-making domain.

In conclusion, the drastic distance metric proposed in this work represents a significant advancement in the area of distance measurement for rankings. With its proven mathematical robustness and practical effectiveness, it has the potential to contribute significantly to decision-making processes across various fields. Future research directions could explore more extensive applications of this metric and further refine its potential through diverse real-world use cases.

***Abstract*—We present a study on the automatic classification of speech acts in the domain of political communication, based on J. R. Searle's classification of illocutionary acts. Our research involves creating a dataset using the US State of the Union corpus and the UN General Debate corpus (UNGD) as data sources. To overcome limited labelled data, we employ a combination of weak supervision and active learning techniques for dataset creation and model training. Through various experiments, we investigate the influence of external and internal factors on speech act classification. In addition, we discuss the potential for further analysis of speech act usage, using the trained model on the UNGD corpus. The findings demonstrate the effectiveness of Transformer-based models for automatic speech act classification, highlight the benefits of weak supervision and active learning for dataset creation and model training, and underscore the potential for large-scale statistical analysis of speech act usage in the domain of political communication.**

I. Introduction

When we use language, we often want to go beyond the mere conveying of information, but rather want to accomplish a communicative goal and perform a social function, such as making a promise or issuing a threat. In his seminal work "How to do things with words", J. L. Austin has called these kinds of utterances illocutionary acts, which is not an act of just saying something, but an act of doing something by saying something [1]. According to Austin, there are two types of utterances: constatives, which make statements about the world, and performatives, which are acts performed by the speaker with the intention of fulfilling a social function. This concept was later developed further by Searle and the general term *speech act* has been developed since for such performative utterances [2]. Unlike interrogative and imperative sentences that are marked with either a "?" or "!" at the end of a sentence, performatives are not orthographically highlighted as such. Indeed, a central insight of Austin is the fact that there is apparently no trivial indicator differentiating constatives from performatives. As humans, we thus have to rely on linguistic and contextual information to properly recognize performatives and to act upon them accordingly.

While speech acts have an important socio-linguistic function in everyday communication, they are also playing a crucial role in political communication, as they are used by politicians to perform specific actions and influence their audience [3, 4]. Examples include promises for the purpose of getting elected, or requesting legislative action. By analysing the use of speech acts in political discourse, researchers can gain a better understanding of the intentions and motivations of political actors and how they seek to influence public opinion.

In this study, we present a robust computational framework for detecting and correctly identifying speech acts in political communication based on large transformer-based language models for automated and scalable analysis of speech acts in large datasets. The contributions of this paper are as follows:

- Our approach is based on Transformer-based language model classifiers [5], and we employ a combination of weak supervision and active learning techniques for dataset creation and model training.
- Through various experiments, we investigate the influence of external and internal factors on speech act classification.
- We show a concrete use case that demonstrates the use and potential of automatic speech act annotation in large text corpora containing political communication.

The use of speech acts in political communication has up to now received only little attention despite their pervasiveness and utility in this mode of communication (see [6, 7]).

Underlying this concept is the idea that the interconnected network of deontic moral forces within society are established and sustained through specific types of speech acts. J.R. Searle postulates that declarative speech acts, in particular, play a pivotal role in creating institutions and institutional facts. Nevertheless, it has not yet resulted in significant changes, possibly due to the substantial challenges involved in operationalizing his ideas for empirical research."

The current literature on the use of speech acts in political communication has mainly focused on individual sentences or small corpora, lacking a larger, macroscopic perspective. However, with the advent of digital resources that are freely accessible and machine-readable, there is an opportunity to analyse larger datasets of political speeches, for instance parliamentary debates [8] or speeches of singular politicians [9]. This availability of material opens up new perspectives for rather empirical research questions along the lines of political sciences, international relations, computational social science and corpus linguistics.

An issue surrounding this topic is the vast amounts of data that need to be processed in order to gain valuable insights into macroscopic patterns of their uses among political actors. Especially since certain types of utterances are quite infrequent and sporadic, the criterion applies that manual sampling would certainly not be able to produce representative distributions for quantitative evaluations in any reasonable amount of time. With the advances of computational approaches for accessing different language phenomena from Natural language Processing (NLP) and Artificial Intelligence (AI) made in recent years, it is now possible to find this language phenomenon in an automated way and with good quality in large amounts of data.

Future applications will be the quantitative analysis of political communication in international institutions [10]. This will provide a computational method for studying how to do international politics with words [11]. With the methodology shown here, the following research questions, for example, become conceivable: How can speech act theory be applied to understand declarations of war, inaugurations, pardons, government statements, etc.? How do international obligations and the self-binding of sovereign states to international norms and rules emerge under conditions of anarchy?

II. Related Work

Automatic speech act classification has been a subject of research for some time, focusing on dialogue acts [12, 13, 14]. Earlier studies on Korean employed various methods, including Hidden Markov Models [15], maximum entropy models [16], and supervised machine learning algorithms [17]. Unlike Austin and Searle's speech acts, dialogue acts specifically target synchronous language used in direct communication and many of the classification schemes used in research do not align with Austin's or Searle's speech act classification.

In recent years, researchers have increasingly utilized Deep Neural Networks (DNNs) in Natural Language Processing (NLP) due to advancements in computing capabilities. This has led to the adoption of more sophisticated approaches in addressing the issue at hand. Notably, recurrent neural networks (RNNs) [18] and convolutional neural networks (CNNs) [19] have been explored as viable options for tackling the challenge of speech act detection. Existing research on speech and dialogue act detection primarily focuses on synchronous language in online communication. However, little attention has been given to speech act detection in political communication, except for notable exceptions such as [20]. The emergence of the Transformer architecture [5] and pre-trained Transformer-based language models like BERT [21] has significantly changed the way NLP is practised, and automated processing of even difficult language problems is becoming increasingly possible. To the best of our knowledge, no previous work exists on classifying speech acts according to Searle's classification of illocutionary acts.

III. Experiment Design

In our experiments, we developed a Transformer-based model specifically designed to classify sentences according to Searle's classification of illocutionary acts, referred to as "speech acts" in this study. We constructed the dataset using weak supervision and further refined it through active learning techniques. Additionally, we explored possible avenues for future research, which encompass improving the model's performance and assessing its applicability and relevance in computational political science studies.

A. Corpora

To construct a suitable dataset for model training and initial analysis, we have selected two corpora of similar yet distinct sub-domains within political communication: the US State of the Union (SOTU) addresses and the speeches delivered at the UN General Debate. The SOTU corpus comprises the State of the Union presidential addresses given annually from 1790 to 2017.[1] In our experiments, the SOTU corpus' temporal range was limited to between 1990 and 2017. The UN General Debate corpus (UNGD) comprises speeches delivered by national representatives, including presidents and foreign ministers, from each UN member country during the annual UN General Debate [8]. Spanning the years 1970 to 2020, this corpus provides a rich collection of political speeches from a diverse range of international stakeholders. Aside from the transcriptions of speeches in English, the UNGD corpus also includes a variety of metadata for each speech such as the year and session of the UN General Debate that the speech was held in, the name of the speaker, their position, the original language of delivery as well as the represented country. We have adopted a standardized format for referencing individual speeches in the UNGD corpus, using the year of the speech and a three-letter country code based on ISO 3166-1 alpha-3 to denote the speaker's country he or she represents, such as ”1979_IRQ” for the 1979 speech of the representative of Iraq.

We formulated the task of identifying speech acts as a multi-class classification problem. To achieve this, we have employed the theoretical framework of illocutionary acts introduced by Searle [2] and identified five classes of speech acts and one open class for sentences where none of the labels can be assigned:

- *ASSERTIVE*, the speaker commits to the truth of a stated expression.
- *EXPRESSIVE*, the speaker expresses their personal thoughts and feelings
- *COMMISSIVE*, the speaker commits themselves to a future action.
- *DIRECTIVE*, the speaker issues orders or instructions to the recipients.
- *DECLARATIVE*, the speaker, using granted institutional powers, alters or defines (social) realities.
- *NONES*, an open class for sentences that contain none of the above speech act types.

B. Heuristic Labelling using Weak Supervision

When creating a dataset to train our model, we need to define the assignment of labels by existing linguistic properties of each class. To assign speech act annotations to linguistic expressions containing the linguistic properties just mentioned, we use the weak supervision library *skweak* [22]. This library enables the generation of so-called weak labels through annotator functions. Although these labelling functions rely on simple heuristics and may not achieve particularly high precision, they effectively enable us to efficiently search for speech acts employed in political communication during the dataset creation process.

A crucial aspect of Austin's seminal work on speech acts pertains to the notion that certain verbs are closely linked to a specific class of speech act, which he coined *performative verbs*. We relate closely to this basic concept in our definition of the relevant linguistic features for speech acts, in order to define heuristics for the labelling functions. We chose the following verb relationships to supervise the labelling process:

- **Assertive**: *think, know, believe, convince, presume, assume, admit*
- **Expressives:** *apologize, condole, lament, deplore, forgive, welcome, thank, forgive, boast*
- **Commissives:** *promise, vow, guarantee, offer, will, refuse, volunteer*
- **Directives::** *ask, order, command, request, beg, plead, pray, invite, permit, advise, must, should*
- **Declaratives::** *announce, declare, dismiss, nominate, pronounce, pass, adopt, support, oppose, advocate, condemn*

To capture general speech act features, we developed several labelling functions that assign a general "speech act" label [*SA*] which is added to the matching sentences. This approach allows us to assign weak labels to encompass general features that are not confined to a specific speech act. Sentences containing performative verbs are assigned the speech act label considered characteristic for them, as shown in the list above. We derived the labelling rules from sample sentences in Austin's work *"How to do things with words"* [1]. Note, that multiple labelling functions can be applied to a single sentence if the criteria are met. In a final step, these weak labels, which represent a supervision signal, are subsequently aggregated to form final labels. This aggregation model takes into account the varying degrees of confidence associated with each weak label. By leveraging the sequential dependencies of the weak labels between sentences, the aggregation ensures a more accurate labelling outcome. The labelling functions can be briefly described as follows:

- **Subject is 1st person**: Assigns the label [*SA*] if the subject of a sentence is either "I" or "we".
- **Main verb is present tense**: Assigns the label [*SA*] if the main verb of a sentence is in present tense.
- **Object is 2nd person**: Assigns the label [SA] if the object of the sentence is the pronoun "you".
- **Sentence contains imperative**: Assigns the label [*DIRECTIVE*] if the sentence is an imperative without an overt subject.
- **Sentence contains interrogative**: Assigns the label [*DIRECTIVE*] if the main verb precedes the subject and the sentence ends with a question mark "?".
- **Sentence contains performative verb**: Assigns the label associated with the performative verb [*ASSERTIVE, EXPRESSIVE, COMMISSIVE, DIRECTIVE, DECLARATIVE*] if the lemma of a performative verb is present in the sentence.

Processing the SOTU as well as the UNGD corpus using this weak supervision approach yields a list of sentences that likely contain speech acts.

C. Active Learning

Active learning is an approach that utilizes query strategies to select the most informative samples from an unlabelled pool of data, guided by a classifier trained on a set of existing labelled data. The goal is to intelligently choose data points for labelling, in order to improve the performance and efficiency of the learning process. Over the years, many query strategies have been proposed by various researchers, most of them using prediction based query strategies [23]. Active learning follows a process that involves two pools: a labelled pool and an unlabelled pool. The goal is to transfer data from the unlabelled pool to the labelled pool. In prediction-based query strategies, a primary model is trained on the labelled pool, which is then used to identify the most informative samples to query from the unlabelled pool. These queried samples are then presented to a domain expert (also known as oracle in active learning jargon), who manually confirms or rejects the labels of the primary model. The labelled samples are subsequently added to the labelled pool. This process continues iteratively until a predefined stopping criterion is met. With this approach, active learning allows the progressive enhancement of the model's performance by actively selecting the most informative samples for annotation.

We used the active learning library Small-Text [24] to facilitate experiments with active learning. This library provides a user-friendly and consistent interface which makes it very simple to set up the experiments. After some initial testing, we selected the prediction-based query strategy *Prediction Entropy* as our choice and set a fixed iteration size of 10 iterations as the stopping criterion. In each iteration, we queried 20 samples.

To effectively utilize the library, it is essential to choose a transformer-based language model as the underlying framework for the classification task. Among the various models we tested, we ultimately opted for the light-weight DistilBERT [25] with the default configuration provided through HuggingFace.[2] This decision was primarily driven by DistilBERT's significantly reduced computational overhead, with minimal performance drawbacks compared to the resource-intensive BERT model. Since the iterative approach involves many training processes, the model accelerates them significantly,

[2] https://huggingface.co/distilbert-base-uncased

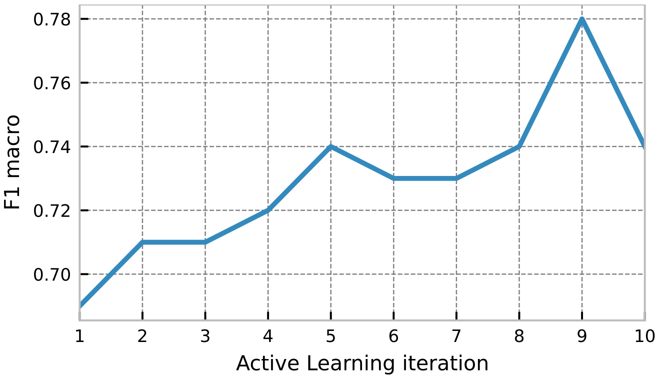

Figure 1. Learning curve of f1 macro performance on test set over all classes

making them more manageable in an interactive setting with domain experts.

The results from the weak supervision process were subsequently filtered by a domain expert, resulting in a valid semi-manual training dataset for initializing the active learning process. Despite the linguistic features serving as a basic codebook for annotating queried samples, a considerable number of samples proved to be non-trivial. Given the fuzzy nature of speech act use and their interpretation, disagreements are unavoidable. For training, we stratified the dataset by class and performed a split, allocating 60% of the data for training and 40% for evaluation. This choice of a 60:40 split was made to ensure that both sets capture a representative sample of each class. By evaluating each iteration's performance using F1-scores for individual classes as well as the macro average, we could effectively track the model's progress over iterations and visualize it through a learning curve.

IV. Experiments and Results

A. Active Learning and Classifier Performance

After applying the weak supervision approach and correcting its output, our initial dataset consisted of 175 samples in the labelled pool and 118 samples in the evaluation set. Once the initial model was trained using the samples found in the labelled pool, we further refined it through the active learning process. In each iteration, we queried, annotated, and then added 20 newly labelled samples to the labelled pool. After each addition, the model was retrained using the augmented labelled pool. This iterative process continued until the stopping criterion of 10 iterations was met.

Looking at Fig. 1, after performing ten active learning iterations, we observed a rise in F1-macro performance from 0.69 of the initial model to 0.78 of the best model in the ninth iteration before the performance cratered somewhat again in the tenth iteration. In Table I we show detailed information about the classification performance of the model trained in the ninth iteration.

Examining the individual F1-scores, we noticed large discrepancies between the highest score of the commissive class and lowest score of the expressive class. In terms of precision, assertives do have a medium performance, indicating that the training examples provide very ambiguous features to the classifier. In terms of recall, expressives and declaratives show comparatively medium performance. In the subsequent experiments presented in sections IV-B, IV-D as well as the showcase demonstrated in section IV-E, we utilized the model trained during the 9th iteration, which incorporated an additional 180 training samples obtained through the active learning process.

Class	Precision	Recall	F1	Support
Assertive	0.71	0.89	0.79	19
Expressive	0.82	0.60	0.69	15
Commissives	0.83	1.0	0.91	24
Directives	0.78	0.96	0.86	26
Declaratives	1.0	0.67	0.80	18
Nones	0.80	0.50	0.62	16
macro average	**0.82**	**0.77**	**0.78**	**118**

Table I
Table presenting the performance of the classifier from the 9th active learning iteration over all speech act classes

B. Adding context sentences in the training data

The current model employed in our research utilizes single sentences as the units of classification. While this approach may simplify the classification task, it is not necessarily evident that speech acts occur independently of each other. Therefore, it is important to acknowledge the potential limitations of this local single sentence approach.

To better understand the relationships between single sentences, we conducted an investigation by visualizing the occurrence of all speech acts from five randomly selected speeches. Figure 2 reveals a strong clustering behaviour in the use of speech acts, even from this small sample.

We conducted an additional analysis by calculating the pointwise mutual information (PMI) between each speech act and its neighbouring co-occurring speech acts in a sample of 100 randomly selected speeches. The PMI measures the statistical association between two events, in this case, speech acts and their neighbouring counterparts. Positive PMI scores indicate a higher than random likelihood of co-occurrence. On the other hand, negative scores indicate a lower than expected likelihood of co-occurrence. Our analysis revealed a significantly higher co-occurrence between speech acts of the same class, as would be expected by random chance. Furthermore, we observed moderately positive associations between directives and commissives, as well as between expressives and commissives. These findings suggest that considering the context of neighbouring sentences might be crucial for accurate classification of speech acts.

To test this hypothesis, we investigated the effectiveness of extending the classification unit by incorporating a window of neighbouring context sentences around a sentence from the trainings set. This approach enables the classifier to capture the contextual information surrounding a sentence. However, as depicted in Figure 3, our findings indicate that this approach

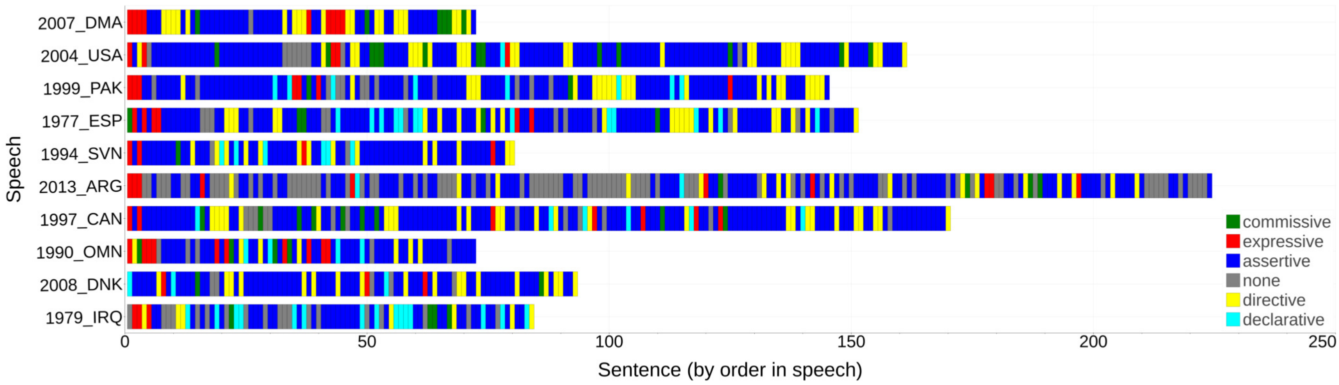

Figure 2. Speech act usage pattern over the course of a speech. The bars represent a speech in full length and the colours mark a respective speech act. It is recognizable that the same speech acts often occur consecutively in the sequence.

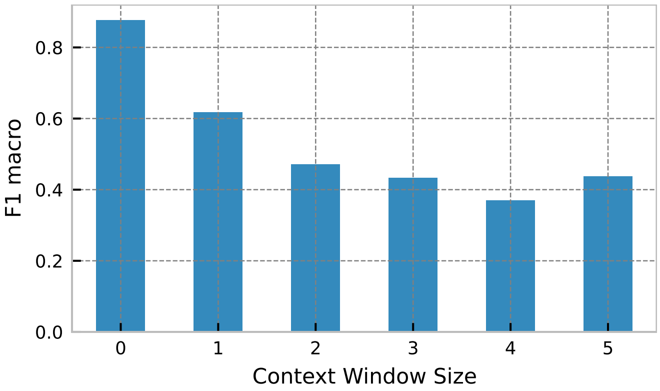

Figure 3. Model performance on the entire dataset (train+test) for various context sizes. The Number of context sentences is equivalent to 2 × Context Window Size.

did not yield a substantial improvement over using a single sentence window.

C. Feature Importance of Metadata

In the preceding section, we demonstrated the significance of linguistic features in the classification of speech acts, as evidenced by the rather promising results obtained from the transformer model. In addition to the raw speeches, the UNGD Corpus includes various metadata, such as the name and position of the speaker, the country represented, and the original language of the speech. To explore the potential significance of metadata in relation to the occurrence of speech acts within the speeches, we trained a separate model in the form of a Random Forest (RF) regressor. This model is aimed to predict the distribution of each speech act class based on the available metadata alone. The objective of this approach is to examine the potential influence of extra-linguistic features, such as metadata, on the distribution of speech acts by examining the *importance* of each feature. The hyper-parameters for the RF model were left at their default values provided by scitkit-learn, which consisted of using 100 trees and the Gini impurity criterion.

We compared the performance of the trained model to a baseline dummy classifier and observed a substantial improvement in goodness of fit for commissives (reducing the mean squared error from 10.75 to 2.4) and directives (reducing the mean squared error from 42.8 to 9.1). These results indicate a significant correlation between the metadata and the distribution of commissives and directives.

To identify the most influential features, we conducted an analysis of feature importances in the model. In RFs, feature importance quantifies the average decrease in impurity across all trees for each feature [26]. Figure 4 showcases the results of this analysis for commissives and directives, providing interesting insights. The feature importance analysis indicates that certain variables have a notable impact on the distribution of speech acts. For commissives, the role of the speaker is a significant variable, with the category of *president* standing out prominently. Additionally, the country represented by the speaker also plays a crucial role, with *USA* and *Japan* being particularly influential factors.

Similarly, for both commissives and directives, the original language of the speech exhibits a strong effect on the distribution of speech acts. Notably, speeches delivered in English demonstrate a substantial influence on the observed distributions.

D. Linguistic Features for Qualitative Assessment

A long-lasting shortcoming of using deep neural networks architectures such as Transformers is the black box nature of these models. Different approaches under the banner of *Explainable AI* such as CAPTUM [27] and shapley values [28] have been investigated in order to elucidate which features are important in a model's prediction. In our investigations, we used CAPTUM which is implemented with the *transformers_interpret* library.[3] This approach assigns *attribution scores* to each of the (sub-)token features which quantify the importance of each feature for the classification of a particular class. These scores are scaled between 1, indicating maximum attribution for classifying this as a particular class and -1,

[3] https://github.com/cdpierse/transformers-interpret

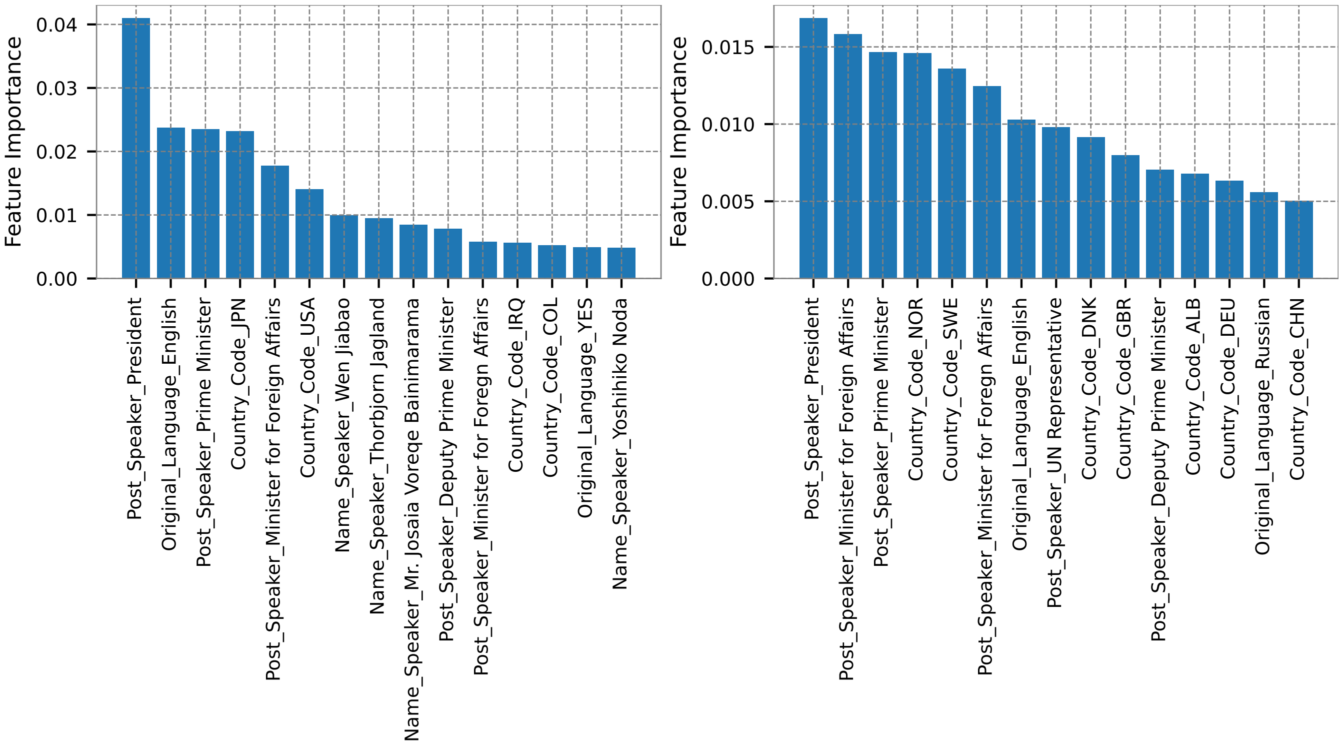

Figure 4. Importance of metadata in commissives and directives

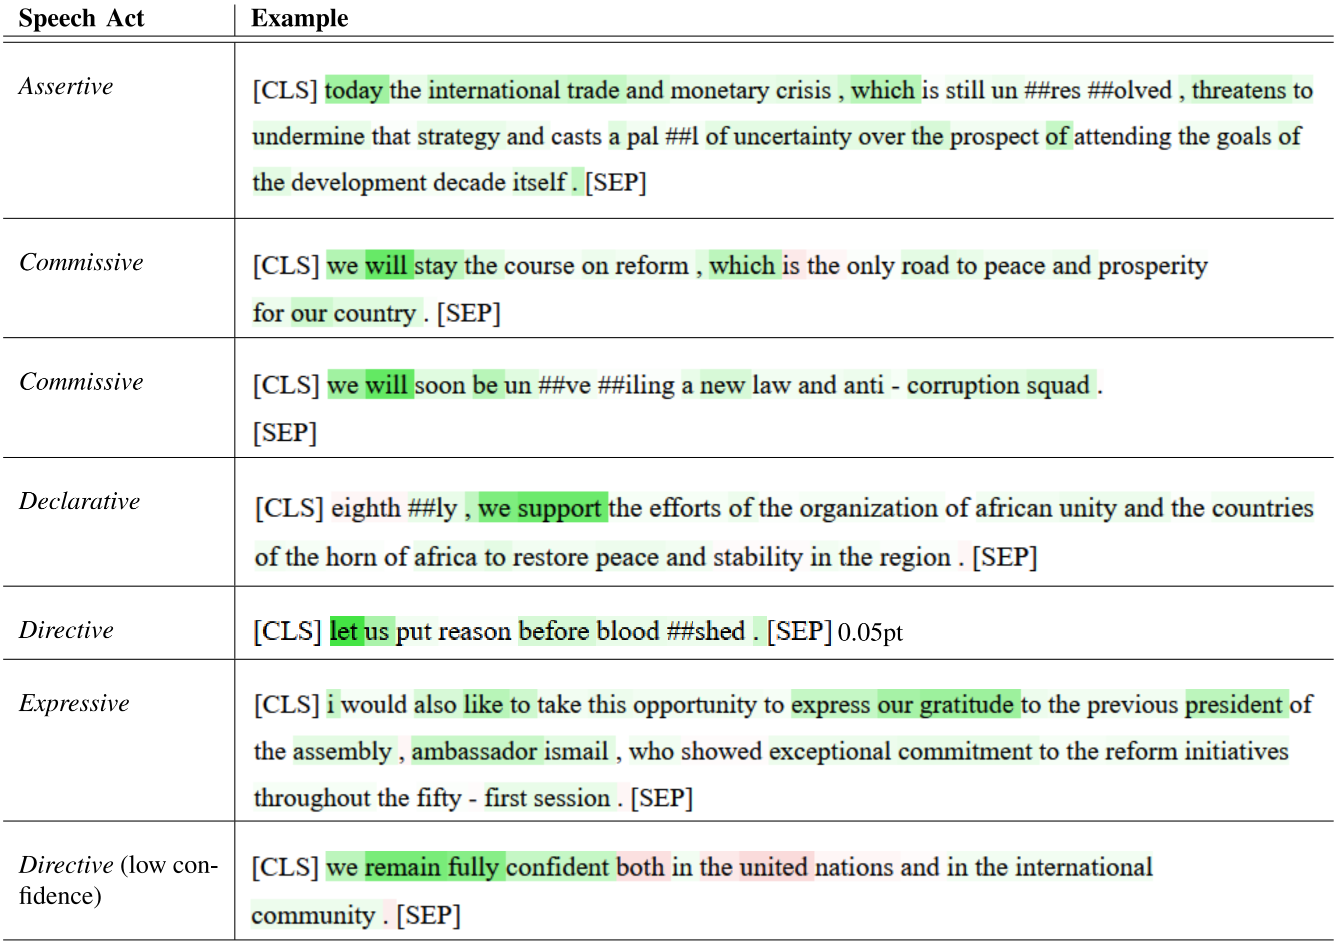
indicating that this feature is strongly associated with class other than the predicted one.

Firstly, we look at the examples with most confidence so that we can understand whether the words shown in Section III-B, each typical of the respective speech act types, are also important features for classification. Second, we investigated which kind of samples expose the lowest confidence in the model in terms of prediction probability in the hope of identifying features that cause uncertainty within the model's prediction confidence. We see a strong connection between Austins's performative verbs and the words that are identified as important features through the training process. As the examples shown in Table 5 demonstrate, the most important features are performative verbs that fit almost prototypically with the examples shown earlier in Section III-B. For example, the phrases *we will* for commissives, *we support* for declaratives or *let us* for directives contain typical performative verbs that are also found in our dataset and are also important features in the classification (see Figure 5). Of interest, however, are the words that do not belong to the group of performative verbs but are nevertheless learned as positive features in each speech act type, as it is shown in Figure 5. Here, assertiva have strong thematic connections to international relations (e.g. *international trade*). Other examples for assertives from the dataset also contain words like *economy* or *cooperation*. Commissiva, on the other hand, have a strong connection to a vocabulary combining promises regarding problems to be solved (e.g. *corruption squad, road to peace*). Declaratives often include country names, as some utterances emphasize support for different states (*Horn of Africa, region*). Directives and expressives function somewhat differently here. Used as rhetorical or linguistic means of communication, expressives typically include addressing specific persons or expressions of appreciation (*ambassador, president, gratitude*). In the case of directives, we often find statements to allow oneself a comment or a motivating request (*reason before bloodshed*).

For the example with a low confidence shown in Figure 5, it turns out that other rather unspecific words are also negatively evaluated and appear in greater accumulation. This greater accumulation of negative words is very characteristic for low confidence classifications in the dataset, although no specific thematic or communicative connections or patterns are recognizable.

This observation shows us perspectives for further use of speech acts. On the one hand, certain speech acts can be expected in certain concrete thematic or regional contexts and one can match this expectation with real political communication (*assertive, declarative, commissive*). Discrepancies or patterns can then be described for different discourses and thus allow for a qualitative assessment. Second, rhetorical devices can be derived as a component of strategic communication (expressives, directives). This is especially interesting, since analyses are conceivable here that refer to power relations between the involved actors.



Speech Act	Example
Assertive	[CLS] today the international trade and monetary crisis , which is still un ##res ##olved , threatens to undermine that strategy and casts a pal ##l of uncertainty over the prospect of attending the goals of the development decade itself . [SEP]
Commissive	[CLS] we will stay the course on reform , which is the only road to peace and prosperity for our country . [SEP]
Commissive	[CLS] we will soon be un ##ve ##iling a new law and anti - corruption squad . [SEP]
Declarative	[CLS] eighth ##ly , we support the efforts of the organization of african unity and the countries of the horn of africa to restore peace and stability in the region . [SEP]
Directive	[CLS] let us put reason before blood ##shed . [SEP] 0.05pt
Expressive	[CLS] i would also like to take this opportunity to express our gratitude to the previous president of the assembly , ambassador ismail , who showed exceptional commitment to the reform initiatives throughout the fifty - first session . [SEP]
Directive (low confidence)	[CLS] we remain fully confident both in the united nations and in the international community . [SEP]

E. Showcase: speech acts as time series data

This section will emphasize the practical application of the model through a demonstrative analysis in the UNGD corpus. We will use sentence-based annotations of speech acts to quantitatively measure the shift in communicative patterns within the UN General Debate. Specifically, we want to demonstrate a method for exploring potential influences of significant political events on speech act usage patterns. It is important to note that this demonstration serves as an illustrative example rather than a rigorous scientific investigation of speech act usage. By highlighting the viability of our approach, we aim to emphasize its potential as a valuable research tool in the fields of political and social sciences. For this purpose, we decided to focus on the political events that unfolded in Ukraine from 2013 to 2014. Later being known as the Maidan Uprising, a series of protests and civil unrest unravelled on November 21, 2013, primarily centred around Kyiv's Maidan Nezalezhnosti (Independence Square) [29]. These protests ultimately led to the Revolution of Dignity in February 2014, albeit with a heavy toll of 108 protesters and 13 police officers losing their lives in the clashes [30]. Consequently, the Ukrainian parliament, with a significant majority of 328 out of 450 votes (approximately 73% of the votes), voted to remove President Viktor Yanukovych from power. Yanukovych disputed the legality of the vote and sought assistance from Russia. Russia criticized the events, labelling them a ”coup”. Subsequently, pro-Russian protests erupted in southern and eastern Ukraine. Russia occupied and eventually gained control of Crimea, while armed pro-Russian groups seized government buildings and declared Donetsk and Luhansk as independent states. This resulted in the onset of the Donbas war, prompting international efforts to diplomatically address and find resolution to the unfolding events within the international community.

To investigate the change in the strategic political communication following those events, we analysed the speech act usage of *directives*, which primarily attempt to motivate the addressees to take an action, of Ukrainian representatives in the UN General Debate. By choosing this scenario, we aim to clearly demonstrate the ways in which events can affect the language used in international political discourse by identifying and quantifying speech acts as an indicator variable.

To identify a statistically significant change in usage pat-

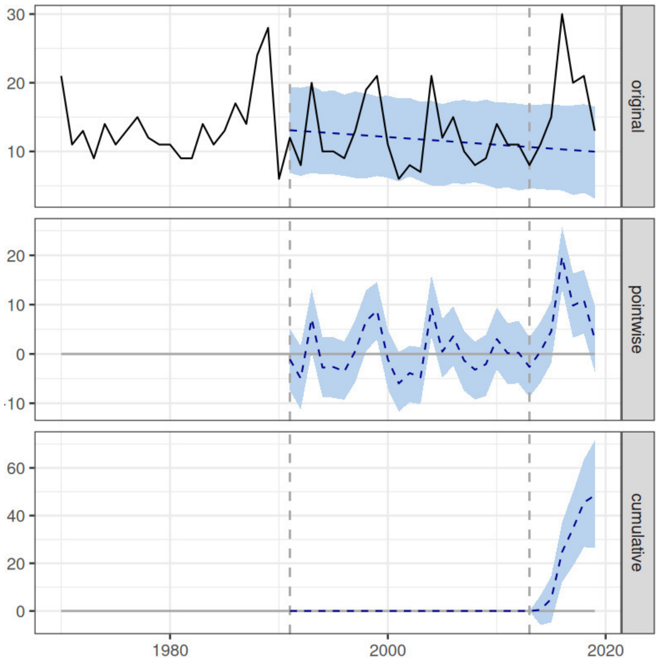

Figure 6. CausalImpact plot comparing directive speech act usage in absolute numbers between the years 1991-2013 and 2014-2019

terns of *directives* between the period starting in 2014 and the most recent available speech in 2019, we utilized the R library *CausalImpact* [31]. Specifically, we compared the *directive* usage frequency of Ukrainian representatives after the Maidan events (2014-2019) with those during the period before the events, which spans from the dissolution of the Soviet Union in 1991 up until 2013. The software creates a Bayesian structural time-series model which is used to predict how the response would have evolved after an event, called intervention, if the event had never occurred. The result is the cumulative effect of the intervention on the time series.

In the model, we see a positive effect on the use of *directive* speech acts in the period between 2014-2019. The first panel in Figure 6 showcases the observed data and a calculated prediction derived from the data of the pre-intervention period. The pre-intervention period is enclosed by two dotted vertical lines and serves as the baseline for comparison with the post-intervention period. The second panel shows the pointwise causal effect of the model, which is the calculated difference between the observed data and the prediction. The third panel presents the cumulative effect of the model, which is the summation of the pointwise causal effect over time. The positive effect on the use of *directive* speech acts observed during the period after the Maidan protests in Ukraine in 2014 is statistically significant and unlikely to be due to random fluctuations. It is important to note that during this period, not only the frequency of directive speech acts increased significantly, but the speeches also showed a general increase in length. This suggests that the involvement and activation of the international community by Ukrainian representatives has increased and become a larger part of Ukraine's political communication.

V. Discussion

In this paper, we investigate for the first time how the linguistic phenomenon of speech acts described by Searle can be automatically identified in text corpora using a transformer-based approach and be made accessible for quantitative and qualitative analyses. In doing so, the study focuses on the identification of speech acts within very large datasets of political communication, which makes the results interesting for political science research. Furthermore, the study presents very transparently which linguistic properties are included for the definition of speech acts. Our experiments demonstrate the effectiveness of using a combination of weak supervision and active learning for dataset creation in the classification of speech acts. Weak supervision enables the identification of samples that satisfy defined linguistic features, while active learning can provide new examples from an unlabelled dataset. The results show a 0.09 increase in F1 score within 9 iterations of the model, indicating the usefulness of these techniques in expanding small datasets and improving model performance. The problems we encountered in identifying *expressives* and *declaratives* in terms of recall indicate that there may be variance between the examples in the training data and the test data, or the linguistic characteristics of these speech acts may be ambiguous, making it difficult for the classifier to properly delineate between these and other classes. However, evaluating the entire process still poses challenges, especially with the limitations of our evaluation set, which has a rather small size. The properties of this set might introduce a high degree of variance and possible biases in the evaluation. To address these challenges, future research will focus on developing a robust evaluation framework and larger evaluation sets for the methods employed.

Aside from linguistic features, our observations indicate that extra-linguistic factors play a role in influencing the distribution of speech acts. Specifically, variables such as the speaker's role, the country represented, and the original language of the speech have shown significant influence on the occurrence and distribution of speech acts. These findings emphasize the importance of considering contextual factors when studying speech acts in political discourse. Understanding the impact of these variables can contribute to the development of more accurate speech act classification frameworks and provide valuable insights into the factors shaping the use of speech acts.

Additionally, our findings suggest tentative evidence of relationships between speech acts, as utterances of the same class tend to occur in proximity to each other. This observation not only contributes to our understanding of how speech acts are used in actual communication, but also provides valuable insights for the classification task. While our initial attempts at utilizing neighbouring utterances did not yield satisfactory results, further exploration in this area holds promise for enhancing the accuracy of speech act classification. One possible approach is to employ techniques such as linear chain Conditional Random Fields (CRFs) modelling [32] or similar sequential models. Such modelling can capture the sequential dependencies among speech acts and exploit the contextual information provided by neighbouring utterances. By incorporating such techniques, we can potentially improve the classification performance by considering the sequential nature of speech acts.

The application of our model concerning the use of *directives* by the representatives of Ukraine demonstrate the potential of utilizing the trained model for quantitative research. We presented a statistical analysis technique to explore the impact of political events on speech act usage patterns. By examining specific periods and comparing them to relevant baselines, we can gain insights into how political events shape language use in international discourse. The approach presented here can be extended to investigate other geopolitical events and their influence on speech act patterns, opening the potential for providing a deeper understanding of the dynamics of political communication, which is crucial for researchers and practitioners in fields such as political science, international relations, and diplomacy. In addition, our analysis of the relevant features with CAPTUM demonstrated that the qualitative evaluation of speech acts has the potential to enhance our understanding of the strategic use of speech acts. Automatic speech act detection can thus contribute to various fields by facilitating empirical studies on persuasive strategies employed by political actors. It not only enables the monitoring of shifts in rhetoric and discourse, but also provides insights into the motivations and intentions behind political speeches. By employing and further developing this technology, researchers can delve deeper into understanding the intricate dynamics of political communication and gain a comprehensive understanding of the strategies and objectives employed by politicians.

***Abstract*—InMap is an interactive and iterative information retrieval-based automated mapping algorithm that produces *code-to-architecture* mapping recommendations. In its original form, InMap requires an architect to provide feedback for each *code-to-architecture* mapping recommendation in a given set produced (*complete feedback*). However, architects may delay/ defer deciding on some of the mapping recommendations provided. This leads us to ask, how would InMap perform if only a subset of the recommendations provided *(partial feedback)* or only a single recommendation *(real-time feedback)* is reviewed by the architect? Through carefully designed mapping experiments, we show that an architect giving *partial* or *real-time feedback* does not harm the recall and precision of the recommendations produced by InMap. On the contrary, we observed from the results of the systems tested a net increase of 2-5% (depending on the approach). This shows that in addition to InMap's original *complete feedback* approach, the two new approaches of collecting feedback presented in this paper, i.e. *partial* and *real-time,* create flexibility in how software architecture consistency checking tool developers may choose to collect mapping feedback and how architects may opt-to provide feedback, with no harm to the recall and precision of the results.**

***Index Terms*—software architecture conformance, automated source code mapping, software architecture consistency, software maintenance.**

I. Introduction

SOFTWARE engineering industry practitioners use *Software Architecture Consistency Checking (SACC)* to check the consistency of a software's implementation with its architectural design [1, 8, 9, 17]. Its importance is derived from the fact that if a software system's implementation no longer conforms to its originally designed architecture, this may lead to failure in fulling its architectural design goals or in meeting intended software quality attributes such as reliability, availability, performance or security [1, 7, 15, 17].

Reflexion Modelling is an effective SACC technique as far as industry acceptance and tool support are concerned [6, 10, 12, 14]. It represents software architecture as a decomposition of a software system into *sub-components/architectural modules* and the *relationships/dependencies* allowed among them [10]. It maps the existing codebase onto the defined architectural modules revealing any irregular dependencies amongst the modules. If no irregular dependencies exist, the system's codebase is said to conform to its architecture. However, if dependencies not prescribed in the architecture exist, then the software's codebase is said to have diverged from its intended architecture – a phenomenon known as *architecture drift* or *architecture degradation* [10, 14, 16].

Mapping code to architecture in Reflexion Modelling is a tedious manual process, especially for large systems [1]. Nevertheless, techniques exist that attempt to 'automate' *code-to-architecture* mapping in SACC methods [3, 5, 12, 18]. Accomplishing this well is no trivial task, as ideally, mapping is done by a system expert knowledgeable about the system, its architecture and its codebase [10]. However, these techniques attempt to correctly predict which architectural module a *portion of the code* would be mapped to. They use various approaches to try and tackle this problem – from code dependency and clustering [5, 11] to machine learning, information retrieval and natural language processing techniques [3, 12, 19, 21, 22].

Furthermore, mapping techniques also differ in how an architect is involved in *verifying* the correctness of the resulting mapping. Some techniques only involve the architect after a complete mapping of the codebase, meaning the architect is given a complete mapping and then can decide if it is correct [3, 11, 12]. Other mapping techniques do it progressively or *interactively* in a *human-in-the-loop* approach. This means that as the mapping takes place, the architect is asked to review the mapping suggestions provided to improve them [19, 20] or resolve the cases that are difficult to map automatically [5].

Interactive mapping techniques have a similar approach to obtaining feedback from an architect as mapping progresses. They require an architect to decide on the correctness of every member of a set of mapping recommendations given. However, it is common to have cases where an architect may need more knowledge of a system [3, 5, 19, 21, 22] and may therefore prefer to *delay/defer* deciding on some mapping recommendations provided. In other words, given a set of 10 mapping recommendations, it is expected to have the architect decide about all 10 before progressing with the mapping. However, the limitation of this approach is that it does not accommodate a situation where an architect may feel that they are only able to make a decision about some of the recommendations produced (not all) or a case where the architect would want to defer deciding on a given recommendation to a later point in the mapping exercise. We thus investigate the effect, in terms of the impact on the recall and precision of the results, of providing *partial feedback* in a code-to-architecture mapping technique we developed in prior studies called InMap [18, 19, 20, 21, 22]. Additionally, we are interested in investigating InMap's behaviour if we update the list of recommendations provided in *real-time*; that is, the cases where a new set of mapping recommendations are provided each time an architect gives feedback for a singular recommendation.

Our contribution through this paper is evidence that an architect giving *partial* or *incomplete feedback* for the mapping recommendations produced by InMap does not harm the recall and precision of the technique's recommendations. InMap, in this modified form, retained recall values similar to its original *complete-feedback* form for all six systems under test. Additionally, we found that the precision of the *partial-feedback* approach is, on average, +/-2% compared to the *complete-feedback* approach. We also show that updating InMap's mapping recommendations in *real-time*, as an architect provides feedback, gives a net increase of 5% for the systems tested. This entails that in addition to InMap's original complete feedback approach, the two new approaches of collecting feedback introduced in this paper, i.e. partial batch and real-time, provide flexibility in how SACC tool developers may choose to collect mapping feedback from an architect when using *human-in-the-loop* mapping techniques. We also show that our InMap mapping technique offers flexibility in how architects may opt to provide feedback with no harm to the recall and precision of the results.

Section II highlights related works. Section III gives an overview of InMap. In Sec IV, we discuss our new approaches to collecting feedback in-depth. Section V explains our experimental setup. The results of the experiments are presented in Section VI and discussed in Section VII. The paper is concluded in Section VIII.

II. Related Work

A few techniques exist that attempt to (auto)-map source code to software architecture in SACC methods like Reflexion Modelling. We broadly classify these into two categories with regard to how they collect feedback from an architect. We classify, as *collaborative mapping* or *just-in-time feedback*, techniques involving the architect as the mapping occurs. These techniques are incremental and involve a *human-in-the-loop*. They get feedback from the architect as the mapping progresses on the premise that the architect's knowledge of the software system can help 'steer' the mapping in the right direction [19, 20]. We classify, as *non-collaborative mapping* or *feedback after-the-fact*, those techniques that attempt to entirely automate the mapping process without involving the architect during the mapping process. An architect only reviews the final results of these techniques after they complete their mapping process, implying the architect is not directly involved in the mapping [7].

A. Collaborative Mapping / Just-In-Time Feedback

Christl et al. propose **HuGME,** a mapping recommendation technique that analyses source code elements' dependencies. HuGME clusters source code elements using an architect's knowledge about its intended architecture [4, 5]. A *dependency-based attraction function*, which minimises coupling and maximises cohesion, is used, which yields a matrix of attraction scores for unmapped entities [23]. All unmapped entities that result in only one candidate having a score higher than the mean of all scores result in a sole recommendation. All unmapped entities with two or more mapping candidates are presented to the architect in descending order as recommendations. HuGME presents the recommendations to the architect to let cluster decisions be made entirely by the architect. HuGME does not attempt to map all source code entities in one complete step; instead, it maps a subset at a time, getting feedback from the architect until no more mapping is possible. This classifies it as a *collaborative mapping technique*. HuGME needs about 20% of a system's codebase to be manually *pre-mapped* by an architect before proceeding with automated mapping and thus suffers from pre-mapping drawbacks [18, 19].

Bittencourt et al. have a mapping recommendation technique that uses *information retrieval (IR).* It has a similar automated mapping approach to HuGME, except that they use *dependency-based attraction functions* with an *IR-based similarity function* [3]. They compute the similarity of an unmapped entity to an architectural module by searching for specified terms within the source of an unmapped entity. They search for an architectural module's name and the names of its mapped entities/classes, class methods and fields. Their technique requires manual pre-mapping before it can automate mapping; hence it suffers from pre-mapping drawbacks similar to HuGME [18, 19]. The results of Bittencourt et al.'s technique show that when there was a smaller pre-mapped code base, there was a decrease in the *f_1-score* of their technique [3].

Naim et al. propose a technique that uses *dependency analysis* and *information retrieval* methods, called ***Coordinated Clustering of Heterogeneous Datasets (CCHD),*** to compute a *similarity score* for source entities [11]. CCHD profits from an architect's feedback on a recovered architecture to iteratively adjust the results until there are no more recommendations for change. These modified results train a classifier that automatically places new code in the "right" architectural module. However, the technique is not necessarily meant for automated mapping in *software architecture consistency checking,* but rather, it was designed for *software architecture recovery* tasks.

None of the above-discussed collaborative mapping approaches directly addresses the different ways an architect can provide feedback as the mapping progresses, namely *complete, partial or real-time.* They all make use of a complete-batch feedback approach for the recommendations they provide.

B. Non-Collaborative Mapping / Feedback After-the-Fact

Olsson et al. use *information retrieval* and *dependency analysis* in their automated mapping technique called **Naive Bayes Classification (NBC)** [12]. They use Bayes' theorem to build a probabilistic model of classifications using words taken from the source entities of a software system. The model provides the probability of words (or tokens) being part of a source entity. This is then enriched with syntactical information on a source entity's incoming and outgoing dependencies, a method called *Concrete Dependency Abstraction* [12]. NBC needs a pre-mapped set to return fruitful results and inadvertently suffers from the downsides that come with the need to pre-map. In recent studies, Olsson et al. refined their technique to create a pre-mapped set using an approach similar to InMap [13]. However, the technique uses a *feedback after-the-fact* approach, implying the architect checks whether the mapping is correct at the end of the process.

C. Manual Methods Supported by Tools

Naming patterns (or *regular expressions*) are commonly used in SACC industry tools. Expressions such as ***/cli/*** or **.cli.* or net.commons.cli.** can be used to map source entities (whether classes or packages) to an architecture module named *CLI.* This approach is used in popular SACC tools such as **Sonargraph Architect** and **Structure101 Studio.** These tools also provide *drag & drop* functionality. However, the limitation of using naming patterns or drag & drop functionality is that they do not solve the problem of reducing the monotony of the mapping process because they are both manual tasks. In large systems with complex mapping configurations, this is a demanding task.

In summary, there exist techniques that attempt to get feedback as the mapping progresses, like HuGME [4, 5] and InMap [19, 21, 22] and others that get feedback from the architect once the mapping task is complete, like NBC [12, 13]. Of those that collect feedback as the mapping progresses, none directly address the alternative ways architects may provide feedback, for example, as a *complete batch,* as a *partial batch* or *as a single recommendation* at a time.

III. InMap Interactive Mapping

In [18, 19], we propose a collaborative mapping technique known as InMap. Using natural language descriptions of a system's architecture modules, InMap can automate mapping a completely unmapped system with no loss in the recall and precision of the recommendations produced [19]. It iteratively and interactively provides mapping recommendations that an architect can review, a batch/set at a time. It uses the architect's feedback in one iteration to guide the recommendations provided in a subsequent iteration. This process continues until the entire system is mapped or no more recommendations can be produced. In our prior studies, InMap automated the mapping of completely unmapped systems with an average recall and precision of 0.97 and 0.82, respectively, for the systems tested. However, InMap does not cater for the fact that an architect may not have full knowledge of the set of recommendations provided and may instead opt to provide partial feedback on the recommendations given. Instead, it assumes or requires that the architect provides feedback for all recommendations produced in a given iteration/batch before a new set of recommendations can be provided in the following iteration.

A. The Algorithm

The InMap mapping technique is comprised of seven steps [19, 21] summarised as follows:

1. A software system's source files are filtered to omit third-party package libraries or system packages/classes that the architect does not want to be part of the mapping exercise.

2. The contents of the filtered source files are stripped of any special characters and programming language-specific keywords.

3. The pre-processed source files are indexed as an inverted index.

4. InMap constructs a query for each architectural module.

5. InMap uses the queries from *Step 4* to search the indexed source files for the similarity of every unmapped class to each architectural module. The query for each architectural module is a combination of (i) its name; (ii) its natural language architectural description; (iii) the names of classes mapped to the module; and (iv) the names of methods contained within classes mapped to the module. In InMap's first iteration, when there are no mapped classes, it uses only information from items (i) and (ii) to construct the query. However, once the first set of classes is mapped, InMap adds items (iii) and (iv) to the query. These last two items 'enrich' the query, as it were, to search for the similarity of any unmapped class to the architectural module in question. Consequently, after each iteration of newly mapped classes, the query to produce the next set of recommendations is different. The queries are used to search the index, resulting in a set of scores for every *class-module pair.* The scores are based on the similarity information retrieval function, *tf-idf.* The *tf-idf* scores

are called *class-to-module similarity scores (SS_{cm})*, where *c* and *m* are a class-module pair in the system under review. *Step 5* results in a matrix of *class-to-module similarity scores (SS_{cm})* for every class against every module. We extended InMap to include hierarchical information contained in a system's codebase, i.e., packages [20, 21], to condense the number of recommendations made to complete the mapping process in SACC techniques. This version of the technique in step five produces a matrix of *package-to-module similarity scores SS_{pm}* derived from *class-to-module similarity scores (SS_{cm})*.

6. InMap uses the matrix of *entity-to-module* scores to produce an ordered list of the best-scoring entities for the given architectural modules in terms of similarity. In this case, an entity is either a class or a package. InMap also uses page size to trim the ordered list to the most likely correct recommendations.

7. The architect reviews the recommendations produced, giving feedback by accepting or rejecting them. After this step, InMap returns to *Step 4* and iterates *Step 4* through *7* until no more recommendations can be produced.

At the time of our study, InMap existed in two versions, a class-based version and a package-based (or hierarchical) version. More detailed descriptions of both mapping algorithms and how their similarity score calculations are derived can be found in [19] and [21], respectively.

B. Research Questions

For our study, we hypothesise that there is more than one way a software architect may choose to provide feedback about code-to-architecture mapping recommendations produced by interactive techniques like InMap. They may do it as a *complete batch* which is how InMap works in its original form [19, 21, 22], but they may also do it as a *partial batch.* For example, if presented with a page of recommendations, the architect might be unsure about a few of them and would opt to postpone making a decision about them. This leads to asking,

> ***RQ1****: What is the effect, in terms of recall and precision, of an architect giving partial batch-feedback in InMap compared to complete batch-feedback?*

Another interesting scenario to investigate is the implication of InMap collecting and updating its list of recommendations in real-time. Rather than waiting for an architect to give feedback for all recommendations provided on a page before presenting a new set of recommendations (what we would describe as an *interactive batch update process*), what would be the behaviour of InMap, in terms of recall and precision if it updated its list of recommendations immediately an architect gives feedback on an individual recommendation (what we would describe as an *interactive real-time update process*)? In other words,

> ***RQ2****: What is the effect, in InMap in terms of recall and precision, to consider feedback from the architect as soon as we receive it (real-time feedback), and how does it compare with batch feedback?*

IV. Method

To properly investigate our research questions, we describe and formally define all three highlighted approaches to collecting feedback from an architect, the prior existing *complete-batch feedback* approach, as well as the two new approaches introduced in this study, namely *partial-batch feedback* and *real-time feedback*. We also illustrate how InMap was modified to accommodate the two new feedback approaches.

A. Complete-Batch Feedback

Complete-batch feedback is used by most interactive mapping techniques [3, 5, 19, 20]. The algorithm gets complete feedback from the architect for all mapping recommendations on a page – see *Fig. 1* for an illustration. The mapping algorithm only generates a new set/page of mapping recommendations in a subsequent iteration once feedback is given for all entities in the given set of the current iteration. This implies:

# of **required recommendations in feedback** = # of recommendations on page

How Complete-Batch Mapping Recommendations in InMap Works: Recall that in step *six*, InMap derives the highest scoring class-to-module pairs, from the class-to-module similarity scores (SS_{cm}) matrix, or package-to-module pairs, from the package-to-module similarity scores (SS_{pm}) and gives them as class/package-to-module mapping recommendations. InMap presents, as recommendations, either the class/package-module pairs above the arithmetic mean of the highest similarity scores obtained for a pair; or the best 30 recommendations (if those above the mean are greater than 30). Thirty gave the most optimal results based on the systems tested. In step *seven*, this final filtered list is presented to the architect to review the recommendations given. An architect gives feedback on the page (batch of 30) recommendations produced. In its original form, the architect's feedback provided to InMap must be complete. The architect is expected to provide feedback (an accept/reject) for every recommendation listed on the page.

Architect provides feedback for a single mapping recommendation following which a new set of recommendations is produced

Fig 3. Illustration of *real-time* feedback. For this approach of collecting feedback, an architect provides feedback for a single mapping recommendation, following which a new set of recommendations is instantly produced and presented.

B. Partial-Batch Feedback

Partial-batch feedback is an alternative approach to collecting feedback about code-to-architecture mapping recommendations. In this form, an architect provides feedback for a subset of the recommendations provided on a given page. This could be because the architect needs to gain sufficient knowledge about some of the code entities (classes/packages) listed in the recommendations provided and would prefer to delay/defer decisions about those entities. The mapping algorithm would use the partial feedback to provide a new set/page of mapping recommendations that may or may not include the entities the architect did not decide on in prior iterations. *Fig. 2* illustrates this. This implies:

1 < # of **required recommendations in feedback** < # of recommendations on page

How Partial-Batch Mapping Recommendations in InMap Works: In step *seven* of InMap's algorithm, an architect is presented with 30 mapping recommendations to review. The architect does not have to give feedback for all 30 recommendations produced and may opt to skip some, essentially delaying or deferring a decision about them. We say delay or defer as these recommendations could reappear, given that they were not outrightly rejected. However, it is also possible that they may not reappear, given that InMap uses the architect's feedback provided to decide the next set of mapping recommendations to produce.

C. Real-Time Feedback

Real-time feedback is another alternative approach to collecting feedback from the software architect about code-to-architecture mapping recommendations. In this form, the mapping algorithm would produce a new set/page of recommendations immediately after an architect provides feedback on any of the recommendations on the page. *Fig. 3* illustrates this. This implies:

# of **required recommendations in feedback** = 1

How Real-Time Mapping Recommendations in InMap Works: In this case, despite InMap providing 30 mapping recommendations, the list of recommendations provided gets updated immediately after the architect provides feedback on a single code entity, i.e. in real-time. Note that it would be ideal to implement this in a way that the position in the ordered set did not matter, implying an architect can give feedback on any individual code entity from anywhere in the list, and the mapping algorithm refreshes the recommendations instantaneously. However, it is important to acknowledge that recommendation results are always presented with the best candidate at the top or beginning of the list and the worst at the bottom or end of the list. Therefore, in both the *partial-batch* and *real-time* feedback approaches, we consider the rank of the recommendation.

V. Evaluation

A. Experimentation

To test the effect of our two proposed alternatives to collecting feedback, we ran experiments on InMap in its original form, i.e. *complete-batch feedback* as our control. We then ran the same set of tests on our *partial-batch feedback* approach and our *real-time feedback* approach. We extended the InMap evaluator tool developed in prior studies of InMap [18, 19, 20, 21, 22] to accommodate the evaluation of our two proposed feedback approaches. The evaluation tool simulates a "human architect" accepting and rejecting the recommendations produced. It uses the oracle class/package mappings provided by knowledge experts of each system, as reported in prior studies of InMap [19, 21, 22]. We used the optimal parameter settings for both InMap's class-based version [18, 19] and InMap's hierarchical package-based version [20, 21], observing what effect both *partial-batch* and *real-time feedback* have on both the class-based and package-based versions of InMap. A batch size of 30 was used for the control experiment, i.e. the *complete-batch feedback*. However, for the *partial-batch feedback,* we tested a range of batch sizes, in addition to a batch size of 30, to observe if different batch sizes affect the results.

For every experiment, we collected the *recall*, *precision* and *f_1-scores* (as a harmonic mean between recall and precision) of the recommendations produced. InMap produces mapping recommendations in descending order of the most likely correct recommendation based on similarity scores. We take it as a norm that as an architect reviews a list of recommendations provided, they start reviewing the list and making decisions in sequential order from the beginning/top to the end/bottom instead of reviewing it randomly. This approach is similar to how most other recommendation or information retrieval-based systems are designed. They surmise that the best candidate in a list of results is found at the beginning/top of the list and the worst candidate at the end/bottom of the list. Therefore, in reviewing both *partial-batch* and *real-time feedback,* we consider the rank of a recommendation.

B. Systems Under Test

We evaluated our modified versions of InMap (*partial-batch* and *real-time feedback*) against InMap in its original form (*complete-batch feedback*) using six Java-based open-source systems used in prior InMap studies. These are *Ant*, a command line and API tool for automating processes; *ArgoUML*, a desktop application for modelling in UML; *JabRef,* a desktop application for managing bibliographic references; *Jittac,* an Eclipse IDE plugin for applying reflexion modelling; *ProM,* a desktop application for mining processes; and *TeamMates* a web application for peer reviews and feedback. These systems all have varying characteristics in terms of the number of lines of code, number of architectural modules, length of architectural descriptions, number of source files, number of classes and number of packages, to name a few. Our prior studies documented their characteristics [18, 19, 20, 21, 22].

C. Replication Package

A replication package of the evaluation tool; the six case systems tested along with their independently produced ground-truth mappings provided by experts knowledgeable about the respective systems; and the complete, partial and real-time feedback mapping approaches and results are all available in the online open-repository at the following link https://doi.org/10.6084/m9.figshare.13714150.

VI. Results

Tables 1, 2 and *3* show the results obtained for both InMap's class-based and package-based algorithms when run using the six test-case systems. They show the recall, precision and f_1-score for each version of the algorithm checked against each feedback approach. Green denotes an increase, whereas red denotes a decrease.

Table 1 gives the results obtained for the control experiment, i.e. the *complete-batch feedback* approach, which is how InMap was initially designed to collect feedback from an architect. The average recall for the six systems tested on the class-based version of InMap was 0.972; the average precision was 0.788, and the average f_1-score of 0.870. The package-based version had an average recall of 0.865, average precision of 0.745 and an average f_1-score of 0.800.

Tables 2 and *3* show the results of the two new approaches, i.e*., partial-batch* and *real-time feedback.* The results show that as far as the recall is concerned, these two ways of collecting feedback seem not to affect the recall – both approaches maintained an average of 0.972 for the class-based version and 0.865 for the package-based version of InMap.

With regard to the precision, we see some variances, albeit minor. For the class-based version of InMap, ProM's precision improved in both approaches, with the most significant result coming from the *real-time feedback* approach (3% increase). However, whereas *partial-based feedback* was the same for Ant compared to *complete-batch,* it surprisingly reduced by 1% for the real-time-based approach. Jittac improved in both approaches, with *real-time feedback* recording a higher increase in precision (5%) between the two approaches. ProM also increased precision for the package-based version using the *real-time feedback* approach. Ant again recorded a slight reduction in this case. It was interesting to observe that InMap's package-based version had more movement in precision compared to the class-based version.

The average f_1-scores of all three techniques show that *partial feedback* did not negatively affect the results compared to *complete feedback.* Furthermore, the f_1-scores show that *real-time feedback* gave the best results for all three approaches to collecting feedback.

VII. Discussion

A. Findings

The results of our investigation show that if we update the list of recommendations provided in real-time, the precision of the recommendations improves on average. This is likely because InMap uses the feedback given by an architect in deciding the next set of mapping recommendations to give. In other words, it benefits from getting information early in the mapping process. When we have a batch size of, say, 30 for both the batch processes, that is, *complete* and *partial*, the architect gives feedback for a minimum of 2 and a maximum equal to the batch/page size, in this case, 30. Now, if we consider that each class/package contains a unit of information that InMap could use to make a more accurate mapping recommendation, then in the batch process, we are delaying the feedback loop. The larger our batch/page size, the more significant the delay in relaying what could otherwise be helpful information in predicting the unmapped source entities. In other words, the results show that even though InMap uses information from the architect's feedback to work out the most suitable recommendations, it does not necessarily benefit from having lots of information given to it at once, say feedback on 100 classes in one go. Instead, having smaller units of information fed into the mapping loop early on is more beneficial. Thus, SACC tool developers and architects are more likely to benefit from using a *real-time feedback* approach. However, although *real-time feedback* offers the best results, the difference between both batch processes was shown to be minor. Therefore, if a tool developer or the users of the tools prefer not to work in real-time but give feedback a batch at a time, that works reasonably well too.

The results also show that for the batch feedback mapping approaches (i.e. *complete feedback* and *partial feedback*), on average, if an architect opts to delay decisions about some of the recommendations provided in a list, the recall and precision of the recommendations InMap provides are not negatively affected. Meaning given a batch size of 30, whether an architect chooses to provide feedback on all 30, i.e. *complete feedback*, or whether an architect decides to provide feedback for at minimum 2 or out of the 30 while delaying the rest, maybe because the architect is unsure and would like to see more/other recommendations first, this would not affect the results negatively. On the contrary, the results showed a slight improvement. This could be attributed to the same reasons that *real-time feedback* showed the best results. When an architect gives *partial feedback*, this is a smaller chunk of information than the batch size. Moreover, since InMap has shown that it benefits from receiving feedback as early as possible, giving feedback, for example, for 8 out of 30 recommendations, provides a smaller chunk of information earlier in the feedback loop than providing recommendations for all 30 at once. However, again, in this case, it does not imply that if a tool developer or architect opts for a *complete batch feedback* approach, then the accuracy of the recommendations will reduce drastically. On the contrary, the results showed *partial-batch feedback* recorded a slight increase over *complete-batch feedback*, which already had some reasonably good results.

We must note that there is a limit to the complete-batch size that can be or should be used. Firstly, if we set the batch size to 50 or 100, it is not practical to make an architect provide complete feedback for such a large quantity before providing

a new set of recommendations of similar size. It is tedious to do so for such a large number at a time and does not help reduce the effort required by an architect, which is a core motivation for automating the mapping processes. Secondly, this study and prior studies [18, 19] have shown that smaller units of information fed back into the algorithm at a time improve the results. So whereas the results might be similar for a batch size of 20, 30 or 40, the same cannot be said for sizes of 50, 100 or 150. Generally speaking, a batch size of 30 was shown to produce the best average results in our previous studies, and the larger the batch size is beyond 30, the less our precision becomes, on average.

Both findings on *real-time* and *partial-batch feedback* show that InMap allows flexibility in how a SACC tool collects mapping recommendation feedback because all three approaches have, on average, f_1-scores within 0.005 of each other. Furthermore, if the developer of a SACC tool decides to implement all three approaches, then this flexibility extends to the architect. They can choose their preferred way of providing feedback, i.e. *complete-batch*, *partial-batch* or *real-time.* Furthermore, they can alternate among these approaches throughout the mapping process without committing to a singular approach.

Interestingly, the package-based version of InMap showed better improvement in the average of the f_1-score for both *partial* and *real-time feedback* over the class-based version, 0.005 versus 0.003, respectively. However, the class-based version of the InMap achieved higher f_1-scores for all approaches compared to the package-based version, 0.87 vs 0.80; therefore, there was less opportunity for improvement for the class-based version compared to the package-based version because it already had reasonably high-scoring results. That said, an approach combining both the class-based and package-based versions of InMap, such as the one introduced in [22], would likely derive improvements from both versions.

B. Limitations & Validity

The two new feedback approaches introduced build on top of InMap's *class* and *package similarity* functions; therefore, the same factors that affect the external validity of InMap's results are inherited by the alternative feedback approaches presented in this paper. That is to say, aspects such as the code commenting quality and style; the number of classes, packages and modules; and the length and quality of the architecture description could likely affect the external validity of our results. Therefore, more case systems with variable attributes would add to the soundness of the results. Nonetheless, the results of the six systems tested and their varying characteristics provide a fair case for the two feedback approaches investigated.

VIII. Conclusion & Future Work

This paper presents two alternative approaches to how an architect can provide feedback on mapping recommendations provided, either as *partial-batch* or *real-time feedback*. They are an alternative to InMap's *complete-batch feedback* approach. Our *partial-batch feedback* approach showed a net increase of 2% in precision for the systems tested, and our *real-time feedback* approach showed a net increase of 5% in precision for the systems tested. This shows that providing *partial–batch feedback* does not harm the precision of the recommendation produced compared to when *complete-batch feedback* is provided. Furthermore, it shows that providing feedback in *real-time* improves the recommendations produced. Moreover, because the results for *complete-batch feedback* were already reasonably good, the 2-5% increase that these two new approaches provide allows for flexibility in how SACC tools that use *human-in-the-loop* approaches can collect feedback; or flexibility in how architects themselves opt to provide feedback. This implies that tools that use InMap's automated interactive mapping algorithm have some flexibility in how they choose to gather feedback from an architect as mapping progresses (*complete* vs *partial* and *batch* vs *real-time*) without suffering a loss in recall and with an insignificant difference in precision. It also offers flexibility for an architect, assuming a SACC tool implements the different ways mapping recommendation feedback can be collected.

In future work, we would like to do more detailed studies with more systems to further test the soundness of the conclusion of this study. We would also like to see how the two new feedback approaches introduced in this work would fair on the version of InMap that integrates both the class-based and package-based versions of the algorithm into one [22]. Lastly, we would like to carry out an exploratory study that examines the cases that are difficult for InMap to map with either mapping version of InMap or either approach to collecting feedback.

***Abstract*—Spectral clustering methods are claimed to possess ability to represent clusters of diverse shapes, densities etc. They constitute an approximation to graph cuts of various types (plain cuts, normalized cuts, ratio cuts). They are applicable to unweighted and weighted similarity graphs. We perform an evaluation of these capabilities for clustering tasks of increasing complexity.**

I. Introduction

DOCUMENT clustering (or text clustering) has a multitude of applications, including topic extraction, fast information retrieval, filtering, authorship discovery, topic drift detection in news streams and social media, automatic document organization etc. ([1], [2], [3], [4])

Two clustering methods are of particular interest in this area, the Graph Spectral Clustering (GSC) and spherical k-means.

Graph Spectral Clustering methods [1] are generally praised for possessing ability to represent clusters of diverse shapes, densities etc. They constitute an approximation to graph cuts of various types (plain cuts, normalized cuts, ratio cuts). They are applicable to unweighted and weighted similarity graphs.

Spherical k-means algorithm [5] is a variant of k-means algorithm that measures similarity of documents based on their cosine similarity, that is quite popular in the domain of text analysis (e.g. for search engines).

In this paper we pose the question: If the grouping method correctly groups certain datasets, can we expect that a combination of these datasets will also be correctly clustered? We will examine the following problem in more detail. Assume that a clustering method can cluster correctly documents from categories $[A, B]$, $[B, C]$, and $[C, A]$. Can we expect the algorithm to cluster correctly data from the mixed set $[A, B, C]$? Let us illustrate this with three datasets, tweets, marked with (single) tags 'lolinginlove', 'tejran', 'anjisalvacion'.

We used standard Python implementation of spectral clustering from scikit-learn library.[1] The affinity matrix was constructed from a k-nearest neighbors connectivity matrix, with the default value of $k = 10$.

In one of the experiments the clustering illustrated in Fig. 1 was obtained for the hashtags 'lolinginlove', 'tejran'. For the hashtags 'tejran', 'anjisalvacion' the nearest neighbor spectral clustering achieves the best clustering agreement visible in Fig. 2. For the hashtags 'lolinginlove', 'anjisalvacion', the nearest neighbor spectral clustering achieves the clustering agreement visible in Fig. 3.

	T\P	0	1	
lolinginlove:	0	1258	0	1258
tejran:	1	8	337	345
		1266	337	1603

F-score: 0.990046

Fig. 1. Spectral clustering with affinity "nearest neighbors" example 1; row labels - "true" clusters, column labels - clustering result

	T\P	0	1	
tejran:	0	324	21	345
anjisalvacion:	1	5	727	732
		329	748	1077

F-score: 0.968385

Fig. 2. Spectral clustering with affinity "nearest neighbors" example 2; row labels - "true" clusters, column labels - clustering result

So, for each pair of the three hashtags we see a very good agreement of clusterings with the target (hashtags). If we look at the hashtags ['lolinginlove', 'tejran', 'anjisalvacion'], we get clustering agreement visible in Fig. 4. We see that more errors are committed here than for each pair of hashtags presented in Figs. 1, 2 and 3, though the increase does not seem to be large in absolute numbers. We will return to this issue in the next section.

Here and in further sections, F-score is computed as follows. We assume that the clustering is to predict the hashtag. The "true" hashtag is identified as the majority hashtag in the cluster. For a given hashtag H we proceed as follows. True positives (TP) are those cases when cluster membership agrees

	T\P	0	1	
lolinginlove:	0	1258	0	1258
anjisalvacion:	1	0	732	732
	1258	732	1990	

F-score: 1.000000

Fig. 4. Spectral clustering with affinity ”nearest neighbors” example 4; row labels - ”true” clusters, column labels - clustering result

with this hashtag. False positives (FP) are the cases which belong to the cluster for which the hashtag H is the true hashtag, but the hashtag for the given document is different from H. True negatives (TN) are the cases which belong to the cluster for which the hashtag H is not the true hashtag, and the hashtag for the given document is different from H. False negatives (FN) are the cases which belong to the cluster for which the hashtag H is not the true hashtag, but the hashtag for the given document is the hashtag H. Computation of precision and recall follows the standard pattern and the F-score is computed for each hashtag separately, and then the average is taken as the F-score for the clustering.

In this paper we study the extent to which this behaviour extends to larger number of clusters. This study is a starting point for a future revision of the studied clustering algorithms.

II. Conceptual Considerations

Despite the example shown above, it is not entirely obvious that given a grouping method that allows to correctly group documents from the categories $[A, B]$, $[B, C]$, $[C, A]$, we can expect that the algorithm will correctly group data from the mixed set $[A, B, C]$.

If the sets $A \cup B$, $B \cup C$ and $C \cup A$ have block diagonal document similarity matrices (after proper reordering the documents), and the blocks are actually within A, B, C then in fact the $[A, B, C]$ similarity matrix will be block diagonal too so that GSC algorithm will cluster A, B, C correctly. This can be seen immediately by inspection of block matrix structure, i.e.

$$S_{A,B} = \begin{bmatrix} S_{A,A} & 0 \\ 0 & S_{B,B} \end{bmatrix} S_{B,C} = \begin{bmatrix} S_{B,B} & 0 \\ 0 & S_{C,C} \end{bmatrix}$$

$$S_{A,C} = \begin{bmatrix} S_{A,A} & 0 \\ 0 & S_{C,C} \end{bmatrix}$$

implies

$$S_{A,B,C} = \begin{bmatrix} S_{A,A} & 0 & 0 \\ 0 & S_{B,B} & 0 \\ 0 & 0 & S_{C,C} \end{bmatrix}$$

Recall that combinatorial Laplacian is computed as $L = D - S$, where S is the similarity matrix and D is the diagonal matrix with elements being sums of corresponding rows of S. Hence

$$L_{A,B} = \begin{bmatrix} L_{A,A} & 0 \\ 0 & L_{B,B} \end{bmatrix} \text{, etc.}$$

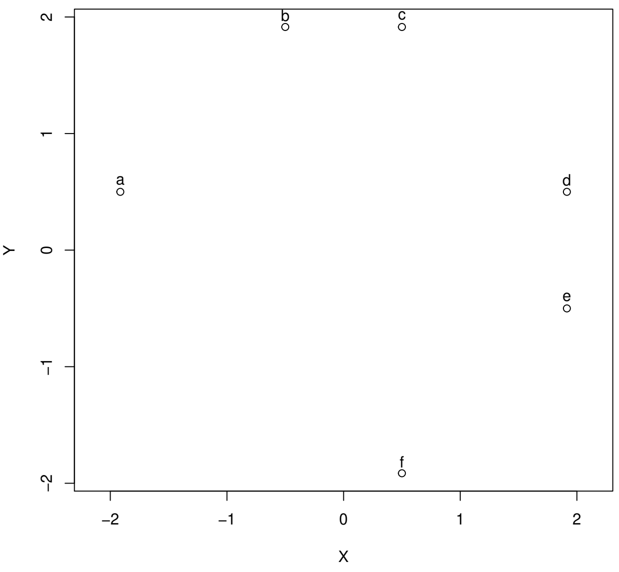

Fig. 5. Visualization of datapoints used to illustrate the increasing clustering problem for k-means

and

$$L_{A,B,C} = \begin{bmatrix} L_{A,A} & 0 & 0 \\ 0 & L_{B,B} & 0 \\ 0 & 0 & L_{C,C} \end{bmatrix}$$

Eigenvalues of $L_{A,B}, L_{B,C}, L_{A,C}$ will become eigenvalues of $L_{A,B,C}$ with corresponding eigenvectors being only extended with zeros appropriately. So theoretically it should be easy to separate the sets A, B, C based on eigenvectors of $L_{A,B,C}$. However, this enthusiasm needs to be mitigated because such a pure block structure rarely occurs, see our example Fig. 1, Fig. 2, Fig. 3, so the ”noise” is inherited in sets with more hashtags as visible in Fig. 4. But there are also further concerns. Spectral clustering is based on lowest eigenvalue eigenvectors of respective Laplacians. But as shown in [6], the two lowest eigenvectors of $L_{A,B}, L_{B,C}, L_{A,C}$ do not need to be lowest three eigenvectors of $L_{A,B,C}$. For higher number of clusters, the situation may be more complex.

If the dataset $A \cup B \cup C$ is well separated in the sense of k-means algorithm, so that a clustering with k-means will yield A, B, C as clusters, then its application to $A \cup B$, $B \cup C$ or $C \cup A$ will also return correct pairs of clusters. But this is not necessarily true for k-means in the reverse direction. Well-separatedness of $A \cup B$, $B \cup C$ and $C \cup A$ does not imply well-separatedness of $A \cup B \cup C$. Let us illustrate this point with a bit artificial example. Consider the datapoints $\mathbf{a} = (-(0.5+\sqrt{2}), 0.5)$, $\mathbf{b} = (-0.5, 0.5+\sqrt{2})$, $\mathbf{c} = (0.5, 0.5+\sqrt{2})$, $\mathbf{d} = (0.5+\sqrt{2}, 0.5)$, $\mathbf{e} = (0.5+\sqrt{2}, -0.5)$, $\mathbf{f} = (0.5, -(0.5+\sqrt{2}))$, see Fig. 5 for visualization. Consider ”hashtags” with their ”documents”: $A = \{\mathbf{a}, \mathbf{b}\}$, $B = \{\mathbf{c}, \mathbf{d}\}$, $C = \{\mathbf{e}, \mathbf{f}\}$. Clustering with k-means of $A \cup C$ into two clusters

TABLE I
TWT.10 DATA SET - HASHTAGS AND CARDINALITIES OF THE SET OF RELATED TWEETS USED IN THE EXPERIMENTS

No.	hashtag	count
0	90dayfiance	316
1	tejran	345
2	ukraine	352
3	tejasswiprakash	372
4	nowplaying	439
5	anjisalvacion	732
6	puredoctrinesofchrist	831
7	1	1105
8	lolinginlove	1258
9	bbnaija	1405

will yield A, C, similarly any two hashtag combinations. But clustering with k-means of $A \cup B \cup C$ will yield three clusters $\{\mathbf{a}\}, \{\mathbf{b}, \mathbf{c}\}, \{\mathbf{d}, \mathbf{e}, \mathbf{f}\}$, not A, C, E.

In all these cases, if some noise is added to fuzzify the well-separatedness, the noise can be more destructive for the set A, B, C than for any of the three mentioned subsets – this affects GSC as well as k-means clustering. This is easily imagined by considering k-means algorithm. The cluster center of A when clustering fuzzified A and B may lie in a different position than when clustering fuzzified A and C.

This behavior will be subsequently illustrated by a series of experiments.

III. Data

We used tweets retrieved from the stream endpoint of Twitter API (a random sample of about 1% of English tweets), collected by one of the Authors for the time period from mid September 2019 till end of November 2022. From this set we extracted the subset TWT.10 used in experiments. It is a collection of top thread tweets related to hashtags listed in Table I. While selecting the data, we imposed the restriction that the tweets had to have one single hashtag (which we treated as an indication of being devoted to a single theme).

IV. Methods

We study two standard versions of Graph Spectral Clustering, available from scikit-learn, and the 6 versions of spherical k-means and 6 versions of our proprietary so-called K-embedding based clustering algorithm.

More precisely the clustering experiments were performed with popular Python libraries: numpy [7], scipy [8], scikit-learn [9] and soyclustering [10] which is an implementation of spherical k-means [11]. In particular, we used

1) `SpectralClustering` class from scikit-learn with two distinct settings of the `affinity` parameter: `precomputed` (affinity from similarity matrix) and `nearest_neighbors` (affinity from graph of nearest neighbors) - as a representative of the spectral clustering, and
2) `SphericalKMeans` class from soyclustering with the following combinations of (`init`, `sparsity`) parameter pairs (the mentioned 6 versions, short names given for reference): ”sc.n”: (’similar_cut’, None), ”sc.sc”: (’similar_cut’, ’sculley’), ”sc.md”: (’similar_cut’, ’minimum_df’), ”k++.n”: (’k-means++’, None), ”k++.sc”: (’k-means++’, ’sculley’), ”k++.md”: (’k-means++’, ’minimum_df’), and
3) K-embedding clustering (our implementation, exploiting spherical k-means – see subsection IV-C). Same combinations of parameter pairs (versions) were used as for `SphericalKMeans` above. The following numbers of eigenvectors were tried: $r = 12$ and higher.

The advantages and disadvantages of these methods are briefly discussed below.

A. Spectral analysis

In fact spectral clustering algorithms constitute a large family, see e.g. [12], [13], [14], which have numerous desirable properties (like detection of clusters with various shapes, applicability to high dimensional datasets, capability to handle categorical variables), yet they suffer from various shortcomings, common to other sets of algorithms, including multiple possibilities of representation of the same dataset, producing results in a space different from the space of original problem, curse of dimensionality, etc. These shortcomings are particularly grieving under large and sparse data set scenario, like in Twitter data.

Let us briefly recall the typical spectral clustering algorithm in order to make it understandable, how distant the clustering may be from the applier's comprehension [12]. The first step consists in creating a similarity matrix of objects (in case of documents based on tf, tfidf, in unigram or n-gram versions, or some transformer based embeddings are the options – consult e.g. [15] for details), then mixing them in case of multiple views available. The second step is to calculate a Laplacian matrix. There are at least three variants to use: combinatorial, normalized, and random-walk Laplacian, [12]. But other options are also possible, like: some kernel-based versions, non-backtracking matrix [16], degree-corrected versions of the modularity matrix [17] or the Bethe-Hessian matrix [18]. Then computing eigenvectors and eigenvalues, eigenvector smoothing (to remove noise and/or achieve robustness against outliers) choice of eigenvectors, and finally clustering in the space of selected eigenvectors (via e.g. k-means). The procedure may be more complex, e.g. one may add loops back to preceding steps based on feedback from quality analysis, like degree of deviation from block-structure of the Laplacian.

From this diversified set we chose the two mentioned implementations available from scikit-learn.

B. Spherical k-means

Spherical k-means was developed in [5] by observing that the squared Euclidean distance between two vectors, $\|\mathbf{x}_i - \mathbf{x}_j\|^2 = \|\mathbf{x}_i\|^2 - 2\mathbf{x}_i^T \mathbf{x}_j + \|\mathbf{x}_j\|^2$, in case of normalized vectors reduces to

$$\|\mathbf{x}_i - \mathbf{x}_j\|^2 = 2(1 - \mathbf{x}_i^T \mathbf{x}_j) \ , \tag{1}$$

and $\mathbf{x}_i^T\mathbf{x}_j = \cos\angle(\mathbf{x}_i, \mathbf{x}_j)$. This makes it very efficient in case of sparse vectors, a typical representation of text documents. Such a variant of k-means suffers dependence on initialization, thus further improvements are proposed, e.g. [19], [20], [21] and [22].

C. K-embedding

K-embedding has the following underlying idea. Let us think for a moment about a particular embedding of the nodes of the graph, based on [23]. Let A be a matrix of the form:

$$A = \mathbf{1}\mathbf{1}^T - I - S \ , \tag{2}$$

where S stands for an affinity matrix, I is the identity matrix, and $\mathbf{1}$ is the (column) vector consisting of ones, both of appropriate dimensions. (Note that here we have to assume that the diagonal of S consists of zeros). Let K be the matrix of the (double centered) form [24]:

$$K = -\frac{1}{2}(I - \frac{1}{n}\mathbf{1}\mathbf{1}^T)A(I - \frac{1}{n}\mathbf{1}\mathbf{1}^T) \ , \tag{3}$$

with $n \times n$ being the dimension of S. $\mathbf{1}$ is an eigenvector of K, with the corresponding eigenvalue equal to 0. All the other eigenvectors must be orthogonal to it as K is real and symmetric, so for any other eigenvector $\mathbf{v}$ of K we have: $\mathbf{1}^T\mathbf{v} = 0$.

Let Λ be the diagonal matrix of eigenvalues of K, and V the matrix where columns are corresponding (unit length) eigenvectors of K. Then $K = V\Lambda V^T$. Let $\mathbf{z}_i = \Lambda^{1/2}V_i^T$, where V_i stands for i-th row of V. Let $\mathbf{z}_i, \mathbf{z}_\ell$ be the embeddings of the nodes i, ℓ, resp. This embedding shall be called *K-embedding*. Then

$$\|\mathbf{z}_i - \mathbf{z}_\ell\|^2 = 1 - S_{i\ell} \tag{4}$$

for $i \neq \ell$. Hence upon performing k-means clustering in this space we *de facto* try to maximize the sum of similarities within a cluster. Note that $K = V\Lambda V^T$ may be quite well approximated if we drop from Λ low eigenvalues and from V their corresponding eigenvectors (which we do in our experiments).

V. Evaluation

For each of the algorithms we perform the following tests. For each pair of datasets associated with two hashtags from Table I (45 pairs in all) the clustering will be performed by each of the mentioned algorithms 10 times (due to stochastic nature of these algorithms) and the average F-score will be computed. Ten pairs with the highest average F-scores will be taken for the next phase. Now datasets associated with 3 hashtags will be created out of these selected pairs plus each of the hashtags not present in the selected pairs. This process is continued till all 10 hashtags are exhausted. In figures, the average value of F over all computations with the given hashtag cardinality is presented plus the average of the top 10 groups of hashtags. The results are summarized in Figs. 6–19.

The next experiment was to compare the F-score obtained by a given set of hashtags, considered in the preceding experiment, and its subsets obtained by removing one of the hashtags. For example, we considered the F-score of ['lolinginlove', 'tejran', 'anjisalvacion'] and the average of F-scores for the subsets ['lolinginlove', 'tejran'], ['lolinginlove', 'anjisalvacion'] and ['tejran', 'anjisalvacion']. We computed the Spearman and Pearson correlations for such pairs (F-score of a set of hashtags and average of its subsets) and presented the results in Table II for each of the analysed clustering algorithms. We have created also a more detailed view for one of the algorithms: spectral clustering with affinity nearest neighbors. Fig. 20 presents the histogram of differences between the average F-score of subgroups and the F-score of the group. Fig. 21 presents the relation between the average F-score of subgroups and the F-score of the group as a scatterplot.

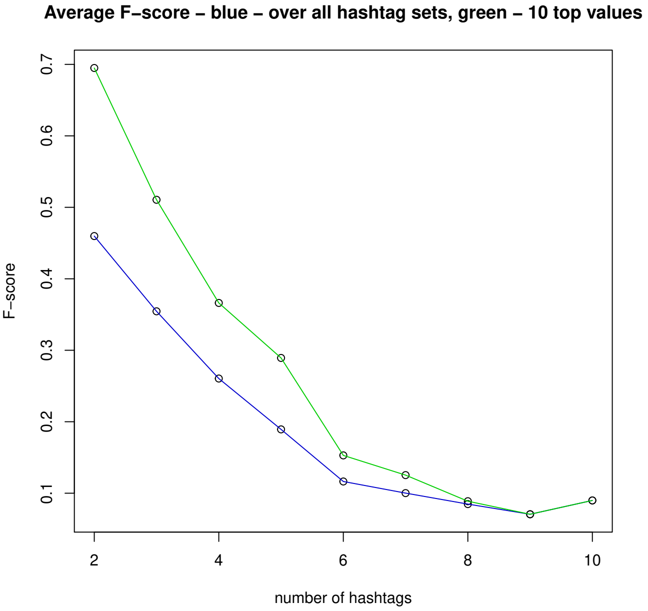

Fig. 6. F-scores for various numbers of hashtags; spectral clustering with affinity nearest_neighbors

VI. Results

As visible from Figs. 6–19, the increase of the number of intended clusters to be discovered constitutes a problem for the clustering algorithms, with even 9-fold decrease of F-score when going from 2 to 10 clusters. This behaviour is consistent throughout all the investigated methods though minor variations of the shape of the curves may be observed.

Spherical k-means clustering with sc.n configuration appears to perform best for the 10 top pairs of hashtags (Fig. 10) and with sc.sc configuration (Fig. 9), followed by K-embedding based clustering with most configurations (Figs. 14–19, except 16).

In most cases the top average of the F-score for next higher number of cluster is usually higher than the average score for the entire previous number of clusters, which indicates that better separation of subgroups gives some advantage for the capability to separate the entire group.

Table II shows Spearman and Pearson correlations between the F-score achieved by grouping a dataset related to a given set of hashtags and by grouping datasets obtained by removing data of one of the hashtags, split by the clustering algorithm. The correlations are generally high and are statistically very significant. This means that clustering capability of subsets of hashtags can be a good indicator of clustering capability for the set of hashtags. The algorithm spherical sc.sc seems to perform best for such a criterion, followed by spherical k++.sc and in the column on Spearman correlation – K-embedding.12plus k++.md.

A more detailed insight into this relationship for one of the algorithms is presented in Figs 20 and 21. Fig. 20 convinces us, however, that generally this clustering capability decreases (the F-score of a group is usually lower than that of the average of the subgroups). Fig. 21 shows additionally, that the high correlations between group and subgroups of hashtags are to be expected rather for low values of F-score. Higher F-score values are responsible for higher variation in supergroup F-score.

VII. Conclusions

The performed experiments demonstrate that, in spite of the generally praised properties, graph spectral clustering methods have still a large space for improvements with respect to increasing number of clusters to be detected. Even if all the subsets of intended clusters may be well separated by the algorithms, their mixture does not so. Same observation can be made about the spherical k-means algorithm.

***Abstract*—An increasing number of Internet of Things (IoT) applications are based on a federated environment. Examples include the creation of federations of NATO countries and non-NATO entities participating in missions (Federated Mission Networking) or the interaction of civilian services and the military when providing Humanitarian Assistance And Disaster Relief. Federations are often formed on an ad hoc basis, with the primary goal of combining forces in a federated mission environment at any time, on short notice, and with optimization of the resources involved. One of the leading security challenges in a federated environment of separate IoT administrative domains is effective identity and access management, which is the basis for establishing a relationship of trust and secure communication between IoT devices belonging to different partners. When carrying out missions involving the military and ensuring security, meeting requirements for immediate interoperability is important. In the paper, an attempt has been made to develop a system architecture framework for secure and reliable data streams distribution in a multi-organizational federation environment, where data authentication is based on IoT device identity (fingerprint). Moreover, a hardware-software IoT gateway has been proposed for the verification process and the integration of Hyperledger Fabric's distributed ledger technology, the Apache Kafka message broker, and data-processing microservices implemented using the Kafka Streams API library. The performance tests conducted confirm the suitability of the developed system framework for processing and distributing audio-video data in a federation IoT environment. Also, a high-level security and reliability assessment was conducted in the paper.**

***Index Terms*—Internet of Things, Blockchain, Distributed Ledgers, Device Authentication**

I. Introduction

WITH technological advances in mobile radio networks, particularly concerning the implementation of 5G technology, and the development and general availability of many electronic devices equipped with a radio interface, we are seeing an increase in industrial-scale applications of the Internet of Things (IoT), occurring in both the civilian and military spheres. Examples of such applications include smart transportation, smart power grids, smart cities, or the Internet of Battle Things (IoBT) [1]. The consequence is the generation of enormous amounts of data by various IoT devices. One of the main problems attracting the attention of many researchers today is the acquisition, analysis, and fusion of these data, their secure and reliable distribution, and context-dependent information sharing. The problem is compounded in these applications when some institutions or organizations using IoT form a federation to enable different parties to cooperate. A prerequisite for effective cooperation between partners in a federation is sharing certain resources belonging to different participants and exchanging information.

One example is the creation of a federation formed of NATO countries and non-NATO mission actors (Federated Mission Networking) [2], where each actor retains control over its capabilities and operations while accepting and meeting the requirements outlined in pre-negotiated and agreed-upon arrangements, such as security policy. The main idea is to join forces in a federated mission environment at any time (zero-day interoperability), on short notice, and with optimization of the resources involved. The expected result is better command and full control of operations and decision-making through improved information sharing. Another example is the interaction of civilian services and the military, which form a federation when providing humanitarian assistance in eliminating natural disasters (HADR - Humanitarian Assistance And Disaster Relief). There are many situations in which federation partners need to exchange information, for example, about the location of each other's troops, detected threats, etc. IoT in a federation environment enhances the ability to get an accurate real-time [3] picture of the situation during an operation, e.g., by deploying mobile IoT devices such as unmanned aerial vehicles (UAVs). Hence, IoT devices operated by different federation partners must securely communicate with each other. To ensure the timely transmission of situational awareness data, the UAV may need to use a partner's resources within the communication range. In this case and many others, it is necessary to establish a trust relationship through mutual authentication of devices belonging to different federation partners, such as between a specific UAV and the partner's data distribution system.

In the case of information exchange in federated environments, where troops belonging to different NATO countries participate, or the military participates jointly with civilian services in HADR operation in an urbanized area, it is most often assumed that 5G mobile radio networks will be used as the main communication medium. To obtain a precise picture of the situation of the so-called situational awareness, there is often a need to transmit image data to other partners forming a federation. In such an environment, audiovisual data streams generated by IoT devices or city surveillance cameras (CCTV) must be considered trustworthy before they can be properly processed and transmitted to selected command posts. The primary way to confirm the reliability of such data is to authenticate the IoT devices that generate it. The presented needs for ensuring the reliability and security of data exchange bring challenges, the solution of which determines the implementation of IoT. The basic problem remains: *how to carry out the acquisition and fusion of data from various sources with different levels of reliability, and operate in computing environments with varying degrees of trust securely and reliably?* To solve it, it is necessary to know the answer to the subquestions in the first place:

- *Identity management gap* - How to manage the identity of devices? How to identify devices?
- *Security gap* - How to securely distribute data among participants in a federated environment? (Taking into account the priorities assigned to devices).
- *Network integration and interoperability gap* - How to organize interconnections, especially between unclassified systems (civilian systems) and military systems?
- *Resilience and centralization gap* - How to ensure data availability in constrained (partially isolated) environments?

Taking into consideration the aforementioned requirements for federated IoT environments and presented sub-questions, it is necessary to use and integrate multiple technologies, e.g., a data authentication mechanism where a unique identity image (fingerprint) is used, distributed ledger, 5G technology, and data distribution and processing systems. A point worth noting is that data distribution systems are often based on the MQTT protocol [4], [5]. The main disadvantage of this type of solution is the need for additional components to acquire and distribute streaming data, such as video data from daylight or infrared cameras.

This paper proposes a framework architecture for secure and reliable data streams distribution in a multi-organizational federation environment, where data authentication is based on IoT device identity. Moreover, a hardware-software IoT gateway has been proposed for the verification process and the integration of Hyperledger Fabric's distributed ledger technology [6], the Apache Kafka message broker, and data-processing microservices implemented using the Kafka Streams API library [7].

The remainder of the article is structured as follows: Section II provides an overview of the related research work that formed the basis for our solution. Section III describes the proposed framework architecture and its main elements, along with the security mechanisms used to enhance confidentiality, integrity, availability, and accountability for data in-transit and at-rest. The main operations for our experimental framework were described in Section IV. The test environment, workloads scenarios, and preliminary benchmarks with results were presented in Section V. The section also includes a high-level security risk assessment considering several security and reliability threats. Section VI presents conclusions and planned future work.

II. Background and Motivation (Related Work)

In this section, we will present related works that have had the greatest impact on the proposed framework architecture for secure and reliable data streams distribution in Federated IoT Environments. These works address the basic problems related to:

- securing data processed by IoT devices with the usage of blockchain technology;
- unique IoT device identification based on the distinctive features (fingerprints);
- the integration of heterogeneous military and civilian systems based on IoT devices, where the requirement for zero-day interoperability must be ensured.

Additionally, at the end of this section, we have briefly discussed our solution against the analyzed works.

A. Blockchain integration with the Internet of Things

The literature presents numerous attempts to integrate the Internet of Things and blockchain (distributed ledger) technology. The work [8] describes the challenges and benefits of integrating blockchain with the Internet of Things and its impact on the security of processed data. Similarly, in the works [9], [10], where a proposal for a 4-tier structural model of Blockchain and the Internet of Things (BIoT) is presented. Guo et al. [11] proposed a mechanism for authenticating IoT devices in different domains, where cooperating distributed ledgers operating in the master-slave mode were used for data exchange. Xu et al. [12] presented the DIoTA framework based on a private Hyperledger Fabric blockchain, which was used to protect the authenticity of data processed by IoT devices. The work [13] proposed an access control mechanism for devices, which used the Ethereum public blockchain placed in the Fog Layer and public key infrastructure based on elliptic curves.

B. Unique IoT device identification using fingerprint methods

Apart from classification methods for identifying a group or type of similar IoT devices [14], an interesting area of research is fingerprint techniques [15], [16], which aim to identify a unique image of a device identity through the appropriate selection of its distinctive features. The fundamental premise of fingerprint methods is the occurrence of manufacturing errors and configuration distinctions, which implies the nonexistence of two identical devices. Subsequently, the main challenge associated with fingerprinting techniques is the selection of non-ephemeral parameters that make it possible to distinguish devices uniquely. Generally, three main fingerprint methods can be identified for IoT devices as a result of distinction:

1) hardware and software features of the device;
2) characteristics of generated network traffic;
3) characteristics of generated radio signals.

The authors of the LAAFFI framework [17] presented a protocol designed to authenticate devices in federated environments based on unique hardware and software parameters extracted from a given IoT device. Concerning distinctive radio features, Sanogo et al. [18] evaluated the Power Spectral Density parameter. The work [19] indicates a proposal to use neural networks to identify devices based on the Physical Unclonable Function in combination with radio features: frequency offset, in-phase (I) and quadrature (Q) imbalance, and channel distortion. Charyyev et al. [20] proposed the LSIF fingerprint technique, where the Nilsimsa hash function was used to determine a unique IoT device network flow. In contrast, the work of [21] demonstrated the Inter-Arrival Time (IAT) differences between successively received data packets as a unique identification parameter.

C. Zero-day interoperability ensuring for heterogeneous military and civilian systems

Meeting the requirement for zero-day interoperability is a significant challenge for NATO coalition countries. Consequently, attempts are being made to integrate data exchange systems belonging to various partners to create an environment called Federated Mission Networking (FMN). For mentioned environment, NATO countries have regularly defined and revised requirements for years [2] and established research groups to identify the optimal solution for coalition data processing systems. Jansen et al. [4] presented an experimental environment consisting of four organizations between which data is distributed in two configurations. The first configuration uses two MQTT broker types (Mosquitto, VerneMQ), while the second configuration is broker-less and disseminates MQTT messages via broadcast and UDP protocol. Suri et al. [5] made an analysis and performance evaluation for eight data exchange systems used within mobile tactical networks. For the research conducted, the superiority of the DisService protocol over solutions such as Redis and RabbitMQ was demonstrated. Additionally, the work [22] proposes a data exchange system for IoT devices based on the MQTT protocol, where data is encrypted using elliptic curves. Moreover, Yang et. al [23] presented a system architecture designed for anonymized data exchange between participants using the Federation-as-a-Service (FaaS) cloud service model. The proposed system architecture was based on the Hyperledger Fabric ledger.

D. Discussion

For most of the reviewed publications, a trusted third-party infrastructure and a private distributed ledger were used to enhance the security of processed data. Compared to the work of Guo et al. [11] (master-slave chain) and Xu et al. [12] (DIoTA framework), our proposed solution is based on a single global instance of the distributed ledger. At the same time, we can freely transfer devices between organizations that are part of the federation, where these devices can use elements of another organization's infrastructure for secure data exchange. The works of [4], and [5] only address the issue of efficient data exchange and do not consider how to secure data streams. Additionally, these works did not consider the evaluation of Kafka, which also enables the handling of MQTT protocol messages. In our work, we proposed using the Kafka broker and stream processing microservices for data distribution.

Moreover, within the proposed framework, we took into account interoperability between military and civilian systems and the limited nature of such environments. Hence, for the proposed system, we have considered the recommendations made by the NATO IST-150 working group [4], which studied disconnected, intermittent, and limited (DIL) tactical networks. Our system uses a publish-subscribe model and Commercial Off-The-Shelf elements that are generally available. Subsequently, we have minimized operational costs, which is essential for ensuring immediate interoperability.

In addition, in our work, we have separated the key used to secure the communication channel for IoT devices from the key used for the data authenticity protection mechanism. Unlike the DIoTA framework, where an HMAC-based commitment scheme and randomly generated keys are used to authenticate messages, we proposed to use the device's unique distinctive features. Consequently, we proposed using a hybrid identity image defined by a combination of several fingerprint methods, primarily based on the parameters of the generated radio signals.

So far, in the publications that we analyzed, we have not noted a solution that, for the problem of secure data exchange, integrates elements of the Hyperledger Fabric blockchain, Kafka broker, and stream-processing microservices.

III. Proposed framework

This section proposes an experimental framework architecture for secure and reliable data (message) stream distribution in a multi-organizational federation environment. Figure 1 shows an example of the system structure for a federation formed from two organizations (Org1, Org2). The Apache Kafka message brokers acquire, merge, and replicate data generated by producers (publishers) and make data available to consumers (subscribers). At the same time, the proposed system enables verification of message streams based on device identity, which is stored redundantly in a distributed Hyperledger Fabric blockchain. Moreover, a hardware-software IoT gateway has been proposed for the verification process. Through which microservices using the stream processing library Kafka Streams API can communicate with the distributed ledger. A crucial aspect of the system architecture is the ability to freely transfer devices between organizations and utilize their

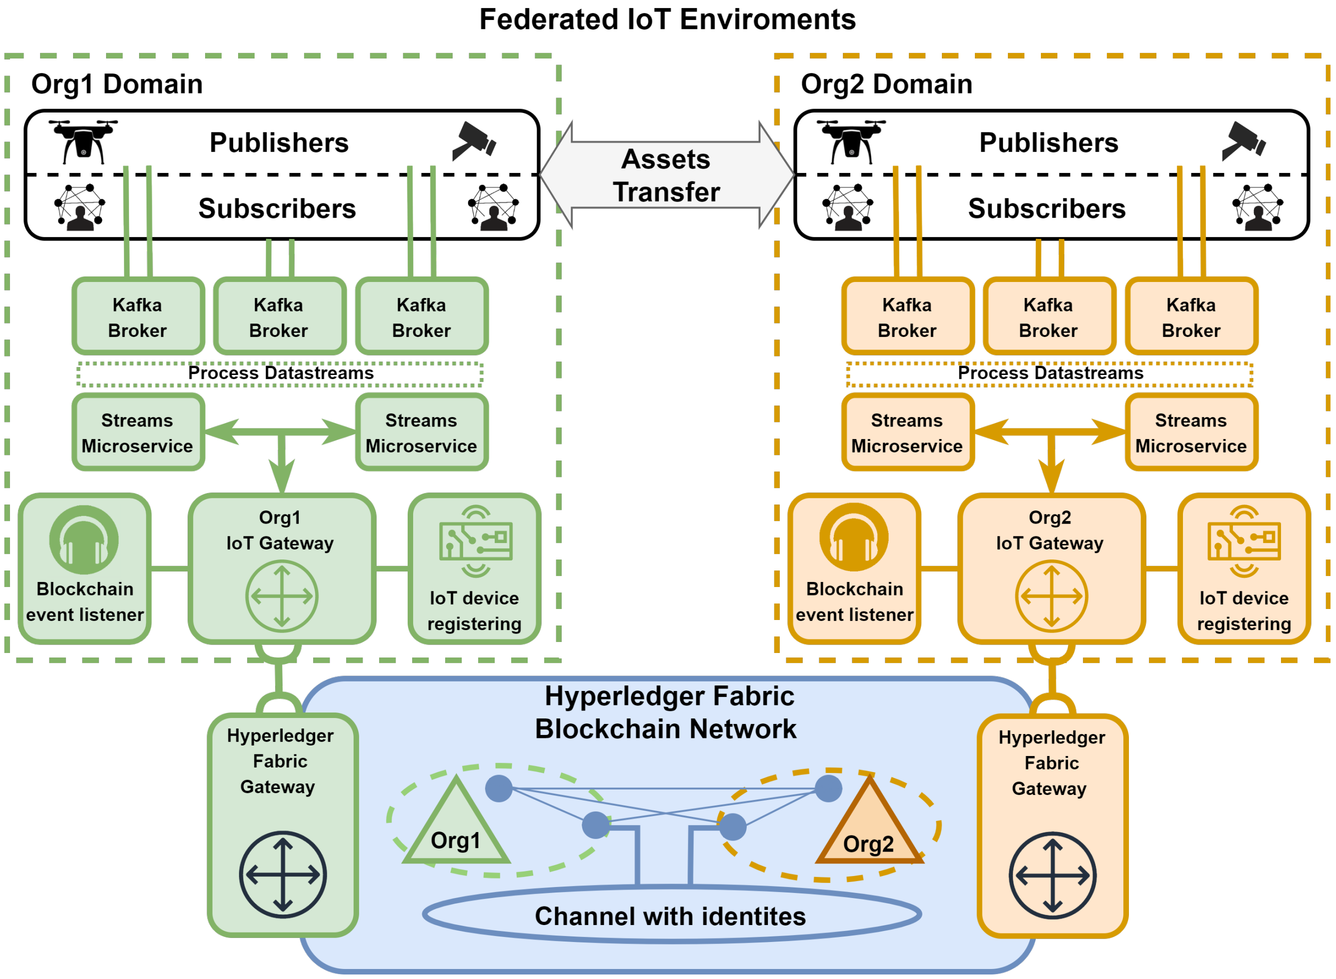

Fig. 1. Proposed framework general overview

Kafka brokers for secure data exchange. In addition, data can be exchanged in any scheme in accordance with the predefined policy, e.g., one-to-many. Furthermore, through the IoT gateway, it is possible to listen for events related to transactions of registering the identity of new devices.

Figure 2 illustrates in detail the proposed solution, where the messages generated by the producers are tagged (sealed) with their identity and then sent using the available communication medium to the broker on a specific topic (e.g., cctv-1-in). Messages sealed in this way are read from the broker by microservices and undergo a verification process. The microservice queries the Hyperledger Fabric blockchain for an image of the device identity for comparison with the identity extracted from the message. The IoT gateway handles all communication with the distributed ledger via an interface to Hyperledger Fabric Gateway services running on the ledger nodes. Successfully verified messages are saved on a dedicated topic (e.g., cctv-1-out) and provided to consumers. Messages which fail verification are discarded by the microservice or written to a previously designated topic to identify faulty (malicious) devices. As pointed out, a device identity image is used to verify the message. The identity is determined in the registration phase by using hybrid fingerprint techniques with a focus on the specificity of the generated radio signals. For a new identity image to be registered in the distributed ledger, the Hyperledger Fabric chaincode is called, which handles the transaction of adding a new identity. Successful registration of the device in the ledger is achieved by obtaining consensus among the organizations belonging to the federation. At the same time, the addition of a new identity implies the generation of an event by the blockchain, which can be handled by dedicated event listening applications (Blockchain Event Listener). In the context of the described solution, these applications were used in terms of reducing the delays associated with the processing of sealed messages. For this purpose, the event listening mechanism was integrated with the Kafka broker and microservices that use local data stores. Also, a dedicated topic (e.g., device-identity) is used for this operation. As a result of the proposed operation, the device identity image can be read from two stores: the on-chain store, called *world state* for Hyperledger Fabric, or the local off-chain store.

In the following headings, the main components of the experimental system and hardware-software IoT gateway are described, along with the reasons for the selection of the proposed elements. Additionally, the description of the various components includes their built-in security mechanisms that enhance confidentiality, integrity, availability, as well as accountability for data in-transit and at-rest.

A. Hyperledger Fabric blockchain

As part of the proposed system architecture, the Hyperledger Fabric solution was chosen. The work [8] provides a performance comparison of various distributed ledger technologies and consensus protocols. In the context of integration with the Internet of Things, mainly Hyperledger Fabric and Ethereum solutions were pointed out as legitimate due to the overall results obtained in experimental studies. Hyperledger Fabric achieved a 10 000 tps transaction throughput [8], for Ethereum throughput was lower. However, only the Proof of Work consensus protocol was benchmarked, and Proof of Stake that is currently used for Ethereum was not included in tests.

Hyperledger Fabric technology is a permissioned blockchain that uses the Practical Byzantine Fault Tolerance (PBFT) consensus protocol. For protocols of this type, all parties must know each other. As a consequence, the Fabric ledger uses public key infrastructure (certificates). The execution of complex business logic (e.g., device registry) is possible by calling multilingual chaincode (Go, Java, Node.js). Chaincode implements a group of smart contracts (transaction steps) and defines an endorsement policy, i.e. which organizations must authorize the transaction.

B. Hyperledger Fabric Gateway

The IoT gateway handles communication with the distributed ledger through an interface to the Hyperledger Fabric Gateway services [6], which allows for:

- performing queries to the world state store and reading the identity from it;
- registering, updating, and revoking IoT device identities from the ledger by calling chaincode;
- handling events generated as a result of approved transactions and blocks.

Moreover, a dynamic mode is proposed to use for the connection profile. This profile uses the ledger nodes' built-in mechanism to identify changes in the network topology on an ongoing basis. As a result, microservices will be able to operate reliably despite the failure of some nodes. Also valuable is the checkpointing mechanism, which makes it possible to resume event listening without losing events due to connection losses.

C. Device Fingerprint

As a part of the registration phase, the image of the IoT device identity will be defined, which will be stored within the device, the Hyperledger Fabric blockchain, and optionally in the local off-chain data store. The identity image will be used as a signing key for messages sent to the Kafka broker. The exact procedures of key management are out of the scope of this article. Consequently, only a general procedure for the mentioned key is presented.

In the registration phase, the device administrator places the device in RF Shielded chamber, which suppresses possible interference affecting the radio waves emitted by the device. Then, using dedicated software and measurement equipment, the device's distinctive features are subjected to a series of tests to define a unique identity image. In this study, a hybrid approach combining several fingerprinting methods is proposed, which is mainly based on the parameters of the generated radio signals. The rationale for this choice is:

- limitations arising from the heterogeneity of the environment and the need to maintain the mobility of IoT devices;
- devices' vulnerability to extreme environmental factors (e.g., temperature, humidity);
- autonomy from the protocols used in the network.

After defining the identity image, the next step is to add it to the distributed ledger. To do this, the chaincode is called, which handles the transaction of adding a new device. Then, an identity image is uploaded to the device. The whole procedure is performed through a secure communication channel with the distributed ledger.

Referring to the format of messages sent to the Kafka broker, Figure 3 shows the general structure for a single message that the broker supports. *Msg_key* and *Msg_value* are a sequence of bytes (binary stream) and represent the payload of a message. The broker or producer can specify the timestamp. Also, the producer can apply message compression or add metadata. The broker assigns the partition number and offset.

The described structure of Kafka messages makes it possible for the broker to accept and handle any format of data. The producer using a data serialization mechanism is the one who determines how to convert the data format of a given protocol (e.g., MQTT) into a bytes representation. Whereas the recipient, through deserialization, defines how to structure the byte string from the broker.

Due to the described Kafka message format and serialization mechanism, it is proposed to use dedicated software running on an IoT device to protect the message depending on its purpose and the required level of security (e.g., classified information). Using this software, it will be possible to:

- authenticating messages;
- signing messages with the identity image and its distinctive characteristics;
- encrypting the message;

Furthermore, this software will be implemented taking into account the parameters of the minimum classes of resource-limited devices, which are defined by RFC 7228 [24].

Partition + offset	

Fig. 3. Kafka message structure

D. Apache Kafka

Considering the multiplicity of data sources (devices) and the need to process messages generated by real-time systems, an Apache Kafka solution has been proposed to enable the streaming processing of data records (messages). For example, Kul et al. [25] presented a framework that uses Kafka and neural networks for tracking (tracking) vehicles, where the dataset was represented as data streams from city surveillance cameras.

Apache Kafka is based on a producer-broker-consumer (publish-subscribe) model and the classification of messages based on their topics. Due to the built-in synchronization mechanism and distributed data (registry) replication between brokers, it is possible to maintain the availability and reliability of data records. In addition, the mechanism of serialization and compression (e.g., lz4, gzip) of data records makes the proposed solution independent of the data format and the protocols used in the network (which is important for heterogeneous environments).

E. Kafka Streams API library

Performing complex operations on data records individually (stream processing) or groups of records (batch processing) requires the selection of an appropriate framework/library. Karimov et al. [26] and Poel et al. [27] evaluated solutions for processing data records. In both works, the Apache Flink framework exceeded in the overall grade other solutions: Kafka Streams, Spark Streaming, and Structured Streaming.

However, in the context of the proposed system architecture, the Kafka Streams API library was chosen, which uses the built-in primitives of Apache Kafka technology like failover and fault-tolerance. Moreover, the library uses a semantic guarantee pattern in which each record (message) is processed exactly once end-to-end. As a result, despite the failure of one of the stream processors (microservice), records will not be lost or double-processed. Spark and Structured Streaming were rejected because these technologies use a micro-batching processing technique, where aggregated data records are processed within defined time windows (threshold). Also, the Apache Flink framework was rejected since it requires a separate processing cluster, which influences operational costs for maintaining the entire infrastructure.

F. On-chain and Off-chain database

It is essential to define and distinguish two categories of data stores within the proposed framework architecture: *on-chain* and *off-chain* stores. World state and transaction log belongs to the on-chain category and refers to the Hyperledger Fabric solution. The world state is a database that determines the current state of the ledger. The transaction log is an exclusively incremental store that acts as a change data capture mechanism where approved and rejected transactions are stored. In contrast, the off-chain category refers to local data stores for applications and microservices that use the Streams API library. For the proposed framework within the on-chain category, the registered identities of IoT devices will be stored. And off-chain stores will serve as additional identity storage to reduce possible delays in the message verification process.

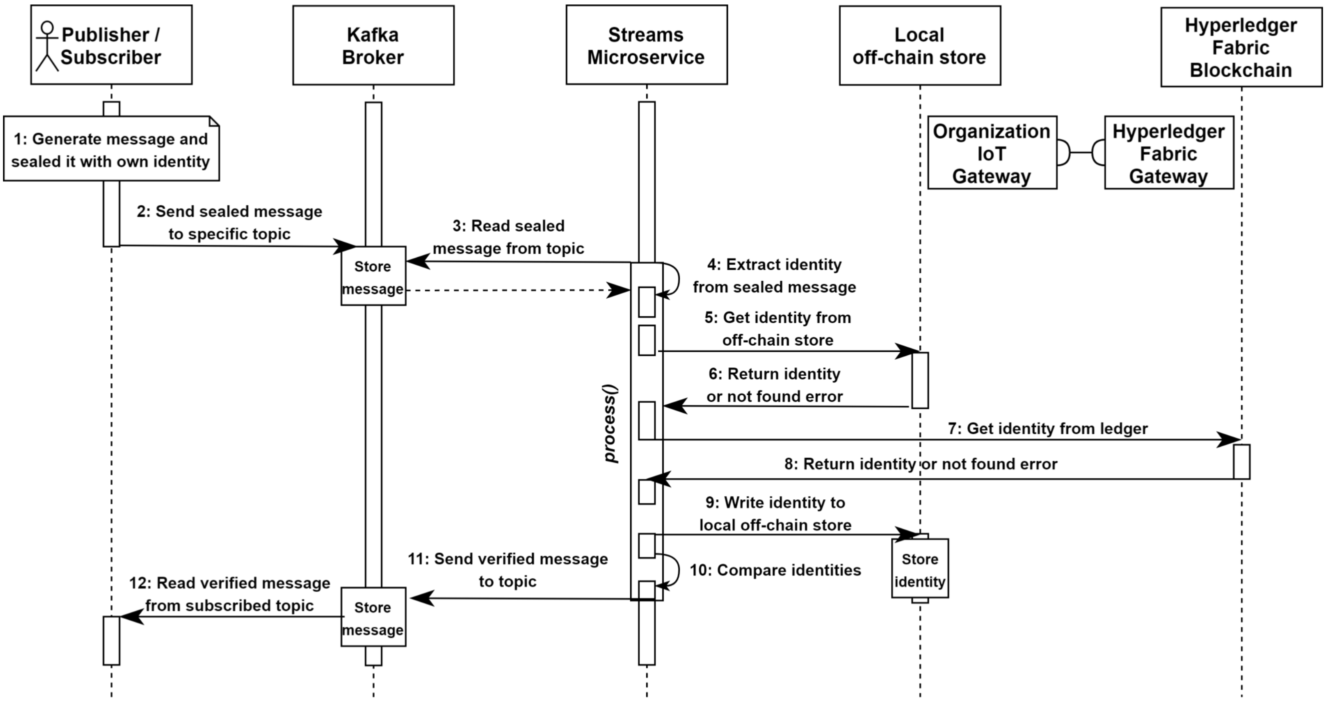
IV. Framework Basic Operations

In this part of the article, the main operations for our experimental framework were presented, taking into account relationships between system elements and message flow.

A. Verification of message streams

In order to verify messages using the distributed ledger, a custom stream processing logic was proposed. Also, a hardware-software IoT gateway was used through which microservices communicate with the Hyperledger Fabric solution. As an optional element, the usage of local off-chain data stores was included. Figure 4 shows a high-level sequence diagram where the steps and message flow are marked for data stream verification operations:

- Step 1: producer (publisher) generates a message and seals it with its own identity image that was beforehand uploaded to the device and the Hyperledger Fabric blockchain during the registration phase;
- Step 2: sealed messages are sent to the Apache Kafka broker to the specific topic using the available and secure communication channel;
- Step 3: microservices sequentially reads the messages from the topic to verify them;
- Step 4: streams microservice *process()* method carries out verification of the message, where the identity image is extracted from the message;
- Step 5: a query to the local off-chain store is made to retrieve the device identity;
- Step 6: the local data store returns the appropriate identity or an error related to its absence;
- Step 7: if identity is retrieved, step 10 is executed. Otherwise, the identity not found error results in a query for the device identity to the distributed ledger, which is executed via an interface to Fabric Gateway services;
- Step 8: the distributed ledger returns the appropriate identity or an error related to its absence;
- Step 9: identity obtained from the ledger is added to the local data store;



Publisher / Subscriber
Kafka Broker
Streams Microservice
Local off-chain store
Hyperledger Fabric Blockchain
Organization IoT Gateway
Hyperledger Fabric Gateway
1: Generate message and sealed it with own identity
2: Send sealed message to specific topic
3: Read sealed message from topic
Store message
4: Extract identity from sealed message
5: Get identity from off-chain store
6: Return identity or not found error
process()
7: Get identity from ledger

10: Compare identities
Store identity
11: Send verified message to topic
12: Read verified message from subscribed topic
Store message

Fig. 4. Sequence diagram for verification of message streams

- Step 10: identities are compared with each other;
- Step 11: as a result of a successful identity comparison, the message is saved to the Kafka topic. The message that does not pass verification is discarded or saved to a previously designated topic to identify faulty (malicious) devices;
- Step 12: depending on the subscribed topics, the shared messages can be read sequentially by the consumer.

B. Adding identities through an event listener

The operation of adding (updating) identity to the local off-chain data store is optional and was proposed because of the possibility of reducing time delays for message verification. Figure 5 shows a high-level sequence diagram for the described operation, where:

- Step 1: the identity of the IoT device is defined;
- Step 2: chaincode, which handles the transaction of adding the new identity to the distributed ledger, is invoked;
- Step 3: the transaction is executed after obtaining approvals of organizations specified by the endorsement policy;
- Step 4: blockchain event listener application listens for events emitted by the distributed ledger;
- Step 5: for an approved and executed transaction, an event related to the registration of a new identity image is emitted;
- Step 6: when a specific event is received by the application (Blockchain Event Listener), the identity image is extracted from the event payload;
- Step 7: the identity is uploaded to a dedicated Kafka topic;
- Step 8: the streaming processing microservice sequentially reads the identities from the dedicated topic;
- Step 9: identity is added to the local off-chain data store, which can be used by the other streaming processor microservices.

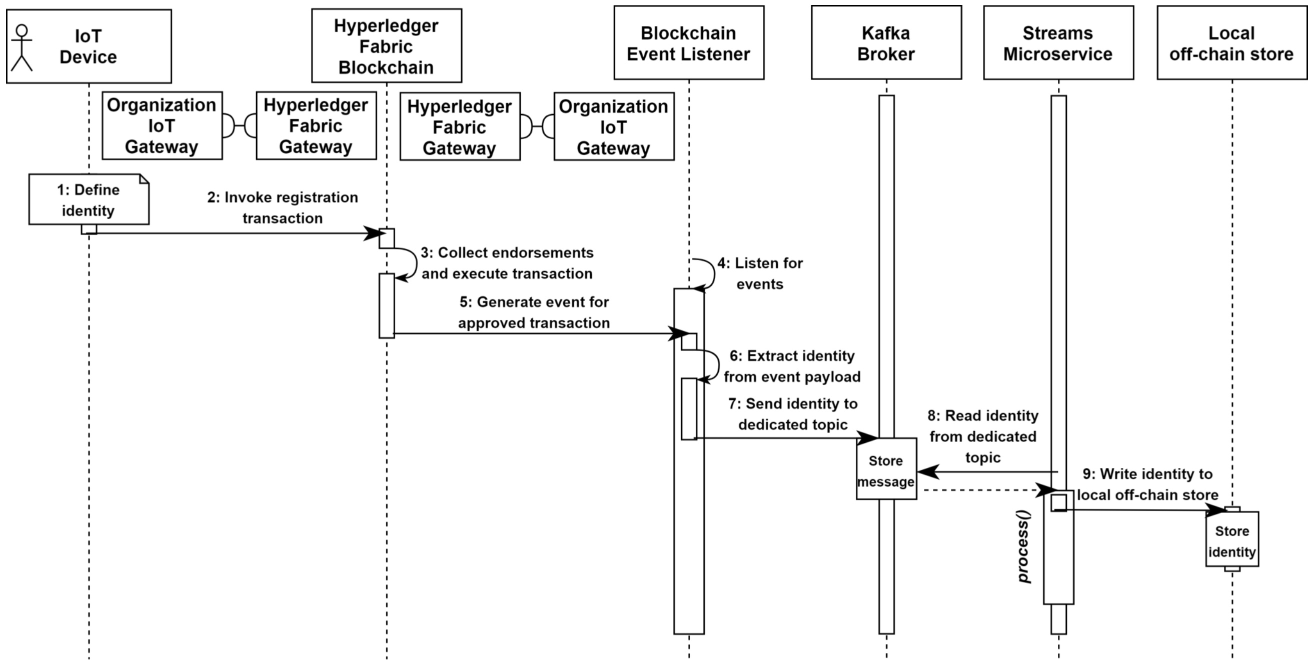
Optionally, the application or microservice can invoke a synchronization query to the Hyperledger Fabric blockchain to compare the integrity of the master identity image from the ledger with the one extracted from the event payload or written by the microservice to the local data store.

V. Framework Evaluation

Performance benchmarking of streaming data processing systems is an extensive challenge that arises from the problem of the global notion of time. This section describes preliminary benchmarks for our framework, where we evaluated the processing-time latency for microservices that were implemented using the Kafka Streams API. The main purpose of the tests was to confirm whether our framework is feasible to process message streams, especially audiovisual streams. Even if our processing logic is dependent on performing identity read operations from the distributed ledger.

A. Setup

The various components of our experimental framework were deployed using the Amazon Web Services (AWS) cloud environment. Figure 6 shows the test environment, which includes:



IoT Device
Hyperledger Fabric Blockchain
Blockchain Event Listener
Kafka Broker
Streams Microservice
Local off-chain store
Organization IoT Gateway
Hyperledger Fabric Gateway
Hyperledger Fabric Gateway
Organization IoT Gateway
1: Define identity
2: Invoke registration transaction
3: Collect endorsements and execute transaction
4: Listen for events
5: Generate event for approved transaction
6: Extract identity from event payload
7: Send identity to dedicated topic
8: Read identity from dedicated topic
Store message
9: Write identity to local off-chain store
process()
Store identity

Fig. 5. Sequence diagram for adding identities through an event listener

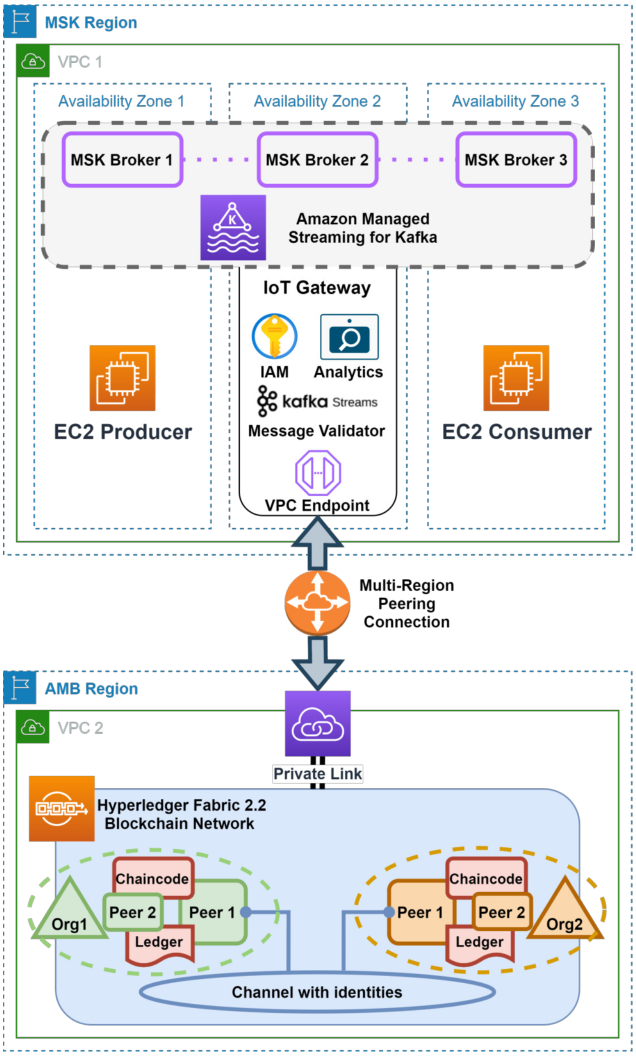


Fig. 6. Test environment overview

- two AWS regions to simulate geographical distances: MSK Region that belongs to Org1, and AMB Region for Org1 and Org2. The Multi-Region link was set using VPC Peering Connection;
- a single Amazon Managed Streaming for Apache Kafka version 2.8.1, deployed in the MSK Region isolated (availability) zones, where three kafka.t3.small brokers (vCPU: 2, Memory: 2GiB, Network Bandwidth: 5Gbps) were set. Each broker has a default configuration with a single partition and a replication factor of 3;
- a single Amazon Managed Blockchain Starter Edition for Hyperledger Fabric version 2.2, deployed in the AMB Region, where a single channel for identities was created within the blockchain network. Also, each member (Org1, Org2) of the channel has two nodes (peers) running of type bc.t3.small (vCPU: 2, Memory: 2GiB, Network Bandwidth: 5Gbps);
- two Amazon Elastic Compute Cloud (EC2) virtual machines of type t2.micro (vCPU: 1, Memory: 1GiB), deployed in the MSK Region in two isolated zones to simulate message producer and consumer;
- a single EC2 instance (t2.micro) deployed in the MSK Region, running as a microservice that verifies messages;
- a single AWS PrivateLink interface (VPC Endpoint) that enables the communication between the microservice and elements of the Hyperledger Fabric.

The AWS cloud due to its pay-as-you-go model and pluggable architecture for Commercial Off-The-Shelf services: Apache Kafka (Amazon Managed Streaming) and Hyperledger Fabric (Amazon Managed Blockchain), enables efficient deployment of our framework. Simultaneously minimizing the operational costs associated with the provisioning, configuration, and maintenance of its various components. As a consequence, our framework is suitable for federated environments for which it is required to ensure zero-day interoperability.

B. *Processing scenarios*

In conducting performance studies (benchmarks) of streaming data processing systems, it is necessary to consider three main metrics [26], [27]: latency, throughput, and the usage of hardware-software resources (CPU, RAM). Furthermore, the overall performance evaluation can be affected by the input parameters (e.g., system configuration) and processing scenarios (workloads) [25]. In the context of the proposed framework, several parameters are listed below:

- parallelization of stream processors (microservices);
- the kind (e.g., join, windowed aggregation) and type of operations (e.g., stateless, stateful);
- configuration for Kafka brokers: number of brokers, partitions, and replication factor [25];
- number of organizations that joined a federated environment;
- the number of nodes of the distributed ledger, and registered devices (identity count);
- the selected programming language for microservices and chaincodes (e.g., Java, Go, Node.js).

Generally, latency defines as the interval of time it takes for a system under test (SUT) to process a message, calculated from the moment the input message is read from the source until the output message is written by SUT. Hence, it is important to distinguish the latency metric [26] into its two types: *event-time latency* and *processing-time latency*. The first mentioned refers to the interval between a timestamp assigned to the input message by the source (e.g., broker) and the time the SUT generates an output message. The second one refers to the interval calculated between the time when an input message is ingested (read) by the SUT, and the time the SUT generates an output message. In this paper, we only prepared and conducted two workload scenarios to test the performance of the proposed processing logic for microservices, where the processing-time latency was measured:

1) Scenario I: involved verifying the input (sealed) message by performing a comparison operation between

TABLE I
PROCESSING-TIME LATENCY METRICS (IN MILLISECONDS)

Identity Count	Avg	Avg Dev	Min	Max	Pop Std Dev	Percentiles [p=0.9; p=0.95; p=0.99]
10000	38.3 (0.76)	3.0 (0.00)	32.7 (0.56)	133.8 (7.80)	5.5 (0.70)	[44.3 (0.76); 47.7 (1.24); 56.7 (2.16)]
20000	39.5 (1.20)	4.0 (0.00)	32.2 (1.28)	143.7 (9.90)	6.6 (0.60)	[46.7 (1.90); 50.7 (1.70); 61.4 (2.00)]
35000	39.9 (1.12)	3.7 (0.42)	32.6 (1.08)	131.2 (5.64)	5.9 (0.54)	[46.5 (1.10); 50.5 (1.30); 60.2 (2.16)]
50000	38.2 (1.28)	3.3 (0.42)	31.7 (1.3)	130.8 (7.76)	5.5 (0.60)	[44.6 (1.72); 47.8 (2.00); 55.7 (2.70)]
100000	38.6 (0.72)	3.3 (0.42)	32.0 (0.40)	139.3 (5.16)	5.5 (0.50)	[44.7 (0.56); 47.8 (0.64); 55.8 (1.64)]

TABLE II
TIME OF DATASTREAM (1000 MSG) RETRIEVAL BY CONSUMER (IN SECONDS)

	Identity Count				
	10000	20000	35000	50000	100000
Scenario I	38.86 (0.64)	39.95 (1.39)	40.19 (0.98)	38.59 (1.22)	39.15 (0.61)
Scenario II	20.42 (0.77)	21.03 (1.20)	21.15 (1.06)	20.39 (1.12)	20.06 (0.69)

the extracted device identity, with the identity stored in the distributed ledger.

2) Scenario II: involved verifying the sealed message by performing a comparison operation between the extracted device identity, with the identity stored in the off-chain data store. For this scenario, all device identities from the distributed ledger were also stored in the off-chain data store.

For all scenarios, the burst at startup technique was applied [27], where each input message was beforehand generated and sealed with a pseudo-randomly device identity. Once a certain number of input messages were generated, a single instance of the microservice responsible for verifying them was invoked. At the same time, within the scenarios, every second message pointed to an identity that was not registered in the distributed ledger. This approach was designed to minimize the impact of optimization (caching) mechanisms.

C. Discussion

Table 1 presents results for workload scenario I, where we determined the processing-time metric:

- average latency (Avg) and average absolute deviations of data points from their mean value (Avg Dev);
- minimum (Min) and maximum (Max) latency;
- standard deviation based on the entire population (Pop Std Dev);
- quantiles of order: p90, p95, p99.

Table 2 presents the average times for consumers to read message streams at the same time when SUT was processing it.

Both tables present the averaged results along with the average absolute deviation shown in brackets calculated for 10 repetitions of each processing scenario. Also, the input parameters for both scenarios were: a number of registered identities (identity count) in the distributed ledger and a fixed number of 1 000 messages. The optimal number of beforehand generated messages was determined through empirical tests for mentioned scenarios. During this, we noted slight increases in the accuracy of the measurements in comparison to 10 000 or 100 000 messages.

Regarding the results (Tab. 1), changing the number of registered identities did not affect the processing-time latency associated with the verification of a single message. An average delay of ~39ms was measured. The minimum delay was 31ms. In contrast, the average deviations for quantiles of the order p90 and p99 do not consecutively exceed ~2ms and ~3ms. For 100 000 registered identities, quantiles of p90 latencies were below ~45ms, and for p99 below ~56ms.

The results shown in Table 2 for workload scenario I are promising as the average time for consumers to read message streams was ~39 seconds. In the context of audiovisual streams, the measured time (1 000/39) represents ~25 frames per second (~25fps). The work of [28] demonstrated that CCTV cameras with a minimum 8fps frame rate are required to correctly identify objects on video. In addition, the results for workload scenario II confirmed the rightness of local off-chain data store usage as a mirco-caching mechanism for message verifying. The usage of mentioned data store almost doubly reduced the reading time of the message stream. An important point for scenario II is that for every second message, the identity did not exist in both data stores.

The collected results were also compared with the results in the works of [25], [26], and [27]. Hence, the rationale of the proposed processing logic for microservices was confirmed. Additionally, the obtained low average deviations indicate the stability of the proposed framework deployed with the AWS Cloud. This characteristic is important in the context of further performance studies (e.g., maximum, sustainable throughput).

D. Security and reliability risk assessment

We have conducted a high-level security risk assessment considering several security and reliability threats across the Application, Network, and Perception layers of the IoT system.

Application Layer:

1) *Storage attack* - the attack consists of changing device identity features. To prevent this attack, access to the device should be properly secured to prevent the change of data stored in it. In our framework, if the device identity is changed, the device will not be able to authenticate itself. It is almost impossible to change data in a distributed ledger without the knowledge and consent of the organization that owns the IoT device.
2) *Malicious insider attack* - the attack consists of the use of credentials by an authorized person. In the framework, access to data stored in the Hyperledger Fabric is possible only by an authenticated and authorized entity that uses an appropriate private key and a valid X.509 certificate. Each access attempt is logged. Resistance to this attack can be enhanced by using Security Information and Event Management (SIEM).
3) *Distributed ledger node failures* - in our framework, we propose each organization has a minimum of two nodes. Since the data in the blockchain is replicated, the failure of a single node does not affect the operation of the entire network.
4) *Kafka cluster (brokers) failure* - in our framework, it is possible to maintain the availability of data generated by IoT devices by using built-in synchronization mechanism and setting an appropriate replication factor.
5) *Denial of Service* – in our framework, the number of ledger nodes, Kafka brokers, microservice, and IoT gateways could be increased to handle more requests. Moreover, using SIEM we can identify specific properties of requests involved in DoS to detect a source of overload and reject all malicious requests at the gateway level.

Network Layer:

1) *Eavesdropping* - the attack involves eavesdropping on transmissions and obtaining messages (credentials). In our framework, we have separated the key used to secure the communication channel for IoT devices from the key used for the data authenticity protection mechanism. Only the registration phase is critical and must be carried out in a protected, trusted environment.
2) *Man-in-the-Middle* - the attack consists in changing the messages sent between the IoT device and the verifying microservices. Any change to the message will prevent it from being verified due to the data authenticity protection mechanism. Moreover, invalid messages can be logged to identify faulty (malicious) devices.

Perception Layer:

1) *Device capture* - the attacker can access the IoT device and generate messages sealed with its identity. In this situation, it is assumed that for such a device, its behavioral pattern (distinctive features) will change. As a consequence, it will be possible to use analytics tools (SIEM) to detect these changes, mainly related to network fingerprints. Moreover, when a compromised device is detected, it can be immediately marked and revoked from the distributed ledger. Also, hardware modules such as TPM can be used to increase device resilience against capture and manipulation.
2) *Malicious device* - the attack involves adding a fake IoT device to the network. In our structure, the process of registering a device takes place once in a protected environment. Therefore, we assume that the process will be coordinated by an authorized person. Therefore, it is not possible to register a fake device. If a device is not registered, it will not be authenticated and messages from such a device will be rejected, and consequently the device will be detected and blocked.
3) *Device tampering* - the attack consists in changing software or hardware components of the IoT device. In our framework, any changes to a unique device fingerprint would generate numerous failed verification attempts.
4) *Sybil attack* - The attack consists in having a multi-identity device by the IoT device. In our framework, this situation is prevented via a secure registration process.
5) *Side-channel (timing) attacks* - attacks consist in obtaining the key by analyzing the implementation of the protocol (e.g., current power consumption, time dependencies). The framework could be susceptible to a timing attack when the device will use unique data to seal messages. In this situation, it is possible to predict from where these data are read, but not the values of these data, therefore we believe that this attack is rather difficult to perform in practice.

VI. Conclusion and Future Work

One of the still unresolved problems is the acquisition, analysis, and fusion of enormous amounts of data generated by various IoT devices, and their secure and reliable distribution. In order to fill the gap, we proposed an experimental framework architecture for secure and reliable message stream distribution in a multi-organizational federation environment.

Deploying our framework within AWS Cloud infrastructure showed that it is suitable for environments where immediate interoperability is required. Moreover, preliminary performance benchmarking and obtained results (~25fps) confirmed the rationale for the usage of our solution to process audiovisual streams. Also, obtained low processing-time latency average deviations indicate the stability of the proposed system. This characteristic is important in the context of further performance studies, like event-time latency and maximum throughput.

Our framework has the potential to serve as the backbone for multiple applications. For instance, it could be incorporated into UAV detection and neutralization systems. This would allow both civilian and military organizations to have full control over air-defense activities, where IoT devices that are part of the smart city and military infrastructure can securely disseminate data about UAV location via our solution. Another possible scenario could involve setting up an ad-hoc system to coordinate international operations aimed at providing humanitarian assistance in eliminating natural disasters (known as HADR - Humanitarian Assistance And Disaster Relief). Our system can be of great help in this case, as it allows for the reliable exchange of data from CCTV cameras and health devices such as SOS wristbands. This would reduce response time for those in need of assistance and lead to better decision-making through improved information sharing.

Future work will focus on the development of a detailed design of a protocol for secure communication of IoT devices with a distributed registry, along with a protocol to enable message sealing that utilizes the identity of the IoT device. Additionally, we intend to conduct a comprehensive evaluation of a security and reliability risk, and we will implement dedicated software to seal messages with device identity.

***Abstract*—Context: research on understanding the laws related to software- project evolution can indirectly impact the way we design software development processes, e.g., knowing the nature of the code-repository content growth could help us improve the ways we monitor the progress of OSS software development projects and predict their future development Goal: our aim is to empirically verify a hypothesis that the OSS code repositories grow in size according to the Pareto principle. Method: we collected and curated a sample of 31,343 OSS code repositories hosted on GitHub and analyzed their content growth over time to verify whether it follows the Pareto principle. Results: we observed that, on average, monotonically growing OSS repositories reach 75% of their final content size within the first 25% revisions. Conclusions: the content size of monotonically growing OSS repositories seems to grow in size according to the Pareto principle with the 75/25 ratio.**

I. Introduction

THE 80/20 rule is often referred to as a means of quantitatively modeling cause-effect relationships between real-world variables. A generalization of this rule is a well-known Pareto principle. The principle states that *roughly 80% of outcomes come from 20% of causes*. This phenomenon has been also studied in the context of Open Source Software (OSS) development. Most of the studies investigated the principle by studying the patterns in the OSS community ways of working—i.e., commits [1], communication [2], [3], issue trackers, while others focused on the modeling the distribution of code smells, architecture, data, and software defects [4], [5].

This research focuses on studying the applicability of the Pareto principle to code repository content growth over the lifespan of OSS projects. In particular, our goal is to empirically verify a hypothesis stating that *monotonically growing OSS code repositories increase their content size over time according to the Pareto principle*, which means that, on average, an OSS code repository reaches 80% of its final content size in the first quantile of the project's lifespan. We narrow our study to projects that have a natural monotonic tendency to grow in size over time (e.g., they are not subjected to significant code removal activities).

Research on understanding the laws related to software-project evolution can indirectly impact the way we design software development processes. For instance, knowing the nature of the OSS code-repository contents growth could help us improve the ways we monitor the progress of OSS software development projects and predict their future development.

This paper is organized as follows. Section II provides more details on the Pareto principle and discussed selected studies on the Pareto principle in Software Engineering. Section III presents the design of our research method to study the applicability of the Pareto principle to the code-repository growth in OSS. Section IV presents and discusses the results and main threats to the validity of our study. The main findings are summarized in Section V.

II. Background and Related Work

A. The Pareto principle

The Pareto principle, also known as the 80/20 or 80 by 20 principle, was formulated in the early 1950s by Joseph Juran [6], but it was based on a relationship that Vilfredo Pareto had noted before—namely that 80% of the world's wealth is owned by 20% of humanity. Since then, numerous studies have shown that this principle holds also for other variables. However, this is not always an exact 80/20 ratio, the values are rather illustrative and will not apply to every situation, but in many cases, the Pareto principle works perfectly. The Pareto principle not only works in many fields, such as resource management, people management, and time management, but also in scientific fields, such as economics, accounting, medical sciences, or computer science.

The Pareto principle is also a generalization for the Pareto distribution presented in Figure 1. This principle is also characterized by the Pareto index, denoted as the alpha coefficient in the figure, which is an indicator of the Pareto principle strength.

B. The Pareto principle in Software Engineering

A large number of OSS projects available on platforms such as GitHub or SourceForge created an opportunity for researchers to study a massive corpus of software projects. Free access to code repositories based on version control systems (VCS) makes it possible to study the evolution of projects over time. This includes numerous studies on the applicability of the Pareto principle to different areas covered by Software Engineering. Most of them focused on studying the applicability of the Pareto principle to model the distribution

This work was supported by the Poznan University of Technology within the project 0311/SBAD/0738.

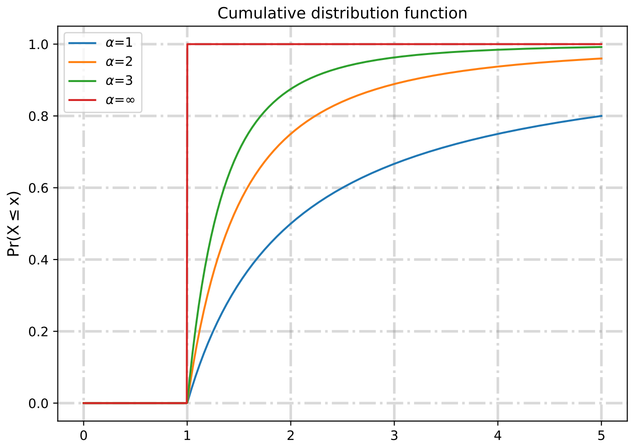

Fig. 1: Examples of cumulative density distribution functions for the Pareto distribution.

of defects, activity, or collaborators in software projects. Here, we briefly summarize the most relevant papers in this area:

- *Architecture smells and Pareto principle: A preliminary empirical exploration* [7] investigated to what extent architecture smell occurrences adhere to the Pareto principle. The authors analyzed 750 Java and 361 C# repositories and detected seven types of architecture smells. They reported that ca. 45% of the Java repositories and 66% of C# repositories followed the Pareto principle in this aspect. This study investigates the Pareto principle in open source, however, its focus is on architectural smells, while our study focuses on the size growth of OSS projects.
- *Long-term evaluation of technical debt in open-source software* [8] studied the evolution and characteristics of technical debt in OSS. In particular, the authors investigated the evolution of three large OSS Java applications (110 releases) with the use of the SonarQube technical debt detector. They reported that the Pareto principle was satisfied for the studied applications, as 20% of issue types generated around 80% of total technical debt. The focus of the study is different that ours, however, the main similarity is that both studies investigate release histories.
- *Towards a theoretical model for software growth* [9] studied 700,000 C source-code files of the FreeBSD operating system to compare different complexity measures in the context of measuring software growth. One of their observations was that all the measures followed a double Pareto distribution. This observation is convergent with the outcomes of our study, however, the original study did not consider the time-related aspect of code evolution.
- *Evidence for the Pareto principle in open source software activity* [3] focuses on analyzing the activity of users in mailing lists on a sample of three OSS software projects. This study is loosely related to our work since the studied object differs from ours.
- *On the central role of mailing lists in open source projects: an exploratory study* [2] regards communication in OSS projects and focuses on communication with the OSS projects' mailing lists. In particular, they empirically verified a hypothesis stating that a few key discussion participants are responsible for most of the messages posted on the mailing list. However, the study did not provide strong evidence confirming the applicability of the Pareto principle to this case.
- *Evaluation and application of bounded generalized Pareto analysis to fault distributions in open source software* [5] aimed at investigating distributions of faults in OSS software projects to see if it follows the Pareto distribution. Therefore, since the object of the study differs from ours, we consider it to be loosely related to our study.
- *Revisiting the applicability of the Pareto principle to core development teams in open source software projects* [1] studies the ratio of produced code size to developers' activity on a sample of 2,496 GitHub projects. This work is not directly related to our research since it focuses on the Pareto principle of code size in ratio to developers' activity and not code size growth over the project lifespan.
- *Empirical study of software quality evolution in open source projects using agile practices* [4] studies the evolution of software quality in two open source projects (Eclipse and Netbeans). They investigated the relationship between Object-Oriented metrics and defect proneness. They observed that a small percentage of compilation units hold most of the reported issues—i.e., it follows the Pareto principle.

As it follows from our literature analysis, most of the papers focus on studying the existence of the Pareto principle in different areas of software development, however, not in the context of repository content increments. Also, most of the studies focus on small samples of OSS projects and often have a form of case studies. On the contrary, our study is based on a massive dataset of OSS projects.

III. Research Methodology

A. Research goal, questions, and metrics

The goal of our study is to investigate a hypothesis that *monotonically growing OSS code repositories increase their content size over time according to the Pareto principle.* Since we aim to verify the hypothesis based on empirical evidence, we frame the problem using the Goal-Question-Metric framework [10]. Our goal (G) is to examine the applicability of the Pareto principle to OSS repository content size growth over the project lifespan. From the goal follows a research question (Q): **What is the average repository content size growth over time in OSS projects?**

Finally, we use the following metrics (M) as the basis for answering the research question:

- **M1: Repository contents size at a given point in time** — this metric presents repository contents size which is expressed by the total lines count of all files in the repository in the given revision. There is no distinction between the types of data that the files contain. Source code files, resources files, comments files, etc. are treated as contents files. We use the **wc** tool [11] to count the number of lines in the files. A point in time is determined based on the resolution defined as the M2 metric.

- **M2: Lifespan unit** defines a resolution unit of the project's lifespan. It is logically expressed as a % value but technically converted to a float in the range between 0 to 1. The lower the metric value, the higher the resolution. The base form of the Pareto principle is the 80/20 ratio. Therefore, it requires a maximum lifespan unit to be at the quintile level (20%). Based on the selected Lifespan unit, the project is sampled at unit-sized points in time, and the number of lines of code is calculated (M1).
- **M3: Repository final size** is the final size of the repository expressed in bytes. A too-small repository may not have visible differences in content growth. Conversely, a repository that is too large may indicate that it is a fixed-size dataset that does not change over time.
- **M4: Repository lifespan** is expressed as the number of commits. Repository lifespan could have a visible impact on the content growth analysis. A repository that has a too short commit history may bias the results since we analyze the distribution of the M1 measure in time. Unfortunately, in practice, some repositories may contain only a single commit. Also, this metric is related to the M2 metric. For instance, when M2 is set to 20%, the minimal repository lifespan (M4) is required to have minimum of 5 commits ($1/0.2 = 5$).

B. Study design

Answering the research question requires a multi-stage procedure, starting from collecting a large corpus of OSS project repositories, analyzing how the code changes over time in these repositories, and drawing conclusions about the applicability of the Pareto principle to the distribution of code increments.

1) Data acquisition and filtering: In the first step, we collect a dataset of projects hosted on GitHub.[1] In particular, we use GitHub API to fetch the data from the projects. The service allows the database to be filtered for repositories that match the expected criteria, but the response output is limited to 1,000 rows. The sample of repositories could be too small for our use case. Also, the quality of projects hosted on GitHub could vary visibly, starting from what we would call "engineered" projects to some toy examples, code snippets, or even repositories that do not contain any code.

Our workaround to these issues is to use a curated list of 1,857,423 GitHub repositories created by Munaiah et al. [12] (RepoReapers[2]) and further curated by Pickerill et al. [13]. The filtered list contains GitHub repositories belonging to so-called "engineered" projects. Munaiah et al. define an engineered project as *"a software project that leverages sound software engineering practices in one or more of its dimensions such as documentation, testing, and project management."* Selecting such projects allow us to narrow the search and increase the relevancy of the obtained sample of OSS projects.

In the following step, we further filter the list of repositories based on the M2, M3, and M4 metrics to select only relevant code repositories. We do not pre-set any filtering thresholds for these measures, but instead, we determine them empirically by observing how making these criteria stricter influences the dataset properties.

Finally, we take into account projects whose content growth is incremental. Therefore, we use linear regression as a tool to identify projects with anomalies related to how their size grows over time. The linear regression is expressed as:

$$y = ax + b$$

where a is a slope and b is an intercept. The slope can be used to evaluate the repository-growth tendency. We are going to determine the a threshold empirically by observing how it affects the presence/absence of outliers in our dataset. We use the PostgreSQL function regr_slope[3] to calculate the slope.

2) Data analysis: The analysis procedure is based on the Git version control tools. Git tools allow comparing changed, added, or deleted lines of code. An atomic set of changes recorded by Git is called a commit or revision. Git repositories consist of a tree of commits. Using the git-ls-tree command, the structure of the commit tree and its metadata can be obtained. The metadata contains information about changes to the file's lines. Using the wc [11] tool, it is possible to count the total amount of code at a specific point in time at which a commit was created.

The data is further normalized and aggregated to obtain the distribution of repository content growth. Each repository has a different project beginning and ending date. The duration of projects has to be expressed as normalized time. Let's define project duration normalized time as NT. NT is a discrete variable with a distribution of every threshold s (M2) which is expressed as a value from 0 which is the beginning date of a project and 1 which is the end date of a project.

$$NT = 0, s, 2s, 3s, ..., 1$$

Each project has a different content size at the end. This means a repository's content size also has to be expressed as a normalized value to a repository's final content size (M1). Let $L(p, NT)$ represents repository content size as a count of lines, where p is the repository. The ending time then is equal to 1 ($NT = 1$).

$$L_{final}(p) = L(p, 1)$$

Having the final repository content size, the normalized repository content size at a given normalized point in time can be calculated:

$$NL(p, NT) = \frac{L(p, NT)}{L_{final}(p)}$$

[1] GitHub https://github.com

[2] https://reporeapers.github.io/

[3] https://www.postgresql.org/docs/9.0/functions-aggregate.html

Having projects lifespan as normalized points in time and normalized repositories content size makes it possible to calculate the distribution of repository content growth:

$$\overline{NL}(P, NT) = \frac{1}{n}\sum_{i=1}^{n} NL(P_i, NT))$$

where P is set of repositories.

In order to ascertain the completeness of the Pareto principle in our study, the distribution of code increments should be close to the theoretical Pareto distribution. The relevant point of the distribution is the point of the searched 80/20 ratio. As a result of the study, the resulting graph may intersect the vicinity of the point, but the whole distribution may not converge to the Pareto distribution. The expected graph should be incremental with a significant increase in the first 20-30% and then a gentle increase up to 100%.

IV. Results and Discussion

A. Data fetching

We fetched code repositories from GitHub using the curated list of links to repositories belonging to so-called “engineered projects” [12], [13]. For each repository, we first downloaded the repository metadata from GitHub API. Next, each repository was downloaded and analyzed. We used the GitStats tool [14] to analyze the tree structure of Git commits. As a result, we collected data from **35,890** OSS software repositories.

The distribution of programming languages of projects is presented in Table I. This classification of projects is based on the GitHub metadata. The table presents the data for the programming languages used in over 100 projects. The distribution of the repository size for the code repositories in our sample is summarized in Table II. The average size of code repository is around 3,343 KB with a standard deviation of ca. 213 KB. The average size is influenced by very large repositories (see Figure 2), thus, the median size is visibly smaller and equal to ca. 180 KB.

TABLE I: The distribution of programming languages of projects

Language	**Projects count**
Java	8886
Python	5756
Ruby	4188
PHP	3313
C++	3134
C#	2196
C	2153
JavaScript	633
HTML	380
CSS	188
Objective-C	124

TABLE II: A summary of code repository sizes (measured in KB).

Average	Median	Standard deviation
3,343.31KB	180KB	212.95KB

B. Calculating the measures

We used the GitStats and wc tools to analyze the repositories and calculate measures M1, M2, M3, and M4. An example of the output generated by the toolset for the Spring Boot repository[4] is as follows:

```
Project name
    spring-boot
Generated
    2022-08-13 00:02:29 (in 344 seconds)
Generator
    GitStats (version 55c5c28),
    git version 2.25.1, gnuplot 5.2
    patchlevel 8
Report Period
    2012-10-21 19:53:52 to 2022-08-12 17:47:38
Age
    3583 days, 3032 active days (84.62%)
Total Files
    8748
Total Lines of Code
    727599 (1726809 added, 999210 removed)
Total Commits
    39150 (average 12.9 commits per active day,
    10.9 per all days)
Authors
    1113 (average 35.2 commits per author)
```

In addition to the report, the toolset allowed us to collect information about the growth of the code repository in time. Figure 3 presents the growth of the Spring framework repository (M1) over time. As we can see, the size (M1) of this repository increases monotonically over time, therefore, it belongs to the population of the projects in the scope of our analysis.

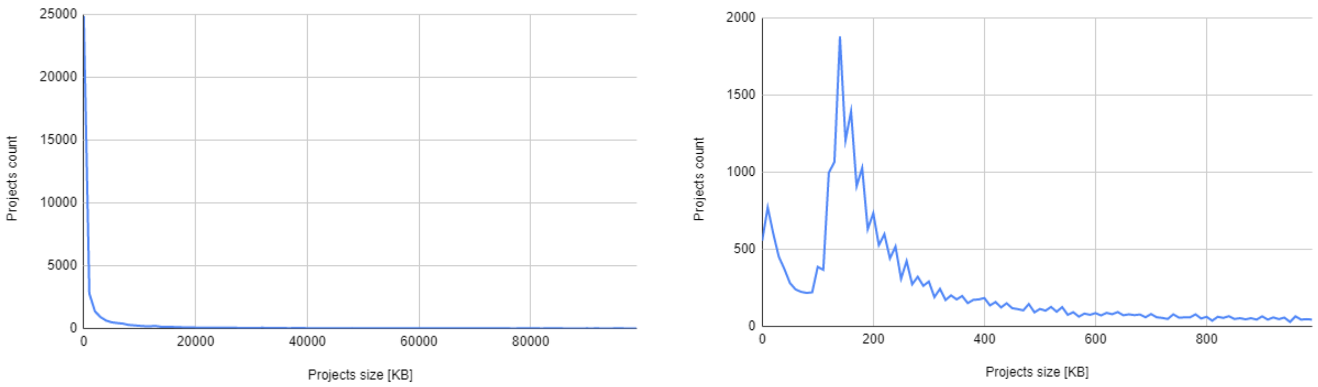
C. Applying filtering criteria

We decided to set the project lifespan unit (M2) to $s = 0.05$, which allowed us to analyze the appearance of the Pareto principle with a minimum resolution of 5%. As it was stated in Section III-A, the maximum lifespan unit for studying the Pareto principle shall not exceed 20% ($s = 0.2$). We set the threshold to 0.05 to increase the resolution since it is rather unlikely to observe the exact 80/20 ratio in a sample of real-life data, but rather some minor variation of that ratio, e.g., 75/25, 70/30, or similar ratios.

We set the following thresholds values of the M3 and M4 measures to initially filter the code repositories:

1) M3: Repository total size of up to 100 MB — we limited the size of the repository to exclude outliers (see Figure 2) and reduce the processing time of a single repository.

[4] Spring Boot – https://spring.io/projects/spring-boot



(a) All projects in the sample

(b) Projects with code repositories of up to 1,000KB

Fig. 2: The distribution of the sizes of the code repositories (KB).

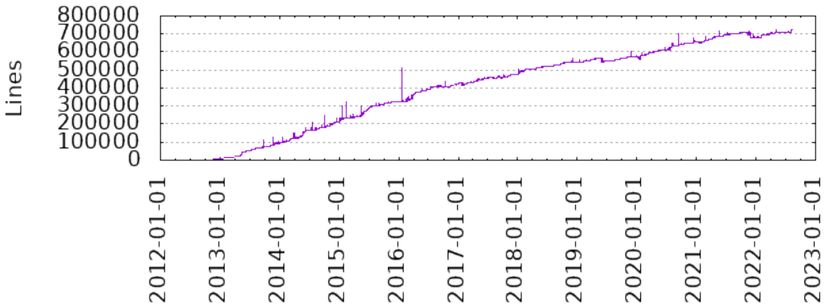


Fig. 3: An example of the repository growth plot for the Spring framework.

2) M4: Repository lifespan — we constraint the minimum repository lifespan to at least 20 commits, which follows from the selected lifespan unit (M2). A lifespan unit of 5% determines the minimum number of commits to 20.

In the following step, we used our toolset to calculate the count of lines (M1) over time (L). The results were stored in a PostgreSQL database. Next, we calculated the normalized repository content size (NL) and normalized project lifespan (NT). Finally, we used both measures to calculate the distribution of repository content growth ($\overline{NL}$).

Figure 4 shows $\overline{NL}$ for the sample of projects filtered based on the M3 and M4 measure thresholds. As the content growth is measured with respect to the final content size of the repository, the 100% content size is achieved at the last point in time. However, we can see that the average normalized size reaches up to 722% of the final size. The reason for that is the presence of outlier projects with visibly non-monotonic, non-incremental growth over time. An example of such a project could be Unity3d-Async-Task[5]:

```
Project name
    Unity3d-Async-Task
Generated
    2022-08-23 19:22:00 (in 0 seconds)
Generator
    GitStats (version 55c5c28),
    git version 2.25.1, gnuplot 5.2
    patchlevel 8
Report Period
    2015-03-07 19:24:45 to 2015-10-01 17:45:15
Age
    209 days, 21 active days (10.05%)
Total Files
    1
Total Lines of Code
    3 (48396 added, 48393 removed)
Total Commits
    58 (average 2.8 commits per active day,
    0.3 per all days)
Authors
    4 (average 14.5 commits per author)
```

As it is visible in Figure 5, the content of this repository was drastically reduced at a single point in time. As it stands from the README.md file, the source code from this repository was moved to another location. Such projects bias the general view of how the content of OSS code repositories grows over time and thus should be removed from the analysis. Unfortunately, manual filtering of such repositories was not feasible due to the size of the sample. Therefore, we decided to use linear regression (as we stated in Section III-B) to identify and remove outlying projects with respect to their

[5] Unity3d-Async – https://github.com/NVentimiglia/Unity3d-Async-Task

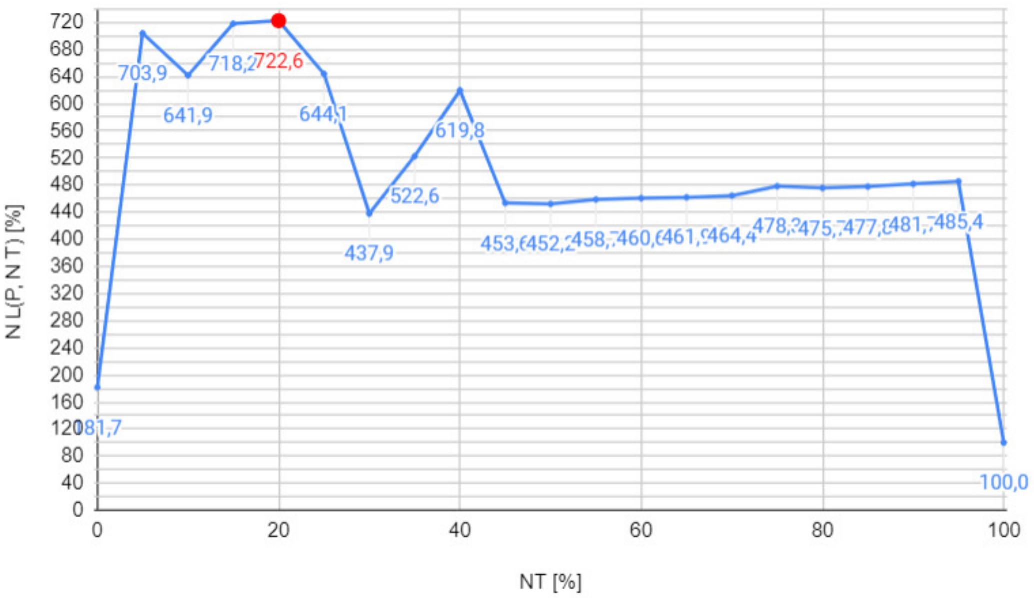

Fig. 4: Aggregated normalized lines count per normalized time expressed in percentage before filtering out the repositories with non-monotonic size growth over time.

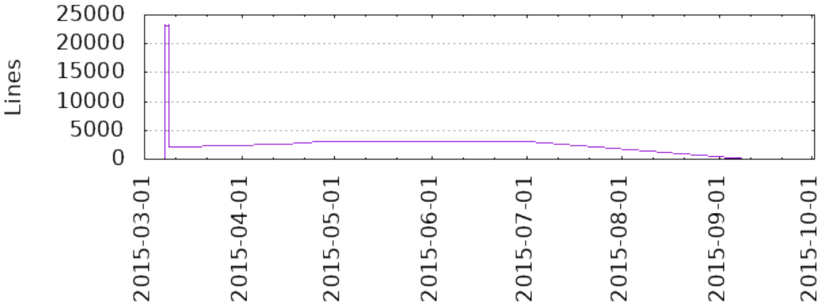

Fig. 5: Content growth in lines of code for Unity3d-Async-Task.

content growth. After applying linear regression and analyzing the slope of the regression functions, we accepted projects for which the slope was between 0 and 5. This allowed us to filter out projects with both suspiciously massive size reductions and suspicious bulk code addition operations in single commits.

The results of applying the filtering criteria are presented in Figure 4. The intensity of line-count growth became growing monotonically. Interestingly, as we can see in the figure (see $NT = 0\%$), projects, on average, are uploaded to GitHub when they contain 30% of their target size. After that, their content growth increases significantly, up to 20% of their lifespans when they reach 90% of their final size, and later, the growth rate flattens out. Unfortunately, we can also see a suspicious drop in size within the last 5% of the projects' lifespan, with a drop of 15% of their content (the pick point for a project content size is ca. 120% of its final size instead of the expected 100%). After investigation, it turned out to be, once again, the effect of outliers in the sample (e.g., moving repositories) that affected the overall picture. Therefore, we decided to introduce one more filtering criterion to identify projects with extensive code removal operations at the end of their lifespans and remove them from the sample. We applied linear regression to the last 10% of the projects' lifespans. Figure 7 shows the results of filtering the sample based on the slope of the regression function (RE). We decided to set the filtering threshold for the slope to $RE = -0.5$, however, as follows from the figure, the results were similar for all considered RE values. The final sample included **31,343** out of the 35,890 initially fetched repositories.

D. The Pareto principle

The analysis of the repository content growth for the curated sample of projects (see Figure 7) shows that, on average, monotonically growing OSS projects are uploaded to GitHub with 28.8% of their final content size. Later, their content

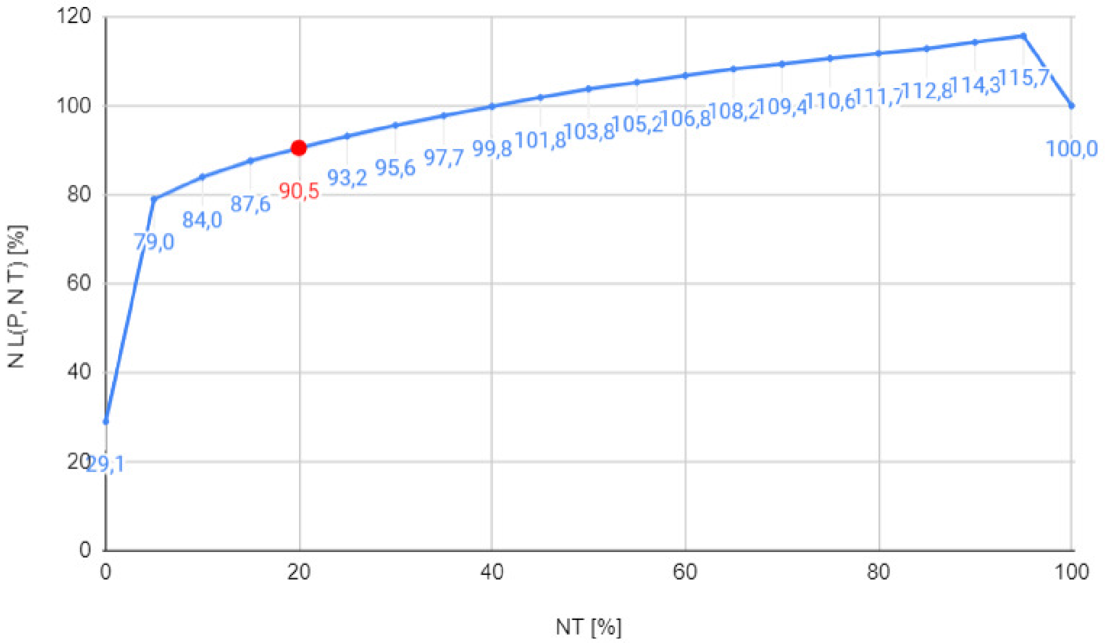

Fig. 6: Aggregated normalized lines count per normalized time expressed in percentage after filtering out the repositories with non-monotonic size growth over time.

size increases dynamically until it reaches ca. 60% of the final content size and over the remaining project lifespan, the repository content increases steadily.

The goal of our study was to investigate a hypothesis that repository content growth for monotonically growing OSS projects is subjected to the Pareto principle. If it is true, we would expect to observe that at the first quintile of the normalized project lifespan, the normalized content size of repositories should be around 80%. The ratio observed in the analyzed sample of projects is 75/25 (on average, 75% of the final repository content size was delivered within the first 25% of normalized project lifespan). Could we accept this observation as a manifestation of the Pareto principle?

As the literature on the Pareto principle suggests, the principle is not strictly bound to the 80/20 proportion. For instance, Dunford, Su, and Tamang [15] state that *"the Pareto Principle is a simplified version of the mathematics behind the Pareto distribution"* and *"the numbers 20 and 80 are not mathematically fixed, but are used as a rule of thumb"*; Boboia and Polinicencu [16] state that *"The 80/20 Rule is not a strict formula. Sometimes the cause-effect relation is closer to the 70/30 ratio than to the 80/20 ratio, but very rarely 50% of the causes lead to 50% of the results."* Therefore, taking into account the results of our study and literature regarding the Pareto principle, we conclude that **the observed 75/25 ratio fits the definition of the Pareto principle and allow us to accept the hypothesis that the content growth over time in monotonically growing OSS repositories is subjected to that principle.**

E. Threats to validity

We identified several threats to validity of our study. The internal validity threats relate to the contents of repositories in the collected sample and their potential impact on the calculated measures, in particular:

- *Extreme sizes of repositories* — our sample may contain repositories that are too small or too large. The size of the repository may indicate inappropriate project content and purpose for our research. To reject such repositories, we used the filtering criteria M3 and M4.
- *Irrelevant repository content* — many of the repositories available on GitHub are toy examples, code snippets, or do not contain any source code. To mitigate the influence of such repositories, we used the curated list of GitHub repositories that are likely to contain "engineered" projects.
- *Non-monotonically growing repositories* — the content of repositories may not be incremental. We used linear regression models to automatically filter out projects with visible deviations in content growth from what we understand to be a monotonically growing project. However, since we were not able to manually inspect each and every project, we should accept the fact that some such projects could be still present in the curated sample.

The external validity regards the possibility of generalizing the results of our study to the whole considered population. First of all, we narrowed the population to monotonically growing OSS projects which gave us better control over the

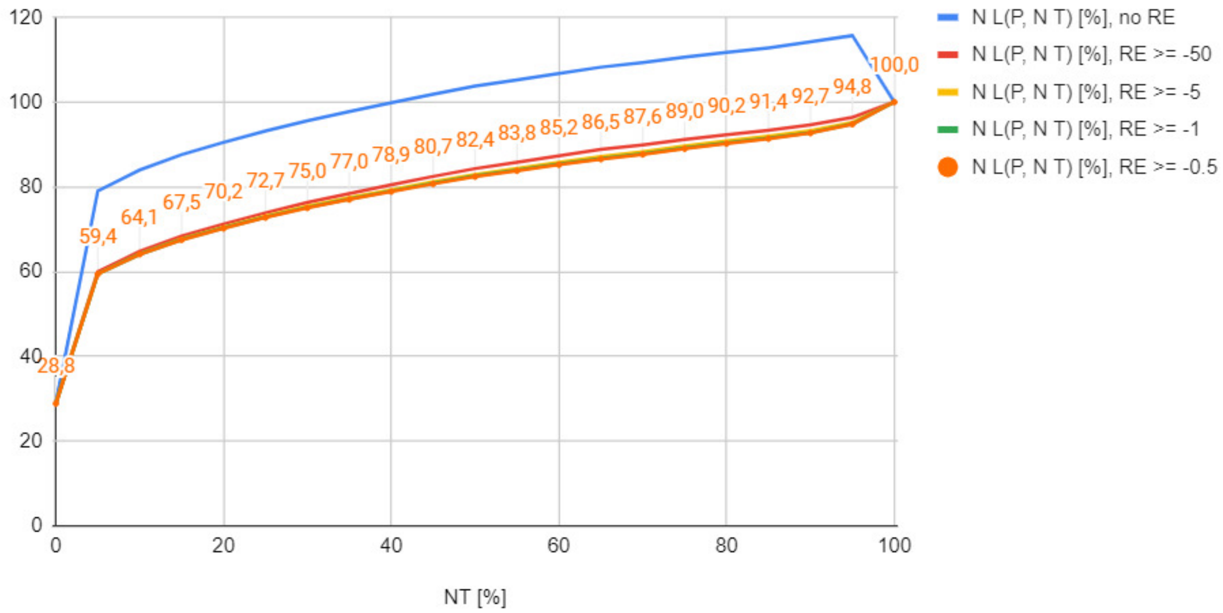

Fig. 7: Aggregated normalized lines count per normalized time expressed in percentage after filtering out the repositories with extensive code-removal actions at the end of their lifespans.

generalizability of our findings (but also narrows it). Secondly, we collected and curated a very large sample of OSS code repositories, which we believe to be a representative sample of the population under study.

V. Conclusions

We analyzed the intensity of OSS repositories' content growth over time to verify a hypothesis that the number of lines in the monotonically growing repositories increases over the project lifespan according to the Pareto principle.

We studied a sample of 31,343 OSS repositories hosted on GitHub and observed that, on average, 75% of the final content size of the repositories is produced within the first 25% revisions in such repositories. Therefore, we claim that this phenomenon is a manifestation of the Pareto principle.

We also observed that monotonically growing OSS projects are, on average, become hosted on GitHub when they already contain 30% of their final code size[6]. Therefore, in many cases, it might be impossible to retrieve the history of code changes for the first ca. 30% of the project's final size. Although studying the causes of this phenomenon was outside of the scope of this study, we suspect that this might be caused by either beginning work on an OSS project as a private project/project hosted outside of the GitHub version control system, or due to the fact that many projects are based on framework skeletons or auto-generated stubs.

The observations made in this study could help to monitor the growth of OSS projects and help to evaluate the current state of such projects.

For future research, we recommend studying the applicability of the Pareto principle to content growth depending on the various sub-criteria such as programming language, community size, etc.

***Abstract*—In this paper we describe polynomial time algorithms for minimizing a separable convex function of the resource usage over time of a set of jobs with individual release dates and deadlines, and admitting a common processing time.**

I. Introduction

IN THIS paper we study variants of the following scheduling problem. There are n jobs $\mathcal{J} = \{J_1, J_2, \ldots, J_n\}$, and a common resource required by a subset of the jobs. Each job J_i has a release date r_i, a deadline d_i, and requires $\mu_i \in \{0, 1\}$ unit of the common resource. All jobs have the same processing time p. A schedule $\mathcal{S}$ specifies a starting time S_i for each job J_i, and it is *feasible*, if $r_i \le S_i \le d_i - p$ holds for each job J_i.

The goal is to find a feasible schedule $\mathcal{S}$, which minimizes a convex function $f : \mathbb{R}_{\ge 0} \to \mathbb{R}$ of the load of the resource throughout the scheduling horizon, i.e.,

$$\min_{\mathcal{S}} \int_{r_{\min}}^{d_{\max}} f(\ell^{\mathcal{S}}(t))dt,$$

where $r_{\min} = \min_i r_i$ is the earliest release date and $d_{\max} = \max_i d_i$ is the last deadline, and $\ell^{\mathcal{S}}(t)$ is the load of the resource at time point t in schedule $\mathcal{S}$, i.e., $\ell^{\mathcal{S}}(t) = |\{i \mid S_i \le t \le S_i + p, \mu_i = 1\}|$.

A variant of this problem, where $p = 1$, $\mu_i = 1$ for all $J_i \in \mathcal{J}$, and for each job J_i a subset of time slots $D_i \subset \mathbb{Z}_+$ is given, rather than an interval $[r_i, d_i]$, is known as the *load balancing problem* and it has been extensively studied by several authors, see e.g., [9], [10], [6]. As it is established in all these papers, this special case has some very nice properties: (i) there always exists a universally optimal solution $\mathcal{U}$, which is optimal for any convex function f of the load $\ell^{\mathcal{U}}$, and (ii) if a schedule $\mathcal{S}$ is *not* optimal, then there exists a pair of time slots $t_0, t_1 \in \mathbb{Z}$, such that $\ell^{\mathcal{S}}(t_0) \ge \ell^{\mathcal{S}}(t_1) + 2$ along with a subset of jobs, which can be rescheduled such that the load of t_0 decreases by one, while the load t_1 increases by one, and the load of all other time slots do not change. The convexity of f ensures that the objective function value of the new schedule is smaller than that of $\mathcal{S}$. Yet another variant is when the jobs have arbitrary integer processing times, but the preemption is allowed, i.e., the processing of any job can be interrupted and resumed later. This variant is studied in [8]. The authors have shown that the above two properties of optimal solutions are preserved. Drótos and Kis [7] study the following resource leveling problem. There is a set of m machines, a set of renewable resources, and a set of n jobs associated with release times, deadlines and resource requirements, each pre-assigned to one of the machines. The jobs have to be sequenced on the machines, while minimizing the sum of the convex functions of the loads of the resources over time. They show that if the starting times of all tasks on all but one machines are fixed, the problem is NP-hard. However, if the ordering of tasks on the remaining machine is also given, then a polynomial time algorithm exists. They also give a heuristic as well as exact branch-and-bound algorithm for solving the problem.

The above scheduling problem can be extended to parallel machine problems, where the jobs have to be assigned to machines, and the jobs assigned to the same machine have to be sequenced. The latter problem was introduced by Blazewicz [4], where all jobs have processing time $p = 1$, and require 0 or 1 unit of a common resource of capacity c. In a feasible solution the jobs are scheduled between their release dates and deadlines, and at most m jobs are processed concurrently, where m is the number of the parallel machines. Moreover, at most c jobs of resource requirement 1 are processed in parallel at any time. Blazewicz described a proprietary polynomial time algorithm for deciding whether a feasible schedule exists. This problem can be reformulated as a scheduling problem with a separable convex cost function. We define a piecewise-linear convex function f as follows: $f(x) = 0$ for $x \le c$ and $f(x) = x - c$ for $x \ge c$. It is easy to see that there is a feasible schedule in which at most c jobs with resource requirement 1 are scheduled concurrently if and only if there exists a feasible schedule of cost 0 w.r.t function f.

In this paper, we deal with two variants of the scheduling

problem with non-preemptive jobs, all of processing time p:

Problem P_1. All jobs require one unit of the common resource, i.e., $\mu_i = 1$ for each job J_i, and the common processing time p is arbitrary positive integer.

We will show by way of an example that in unlike the load balancing problem with $p = 1$, for general p, there is no universally optimal solution (Section III). Furthermore, improving a non-optimal schedule may be far more complicated than in the case with unit length jobs. We will reduce the problem to a minimum cost circulation problem with convex cost functions on the arcs in an appropriately defined network, which permits the application of efficient combinatorial methods for finding optimal solutions (Section IV).

Problem P_2. Only a subset of the jobs require one unit of the common resource, and $p = 1$. In addition, there are m machines (resources of unit capacity), and each job has to be assigned to one of the machines. The jobs assigned to the same machine must be processed in non-overlapping time slots.

We describe a network-flow based method with convex cost functions on the arcs in Section V. As a by-product, our method can also answer the decision problem of [4].

II. Related work

We have already summarized the most relevant results on load balancing, resource leveling, and deadline scheduling of jobs on parallel machines using a bounded capacity resource in the introduction. In the following we focus on parallel machine scheduling problems with equal job processing times.

Brucker and Kravchenko [5] investigate the problem where equal-length jobs have to be scheduled on m identical parallel machines. For each job, a release time and a deadline is given. They present a polynomial time algorithm that finds a feasible schedule and minimizes the weighted sum of the completion times. Their method is based on an integer programming formulation of the problem, solving the linear relaxation and rounding the solution appropriately. A similar problem is considered by Kravchenko and Werner [12], but the time interval between the earliest release date and the latest deadline is divided into several smaller intervals, and for each of them, the number of available machines is given. They present a linear programming approach to find a feasible schedule that minimizes the maximum number of machines used by the jobs. Further results can be found in [2], [3], and for a survey, see [13].

III. Properties of optimal solutions

In the introduction we emphasized that the load balancing problem with common job processing time $p = 1$ admits a universally optimal solution, i.e., one which is optimal for any convex cost function. The following example shows that for $p > 1$ this is not the case by providing two different convex functions with two different unique optimal solutions.

Example III.1. *There are 9 jobs, where J_1 and J_2 have release dates $r_1 = r_2 = 0$ and deadlines $d_1 = d_2 = 5$, and J_3 through J_8, have release dates $r_3 = \cdots = r_8 = 5$ and deadlines $d_3 = \cdots = d_8 = 10$. Furthermore, job J_9 has release date $r_9 = 0$ and deadline $d_9 = 14$. The processing time of all the jobs is $p = 5$. Notice that in a feasible schedule, the place of jobs $J_1, \ldots, J_8$ is fixed: J_1 and J_2 are processed from 0 to 5, and $J_3, \ldots, J_8$ are processed from 5 to 10. The feasible schedules differ only in the starting time of J_9. Firstly, we want to minimize the function $f_1(x) = x^2$ of the load. It is not difficult to check that in the optimal solution, J_9 is processed in the interval $[9, 14]$. Let S_1 denote this solution, and the cost of S_1 is $5 \cdot 2^2 + 4 \cdot 6^2 + 7^2 + 4 \cdot 1^2 = 217$. We get a feasible, but not optimal solution by processing J_9 in $[0, 5]$. Let S_2 denote the solution we get in this way. The cost of S_2 with respect to f_1 is $5 \cdot 3^2 + 5 \cdot 6^2 = 225 > 217$, and indeed, S_2 is not an optimal solution w.r.t. f_1. Now consider the convex function $f_2(x) = 0$ for $x \leq 6$, and $f_2(x) = x - 6$ for $x \geq 6$. It is easy to show that S_2 is the only optimal solution w.r.t. f_2.*

The example above suggests that the approaches for $p = 1$ may not be straightforwardly generalized for $p > 1$.

IV. A combinatorial approach for problem P_1

We first give a linear programming formulation of problem P_1 in Section IV-A. Then, we show that the problem can be equivalently described as a minimum-cost circulation problem in a network with piecewise-linear convex cost functions on the arcs (Sections IV-B), and how to determine an optimal solution for our scheduling problem from an optimal circulation in Section IV-C. Finally, based on these results, we propose a new combinatorial algorithm for a parallel machine scheduling problem (Section IV-D).

A. Initial problem formulation and solution method

Firstly, we introduce additional notation. Let $\mathcal{I} = \{I_1, I_2, \ldots, I_L\}$ be the set of all different time slots of length p in

$$\bigcup_{i=1}^{n} \left(\{[r_i + kp, r_i + kp + p] \mid k \in \mathbb{Z},\ r_{\min} \leq r_i + kp \leq d_{\max} - p\}\right.$$
$$\left.\cup \{[d_i + kp, d_i + kp + p] \mid k \in \mathbb{Z},\ r_{\min} \leq d_i + kp \leq d_{\max} - p\}\right).$$

The following lemma states an important property about the structure of an optimal schedule, and it generalizes Lemma 3 of [2].

Lemma 1. *There is an optimal schedule, where each job is processed in one of the intervals in $\mathcal{I}$.*

Proof. Suppose the statement of the lemma does not hold for a problem instance with jobs $\mathcal{J}$ and processing time p. Let $\mathcal{S}^*$ be an optimal schedule such that the number of jobs which are not scheduled in some time slot in $\mathcal{I}$ is minimal. Let H be the subset of all those jobs that are not scheduled in some time slot in $\mathcal{I}$ by $\mathcal{S}^*$.

Let $\delta \in \mathbb{R}^{n+1}$ be a vector representing the load of the resource in $\mathcal{S}^*$, that is, for $\ell \in \{0, \ldots, n\}$, δ_ℓ equals the total size of time intervals in which the load of the resource is ℓ. Clearly, $\sum_{\ell=0}^{n} \ell \cdot \delta_\ell = n \cdot p$, and the cost of $\mathcal{S}^*$ is $\sum_{\ell=0}^{n} f(\ell)\delta_\ell$.

Let $\epsilon > 0$ be the smallest value such that starting all the jobs in H by ϵ time earlier, or later, at least one of the jobs in

H is scheduled in a time slot $I \in \mathcal{I}$. Let $\mathcal{S}_1$ be the resulting schedule. Such a shift induces a vector $\mu \in \mathbb{R}^{n+1}$ such that $\delta + \mu$ represents the load of the resource in schedule $\mathcal{S}_1$.

The cost of the schedules $\mathcal{S}^*$ and $\mathcal{S}_1$ are related by

$$cost(\mathcal{S}_1) = cost(\mathcal{S}^*) + \Delta,$$

where $\Delta = \sum_{\ell=0}^{n} f(\ell)\mu_\ell$.

Since $\sum_{\ell=0}^{n} \ell \cdot \mu_\ell = 0$ must hold, $\delta - \mu$ also represents the resource usage of some feasible schedule $\mathcal{S}_2$, namely, the one obtained by shifting all jobs in H in the opposite direction by ϵ. The cost of $\mathcal{S}^*$ and $\mathcal{S}_2$ are related by

$$cost(\mathcal{S}_2) = cost(\mathcal{S}^*) - \Delta.$$

Unless $\Delta = 0$, this implies that $\mathcal{S}^*$ is not optimal. Hence, $\Delta = 0$, and $\mathcal{S}_1$ is an optimal schedule in which some job in H is scheduled in a time slot in $\mathcal{I}$, which contradicts the choice of $\mathcal{S}^*$. □

Let $\mathcal{C} = \{c_0, c_1, \dots, c_H\}$ be the ordered set of all different left and right endpoints of $I_1, I_2, \dots, I_L$ such that $c_0 = r_{\min}$ and $c_H = d_{\max}$. Let K_h denote the interval $[c_{h-1}, c_h]$ for $h = 1, \dots, H$.

For any subset X of the jobs, let $N(X)$ consist of all those time slots $I_k \in \mathcal{I}$, which are feasible for at least one of the jobs in X, that is, $N(X) = \{I_k \mid I_k \subseteq [r_i, d_i]$ for some $J_i \in X\}$. We say that $N(X)$ is *connected* if the time slots in $N(X)$ are consecutive. Let $\mathcal{X}$ denote those subsets X of $\mathcal{J}$ such that $N(X)$ is connected.

In our formulation we have the following three types of variables:

- x_k: the number of jobs processed in time slot I_k;
- b_X: the number of jobs scheduled in the time slots $N(X)$;
- t_h: the number of jobs that require the resource in K_h, that is, $t_h = \sum_{I_k \supset K_h} x_k$.

Consider the following mathematical program:

$$\text{minimize} \sum_{h=1}^{H} |K_h| f(t_h)$$

$$\begin{aligned}
&\text{s.t.} && \sum_{I_k \in N(X)} x_k - b_X = 0, \quad \text{for all } X \in \mathcal{X} && (1)\\
& && b_X \geq |X|, \quad \text{for all } X \in \mathcal{X} && (2)\\
(IP): & && b_{\mathcal{J}} = n && (3)\\
& && \sum_{k: I_k \supseteq K_h} x_k - t_h = 0, \quad \text{for each interval } K_h && (4)\\
& && x_k \geq 0, \quad \text{for all } k = 1, \dots, L && (5)\\
& && x_k \in \mathbb{Z}, \quad \text{for all } k = 1, \dots, L. && (6)
\end{aligned}$$

Note that $|K_h| = c_h - c_{h-1}$, while $|X|$ denotes the cardinality of X. In order to show that (IP) is a proper formulation for problem P_1, we define the bipartite graph $G_{(x,b,t)} = (V_{\mathcal{I}} \cup V_{\mathcal{J}}, E)$ for a feasible solution (x, b, t) of (IP). For each job $J \in \mathcal{J}$, $V_{\mathcal{J}}$ contains a unique node v_J, and for each time slot $I_k \in \mathcal{I}$, $V_{\mathcal{I}}$ contains x_k nodes $v_k^{(1)}, \dots, v_k^{(x_k)}$ corresponding to I_k. For each job J_i and $I_k \subset [r_i, d_i]$, E contains the edge $(v_{J_i}, v_k^{(l)})$ for $l = 1, \dots, x_k$. For any $X \subseteq \mathcal{J}$, let V_X denote the set of nodes $\{v_J \mid J \in X\}$, and $N(V_X)$ the set of time slot nodes adjacent to any node in V_X in $G_{(x,b,t)}$. Then, constraints in (1) and (2) ensure that for any subset of jobs $X \in \mathcal{X}$, $N(V_X) \geq |V_X|$. The following result shows that this condition holds for all nonempty subsets of the nodes, not only for those in $\mathcal{X}$.

Lemma 2. *Let (x, b, t) be a feasible solution to (IP). Then, for every nonempty subset X of the jobs $\mathcal{J}$, $|N(V_X)| \geq |V_X|$.*

Proof. Let $X \subseteq \mathcal{J}$ be arbitrary subset of the jobs and let V_X denote the corresponding subset of nodes in $V_{\mathcal{J}}$. Let $N(V_X) \subseteq V_{\mathcal{I}}$ denote the nodes that are adjacent to at least one node in V_X. Then $N(V_X)$ can be partitioned into $N(V_{X_1}), N(V_{X_2}), \dots, N(V_{X_r})$ such that $X = X_1 \cup X_2 \dots \cup X_r$, the X_l are disjoint and $N(X_l)$ is connected for each $l = 1, \dots, r$. Since (x, b, t) is a feasible solution to (IP), $|N(V_{X_i})| \geq |V_{X_i}|$ holds for all $i = 1, 2, \dots r$ and $|N(V_X)| \geq |V_X|$ follows. □

Constraint (3) ensures $|V_{\mathcal{J}}| = n$, therefore, we have:

Lemma 3. *Let (x, b, t) be a feasible solution to (IP). Then $G_{(x,b,t)}$ admits a perfect matching.*

Proof. It follows from Lemma 2 and from the well-known theorem of Hall (see e.g. [1]). □

The following result shows how to map feasible solutions of (IP) to feasible schedules of the same cost and vice versa.

Lemma 4. *For any feasible solution (x, b, t) of (IP), there is a feasible schedule, where x_k jobs are processed in time slot I_k and the load of the interval K_h is t_h. Conversely, from every feasible schedule, where the jobs are scheduled in the time slots of $\mathcal{I}$, one can obtain a solution (x, b, t) of the same cost satisfying (1) - (6).*

Proof. To prove the first part of the lemma, suppose (x, b, t) satisfies (1) - (6). Then by Lemma 3, $G_{(x,b,t)}$ admits a perfect matching M. If $(v_J, v_I) \in M$, schedule job J in time slot I. Then for any $I_k \in \mathcal{I}$, the number of jobs processed in I_k is the number of nodes in $V_{\mathcal{I}}$ representing I_k which is exactly x_k. t_h represent the load of interval K_h in the solution by eq. (4), therefore, the load of K_h is t_h in the schedule.

To show the second part, let $\mathcal{S}$ denote a feasible schedule. For all time slots $I_k \in \mathcal{I}$, let x_k denote the number of jobs processed in I_k, and for each interval K_h, $h = 1, \dots, H$, let t_h denote the number of jobs that are executed during K_h. For an arbitrary $X \in \mathcal{X}$, let b_X denote the total number of jobs that are processed in the time slots of $N(X)$. Then (x, b, t) satisfies (1) - (6) and it has the same cost as $\mathcal{S}$. □

The following statement shows how to map optimal solutions (x, b, t) to perfect matchings in $G_{(x,b,t)}$, and vice versa.

Proposition 1. *If (x, b, t) is an optimal solution to (IP), then any perfect matching in $G_{(x,b,t)}$ corresponds to an optimal*

Algorithm 1 Calculation of optimal schedule

```
Require: $n \geq 0$, $p \geq 1$, $\{r_i, d_i\}$ for $i = 1, \ldots, n$, function $f$
Ensure: Optimal schedule $\mathcal{S}$;
1: Solve $(IP)$, and let $(x, b, t)$ be an optimal solution;
2: Define the graph $G_{(x,b,t)}$, and find a perfect matching $M$ in it;
3: Construct schedule $\mathcal{S}$ by assigning the jobs to the time slots as specified by $M$;
```

schedule. Conversely, any optimal schedule $\mathcal{S}$ induces an optimal solution (x, b, t) to (IP).

Proof. Follows easily from Lemma 3 and Lemma 4. □

By Proposition 1, we can solve the scheduling problem by Algorithm 1: Since finding a perfect matching in a bipartite graph can be done in polynomial time [1], it remains to solve (IP) efficiently. In the remainder of this section, we sketch our approach for solving (IP) in polynomial time by a combinatorial method based on network flows.

Firstly, we observe that the size of (IP) can be polinomially bounded in the size of the input.

Lemma 5. *The size of the linear system (1)-(6) is polynomial in the size of the input.*

Proof. To prove that the size of system (1)-(6) is polynomial in the size of the input, it is enough to show that the number of constraints in (2) and (4) is polynomial in the input size. Observe that $L = |\mathcal{I}|$ is $\mathcal{O}(n^2)$. All $X \in \mathcal{X}$ can be obtained the following way. One can construct $\mathcal{O}(L^2)$ possible connected $N(X)$ sets of time slots by determining the earliest and latest time slot. Then it remains to check whether there is an $X \subseteq \mathcal{X}$ such that $N(X)$ is exactly the set of time slots feasible for at least one jobs in X. Therefore $|\mathcal{X}|$ is polynomial in L. There are H intervals K_h and the endpoints of each of them coincide with endpoints of time slots in $\mathcal{I}$, therefore $H = \mathcal{O}(L)$ and the number of constraints in (4) is polynomial in the input size. □

Since we are only interested in the values of f at integer loads only, we can replace f with a piecewise linear convex function $\tilde{f}$ with integer break points, where $\tilde{f}(z) = f(z)$ for all $z \in \mathbb{Z}_{\geq 0}$. Furthermore, one can assume that the first break point of $\tilde{f}$ is at 0 and the last one is at most n, since there are n jobs. It is not difficult to see that for such an $\tilde{f}$, the optimal value of (IP) coincides with the optimal value of

$$(IPWL): \qquad \text{minimize} \sum_h |K_h| \tilde{f}(t_h) \quad \text{s.t. } (1) - (6).$$

In fact, the matrix of (1) - (6) is totally unimodular, see Lemma 6, which permits to get rid of the integrality condition (6) by a result of Meyer. Meyer [14] has shown that an optimization problem with a separable piecewise linear convex cost function with integer break points, and a totally unimodular constraint matrix always admits and integer optimal solution. This means that in (IPWL) we can drop constraint (6), while preserving integer optimal solutions:

$$(PWL): \qquad \text{minimize} \sum_h |K_h| \tilde{f}(t_h) \quad \text{s.t. } (1) - (5).$$

Karzanov and McCormick [11] describe efficient polynomial time algorithms for minimizing a separable convex cost function over the linear space $Mx = 0$, provided M is a totally unimodular matrix. More specifically, for every coordinate x_e of x, there is a convex function $w_e : \mathbb{R} \to \mathbb{R}$. If E is the set of coordinates of x, the problem is to find x such that $Mx = 0$, while $\sum_{e \in E} w_e(x_e)$ is minimized. It is assumed that $\{x : Mx = 0\}$ contains a non-zero point and the minimization problem has a finite optimal solution. The authors have shown how to solve the problem efficiently for different classes of convex functions, assuming there is an oracle that solves the following problems:

1) given a point $r \in \mathbb{R}$, return $c_e^{\vdash}(r)$ and $c_e^{\dashv}(r)$, where $c_e^{\vdash}(r)$ and $c_e^{\dashv}(r)$ are the right and left derivatives of w_e at r. The convexity of w_e implies the existence of the right and left derivatives;
2) given a slope $s \in \mathbb{R}$, return a point r with $c_e^{\dashv}(r) \leq s \leq c_e^{\vdash}(r)$.

In the case of piecewise linear convex functions, such an oracle is easy to implement.

Karzanov and McCormick proposed two different algorithms for solving such problems: the Minimum Mean Canceling Method (MMCM) and the Cancel and Tighten algorithm. Both methods are iterative, and in general case, these algorithms involve solving linear programs in each iteration. Although the number of iterations is polynomial in the size of the input, the running time is not as impressive due to solving linear programs. However, when $\{x : Mx = 0\}$ is the space of circulations in a graph G (that is, M is the node-edge incidence matrix of G), then there is no need to solve linear programs, and each iteration of the Cancel and Tighten algorithm takes $\mathcal{O}(|E(G)| \log |V(G)|)$ time, and the total number of iterations is $\mathcal{O}(|V(G)| \log(|V(G)|C))$, where C denotes the absolutely largest finite slope. The impressive running time motivates the question whether our problem can be reformulated as a minimum cost circulation problem in a network with piecewise-linear convex cost functions on the arcs.

B. Reformulation as a circulation problem in a network

First of all, observe that in the objective function of (PWL), we have convex functions only for variables t_h, and the system has lower or upper bound constraints for variables x_k and b_X. The function corresponding to t_h is $|K_h|\tilde{f}(\cdot)$. The breakpoints of $\tilde{f}(\cdot)$ are $0, 1, \ldots, n$, and the slopes between these breakpoints are $s_l = |K_h|(\tilde{f}(l) - \tilde{f}(l-1))$ for $l = 1, \ldots, n$, noting that $s_1 \leq s_2 \leq \cdots \leq s_n$, since $\tilde{f}$ is convex (if $s_l = s_{l+1}$ then

b_l is not a real breakpoint, but it is not a problem). Then we have

$$w_h(z) = \begin{cases} |K_h|\tilde{f}(0) + s_1 z & \text{if } 0 \le z \le 1 \\ |K_h|\tilde{f}(1) + s_2(z-1) & \text{if } 1 \le z \le 2 \\ \dots & \\ |K_h|\tilde{f}(n-1) + s_n(z-n+1) & \text{if } n-1 \le z. \end{cases}$$

It is not difficult to show that we get an equivalent problem by introducing convex cost functions w_k and w_X for the variables x_k and b_X and moving the lower and upper bound constraints to w_k and w_X the following way. Let K be a sufficiently large positive number. Since we want a variable x_k to be non-negative, w_k has a breakpoint at 0 and the slope before 0 is $-K$ and the slope after 0 is 0, that is

$$w_k(z) = \begin{cases} -Kz & \text{if } z \le 0 \\ 0 & \text{if } z \ge 0. \end{cases}$$

Similarly, if $X \neq \mathcal{J}$, w_X has a breakpoint at $|X|$ and the slope before $|X|$ is $-K$ and after $|X|$ is 0, i.e.,

$$w_X(z) = \begin{cases} -K(z-|X|) & \text{if } z \le |X| \\ 0 & \text{if } z \ge |X|. \end{cases}$$

If $X = \mathcal{J}$, w_X has a breakpoint at n and the slope before n is $-K$ and after n it is K, that is

$$w_{\mathcal{J}}(z) = \begin{cases} -K(z-n) & \text{if } z \le n \\ K(z-n) & \text{if } z \ge n. \end{cases}$$

Therefore, (PWL) can be reformulated as

$$\begin{aligned} &\text{minimize} \sum_{k=1}^{L} w_k(x_k) + \sum_{X \in \mathcal{X}} w_X(b_X) + \sum_{h=1}^{H} w_h(t_h) \\ &\quad\text{s.t.} \\ (PWL2): &\sum_{I_k \in N(X)} x_k - b_X = 0 \quad \text{for all } X \in \mathcal{X}; \\ &\sum_{k: I_k \supseteq K_h} x_k - t_h = 0 \quad \text{for all intervals } K_h. \end{aligned}$$

The following lemma plays a crucial role in our method.

Lemma 6. *Let M denote the matrix of the following system:*

$$\sum_{I_k \in N(X)} x_k - b_X = 0 \quad \textit{for all } X \in \mathcal{X};$$

$$\sum_{k: I_k \supseteq K_h} x_k - t_h = 0 \quad \textit{for all intervals } K_h.$$

Then M^T is a network matrix.

Proof. Observe that M can be written as $M = (A, -I)$, where $A \in \mathbb{R}^{a \times L}$ is an interval matrix and $-I \in \mathbb{R}^{a \times a}$ is a negative identity matrix, where $a = |\mathcal{X}| + H$ is the number of constraints in (1) and (4). Therefore if y is a column of M^T, then y has some 1 entries in consecutive positions in the first L coordinates, and in the remaining a coordinates, y has a unique -1 entry. All other coordinates of y are 0. We construct a network D with a spanning tree T and show that each non-tree edge corresponds to a column of M.

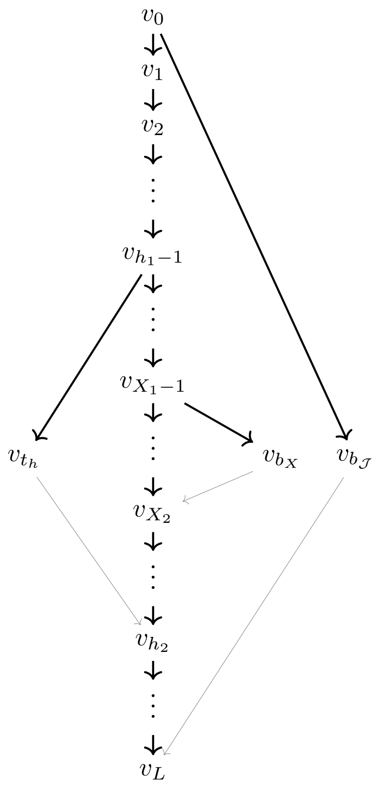

Fig. 1: Network D. Thin arcs correspond to non-tree edges, thick arcs are the edges of T.

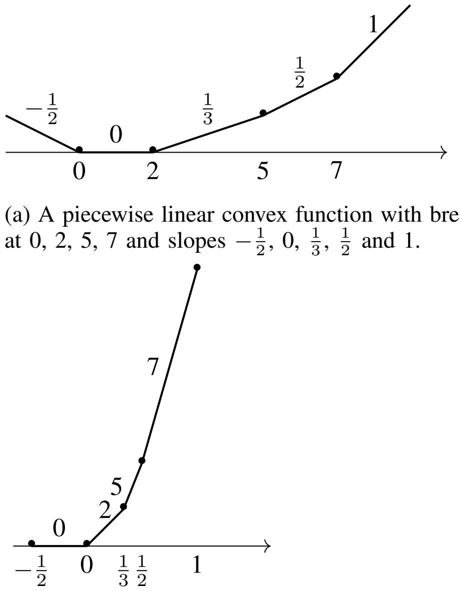
Let $P = v_0 \to v_1 \to \cdots \to v_L$ denote a directed path of length L, where the kth edge $v_{k-1} \to v_k$ represents the kth p-length time slot I_k, and we say it corresponds to variable x_k. At the beginning, $D = P$ and $T = P$. Then we add new nodes and edges to D and T the following way: we take all constraints from (1) and (4) one by one, and for each of them, we connect nodes representing the first and the last time slot in the constraint with a new path of length 2. More precisely, consider constraints in (1) and suppose equation $\sum_{I_k \in N(X)} x_k - b_X = 0$ is one of them. We add a new node denoted by v_{b_X}. Let X_1 denote the index of the first time slot and X_2 the index of the last time slot in $N(X)$. We add edges $v_{X_1-1} \to v_{b_X}$ and $v_{b_X} \to v_{X_2}$. We extend T with the first new edge $v_{X_1-1} \to v_{b_X}$, and we say the tree edge $v_{X_1-1} \to v_{b_X}$ corresponds to variable b_X. The other new edge $v_{b_X} \to v_{X_2}$ becomes a non-tree edge. We proceed similarly with equations in (4) of the form $\sum_{k: I_k \supseteq K_h} x_k - t_h = 0$: we connect the first and the last time slot in $I_k : I_k \supseteq K_h$ with a 2-length path containing two new edges and extend T with the first new edge in the same way as before. Fig. 1 illustrates the network constructed this way. It is not difficult to check that a column in M^T corresponding to a constraint from (1) or (4) is represented by a non-tree edge in the network. □



(a) A piecewise linear convex function with breakpoints at 0, 2, 5, 7 and slopes $-\frac{1}{2}$, 0, $\frac{1}{3}$, $\frac{1}{2}$ and 1.

(b) The dual piecewise linear convex function. The breakpoints are the slopes and the slopes are the breakpoints of the function in Fig. 2a.

Fig. 2: A piecewise linear convex function and its dual.

For simplicity, tree edges in D corresponding to variables x_k, b_X and t_h are denoted by e_{x_k}, e_{b_X} and e_{t_h}. In the next part, we dualize the problem and solve the dual problem instead of the original primal formulation. To this end, we need dual variables for non-tree edges represented by the rows of M. For a non-tree edge, let z_X denote the corresponding dual variable if the edge derives from a constraint in (1), and let z_h be the dual variable if it derives from a constraint in (4). For a non-tree edge e, let C_e denote the tree edges in e's fundamental cycle.

In order to obtain the dual of $(PWL2)$, we have to determine the duals of the functions w_k, w_X and w_h, respectively. It is known (see e.g. [11]) that the dual $\tilde{f}^*(\cdot)$ of a piecewise-linear convex function $\tilde{f}(\cdot)$ is obtained by exchanging the slopes and breakpoints of $\tilde{f}$, that is, the slopes of $\tilde{f}$ will be the breakpoints of $\tilde{f}^*$ and the breakpoints of $\tilde{f}$ will be the slopes $\tilde{f}^*$, see Fig. 2 for an illustration.

The dual functions of w_X, w_k and w_h are denoted by w_X^*, w_k^* and w_h^*, respectively, and these functions have the following forms.

If $X \neq \mathcal{J}$, we have

$$w_X^*(z) = -|X|z, \qquad 0 \le z \le K,$$

and if $X = \mathcal{J}$,

$$w_X^*(z) = -nz, \qquad -K \le z \le K.$$

For w_k^*, we have

$$w_k^*(z) = 0, \qquad z \ge 0,$$

and finally w_h^* can be written as

$$w_h^*(z) = \begin{cases} 0, & \text{if } z \le s_1, \\ z - s_1, & \text{if } s_1 \le z \le s_2, \\ -s_1 + s_2 + 2(z - s_2) & \text{if } s_2 \le z \le s_3, \\ \dots & \\ -\sum_{i=1}^{r-1} s_i + (r-1)s_r + & \\ \quad r(z - s_r), & \text{if } s_r \le z \le s_{r+1}, \\ \dots & \\ -\sum_{i=1}^{n-1} s_i + (n-1)s_n + & \\ \quad n(z - s_n), & \text{if } z \ge s_n. \end{cases}$$

Using w_X^* and w_h^*, the dual of $(PWL2)$ can be concisely expressed as follows:

$$\begin{aligned} & \text{minimize} \sum_{X \in \mathcal{X}} w_X^*(z_X) + \sum_{h=1}^{H} w_h^*(-z_h) \\ & \text{s.t.} \\ & \qquad \sum_{e_{b_X}: e_{x_k} \in C_{e_{b_X}}} z_X + \sum_{e_{t_h}: e_{x_k} \in C_{e_{t_h}}} z_h + \lambda_k = 0, \\ (DP) \quad & \qquad \lambda_k \ge 0, \ \text{for all } k = 1, \dots, L \\ & \qquad 0 \le z_X \le K, \quad \text{for all } X \in \mathcal{X}, \ X \neq \mathcal{J} \\ & \qquad -K \le z_{\mathcal{J}} \le K. \end{aligned}$$

Notice that the lower bound for λ_k coincides with the left endpoint of the domain of w_k^*, and the lower and upper bounds for z_X and $z_{\mathcal{J}}$ coincide with the left and right endpoints of the domain of w_X^* and $w_{\mathcal{J}}^*$.

Since the matrix of problem $(PWL2)$ is the transpose of a network matrix, (DP) is a network circulation problem, the only problem with it is that in the objective function we have $w_h^*(-z_h)$, i.e., the negative of z_h is substituted in the convex function w_h^*. However, it is easy to overcome this issue by reversing the arcs e_{t_h}. So, our final network has the same set of nodes and arcs as D, except that the arcs e_{t_h} are directed oppositely. For an edge e_{x_k}, the lower bound for the flow value λ_k is 0 and there is no upper bound, while the cost is 0. For an edge e_{b_X}, let the cost function be the piecewise linear w_X^* and if $X \neq \mathcal{J}$, the lower bound is 0 and the upper bound is K, and when $X = \mathcal{J}$, the lower bound is $-K$ and the upper bound is K. For an edge e_{t_h}, we have no lower or upper bounds and the cost function is the piecewise linear w_h^*. There are no lower or upper bounds for the flows on non-tree edges in D, and the cost function is 0.

Proposition 2. *The minimum cost circulation problem defined above is equivalent to the problem (DP). The cost of a minimum cost circulation is equal to the optimal value of (DP).*

The minimum cost circulation problem defined above can be solved by the Cancel and Tighten method described in [11]. Remember, the number of iterations is $\mathcal{O}(|V(G)| \ \log(|V(G)|C))$, and one iteration takes

$\mathcal{O}(|E(G)| \log |V(G)|)$ time. Observe that $C = \mathcal{O}(n)$ holds in our case. It can be assumed that the length of the scheduling horizon $d_{\max} - r_{\min}$ is at most $2np$. Therefore, the number of different p-length time slots is $\mathcal{O}(n^2)$, and the number of constraints in (1) and (4) is $\mathcal{O}(n^4)$. Hence, $|V(G)| = \mathcal{O}(n^4)$ and $|E(G)| = \mathcal{O}(n^4)$ in our case.

C. Solution of the primal problem $(PWL2)$

By Proposition 2, an optimal solution to (DP) can be obtained by solving a minimum cost network circulation problem with convex cost functions on the arcs, using an algorithm of [11]. It remains to show how to determine the primal optimal solution for $(PWL2)$. Since the dual space of circulations is the space of co-circulations, the optimal primal solution is represented by an appropriate co-circulation. One can read out the following lemma from [11].

Lemma 7. *Let x_e^*, $e \in E$ denote an optimal solution to the minimum cost circulation problem. If h_e, $e \in E$ is a co-circulation satisfying $c_e^{\dashv}(x_e^*) \leq h_e \leq c_e^{\vdash}(x_e^*)$ for all $e \in E$, then h_e, $e \in E$ is an optimal solution to the dual problem, where $c_e^{\dashv}$ and $c_e^{\vdash}$ are the corresponding left and right derivatives, respectively.*

If an optimal solution x_e^*, $e \in E$ is given, then by Lemma 7, an optimal co-circulation is easy to obtain. For $e \in E$, let u_e and v_e denote the starting and ending node of e, respectively. Then finding a co-circulation satisfying $c_e^{\dashv}(x_e^*) \leq h_e \leq c_e^{\vdash}(x_e^*)$, $e \in E$ is equivalent to finding node potentials π satisfying $\pi(v_e) - \pi(u_e) \leq c_e^{\vdash}(x_e^*)$ and $\pi(u_e) - \pi(v_e) \leq -c_e^{\dashv}(x_e^*)$ for all $e \in E$. Such node potentials π can be found by a shortest path algorithm in the directed graph we get by adding edges $e \in E$ to the graph in reverse direction as well. The edge lengths are $c_e^{\vdash}(x_e^*)$ for edges with original orientation and $-c_e^{\dashv}(x_e^*)$ for edges with reverse orientation. Since $c_e^{\vdash}(x_e^*)$ and $c_e^{\dashv}(x_e^*)$ are integral values in our case, the optimal co-circulation found by a shortest path algorithm is integral as well.

D. Application to a parallel machine scheduling problem to minimize the total completion time of the jobs

In this subsection we show how to apply the previously introduced techniques to a problem investigated by Brucker and Kravchenko [5]. There are n jobs with common processing time p, each of them having a release date and deadline. In addition, there are m identical parallel machines. In a feasible schedule each job is processed between its release date and deadline on one of the machines, and at most m jobs are processed concurrently at any time. The goal is to find a feasible schedule, if one exists, that minimizes $\sum C_i$, where C_i denotes the completion time of J_i.

To begin with, we formulate the problem similarly to (IP). Recall the definitions of the set of time slots $\mathcal{I}$, and set of intervals $\{K_h\}_{h=1,\dots,H}$. Let $C(I_k)$ denote the right endpoint of $I_k \in \mathcal{I}$. Variables x_k, b_X and t_h denote the same quantities as in (IP).
