$$

The objective function (7) expresses the total completion time of the jobs. The rest of the constraints are analogous to that of (IP). For a feasible solution (x, b, t), one can construct a bipartite graph $G_{(x,b,t)} = (V_{\mathcal{I}} \cup V_{\mathcal{J}}, E)$ in the same way as in Section IV-A. Analogously to Lemma 2, one can show that $G_{(x,b,t)}$ admits a perfect matching and Proposition 1 holds. Therefore, the problem can be solved efficiently if one can solve (IP') efficiently. From Lemma 5, it follows that the size of (IP') is polynomial in the size of the input, and similarly to Lemma 6, one can show that the transpose of the matrix of the system is a network matrix. Since the cost functions on the arcs are linear functions of the flows, the dual is a circulation problem with liner costs on the arcs, and a simple minimum cost flow computation finds an optimal solution.

V. A SOLUTION TO PROBLEM P_2

This section is devoted to problem P_2. We aim to schedule the jobs on m parallel machines in a way that the load is as balanced as possible. We deal only with the case, where the processing time of the all jobs is $p = 1$, but the resource requirement of the jobs can be 0 or 1. We show that this problem can be solved by a single minimum cost flow computation in a network with convex costs on the arcs in Section V-A. Then, we apply our formulation to the decision problem of [4] in Section V-B.

A. A network flow formulation to solve P_2

In order to describe a network flow representation of the scheduling problem, we define the time slots for the jobs. Let $\mathcal{I}' = \{I_1, \dots, I_{L'}\}$ be the set of all different unit-length time slots in the set

$$\bigcup_{i=1}^{n} \{[r_i + k, r_i + k + 1] \mid \forall\ k \in \mathbb{Z} \\ \text{s.t. } 0 \leq k \leq \min\{n-1, d_i - r_i - 1\}\}\,.$$

Note that for each job it suffices to consider only the first n unit-length time slots, since there are n jobs. We define the network D' as follows. For every job, there is a job node in

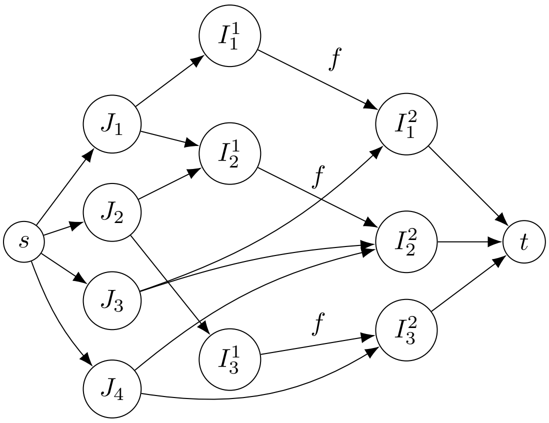

Fig. 3: Network D' for Problem P_2, where jobs J_1 and J_2 require one resource unit and jobs J_3 and J_4 require 0. The cost is measured by the convex function f on three edges, the remaining edges have zero cost.

D'. For simplicity, the job nodes are denoted by $J_1, \ldots, J_n$. For each $I_k \in \mathcal{I}'$, there are two time slot nodes in D' denoted by I_k^1 and I_k^2. Furthermore, there is a source node s and a sink node t. From s, there is an arc to every job node of capacity 1. If J_i requires 1 unit of the resource, that is, $\mu_i = 1$, then there are arcs from J_i to all the nodes I_k^1 such that I_k is feasible for J_i. When $\mu_i = 0$, there are arcs from J_i to all the nodes I_k^2, such that I_k is feasible for the job. All these arcs have infinite capacity. For all $I_k \in \mathcal{I}$, there is an arc from I_k^1 to I_k^2 of infinite capacity, and the cost function on this arc is f. The cost function on all other arcs is 0. Moreover, there is an arc from I_k^2 to t of capacity m. See Fig. 3 for an illustration.

Proposition 3. *The optimal feasible schedules are in one to one correspondence with the integral minimum cost feasible flows, where the total flow leaving s is n.*

Despite of D' having convex costs on some edges, a similar network having only linear costs can be constructed in a similar way as in [8], and the problem can be solved by any minimum cost network flow algorithm.

B. Application to a scheduling problem with a resource of bounded capacity

By choosing the convex function f properly, one can decide the feasibility problem considered by Blazewicz [4] as described in Section I. If c denotes the resource capacity, then let f denote the following piecewise linear function: $f(x) = 0$ if $x \leq c$ and $f(x) = x - c$ if $x \geq c$, where c is the capacity of the resource. Then there exists a feasible schedule using m machines, where each job is processed in a time slot between its release time and deadline if and only if there is feasible flow of zero cost in the previously constructed network D'. Notice that there is no need to solve a flow problem with arc costs. Let the network D'' be obtained from D' by removing all arc costs and setting the capacity of the arcs from I_k^1 to I_k^2 to c. Then we have the following result.

Proposition 4. *The scheduling problem of [4] with a bounded capacity resource admits a feasible solution if and only of the network D'' admits a feasible flow of value n.*

VI. Preliminary computational results

We have implemented Algorithm 1 including the Cancel and Tighten method in C++ for solving Problem P_1 on randomly generated problem instances. The goal of the test runs was to assess how sensitive is the method to two problem parameters: the number of the jobs n, and the ratio of the common processing time and the size of the time windows of the jobs, i.e, $q = p/(d_i - r_i)$. We generated three problem instances for each combination $(n, q) \in \{20, 50, 100\} \times \{0.1, 0.4\}$. The common job processing time was $p = 8$. The time horizon spanned 100 time units, and for each job J_i the release date and deadline satisfied the constraint $r_i \geq 0$, $d_i = \lceil r_i + p/q \rceil$, and $d_i \leq 100$. We used the same piecewise linear convex function f in all cases, where $f(0) = 0$, f has breakpoints at $1, 2, \ldots, n$, and the slope after breakpoint i is i.

The code was compiled with Visual Studio 2019, and the tests were run on a notebook computer with Intel Core I7 processor and Windows 11. We summarize the computational results in Table I. We provide averages (rounded to nearest integers) over 3 problem instances for each combination of the parameters n and q. In each case, we provide the average number of nodes and edges of the network D, the average number of iterations, the average CPU time, and also the average optimum values. All values are rounded to the nearest integers. As we can see, the CPU time strongly correlates with the number of graph edges. On the other hand, the number of iterations lightly increases with the number of the jobs, but for the same number of jobs, it is smaller for $q = 0.4$ than for $q = 0.1$. In fact, this is what we expected, since problem instances with a larger ratio q permit less freedom to choose the starting times of the jobs.

VII. Conclusion

In this paper we gave polynomial algorithms to two load balancing problem. A possible direction for a future research is to investigate a problem slightly more general than Problem P_2. While the common processing time in P_2 is one time unit, it is an interesting question what can be said if the common processing time is greater than one time unit. The complexity of this problem is still open. One possible next step would be to derive an approximation algorithm for the problem.

***Abstract*—This paper addresses the problem of an aerial moving target search with a radar on an airborne platform. An observation of the radar is modeled as a cone covering a set of regions of the search area. We assume overlapping cones of observation, and we want to find the discrete allocation plan of search effort to the cones in order to optimize target detection. For the stationary target search with overlapping cones, we present a dynamic programming algorithm that computes the optimal allocation. An approximate greedy heuristic, which is more appropriate in a real time context, is also presented and assessed. The moving target search problem is solved with the Forward And Backward (FAB) algorithm coupled with the different stationary search algorithms. In this paper, we use a radar detection model that has been shown to be more realistic than the ones usually considered. Also, several models of movement of the target are considered with different Markovian transition matrices. We compare the performance of the mentioned algorithms on several scenarios.**

I. Introduction

SEARCHING for a moving target with a sensor is a complex problem, especially when the search area is large. This has been the subject of much research in the past, as evidenced in literature reviews by Stone [1] and by Rapp [2].

In general, one seeks to optimize an objective related to the probability of detecting one or more moving targets. The search area is discretized into identical regions and a sensor plan is computed over a fixed horizon. All regions are associated with prior probabilities of presence of targets. The probability of detecting targets in a region depends on the amount of search effort invested in it, the visibility of the region, and the probability that targets are present in the region.

Depending on the type of the platform (drone, satellite) or sensor (radar, camera), several approaches exist (see the review in [2] and references included therein). One can try to solve a *path constrained search*, where the subset of regions that will be observed and the order of visit of these consecutive regions must be determined (see [3], [4]). One can instead try to find the quantities of effort (discrete or continuous), constrained by a budget, to allocate independently to each region, at each time step, in order to maximize the probability of detecting the targets over the time horizon considered [1], [5], [6]. The search plan can be computed using the Forward-and-Backward algorithm (FAB) [7], [5], [6], Branch and Bound methods [8], or MILP [9] among others (see [2]).

In the problem we address, the search effort cannot be allocated independently to each region. Indeed, each observation of the radar is characterized by a *cone* that covers a set of regions. Moreover we assume that the cones may overlap, so that a region can be covered by several observation cones. This model applies for 2D as well as for 3D dimensional cones. As pointed out in chapter 14 of [10], an important parameter of the search plan design is *beam search spacing*, that defines the maximum number of consecutive overlapping cones. In this paper, we investigate its role in the efficiency of search plans and algorithms. We consider here discrete search effort on each cone which means we deal with the number of observations.

In [11], the authors consider a similar context for a continuous search effort and propose a customized version of the Forward-And-Backward algorithm to solve it, without proving its optimality. Path search have been considered in [9] where several regions are observed at the same time from each position and a region can be observed from several positions. The solution proposed is a mixed integer programming method. In [12], the authors addressed the problem of a moving target search with a radar where the cones of observation are disjoint: each region is covered by a single cone of observation. They show that for continuous effort the FAB algorithm is still optimal, and adapt the FAB algorithm to the discrete effort case. None of these works address the problem of allocating a discrete search effort to overlapping cones.

Another relevant issue in target search is the detection model. Chapter 2 of [13] presents an extensive literature review on detection models and quotes that in most of the papers the visibility of a region depends only on the distance from the radar. However, one of the main characteristics of radar measurements is that the detection probability also decreases on the borders of an observation cone. Such a model was first proposed in [11]. In this paper we consider a general model where the detection probability of a single observation depends arbitrarily on the region and on the observation cone.

In this work, we address a moving target search with a radar by considering overlapping cones of observation for the allocation of discrete search effort and with a new detection model. Unfortunately, in this case the usual algorithm to optimize the probability of finding a stationary target given by [1] is not optimal. Thus, we face up a combinatorial optimisation problem to compute the optimal quantity of effort to allocate at each time step.

We present a dynamic programming algorithm that finds the optimal allocation of effort for a stationary target search case with overlapping cones of observation. Operational considerations require a short execution time of the algorithm. Therefore, we study different computational heuristics. Among them we propose a greedy algorithm which approximates efficiently the optimal solution. All stationary algorithms are then used in a FAB algorithm to solve the moving target search. We then present numerical experiments to compare the performance of these different algorithms in different scenarios. Among them we consider different models of target movement.

This paper is organized as follows. Section II details the framework of the target search. In Section III we present the dynamic programming algorithm that finds the optimal allocation for a stationary target search while Section IV is devoted to heuristics and an upper bound. We recall the moving target search problem and the FAB algorithm in part V. At last Section VI focuses on the numerical experiments.

II. Framework

The search problem that we consider is the following:

a) the target: An airborne platform faces a search area, which is partitioned into J regions. We assume a single target. The target position is unknown but we assume that we know its movement model. Similarly as in previous works, namely [1], the target moves from one region to another, at each time step $t \in \{0, \dots, T\}$, following a Markovian transition model with some transition function $\pi_t(i,j)$ defined for all pair of regions $i, j \in \{1, \dots, J\}$ and $t = 0, \dots, T$. As soon as we know the prior probability $p_0(j)$ that the target is initially located in a region j, we deduce $p_t(j)$ which is the probability that the target is in region j at time t. A trajectory is a sequence of regions $\omega = (\omega_t)_{t=0,\dots,T}$.

b) the sensor: We also assume a single sensor that observes the search area such that at each time step, it has a budget of observations that it can allocate to one or several angles. An observation made by the sensor in an angle encompasses all the regions covered by the cone defined by the angle and the position of the sensor. We define M_a as the set of regions observed in angle a (see Figure 1) and conversely by Y_j the set of angles covering region j. We say that two angles a, a' overlap if $M_a \cap M_{a'} \neq \emptyset$.

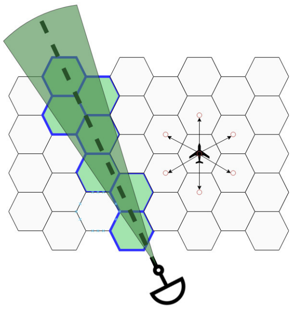

Fig. 1. A single cone of observation and the regions being observed.

We assume that the set of angles A is indexed such that each region of the search area is observable from at least one angle and from at most N consecutive angles. In Figure 2, we present three examples for $N = 1, 2, 3$. The set A is indexed from left to right. In each example, there are four cones of observation and a region indicated by a red circle. The cones that cover the region are represented in green such that an area covered by several green cones appears darker. The other cones of observation are represented in white. For $N = 1$, the search area is partitioned into disjoint cones of observation. For $N = 2$ the red circle is covered by angles 2 and 3, and for $N = 3$, the red circle is covered by angles $1, 2, 3$.

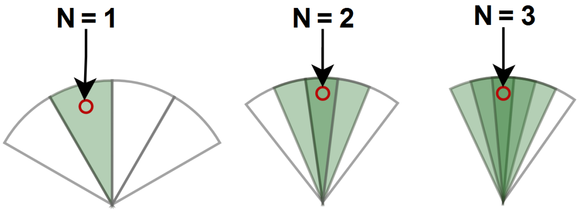

Fig. 2. Example of overlapping cones of observation.

c) the search plan: We define the search plan Z as a matrix of shape $|A| \times (T+1)$. It defines at each time step $t = 0, \dots, T$, an allocation vector $\zeta(t)$ whose components $\zeta_a(t)$ define the number of observations made in the angle a at time t for $a \in A$.

We define $\kappa(a) \in \mathbb{R}^+, \kappa(a) \geq 1$ the cost of investing an effort to the angle a. The cost of an allocation vector $\zeta(t)$ is

$$K(\zeta(t)) = \sum_{a \in A} \zeta_a(t) \cdot \kappa(a) \,.$$

At each time step, we construct an allocation vector $\zeta(t)$ such that its cost is bounded by a budget C_t.

d) The detection model: The range of a radar is not uniform in an observation cone: it is at its highest in the center of the cone and decreases on the borders. In our model, we assume that a region-angle couple (j, a) such that $a \in Y_j$ is associated with a visibility coefficient $\alpha_{j,a} \in [0,1]$ representing the conditional probability of detecting the target in the region j when the sensor makes one observation in the angle a, provided that the target is in the region j. We also assume that the observations are independent.

We call this model "*realistic*": the coefficient depends on the distance of the region to the radar and the angular offset to the center of the observation cone. We also consider in our experiments the usual model where the coefficient only depends on the distance. It is called "*distance*" model. In this case $\alpha_{j,a} = \alpha_j$ for all $a \in Y_j$. Figure 3 illustrates these two models.

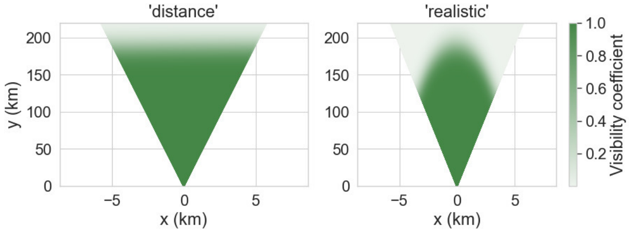

Fig. 3. Two types of detection models in a single cone of observation.

Consider a single time step t of the plan and the allocation of effort vector ζ at this time step (t is omitted in the notation). The detection function $b(j, \zeta)$ is the conditional probability of detecting the target in a region j for an effort vector ζ given that the target is located in j. It can be expressed by the following property:

Property 1 (Detection function)**.**

$$b(j, \zeta) = 1 - \prod_{a \in Y_j} (1 - \alpha_{j,a})^{\zeta_a} . \tag{1}$$

Proof. Let D_j and $\bar{D_j}$ be respectively the events associated with a detection and a non detection of the target in the region j. Let C_j be the event associated with the target located in j. By definition, The detection function in a region is defined as: $b(j, \zeta) = \mathbb{P}(D_j|C_j) = 1 - \mathbb{P}(\bar{D_j}|C_j)$.

Now, we know that for each observation of j in angle a, the probability of missing the target, given it is present, is $1-\alpha_{j,a}$.

So, if ζ_a independent observations are made in angle a, the conditional probability of missing the target in region j, given C_j is $(1 - \alpha_{j,a})^{\zeta_a}$.

Finally, as region j is covered by all angles $a \in Y_j$, and as all observations are independent, the probability $\mathbb{P}(\bar{D_j}|C_j)$ of missing the target, given it is in region j, is $\prod_{a \in Y_j}(1-\alpha_{j,a})^{\zeta_a}$ so that the property hold.

□

When we use the "distance" model, since the value of $\alpha_{j,a}$ is the same for any a in Y_j, then the formula is simplified to

$$b(j, \zeta(t)) = 1 - (1 - \alpha_j)^{\sum_{a \in Y_j} \zeta_a(t)} . \tag{2}$$

e) the objective function: Let $P_t(Z, \omega)$ be the conditional probability of detecting the target before the time horizon t given the target follows the trajectory ω and the allocation plan is Z. $P_t(Z, \omega)$ is defined as follows:

$$P_t(Z, \omega) = 1 - \prod_{s=0}^{t} \big(1 - b(\omega_s, \zeta(s))\big) . \tag{3}$$

As in [1], we consider a generic objective function composed of any linear combination of such probabilities:

$$\hat{P}_T(Z) = \mathbb{E}\left[\gamma_{T+1}(\omega) + \sum_{t=0}^{T} \gamma_t(\omega) \cdot P_t(Z, \omega)\right] . \tag{4}$$

Two remarkable objectives can be formulated by adjusting the coefficients γ_t:

- The maximization of the probability $P_T(Z)$ of detecting the target before the time horizon T by executing the allocation plan Z: ($\gamma_t = 0$ for $t = 0, \ldots, T-1$, $\gamma_T = 1$ and $\gamma_{T+1} = 0$).
- The minimization of the mean completion time $M_T(Z)$ (i.e. the expected number of time steps until the target is detected or the time horizon T is reached). By setting $\gamma_t = 1$ for $t = 0, \ldots, T$ and $\gamma_{T+1} = -(T+1)$, we get the objective $-M_T(Z)$ to be maximized.

The global objective of the planning algorithm is thus to find the feasible plan (satisfying the budget constraint) Z^* that maximizes $\hat{P}_T(Z)$.

III. Optimal stationary target search

The Forward and Backward algorithm decomposes the moving target search problem into successive resolutions of stationary target search problems at each time step. Hence, we first consider the problem of stationary target search. The aim is to minimize the probability of missing the target at a single time step t, given the probabilities of the target presence in every region, and a budget C for the observations.

For the sake of clarity, in this section we do not use the time step t in our notations and $\zeta_a(t)$ is denoted by ζ_a. We present a dynamic programming algorithm to compute the optimal allocation of effort to angles bounded by a budget C for the search of a stationary target when the cones of observation overlap.

The stationary target search problem can be formulated as a convex mathematical program:

$$\min \quad 1 - P(\zeta) = \sum_{j=1}^{J} p(j) \cdot \prod_{a \in Y_j} (1 - \alpha_{j,a})^{\zeta_a} \tag{5}$$
$$\text{s.t.} \sum_{a \in A} \kappa(a) \cdot \zeta_a \leq C \text{ and } \zeta_a \in \mathbb{N}, \forall a \in A .$$

To our knowledge, the complexity of this problem is unknown, even in the simpler case considered in [1] where the effort applies independently to regions and assuming unit costs. The complexity of the algorithm presented in [1] depends linearly on the maximal number of observations, which is constrained by the budget, and thus is pseudo-polynomial. However from a practical point of view, in the operational instances the maximum number of observations is usually far lower than the number of regions, or cones in our case which makes the algorithm polynomial.

A. Properties

The algorithm uses the fact that at most N consecutive cones of observation overlap (as illustrated in Figure 2) to decompose the problem into elementary subproblems and computes the optimal solution iteratively by considering consecutive angles.

We consider the tuple $(a_k)_{k=1,\ldots,|A|}$ of the angles of A in increasing order. For each phase $k \in \{1, \ldots, |A|\}$ of the algorithm, we define the set of regions R_k that are observable from angle a_k but not from any angle $a_{k'}$ with $k' > k$.

For example in Figure 2, when $N = 2$, there are 4 cones of observations associated to the angles $(a_k)_{k=1,\ldots,4}$. The red circle is covered by the cones a_2 and a_3 but not by a_4. The circle belongs to R_3. Note that in an operational instances the number of angles is far greater than 4.

Property 2. *The sets $(R_k)_{k=1,\ldots,|A|}$ form a partition of the set of regions.*

Note that, since the R_k are disjoint, Property 2 implies that the probability of detecting the target $P(\zeta)$ (given by Eq. (5)) can be computed by summing the probabilities of detecting the target in each R_k, for $k = 1, \ldots, |A|$.

Let us denote by $n_k = \min(N, k)$ the maximum number of angles that can observe a region in R_k. Notice that for $k = |A|$, R_k contains all regions observable by angle a_k, so there might be a region in R_k covered by N angles.

Property 3. *A cone M_a intersects R_k if and only if $a \in \{a_{k-n_k+1}, \ldots, a_k\}$.*

Property 3 implies that the probability of missing the target in R_k can be determined using the allocation of effort on $\{a_{k-n_k+1}, \ldots, a_k\}$, which can be expressed as a list of n_k values: $\zeta_{a_k}, \ldots, \zeta_{a_{k-n_k+1}}$ for $k = 1, \ldots, |A|$.

We define $W_k(\zeta_{a_k}, \ldots, \zeta_{a_{k-n_k+1}})$ the probability of missing the target in R_k as:

$$W_k(\zeta_{a_k}, \ldots, \zeta_{a_{k-n_k+1}}) = \sum_{j \in R_k} p(j) \prod_{l=k-n_k+1}^{k} (1 - \alpha_{j,a_l})^{\zeta_{a_l}} . \tag{6}$$

Let us define the partial objective of order k as:

$$Part_k(\zeta) = \sum_{l=1}^{k} W_l(\zeta_{a_l}, \ldots, \zeta_{a_{l-n_l+1}}) . \tag{7}$$

The partial objective $Part_k(\zeta)$ is thus the part of the global objective (5) that excludes the part of the area covered by the cones of the angles $a_{k+1}, \ldots, a_{|A|}$. Notice that our objective is then:

$$1 - P(\zeta) = Part_{|A|}(\zeta) \tag{8}$$

B. The algorithm

We now define the dynamic programming scheme to minimize $Part_{|A|}(\zeta)$, where each phase k corresponds to the decision concerning the effort ζ_{a_k}. The $n_k - 1$ past decisions at phase k are summarized into a state $E = (B, x)$ where:

- B is an integer between 0 and C representing the remaining budget available for the decisions of the phases k to $|A|$;
- x is a list of $n_k - 1$ elements representing the last decisions made in reverse chronological order (thus concerning the angles $a_{k-1}, \ldots, a_{k-n_k+1}$).

In this context, the initial state is $(C, null)$ (where $null$ represents an empty list). If x is a list of values we denote by $x[p]$ the p^{th} element of the list, and by $x[p \ldots q]$ the sub list of x with elements indexed from p to q. Moreover if u is an element or another list we denote by $x \cdot u$ the concatenation of x and u.

The transitions of the dynamic programming scheme are defined as follows:

If at phase k the system is in state $E = (B, x)$, the decision δ (effort on angle a_k) satisfies $\delta \in \{0, \ldots, \left\lfloor \frac{B}{\kappa(a_k)} \right\rfloor\}$. For such a decision δ, we define $x' = \delta \cdot x[1 \ldots n_k - 2]$, $\delta' = x[n_k - 1]$, and $B' = B - \delta\kappa(a_k)$. The pair (B', x') is the resulting state of the decision δ at phase $k+1$. Notice that $x = x'[2 \ldots n_k - 1] \cdot \delta'$, and $B = B' + x'[1]\kappa(a_k)$. This will be used in Property 4.

The immediate cost of the decision δ is then $W_k(\delta \cdot x)$. Using the previous notations, we observe that $W_k(\delta \cdot x) = W_k(x' \cdot \delta')$.

Let $F_k(B, x)$ be the minimal value of $Part_{k-1}(\zeta)$ where ζ is subject to the two constraints:

$$\sum_{l=1}^{k-1} \zeta_{a_l} \leq C - B ,$$

$$\zeta_{a_{k-1}}, \ldots, \zeta_{a_{k-n_k+1}} = x .$$

We can now express the optimal objective of the stationary search as follows:

$$\min_x F_{|A|+1}(0, x) \tag{9}$$

Property 4. *The values $F_k(B, x)$ satisfy the following recurrence equation:*

$$F_{k+1}(B', x') = \begin{cases} F_k(B' + x'[1]\kappa(a_k), x = x'[2 \ldots n_k - 1]) + W_k(x') \text{ if } k < N \\ \min\limits_{0 \leq \delta' \leq C'} \Big(F_k\big(B' + x'[1]\kappa(a_k), x = x'[2 \ldots n_k - 1] \cdot \delta'\big) + W_k(x' \cdot \delta') \Big) \\ otherwise. \end{cases} \tag{10}$$

where $C' = \left\lfloor \frac{C - B' - \sum_{i=1}^{n_{k+1}-1} x'[i]\kappa(a_{k+1-i})}{\kappa(a_{k-n_{k+1}})} \right\rfloor$.

Proof. Let ζ be the optimal allocation solution of $F_{k+1}(B', x')$. By the decomposition of the values $Part_k$ as a sum of W_l values in (7), we can see that if $k < N$, $n_{k+1} = n_k + 1$ and $x' = \zeta_{a_k}, \ldots, \zeta_1$ contains the effort of all the first angles that led to a remaining budget B'. So for earlier decisions, all the allocation of effort is know and thus $F_{k+1}(B', x') = Part_k(\zeta) = W_k(x') + F_k(B' + x'[1]\kappa(a_k), x = x'[2 \ldots n_k - 1])$.

Assume that $k > N$, so that $n_{k+1} = n_k = N$. Setting $\delta' = \zeta_{a_{k-n_k+1}}$, we have $x' \cdot \delta' = \zeta_{a_k}, \ldots, \zeta_{a_{k-n_k+1}}$. Setting $x = x'[2 \ldots n_k - 1] \cdot \delta'$, the allocation ζ considered for angles a_1

to a_{k-1} defines a feasible solution of the sub problem whose optimal value is $F_k(B' + \kappa(a_k)x'[1], x)$. So $F_{k+1}(B', x') = Part_{k-1}(\zeta) + W_k(x' \cdot \delta')$ is not less than the right hand side of the equality.

Conversely, consider any $\delta' \leq C'$. Set $x = x'[2 \dots n_k - 1] \cdot \delta'$. Let ζ' be the optimal plan solution of $F_k(B' + \kappa(a_k)x'[1], x)$. We can define the plan ζ'' such that $\zeta''_{a_l} = \zeta'_{a_l}$ if $l < k$, and $\zeta''_{a_k} = x'[1]$, and obtain a feasible solution of the sub problem for which $F_{k+1}(B', x')$ is the optimal value. So we get:

$$\begin{aligned} F_{k+1}(B', x') &\leq Part_k(\zeta'') = Part_{k-1}(\zeta') + W_k(x' \cdot \delta') \\ &= F_k(B' + \kappa(a_k) \cdot x'[1], x) + W_k(x' \cdot \delta'). \end{aligned} \tag{11}$$

Hence the reverse inequality holds. □

The forward dynamic programming algorithm issued from Property 4 computes for each phase k from 1 to $|A|$ and for each possible state (B', x') of this phase the value $F_k(B', x')$. Algorithm 1 shows this first part that computes the minimal target missing probability. The computation of the optimal effort allocation ζ is then done using classic dynamic programming approach by searching among the stored values $F_k(B', x')$ which decisions gave the optimal value, with a lower complexity.

Algorithm 1 DP algorithm

```
for all $B \leq C$ do
    $F_1(B, null) = 1$
end for
for $k = 2$ to $|A| + 1$ do
    for all possible couples $(B', x')$, with $length(x') = n_k - 1$ do
        Compute $F_k(B', x')$ using equation (10)
    end for
end for
return $\min_x F_{|A|+1}(0, x)$
```

We can now analyze the complexity of Algorithm 1.

Property 5. *The time complexity of Algorithm 1 is:*

$$\mathcal{O}\left(|A| \cdot N \cdot J \cdot C^N\right).$$

It is pseudo-polynomial for fixed N.

Proof. Let us denote by $z_{max} = \left\lfloor \dfrac{C}{\min_{a \in A} \kappa(a)} \right\rfloor$ the maximum number of observations in an angle. For each iteration of the outer loop, $k \in \{2, \dots, |A| + 1\}$ a state (B', x') is composed of the remaining budget and the at most $N - 1$ last decisions composing x'. The space needed to store each value $F_k(B', x')$ is therefore $\mathcal{O}(|A| \cdot C \cdot z_{max}^{N-1})$. Now for each $F_k(B', x')$, the time complexity of the computation of the recurrence equation (10) depends on the number of different δ' values, which can be bounded by z_{max}. For each δ' the computation of $W_k(x'.\delta')$ is in $\mathcal{O}(N \cdot |R_k|)$. As $\min_{a \in A} \kappa(a) \geq 1$, $z_{max} \leq C$. This gives the whole time complexity of the algorithm. □

Notice that in real applications, N is usually quite small and ranges from 2 to 6 (in the 3D case), and the budget and z_{max} are usually far lower than J, which makes this approach tractable in practice.

IV. Heuristics and bounds

This section is devoted to the presentation of some heuristics methods and a relaxation for the stationary target search.

A. Greedy algorithm

We first present an iterative algorithm that approximates the optimal search effort allocation. This algorithm is an adaptation of the optimal greedy algorithm for the computation of the allocation of discrete effort in the case of disjoint cones of observation and unit costs which was proposed in [12]. Due to the overlapping of the observation cones, the conditions that ensured its optimality vanish. However our experiments, in section VI, shown that it provides a fast and high quality approximation of the optimal solution. We first detail the concept of rate of return of angles on which the algorithm is based and we then present the complete algorithm.

1) Rate of return of angles: Let us first define $p^{(ang)}(a)$ as the probability that the target is in the cone associated with the angle a. We have

$$p^{(ang)}(a) = \sum_{j \in M_a} p(j)\,. \tag{12}$$

We define $b'(j, \zeta, a)$ as the *rate of change* of the function $b(j, \zeta)$ for an additional effort in the angle a by:

$$\begin{aligned} b'(j, \zeta, a) &= b(j, \zeta + \mathbf{1_a}) - b(j, \zeta) \\ &= \alpha_{j,a} \prod_{a' \in Y_j} (1 - \alpha_{j,a'})^{\zeta_{a'}}\,. \end{aligned} \tag{13}$$

Where $b(j, \zeta)$ is defined in Equation (1) and where $\mathbf{1_a}$ is the unit vector of length A such that $\mathbf{1_a}(\mathbf{a}) = \mathbf{1}$ and $\mathbf{1_a}(\mathbf{a'}) = \mathbf{0}$ for $a' \neq a$. As it can be seen in the Equation (13), the value of $b'(j, \zeta, a)$ depends not only on angle a but also on all the angles that cover the region j.

We define the *angular detection function* $\beta(a, \zeta)$ as the conditional probability of detecting the target in one of the regions in the cone associated with an angle a, for an allocation of effort ζ on angles, given the target is located in the cone. The angular detection function $\beta(a, \zeta)$ is:

$$\beta(a, \zeta) = \frac{\sum_{j \in M_a} p(j) \cdot b(j, \zeta)}{p^{(ang)}(a)}\,.$$

We define β' as the *angular rate of change* of the function β for an additional effort in angle a by:

$$\beta'(a, \zeta) = \frac{\sum_{j \in M_a} p(j) \cdot b'(j, \zeta, a)}{p^{(ang)}(a)}\,.$$

We then define $\rho(a, \zeta)$ as the *rate of return* function. It represents, for an allocation ζ, the ratio between the increase of the probability of detection for a new increment of effort in the angle a, and the investment cost generated by the same increment. It equals:

$$\rho(a,\zeta) = \frac{p^{(ang)}(a)\beta'(a,\zeta)}{\kappa(a)} = \frac{\sum_{j\in M_a} p(j)\cdot b'(j,\zeta,a)}{\kappa(a)}. \tag{14}$$

In the overlapping cones case, the value of the *rate of return* $\rho(a,\zeta)$ depends not only on the value of effort ζ_a but also on the allocation of effort ζ to all the angles that cover any region j covered by a. Algorithm 2 summarizes the main steps. Starting from a null allocation of effort, at each iteration an additional unit of effort is added in the angle with the best rate of return until the budget is reached (as we assumed costs not less than 1, there are at most C such iterations). To compute or update the rate of returns, each region j appears at most N times in the sums, and there are at most N terms in the computation of $b'(j,\zeta,a)$. The complexity of this algorithm is thus $\mathcal{O}(C\cdot|A|\cdot J\cdot N^2)$.

Algorithm 2 Greedy algorithm

```
$\zeta = (0,\dots,0), B = 0$, and Compute $\rho(a,\zeta), \forall a \in A$
while $\exists a \in A$ such that $B + \kappa(a) \leq C$ do
    Compute $a* = \underset{a\in A, B+\kappa(a)\leq C}{argmax} \quad (\rho(a,\zeta))$
    $\zeta = \zeta + \mathbf{1}_{a*}$
    $B = B + \kappa(a^*)$
    Update $\rho(a,\zeta)$ for all $a$ such that $M_a \cap M_{a^*} \neq \emptyset$
end while
```

In the non-overlapping cones case and unit costs, the optimisation problem can be exactly solved using this algorithm [12]. In our case this result does not hold. Hence, our heuristic is suboptimal.

B. Adapted Random Permutation Scan Method

We now introduce an algorithm adapted from the conventional *random permutation scan* method as described in [14], referred to as *RPSM* in the following. The original strategy entails a comprehensive sweep of the entire search area in the absence of any prior information about the target's position. During each iteration, the radar conducts an observation in each considered direction following a random order. The algorithm stops when the budget of observations runs out.

In this study, we have adapted this method to scenarios where there is prior knowledge about the target's location. The set of considered angles corresponds to those that cover at least one region j such that $p(j) > 0$ thus we consider angles such that $p^{(ang)}(a) > 0$.

a) The algorithm: A buffer H is used to store the angles that have not been observed yet. The buffer is initialized with the set of angles covering at least one region with a positive prior on target presence (*i.e.* $p^{(ang)}(a) > 0$). When the buffer is empty, it is reinitialized with the same set of angles.

The markovian transition matrix is used to compute the probability of presence of the target at each timestep. Hence at time step t, the probability $p_t(j)$ is computed recursively from the prior probability p_0 and the transition matrices π_t of the Markov chain. The set of angles covering at least one region with a positive prior on target presence is updated consequently at each timestep. An allocation plan is initialised to a null plan and allocations are computed sequentially with Algorithm 3. When the buffer is empty, it is updated with $\{a \in A : p_t^{(ang)}(a) > 0\}$.

Algorithm 3 RPSM adapted to target search with priors

```
$\zeta = (0,\dots,0)$, $B = 0$
$H = \{a \in A : p^{(ang)}(a) > 0\}$
while $\exists a \in H, B + \kappa(a) \leq C$ do
    Sample $a$ from $H$ without replacement
    if $B + \kappa(a) \leq C$ then
        $\zeta = \zeta + \mathbf{1}_a$
        $B = B + \kappa(a)$
    end if
    if $H = \emptyset$ then
        $H = \{a \in A : p^{(ang)}(a) > 0\}$
    end if
end while
```

This algorithm is used as a baseline for the search of a stationary and moving target.

C. Relaxation of the problem for the computation of an upper bound

For the moving target search problem, the FAB algorithm is guaranteed to converge to the optimal plan when the search effort is continuous but not when it is discrete (see [1]). As in [12], we use the value of the optimal payoff obtained in the continuous case as an upper bound on the optimal value of the payoff obtainable in the discrete case. The aim is then to measure the efficiency of the discrete approach with respect to the bound given by the continuous optimal solution.

The detection function and the objective functions (stationary and moving target) have the same formulation both in discrete and continuous cases. These functions can thus be used to compute the optimal allocation of effort in the continuous case.

Computing the optimal allocation of continuous effort for a stationary target search is a quite difficult convex optimization problem. Henceforth, we propose here to further relax the problem in order to compute an allocation on disjoint angles that provides a simpler upper bound for the optimal probability of detection on this problem. This relaxation requires that $\kappa(a) = 1\ \forall a \in A$.

The relaxed instance I' is defined by splitting each angle a into N disjoint cones of same area: $u_1(a),\dots,u_N(a)$. The budget of I' is $C' = C\cdot N$. The visibility coefficients are such that for each region $j = 1,\dots,J$, if a' is an angle of instance I', then $\alpha'_{j,a'} = \alpha_j = \max_{a\in Y_j}\alpha_{j,a}$.

Property 6. *A continuous allocation ζ for the original instance I defines a feasible continuous allocation ζ' for the relaxed instance I', by allocating ζ_a effort to each of the N cones issued from angle a. If a' is an angle of I' then: $\zeta'_{a'} = \sum_{a,\exists i,u_i(a)=a'}\zeta_a$. Moreover $P(\zeta') \geq P(\zeta)$.*

Proof. The allocation ζ' is feasible for the relaxed instance I' because

$$\sum_{a' \in A'} {\zeta'}_{a'} = \sum_{a'} \sum_{a, \exists i, u_i(a)=a'} \zeta_a = \sum_a N \cdot \zeta_a \leq N \cdot C = C'.$$

Let us first observe that for a region j, since for any angle a, $\alpha_{j,a} \leq \alpha_j$,

$$\prod_{a \in Y_j} (1 - \alpha_{j,a})^{\zeta_a} \geq \prod_{a \in Y_j} (1 - \alpha_j)^{\zeta_a}.$$

Thus,

$$1 - \prod_{a \in Y_j} (1 - \alpha_{j,a})^{\zeta_a} \leq 1 - \prod_{a \in Y_j} (1 - \alpha_j)^{\zeta_a}. \qquad (15)$$

Now consider the new instance I'. For each region j, there exists a unique angle $a'(j)$ that covers j (since in I' we have disjoint observation cones). Hence

$$\begin{aligned} P(\zeta') &= \sum_{j \in J} p(j) \left(1 - (1 - \alpha_j)^{\zeta'_{a'(j)}}\right) \\ &= \sum_{j \in J} p(j) \left(1 - (1 - \alpha_j)^{\sum_{a \in Y_j} \zeta_a}\right) \\ &= \sum_{j \in J} p(j) \Big(1 - \prod_{a \in Y_j} (1 - \alpha_j)^{\zeta_a}\Big). \end{aligned}$$

From (15), we deduce that $P(\zeta') \geq P(\zeta)$. □

We can compute the optimal allocation of continuous effort on disjoint cones of observations for the relaxed instance I' with the algorithm presented in [12]. We can then use it to compute an upper bound on the optimal allocation of continuous effort to overlapping cones for the search of a moving target.

V. Moving target search

We now consider the moving target search problem with objective function given by Eq. (4). The mathematical formulation of this problem is:

$$\begin{aligned} &\max \ \hat{P}_T(Z) && (16) \\ &\text{s.t.} \ \sum_{a \in A} \zeta_a(t) \cdot \kappa(a) \leq C_t \ \text{ for } t = 0, \dots, T\,. \\ &\qquad \zeta_a(t) \in \mathbb{N}\,, \forall a \in A, \ \text{ for } t = 0, \dots, T\,. \end{aligned}$$

Here this problem is solved by using the FAB algorithm [7] which is a generalization of Brown's recursion [15]. Both algorithms adapted to an allocation to disjoint angles have been presented in [12].

Let us recall the principles of the FAB algorithm [1]. Starting from an initial plan Z_0, at each iteration (outer loop) the FAB algorithm computes a new plan, until two successive plans are equal, or the allowed number of iterations is reached.

In an iteration of the outer loop, starting from a plan Z, the computation of a new plan is done iteratively in an inner loop for each time step $t = 0, \dots, T$. At a time-step t of the inner loop, the algorithm computes the values $q(j, Z, t)$ for each region j. To give an intuition, when the objective is the detection probability before horizon T, $q(j, Z, t)$ represents the probability that the target is in region j at time t and is not detected at any time other than t according to the current plan Z. The plan Z is then updated by computing an optimal stationary allocation for time t, using $q(j, Z, t)$ for $j = 1, \dots, J$ as a prior probability distribution of target presence in the regions.

The computation of q values is done by using the markovian target movement, by decomposing q into a product of two functions R and S.

$$q(j, Z, t) = R(j, Z, t) \cdot S(j, Z, t)\,. \qquad (17)$$

When the objective is the detection probability before horizon T, $R(j, Z, t)$ (resp. $S(j, Z, t)$) represents the probability that the target is in region j at time t and has been missed in time steps $t+1, \dots, T$ (resp. $0, \dots, t-1$) withs the plan Z. Those functions can be expressed with a recursive form thanks to the markovian property of the target movement (see details in [1]).

$$\begin{aligned} &R(j, Z, t) = E_{jt}[\gamma_t(\omega)] + \\ &\quad \sum_{i=1}^{J} R(i, Z, t+1) \cdot \big(1 - b(i, \zeta(t+1))\big) \cdot \pi_t(j, i)\,. \qquad (18) \end{aligned}$$

$$\begin{aligned} &S(j, Z, t) = \\ &\quad \sum_{i=1}^{J} S(i, Z, t-1) \cdot \big(1 - b(i, \zeta(t-1))\big) \cdot \pi_{t-1}(i, j)\,. \qquad (19) \end{aligned}$$

The value $E_{jt}[\gamma_t(\omega)]$ is the expectation of the coefficient γ_t of the objective function over trajectories such that the target is in region j at time t. Notice that it only depends on the target movement and does not depend on the plan, so that it can be pre-computed.

The initial values, for $j = 1, \dots, J$, are $S(j, Z, 0) = p_0(j)$ and $R(j, Z, T) = E_{jT}[\gamma_T(\omega)]$.

Notice that in the inner loop of the FAB algorithm, the plan Z is updated iteratively for increasing time steps. So the future of the plan does not change between two consecutive iterations of the innerloop and thus $R(j, Z, t)$ according to (18) can be computed before the inner loop for each region j and each t. At each iteration t of the inner loop, for each region j, $S(j, Z, t)$ can be computed using (19) with the plan updated in the previous iteration.

If we start from a null plan, then the first iteration of FAB computes a myopic plan where the optimal stationary effort allocation of time t is computed from the target move probabilities at time t regardless of the allocation in the previous time steps. But the algorithm can be used with different initial plans.

Unlike the continuous effort case, the algorithm FAB for a discrete effort is not guaranteed to converge to the optimal plan. However, there exists a necessary condition of optimality.

Proposition 1 (From Theorem 3.4 [1])**.** *Assume we have a discrete-effort exponential detection function by region $b(j, \zeta)$.*

If Z is optimal, then for all t the allocation $\zeta(t)$ is an optimal allocation for the stationary target search with prior distribution q.

Therefore, finding, with dynamic programming, the optimal stationary plan at each step t ensures that the plan computed with FAB satisfies the necessary conditions which only guarantees that the returned plan is a local optimum.

In order obtain an optimal plan, we may consider a nonlinear integer program. Indeed, as stated in Section 3.3.2 of [1], when the effort is allocated in each region j independently, one can express the moving target search problem as a nonlinear integer program. However, even in this simple case, this is of a little theoretical and practical use since the objective function is computed by considering all the possible trajectories ω of the target. Hence, this does not scale to our problem with at least 1500 regions.

VI. Experimental results

In this section, we study the efficiency of the algorithms presented in the previous sections, in terms of solution quality and computational effort. We implemented the models and algorithms of the previous sections and designed different realistic scenarios, inducing our experimental parameters, and generated random instances according to these scenarios. The algorithms were implemented in Python and we ran scenarios on an two Intel Xeon E5-2690v3 (24 cores / 2.60 GHz).

Even though the algorithms presented in this paper could be used with a 3D search area, we assumed a stationary airborne platform facing a 2D search area discretized in regions spaced 10km apart, with a total of 1500 regions. The regions are arranged in a honeycomb pattern for an efficient use of 2D space. Using smaller distances between regions would improve the realism of the scenarios. However, it hugely increases the number of regions in the search area (e.g a distance of 1km gives 155000 regions) and then the computation time. In our study, we chose the parameters so that the dynamic programming algorithm could run in a reasonable time. We expect that the behaviour of the algorithms remains consistent for both small and large regions.

The target moves between two adjacent regions at each timestep. Considering the maximum relative speed of fighter jets, we consider a timestep to last roughly 7s in these experiments.

The platform has a radar that can make observations in the angular domain $[-60°; +60°]$. A radar "dwell" (name for an observation) in a direction affects the regions located in a cone of geometric height 250km and angular diameter 3 degrees. We consider set of angles such that they are equally spaced in the angular domain and each associated with an observation cone of angular width 3°.

The maximum number of cones N covering a region is related to the angular separation between angles and the number of angles. When the angular separation between angles is 3° we have $N = 1$ and $|A| = 40$; if the angular separation is 1.5°, $N = 2$ and $|A| = 79$. The radar is considered to use a single mode.

In the experiments, we assumed a fixed cost for making an observation in an angle a to $\kappa(a) = 1$.

In each scenario, an area of interest is initialized. The area of interest is the set of regions that have a nonzero probability of containing the target. This set is fully contained in the part of the search area that is visible from the radar.

The experiments use six parameters for the tested scenarios:

- **FOV_portion**: Determines the size of the area of interest as its portion of the total observable area. It can be 0.05, 0.5, or 1.0.
- **Horizon**: The number of time steps for the search. It can be 1, 2, 5, or 10.
- **Budget**: The number of observations that can be made during a time step. It can be 1, 2, 5, 10, 20, 40, or 50.
- **N**: The maximum number of consecutive cones covering a region (see Figure 2). It can be 1, 2 or 3. Higher values did not lead to significantly different results from what was observed at $N = 3$.
- **visibility**: Indicates the detection model used (see Figure 3) either "*distance*" or "*realistic*".
- **movement_type**: Defines the movement transition matrix. Can be "drone" or "jet". "drone" defines a uniform distribution over all possible direction. "jet" selects a random direction and then defines a distribution where there is 0.9 chance of going in this direction and 0.1 of remaining in the current region. The probability is 0 in all other directions. It approximates the movement model of a fighter jet that does not change direction.

A dwell is considered to last 100ms, allowing for a maximum of 70 observations per time step in different angles. We limited the number of observations to 50 per time steps and the horizon to 10, as larger values do not lead to significantly different results.

In the following experiments, we first focus on the problem of a stationary target search. We evaluate how using a detection model that depends only on the distance can negatively impact the performance of the allocation computed. Then, we evaluate the error of the probability obtained with the greedy algorithm compared with the optimal probability given by the dynamic programming algorithm. Then, we compare the probability of detection obtained with the dynamic programming algorithm with the baseline and the upper bound.

The second part experiments the moving target search. We show how increasing the maximum number N of observation cones covering a region of the search area affects the mean completion time of the plan. Also, we exhibit the performance of the algorithms FAB + greedy algorithm and FAB + dynamic programming for a fixed value of N in terms of the objective function and computation time. Finally, we show how the target movement model affects the mean completion time of the plan.

A. Stationary target search

1) Error caused by the use of the "distance" detection model: In the literature, the detection model used for the radar is often only a function of the distance to the radar. In this section, we evaluate the error caused by the use of such a model compared to the "*realistic*" detection model.

To do so, we compute optimal allocations for stationary target search for the allocation of search effort on overlapping cones of observations such that $N = 3$ on different scenarios. We vary the budget and the FOV_portion. We first compute the optimal allocation for the "realistic" detection model and obtain the optimal probability of detection. Then, we compute the optimal allocation for the "distance" detection model and compute the detection probability of this last allocation by using the "realistic" detection model. We compute the mean absolute error of the probability of detection obtained with the "distance" detection model as compared to the optimal probability. We also show values ranging from the 5th to the 95th percentile of the error.

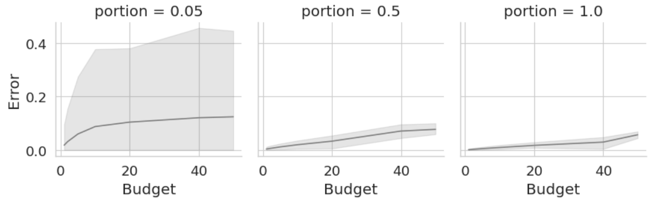

Fig. 4. Error caused by the use of the "distance" detection model.

In Figure 4 we see that the mean error is larger than 0.1 in many cases (especially when the area of interest is small) and the error can even achieve values above 0.4 for some scenarios for large values of budget. The use of the "distance" detection model therefore leads to a significant error in the probability of detection. We will use the more realistic detection model in the remaining experiments.

2) Comparison between the greedy algorithm and the dynamic programming algorithm: Algorithms 1 and 2 are both used as a module of the FAB algorithm, it is therefore interesting to study their behaviour in the simpler context of the stationary target search.

We ran both algorithms on different scenarios. We then computed the mean absolute error of the probability of detection obtained with the greedy algorithm as compared to the optimal probability obtained with dynamic programming.

Figure 5 depicts this error for small (left) to large (right) areas of interest w.r.t the budget of observations and parameter N. We computed the error only for $N = 2$ and 3 because using larger values requires amounts of memory unavailable to us to run the dynamic programming algorithm. The shaded areas around the curves represent the values between the 5th and the 95th percentile of the error.

We observe that the error is small. It is 0 in 81% of the simulations, rarely takes value above 0.02: the maximum error observed was 0.056. There seems to be a relationship between the size of the area of interest, the budget of observations and the error. For small areas of interest, there tends to be a higher error for small budgets. On the contrary for large areas of interest, there tends to be higher error for large budgets.

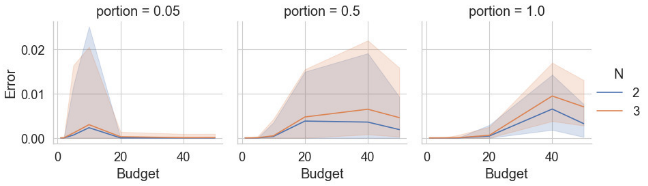

Fig. 5. Error of the greedy algorithm w.r.t. budget for different values of FOV_portion (columns), detection model (rows) and N (color).

Overall, we observed that the greedy algorithm is a good approximation of the optimal plan for the search of a stationary target. It also has a much lower space and time complexity, as shown in Section III-B.

3) Stationary target search: comparison between the optimal solution, RPSM and the relaxation: In Figure 6, we observe the optimal probability of detection computed with the dynamic programming algorithm w.r.t. budget, and we compare it with the one obtained with the random permutation scan method and the upper bound provided by the relaxation of the problem. We show the results for different sizes of the area of interest (columns) and different values of N the maximum number of cones that cover a region (rows). We show the results up to $N = 3$ because larger values do not lead to results significantly different from the ones obtained with $N = 3$.

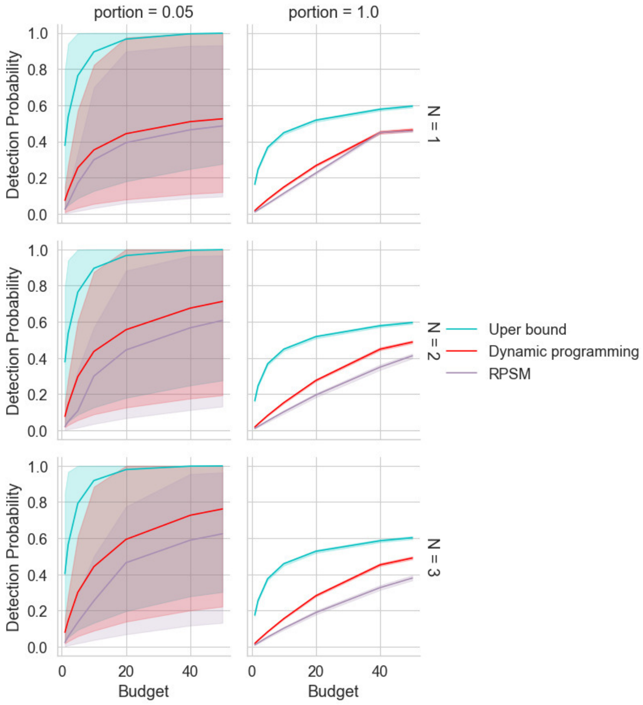

Fig. 6. Probability of detection obtained with three algorithms w.r.t. budget for different values of FOV_portion (columns) maximum number of cones that cover a region (rows).

First, we see that the upper bound provided by the relaxation is far larger than the optimal probability of detection. This bound is not very informative. To get a more informative bound, we should solve the convex program corresponding to the relaxation with gradient techniques.

Our analysis demonstrates a correlation between the magnitude of N and the disparity in performance between the greedy algorithm and RPSM. When applied to a large area of interest, both algorithms exhibit similar performance for $N = 1$. An increment of N to 3 causes a slight enhancement in the greedy algorithm's performance by 4%, whereas RPSM's performance concurrently diminishes.

Conversely, when the area of interest is smaller, the performance difference between the two algorithms becomes greater. Increasing the N value from 1 to 3 in this context brings mutual benefits: a significant 17% increase for the greedy algorithm and a modest 3% improvement for RPSM.

In the context of the search of a stationary target, the increase in N almost does not benefit RPSM due to its inherent constraint of allocating substantial effort to regions with low probability of detection. Conversely, the greedy algorithm derives significant advantages from such increases in N.

B. Moving target search

In this section, we evaluate the performance of our algorithms in the context of the moving target search.

1) Interest of increasing N for the moving target search: In Figure 7, we first observe the mean completion time (referred by ”meantime” in the remaining of this section) obtained with FAB+dynamic programming w.r.t budget for different values of N. We observed comparable results across different values of horizon, and the difference of performance between the algorithms are best observed for larger values of horizon. We therefore isolate the results for a horizon of 10.

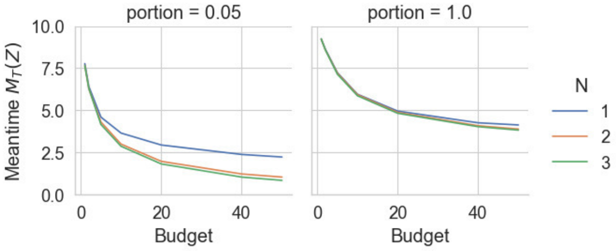

Fig. 7. Meantimes w.r.t. budget obtained with FAB + dynamic programming for N= 1,2,3 for different values of FOV_portion.

In our observations, an increase in the value of N induces a decrease in the meantime. Specifically, for a smaller area of interest, we witness a 6% enhancement in efficiency when N is incremented from 1 to 2, followed by a further 2% improvement as N increases from 2 to 3. This trend shows the diminishing benefits of increasing N.

2) Meantime for different algorithms: In Figure 8, we compare the meantimes obtained with FAB+greedy algorithm, FAB+dynamic programming and RPSM w.r.t. budget, for a fixed horizon = 10. we observe it for different sizes of area of interest.

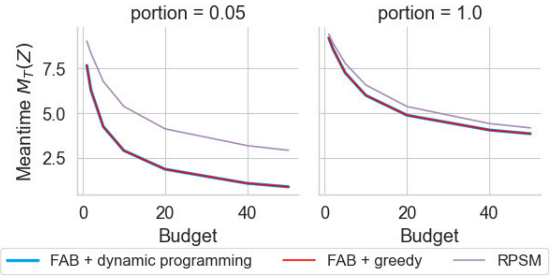

Fig. 8. Comparison of meantimes obtained with different algorithms (the red line is behind the blue line)

Our analysis reveals that the meantimes of plans computed by FAB coupled with dynamic programming and FAB with the greedy algorithm are remarkably similar. Indeed, in 0.45% of the instances, their results are identical.

The mean absolute error in meantime between FAB + greedy algorithm and FAB + dynamic programming is marginal, at 0.002 timesteps (1 timestep = 7 seconds in our experiments, so 0.014 seconds). The peak recorded performance advantage of FAB + dynamic programming over FAB + greedy method amounted to 5.25% of the computed meantime (1.15 seconds gained).

We observed that the adaptation of RPSM to moving target search always performs worse than FAB, especially when the area of interest is small.

3) Comparison of computation times: In Figure 9, we observe the mean computation times of FAB + dynamic programming and FAB + greedy for different values of N, w.r.t. the horizon.

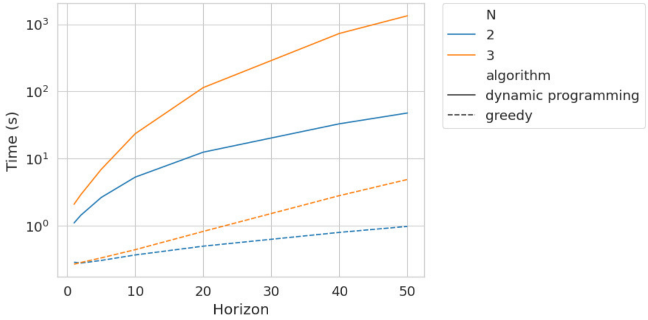

Fig. 9. Computation times for FAB + dynamic programming and FAB + greedy algorithm for different values of N

We observe that FAB + greedy algorithm is several order of magnitudes faster to compute the allocation plan than FAB + dynamic programming. FAB + greedy is often under 1s while FAB + dynamic programming can take several dozens of minutes. Consistently with the worst case time complexity, we also observe that the computation time of the dynamic programming algorithm increases faster with N than the computation time of the greedy algorithm. In a context where allocations must be computed in real time, the greedy algorithm therefore provides a good approximation of the plan computed with FAB + dynamic programming in a very reasonable amount of time. Furthermore, there is a tradeoff to be made between plan quality and computation time as using higher values of N affects both significantly.

4) Search for targets with different movement models: In Figure 10, we observe the meantime of plans for different target moves w.r.t. the budget. We isolate the experiments where horizon = 10 and the area of interest is small. Indeed, these are cases when the difference between the results are best observed.

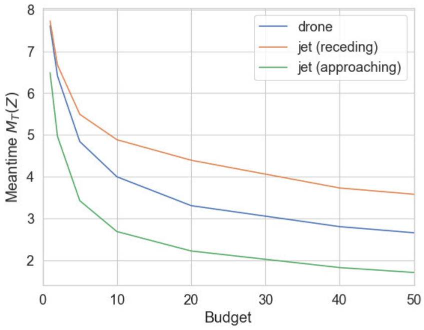

Fig. 10. Meantime for different target types

We can see that when we have a prior on the target direction, it is easier to detect it when it is approaching us and harder when it is receding. When the target moves like a drone and we do not have a prior on its direction, the meantime lies between the meantimes for the two type of jet moves. Note that in the case of a receding target, our model is optimistic because we do not consider ground echoes. Overall, when the target is a jet and we have a prior on its direction, the prior heavily impacts the meantime.

VII. Conclusion

We proposed an optimal algorithm and a fast heuristic for the problem of search of a stationary target with a radar by considering overlapping cones of observation and discrete effort. This allowed us to compute better plans in diverse contexts for moving targets. We also proposed a detection model for the radar which is more realistic than the ones generally used in the literature. Those algorithms were compared in different scenarios for the search of stationary and moving targets. The experiments showed that the realistic detection model gives allocation plans that are significantly different from the one that was previously used in the literature. Using overlapping cones observations led to a notable improvement of the solution obtained. The use of the greedy approximation gave very close to optimal solutions for the stationary search and reduced drastically the computation time for the search of a moving target. Finally, we demonstrated that a prior on the target's direction heavily impacts the mean completion time of the plan.

Future work should consider further theoretical and practical issues. Among them is the complexity of the stationary target search problem. Live experimentations of such algorithms in real conditions remain to be done in order to demonstrate their maturity. Also, other modern important issues are related to the more general problem of searching and tracking multiple targets with multiple assets like e.g. jet fighters and remote carriers embedding different types of active and passive sensors.

***Abstract*—The paper presents a survey-based study that aimed to determine the prevalence of anti-patterns in the Scrum software development methodology. A total of 35 anti-patterns were selected from the literature review, and 42 respondents working in software development organizations located in Poland indicated whether they had encountered each anti-pattern in their organizations. The study found that "Unfinished Tasks" was the most prevalent anti-pattern, highlighting the importance of proper planning and task management within sprints. Additionally, several other common anti-patterns were identified, including daily scrums being extended beyond the recommended time, user stories not being fully refined, and the sprint goal not being defined at the sprint planning meeting. The findings of this study provide valuable insights into the current state of Scrum methodology in software development organizations and highlight areas where there is room for improvement.**

I. Introduction

We are agile! – many organizations proudly proclaim. However, as practice shows, it is always easy to say, but much more harder to accomplish [1]. Since the publication of the Agile Manifesto in 2001 [2], the number of development projects conducted according to the agile approach has been steadily increasing. Nowadays, this approach is also increasingly used outside the domain of software development [3]. However, implementing an agile approach requires more than putting the right processes in place. It requires a change in mindset and attitude toward managing projects.

Scrum has gained significant traction over the years due to its flexibility, iterative approach, and focus on cross-functional team collaboration. It is the most popular software development methodology of all available agile approaches [4], with 9 out of 10 respondents in the State of Agile Report claiming to use it [5]. However, as with any methodology, there are always risks of anti-patterns – common mistakes or misapplications of the methodology that can hinder its effectiveness. A Scrum anti-pattern is defined as a harmful practice within the Scrum framework that may appear convenient at first but proves detrimental in the long run [6].

The aim of this study was to investigate the current state of Scrum implementation in software development organizations located in Poland. For this purpose, a survey was conducted among practitioners to determine the prevalence of Scrum anti-patterns, which are common mistakes or pitfalls in the application of a methodology. They can lead to poor performance, low productivity, and other negative outcomes.

II. Related Work

Based on the interview conducted among 18 respondents, representing 11 IT organizations located in Finland, Eloranta et al. [6] identified ways of potentially harmful mishandling of Scrum. The findings show that a) sprints were too long since the teams could not respond to customer requests and the feedback loop became too long, b) the system testing was performed in the next sprint by a separate team, as well as testing took place at the end of the sprint; in addition, in some cases there was the lack of automation tools employed in the testing, and c) the progress of the work was not made visible with burn-down charts to the teams, thus a phenomenon, termed as "invisible progress" occurred.

Matthies et al. [7] discussed experiences from a classroom project in which a group of 38 students was responsible for developing a single system by using a scaled version of Scrum. In conclusion, the authors argue that the combination of tutor observations, surveys, along with initial testing of automated process analysis leads to better understanding the Scrum adoption, as well as detecting agile practices violations for every team in every sprint, including prolonged and varied duration of sprint, moving testing to the next sprint, and invisible progress.

On a basis of a grounded theory approach, Carew and Glynn [8] investigated how productivity, effectiveness and workflow priorities were influenced by adopting the Scrum. In general, a number of agile anti-patterns were recognized with a negative impact on these three facets, including decision-making incapacity, incomplete deliverables (working code), ad-hoc work requests, and an inability to actually define when work items were completed to the required "Definition of Done", just to name a few.

Through the observation of the two teams, including 14 members who in majority were software developers, as well as acting as a product owner, agile coach, or scrum master, Mortada et al. [9] investigated the cases of four Scrum activities separately practiced among these teams. In total, 13 deviations from Scrum guidelines were identified, including:

IEEE Catalog Number: CFP2385N-ART ©2023, PTI

- four related to the daily scrum event, namely: (1) not all key questions are addressed, (2) not all team members contribute, (3) daily scrum events take longer than 15 minutes, and (4) no fixed time for the daily scrum event;
- seven related to the sprint planning, namely: (5) stories are not refined in the product backlog, (6) no calculation of resources available for the upcoming sprint, (7) sprint goal is defined at the end of the planning meeting, (8) no break down of large stories, (9) no agenda used for the planning meeting, (10) stories are not estimated, and (11) stories not formulated completely;
- two related to the sprint demonstration, namely: (12) sprint does not end with a demonstration, and (13) demonstration to the wrong audience.

Moreover, these agile anti-patterns were also reported to have negative impact on the product quality and team morale.

Based on the interviews conducted with software professionals working in Scrum teams, Çetin and Durdu [10] aimed to explore how the Scrum was practically implemented, and in particular uncover what were the differences between these implementations and the original Scrum model. Their findings show that in some organizations daily Scrum meetings, sprint retrospectives, as well as the burndown charts, were not always implemented.

Having collected data from approximately 40 different software development teams of a large Scrum organization, Heikkila et al. [11] investigated how the requirements were planned and managed, how well the requirements planning and management practices matched Scrum guidelines, and whether the changes were perceived harmful. The findings show that only 30% of user stories were set in progress, while 32% of user stories were closed during the sprint planning day and the sprint review day, respectively. The respondents indicated two reasons why user stories last for multiple sprints, namely the inter-team dependencies and the dependencies to third parties, and the difficulty of splitting user stories into pieces that can be implemented in a single sprint. In conclussion, the authors argue that these two deviations from the Scrum user story management and planning process cannot be categorized as harmful.

McKenzie et al. [12] conducted interviews with eight New Zealand video game development studios with the aim to empirically determine how and why agile frameworks were applied. In this extent, the authors recognized several limitations due to the common misunderstanding in key areas around project management and collaboration, demonstrated by missing retrospectives, and ambiguity related to the status of tasks.

Last but not least, Perry [13] discussed the issue of misunderstanding of the end user role with the ultimate customer. The author concludes that "by focusing on the intermediary rather than on the end user that we do the people who have to work with the system a disservice".

TABLE I
ANTI-PATTERNS SELECTED AFTER LITERATURE REVIEW

Anit-pattern	**Source**
Sprints that are too long	[6], [7]
Variable lengths of sprints	[7]
Unfinished tasks	[8]
Testing in next sprint	[6], [7]
Invisible progress	[6], [7]
Not everyone actively participate in the meeting	[9]
Daily Scrum lasts longer than 15 minutes	[9]
The Daily Scrum does not take place at a fixed time of day	[9]
Not all key issues are addressed	[9]
Daily scrums are not held every day	[10]
Disordered product backlog	[7], [6]
Extensive requirements documentation instead of user stories	[7], [6], [9]
User stories that are too extensive	[11]
PO without authority, has negligible influence on the selection of tasks to be implemented	[7], [6]
Stakeholder indecisiveness – requirements come from multiple stakeholders and compete for prioritization	[8]
Lack of unanimity whether the task has been completed	[8], [12]
An indirect customer who is service provider of its own customer	[13]
PO delegated by a client and does not understand the role	[7], [6]
Exact estimation instead of relative estimation of items	[7]
Item estimation imposed to the team	[7], [6]
No estimation of resources available for the upcoming sprint	[9]
Sprint planning meeting has no agenda	[9]
Sprint goal set at the end of the meeting or not at all	[9]
Not breaking large user stories into smaller ones during a meeting	[9], [11]
Disruptions in the development process – other areas of the project are developed in turn without one being completed	[8]
Adding items during sprint	[8], [11], [7], [6]
User stories are not fully refined	[9]
A burndown chart is not used	[10]
Semi functional teams	[7], [6]
Insufficient technical knowledge[8]	
Lack of business knowledge	[8]
No or too long waiting for feedback (lack of Sprint review or stakeholders do not show interest)	[7], [12], [9]
The sprint does not end ends with a demonstration	[9]
Demonstration for the wrong targets	[9]
Missing retrospectives	[7], [12]
Combining the two meetings into one	[10]

III. SURVEY DESIGN

To prepare the survey, a literature review was conducted to identify common Scrum anti-patterns. For this purpose, articles in the Web of Science, IEEE Explore, and Scopus databases were searched for the keywords *Scrumbut*, *Scrumfall*, or *Scrum anti-patterns*. A total of 81 articles were found, which were then filtered by title, abstract and content. Finally, 8 articles were identified that described common Scrum anti-patterns [6], [7], [8], [9], [10], [11], [12], [13].

Based on this literature review, 35 Scrum anti-patterns were selected for the survey, which are shown in Table I. To systematize, they were then assigned to one of 7 sections, i.e. Sprint, Daily Scrum, Product Backlog, Product Owner, Sprint Planning, Development Team, and Completing the Sprint. For each of the anti-patterns, survey respondents who indicated that they use or have used Scrum in their development process responded whether and how often they had encountered such a problem in their organizations. A five-point Likert scale was used, along with an additional option of "I don't know". The survey was prepared in Polish.

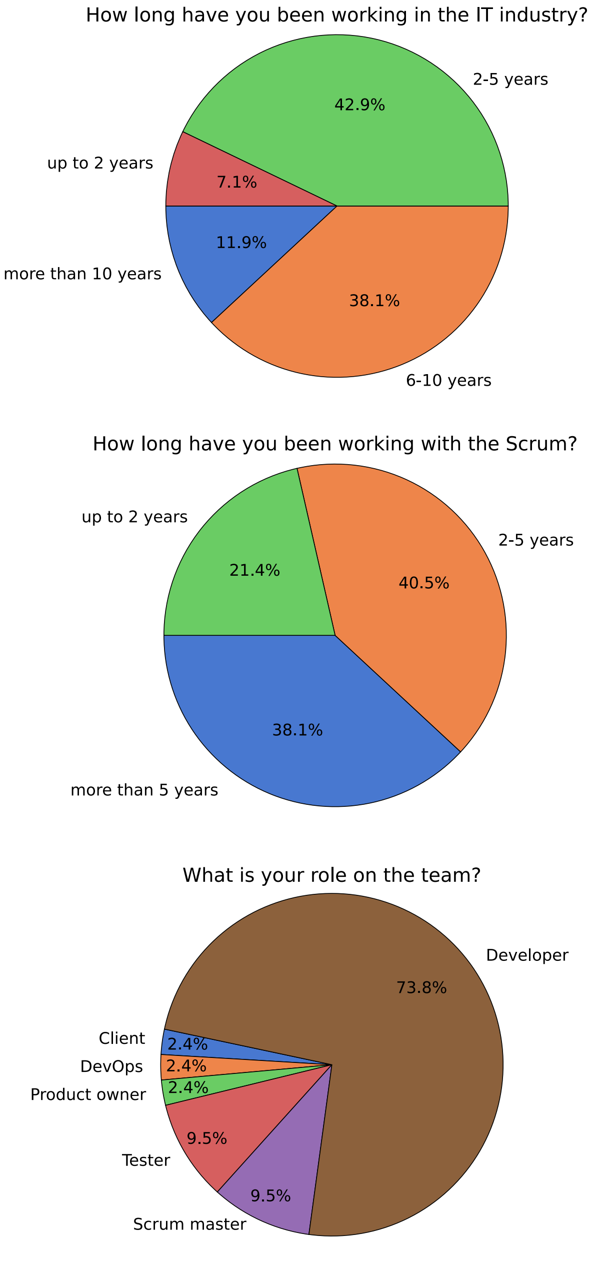

Fig. 1. Experience of survey participants

A. Sprint

The Scrum Guide suggests that sprints should last one month or less and that their length should remain constant throughout the project. Testing and all tasks related to both adding new functionality and testing new code should be completed at the end of the sprint. In addition, progress should be tracked using a burndown chart [14]. The identified anti-patterns that belong to this section are presented in Table II.

B. Daily Scrum

Daily Scrum should take place every day at a fixed time. Each team member should actively participate in the meeting and answer key questions (What did I do yesterday? What will I do today? What obstacles did I encounter?) The meeting should last no longer than 15 minutes [14]. The anti-patterns that have been identified and fall under this section are presented in Table III.

C. Product Backlog

The product backlog should contain items rather than traditional large documentation. The items should be sorted by risk factor and value, and can take the form of user stories that are small enough to be completed in a single sprint [14]. The identified anti-patterns are presented in Table IV.

D. Product Owner

The product owner (PO) represents the interests of the stakeholders and manages the product backlog. Any changes to the backlog can only be introduced by the product owner, and the decisions made should be respected by the entire team [14]. The identified anti-patterns that are part of this section are listed in Table V.

E. Sprint Planning

Sprint planning is the process of deciding what will be worked on in the sprint. Developers should be involved in the selection of tasks, but the product owner has the final decision. Tasks are broken down into smaller ones as needed [14]. The identified anti-patterns are presented in Table VI.

F. Development Team

Programmers in Scrum should form a self-sufficient team with good knowledge of the technical and business knowledge. They should have the competence to both develop and test new versions of software [14]. In this section, 3 anti-patterns were identified and are presented in Table VII.

G. Completing the Sprint

Two meetings should be held at the end of the Sprint. A Sprint Review for the customer, where feedback is received and a demonstration is given, and a Retrospective for the Scrum Team, where they discuss what went well and what went wrong during the Sprint [14]. Table VIII presents the anti-patterns associated with this section.

IV. Results

The survey was conducted in May and June 2022. The invitation to participate was published on LinkedIn and on social media. A total of 42 people took part in the survey.

At the beginning of the survey, information about the participants' experience in IT and Scrum projects was collected. The results are shown in Figure 1. Most of the respondents have commercial IT experience of more than 5 years, and only three have worked in the industry for less than 2 years. Regarding the work with the Scrum methodology, 16 had more than 5 years of experience, 17 between 2 and 5 years, and only 9 less than 2 years. Developers dominated the survey with 31 respondents. In addition, 4 scrum masters and 4 testers participated in the survey, as well as one product owner, one DevOps, and one customer representative.

A. Sprints

The results of the survey regarding sprints are shown in Table II and Figure 2. Of the 5 anti-patterns identified, two were mostly indicated as occurring rarely or never. All respondents indicated that the sprint length is always or mostly in line with the Scrum Guide. In addition, 66% indicated that sprints are always the same length, and only one participant indicated that the opposite is often the case.

In the case of the invisible progress anti-pattern, responses were fairly evenly distributed. Twenty respondents reported that this never or rarely occurs, and 21 reported that it sometimes, often, or always happens.

The results of the survey, on the other hand, confirmed the presence, the last two anti-patterns. None of the respondents stated that there is never a situation where all the tasks that are supposed to be completed in a sprint are completed. In addition, 66% indicated that always or often not all tasks are completed in a given sprint, and 26% that this occurs sometimes. This led to the identification of another anti-pattern – testing in the next sprint. Only 11 respondents reported that this doesn't or rarely happen, while as many as 19 reported that it often or always is the case.

B. Daily Scrum

Table III and Figure 3 shows the results of the daily scrum related anti-patterns. Based on the responses, it can be concluded that daily Scrum in most cases actually take place every day. Only 2 respondents reported that it sometimes happens that a meeting is not held every day, and another two that it is the norm.

For the next two anti-patterns "Not everyone actively participates in the meeting" and "Not all key issues are addressed," the responses indicate that such situations do occur in some organizations. For the latter, only 8 respondents indicated that this never happens.

TABLE II
Sprint related anti-patterns

Question	I don't now	Never	Rarely	Sometimes	Often	Always
Sprints that are too long	1	33	5	3	0	0
Variable lengths of sprints	1	28	10	2	1	0
Unfinished tasks	0	0	3	11	19	9
Testing in next sprint	3	5	6	9	15	4
Invisible progress	1	5	15	13	6	2

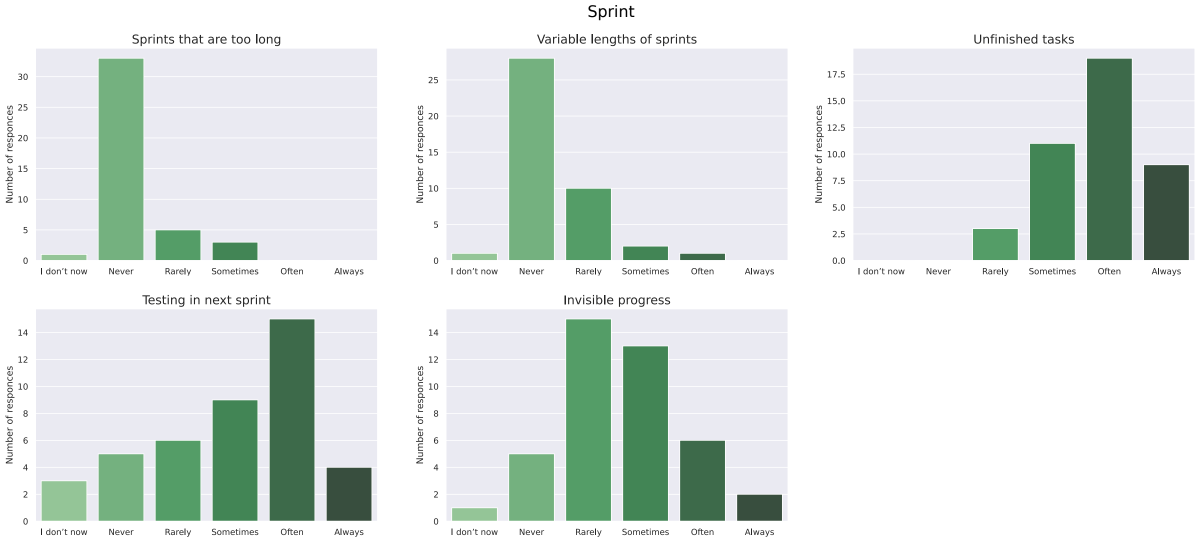

Fig. 2. Sprint related anti-patterns

TABLE III
DAILY SCRUM RELATED ANTI-PATTERNS

Question	I don't now	Never	Rarely	Sometimes	Often	Always
Not everyone actively participate in the meeting	0	15	9	12	3	3
Daily Scrum lasts longer than 15 minutes	0	1	9	9	16	7
The Daily Scrum does not take place at a fixed time of day	0	33	6	3	0	0
Not all key issues are addressed	1	8	16	13	2	2
Daily scrums are not held every day	1	28	9	2	0	2

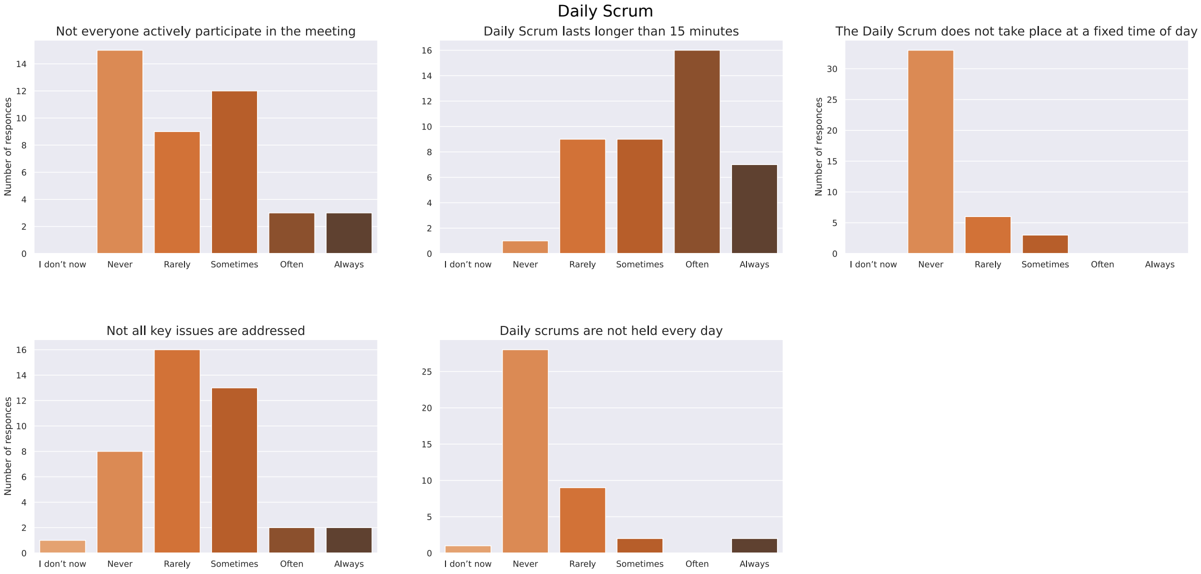

Fig. 3. Daily scrum related anti-patterns

The analysis of the survey results shows that the Daily Scrum goes beyond the recommended 15 minutes in a significant number of cases. Only one respondent reported that it never happens, and as many as 23 that always or often.

C. Product Backlog

The analysis of the responses related to the product backlog showed that the anti-patterns "Extensive requirements documentation instead of user stories" and "User stories that are too extensive" occur rarely in projects. None of the respondents indicated that this situation always occurs, and only 2 and 7, respectively, indicated that it often happens.

On the other hand, in the case of the anti-pattern concerning disordered backlog, more than half of the responses indicated that this situation happens sometimes, often or always. Detailed data with results are shown in Table IV and Figure4.

D. Product Owner

The analysis of the responses related to the product owner showed that only the anti-pattern "Stakeholder indecisiveness" is the common issue among the respondents' organizations. It was reported by 32.5% as often or always occurring. Of the remaining anti-patterns, all received more than 63% of responses that they never or rarely occur. The detailed results of the survey are presented in Table V and Figure 5.

It should be noted that this section of questions was characterized by the highest number of "I don't know" responses. This may indicate that respondents do not fully understand the role of the product owner.

E. Sprint planning

Among the 10 anti-patterns for sprint planning, as many as 2 received 40% or more "Often" or "Always" responses. These are "Sprint goal set at the end of the meeting or not at all", "User stories are not fully refined" and "A burndown chart is not used".

Of the remainder, only the "No estimation of resources available for the upcoming sprint" anti-pattern can be reported as relatively rare, with 64% reported for the "Never" and "Rarely" responses. All others are relatively often identified as occurring in respondents' projects. As can be seen in Table VI and Figure 6, all the others are relatively common in respondents' projects.

F. Development team

The results of the survey with respect to the development team are shown in Table VII and Figure 7. The anti-pattern "Insufficient technical knowledge" was not indicated by any respondent as occurring always and only by four as sometimes.

TABLE IV
PRODUCT BACKLOG RELATED ANTI-PATTERNS

Question	I don’t now	Never	Rarely	Sometimes	Often	Always
Disordered product backlog	1	6	12	12	7	4
Extensive requirements documentation instead of user stories	2	14	13	10	3	0
User stories that are too extensive	1	11	12	11	7	0

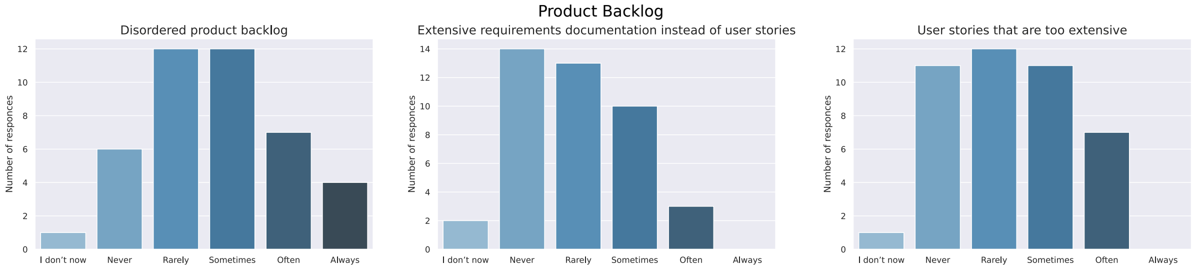

Fig. 4. Product backlog related anti-patterns

TABLE V
PRODUCT OWNER RELATED ANTI-PATTERNS

Question	I don’t now	Never	Rarely	Sometimes	Often	Always
PO without authority, has negligible influence on the selection of tasks to be implemented	1	19	10	6	5	1
Stakeholder indecisiveness – requirements come from multiple stakeholders and compete for prioritization	1	8	11	7	8	5
Lack of unanimity whether the task has been completed	1	12	16	10	2	1
An indirect customer who is service provider of its own customer	9	14	7	7	4	1
PO delegated by a client and does not understand the role	7	17	8	5	4	0

TABLE VI
SPRINT PLANNING RELATED ANTI-PATTERNS

Question	I don’t now	Never	Rarely	Sometimes	Often	Always
Exact estimation instead of relative estimation of items	2	11	8	10	5	6
Item estimation imposed to the team	0	17	6	6	10	3
No estimation of resources available for the upcoming sprint	0	16	11	7	5	3
Sprint planning meeting has no agenda	3	15	9	9	4	3
Sprint goal set at the end of the meeting or not at all	2	7	8	6	10	10
Not breaking large user stories into smaller ones during a meeting	3	8	12	10	8	2
Disruptions in the development process – other areas of the project are developed in turn without one being completed	2	7	8	17	8	1
Adding items during sprint	0	3	18	11	8	2
User stories are not fully refined	0	2	5	18	10	7
A burndown chart is not used	2	8	5	11	5	11

More than half of respondents indicated that they had never or rarely encountered “Semi functional teams” anti-pattern.

Lack of business knowledge, on the other hand, received the most responses about its occurrence, with more than 65% of the responses indicating that it happens sometimes, often, or always.

G. Completing the sprint

None of the anti-patterns classified in the sprint completion section are present in a significant proportion of respondents’ organizations. Table VIII and Figure 8 shows that only “The sprint does not end ends with a demonstration” was reported as often or always present in 36.8% of the responses.

Among the rest, however, “Missing retrospectives” and “Combining the two meetings into one” can still be distinguished as the ones with a significant proportion of “Sometimes”, “Often” and “Always” answers.

H. Summary of the results

To identify the most common anti-patterns, an prevalence rate was calculated based on the survey results. The weighted sum of responses was calculated using the following weights: “I don’t know” – 0, “Never” – 0, “Rarely” – 1, “Sometimes” – 2, “Often” – 3, and “Always” – 4.

The final score was then calculated for each sum as a fraction of the maximum score possible, i.e. 168. Table IX lists all the anti-patterns ordered by calculated score.

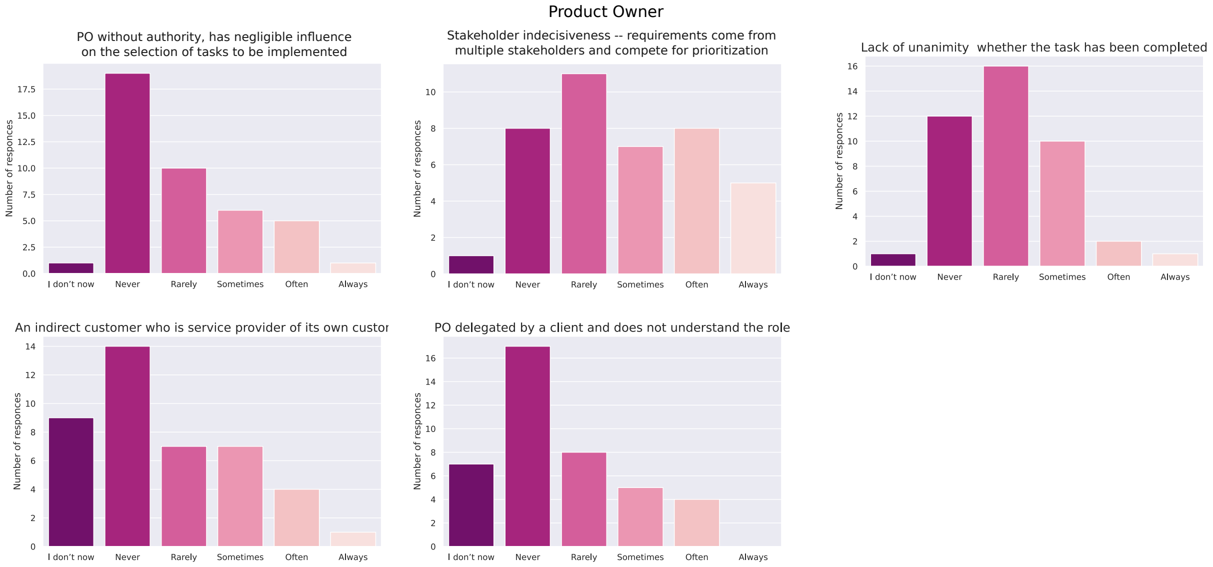

Fig. 5. Product owner related anti-patterns

TABLE VII
DEVELOPMENT TEAM RELATED ANTI-PATTERNS

Question	I don't now	Never	Rarely	Sometimes	Often	Always
Semi functional teams	2	12	10	7	7	4
Insufficient technical knowledge	0	13	14	10	5	0
Lack of business knowledge	1	8	6	10	15	2

TABLE VIII
COMPLETING THE SPRINT RELATED ANTI-PATTERNS

Question	I don't now	Never	Rarely	Sometimes	Often	Always
No or too long waiting for feedback (lack of Sprint review or stakeholders do not show interest)	2	13	13	4	9	1
The sprint does not end ends with a demonstration	4	12	8	4	8	6
Demonstration for the wrong targets	10	13	6	6	5	2
Missing retrospectives	0	23	5	5	5	4
Combining the two meetings into one	4	19	6	5	3	5

V. DISCUSSION

In terms of the prevalence of anti-patterns studied, "Unfinished Tasks" received the highest score. A situation in which some tasks are not completed within a sprint is in clear contradiction to Scrum's guidelines, which states that "Sprint may be considered a short project" [14]. Of the respondents, only 3 people reported that such a situation rarely happens, and none that it never does. In our opinion, this is a serious violation of the guidelines and indicates not so much poor work by the development team, but rather poor planning of the tasks to be completed within the sprint.

The second most common anti-pattern is extending daily scrums beyond the recommended 15 minutes. Only one respondent reported never having such a situation and 9 rarely. This situation may stem from an incomplete understanding of the Scrum Guide, which openly states that "Daily Scrum is not the only time developers are allowed to adjust their plan" [14]. Daily Scrum should only focus on progress and planning for the next day's work. In practice, in addition to progress reports and planning for the next day's work, this meeting is often used to discuss other issues, such as resolving technical problems that have arisen. We believe this is not a serious problem, but it should be encouraged to limit these meetings to recommended purposes only, and other issues should be resolved in additional meetings, perhaps in a limited group.

Another anti-pattern with the comparable prevalence score is "User stories are not fully refined". This problem stems directly from the problem of requirements engineering. Unlike traditional software development methods, the Scrum methodology does not formally define how requirements are elicited. This can lead to less commitment and dedication to creating comprehensive user stories. Therefore, it is necessary to promote a balanced approach to requirements definition in

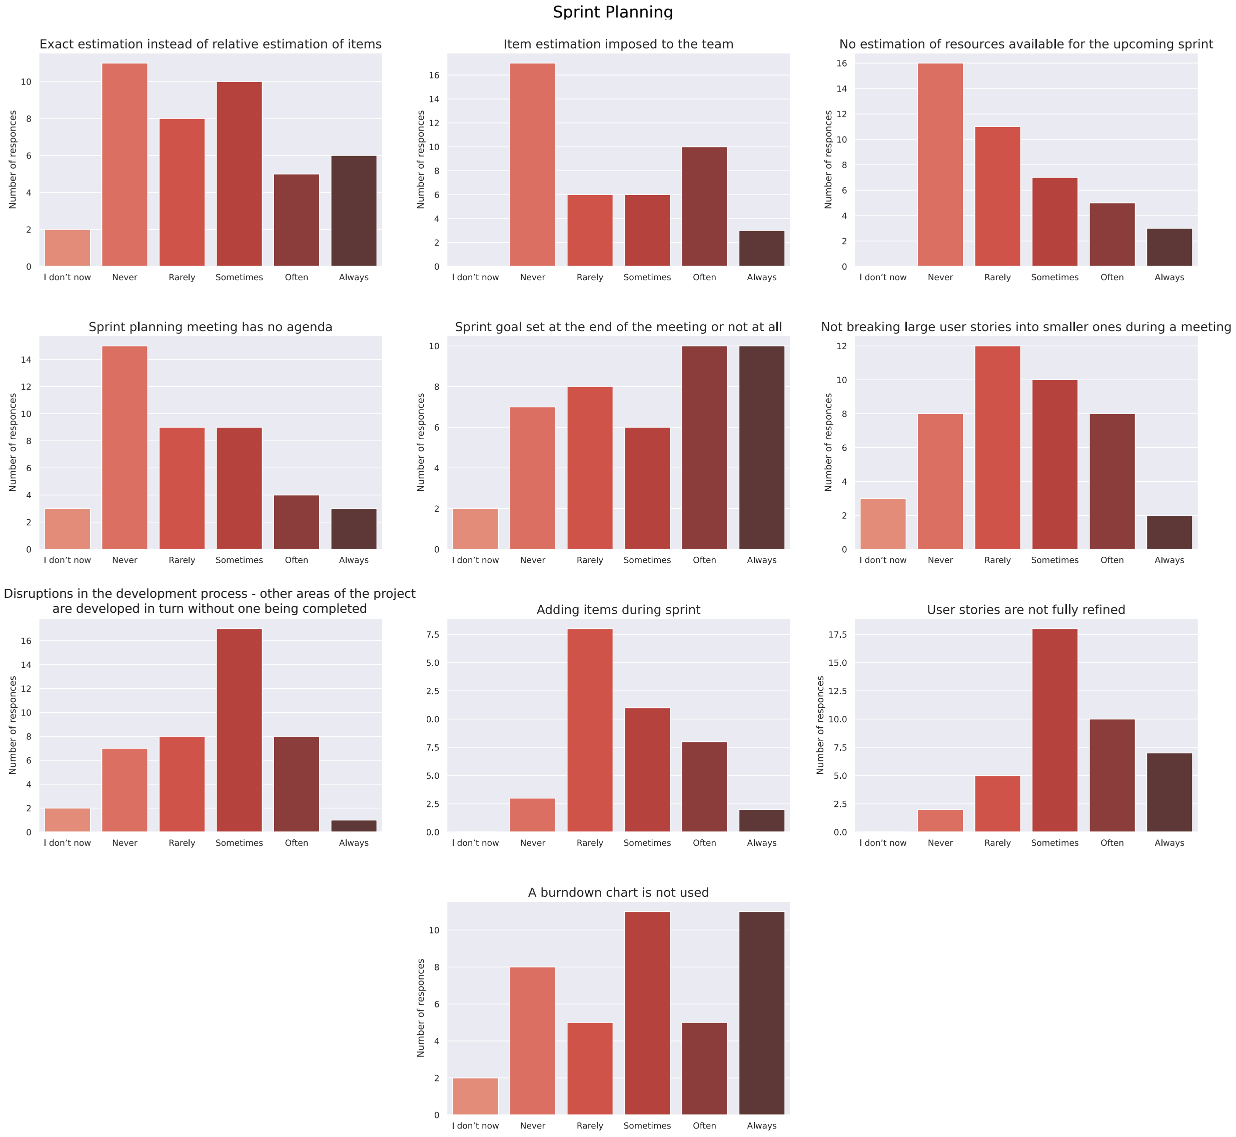

Fig. 6. Sprint planning related anti-patterns

agile software development organizations.

According to the Scrum Guide, the sprint goal should be defined at the sprint planning meeting. However, the survey results show that this is often not the case and that the goal is not defined at all or only at the end of the sprint. In our view, this is a serious violation of Scrum principles. Clear visibility of the purpose of the sprint leads to better coordination of work and greater involvement of team members.

Another anti-pattern in order of the prevalence score relates to not using the burndown chart. However, this is not the only way to visualize the project's progress. Therefore, we cannot draw too far-fetched conclusions here.

The last anti-pattern with prevalence score above 50% is "Testing in next sprint". This can be linked to the previously described prevalence of not completing tasks defined for the sprint. In our opinion, this is also a very important issue. Lack of testing leads to delivery and demonstration of potentially non-working software at the end of Sprint. Scrum guide defines increments that are produced within a single sprint must be usable. Without thorough testing, this cannot be guaranteed. Therefore, it is important to emphasize to the stakeholders of the Scrum project the importance of continuous testing of the delivered functionality.

The least common anti-patterns are related to the length of sprints and Daily Scrums. The respondents confirmed that in their organizations, the length of the sprint is usually within the guidelines and is constant throughout the project. Furthermore, Daily Scrums are held daily and at fixed times.

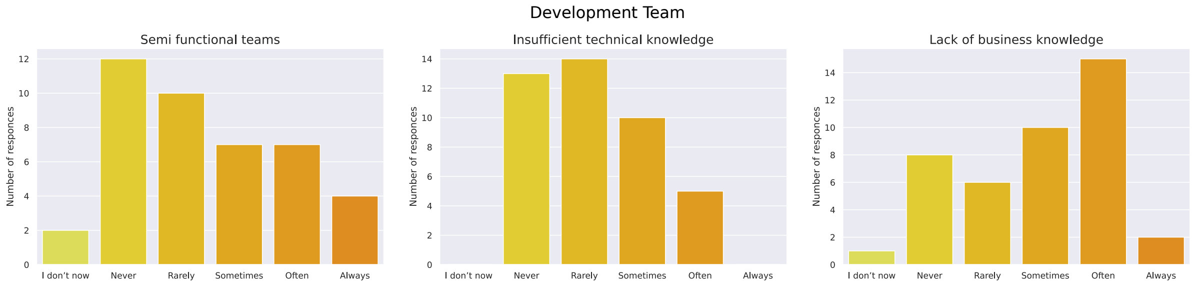

Fig. 7. Development team related anti-patterns

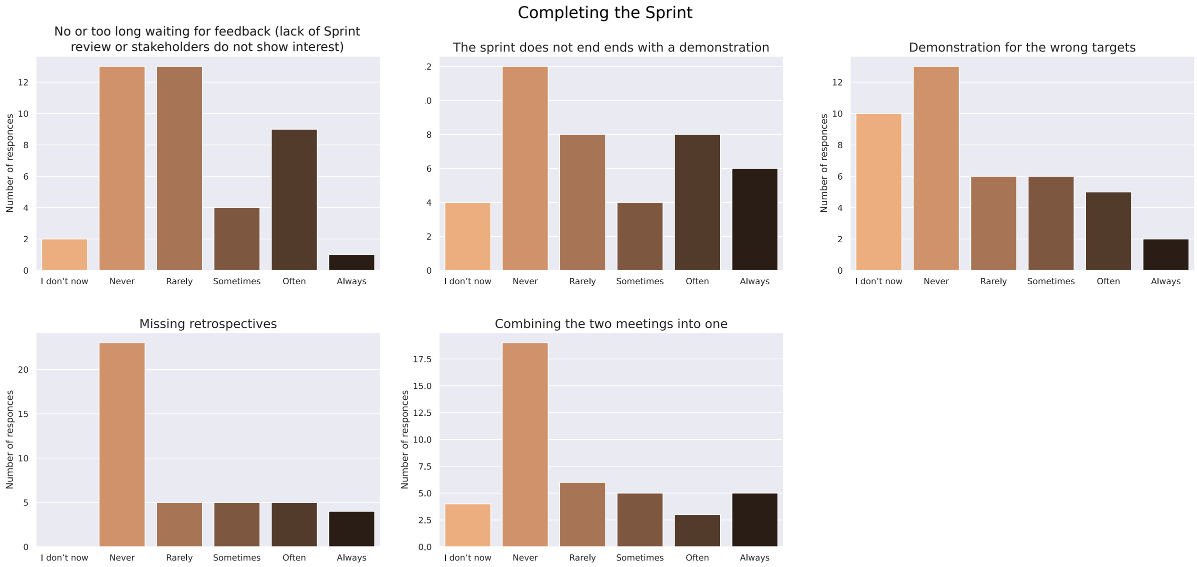

Fig. 8. Completing the sprint related anti-patterns

VI. Conclusion

The aim of the study was to determine the prevalence of 35 anti-patterns in Scrum software development methodology in Polish companies. Through a survey of industry professionals, we identified 6 most common issues in the organizations of the respondents. Among them, we believe that “Unfinished Tasks”, “User stories are not fully refined”, “Sprint goal set at the end of the meeting or not at all” and “Testing in next sprint” are the most critical. Although the presence of the remaining anti-patterns may not be critical to project success, they do indicate areas where teams can improve their adherence to Scrum principles. Overall, the findings of this study provide valuable insights into the current state of Scrum methodology in software development organizations.

While this study has provided valuable insights into the current state of Scrum methodology in software development organizations, further research is needed to understand the underlying causes of these issues. In future research, we aim to focus on investigating why these anti-patterns occur and what factors contribute to their persistence. This could be achieved through in-depth interviews with experienced project managers and Scrum Masters who have encountered these anti-patterns in their work. Such interviews could shed light on the organizational and cultural factors that lead to the breaking of Scrum rules and provide guidance on how to address these issues effectively. By gaining a deeper understanding of the root causes of these anti-patterns, organizations can take more targeted and effective action to improve their Scrum practices and increase the success of their projects.

TABLE IX
PREVALENCE SCORE OF ANTI-PATTERNS

	Anti-pattern	Weighted sum	Score
1.	Unfinished tasks	118	70.24%
2.	Daily Scrum lasts longer than 15 minutes	103	61.31%
3.	User stories are not fully refined	99	58.93%
4.	Sprint goal set at the end of the meeting or not at all	90	53.57%
5.	A burndown chart is not used	86	51.19%
6.	Testing in next sprint	85	50.60%
7.	Lack of business knowledge	79	47.02%
8.	Disordered product backlog	73	43.45%
9.	Adding items during sprint	72	42.86%
10.	Disruptions in the development process – other areas of the project are developed in turn without one being completed	70	41.67%
11.	Stakeholder indecisiveness – requirements come from multiple stakeholders and compete for prioritization	69	41.07%
12.	Invisible progress	67	39.88%
13.	Exact estimation instead of relative estimation of items	67	39.88%
14.	Not breaking large user stories into smaller ones during a meeting	64	38.10%
15.	The sprint does not end ends with a demonstration	64	38.10%
16.	Semi functional teams	61	36.31%
17.	Item estimation imposed to the team	60	35.71%
18.	Not all key issues are addressed	56	33.33%
19.	User stories that are too extensive	55	32.74%
20.	Not everyone actively participate in the meeting	54	32.14%
21.	No estimation of resources available for the upcoming sprint	52	30.95%
22.	No or too long waiting for feedback (lack of Sprint review or stakeholders do not show interest)	52	30.95%
23.	Sprint planning meeting has no agenda	51	30.36%
24.	Insufficient technical knowledge	49	29.17%
25.	Lack of unanimity whether the task has been completed	46	27.38%
26.	Missing retrospectives	46	27.38%
27.	Combining the two meetings into one	45	26.79%
28.	Extensive requirements documentation instead of user stories	42	25.00%
29.	PO without authority, has negligible influence on the selection of tasks to be implemented	41	24.40%
30.	Demonstration for the wrong targets	41	24.40%
31.	An indirect customer who is service provider of its own customer	37	22.02%
32.	PO delegated by a client and does not understand the role	30	17.86%
33.	Daily scrums are not held every day	21	12.50%
34.	Variable lengths of sprints	17	10.12%
35.	The Daily Scrum does not take place at a fixed time of day	12	7.14%
36.	Sprints that are too long	11	6.55%

***Abstract*—Food authenticity is a significant concern in the meat industry, demanding effective detection methods. This study explores the use of multispectral imaging (MSI) and deep learning for meat adulteration detection. We evaluate different deep learning models using transfer learning and preprocessing techniques in a multi-level adulteration classification task. In addition, we propose a novel approach called one-band mixed augmentation for band selection in MSI data, which outperforms traditional reflectance-based feature selection and enhances model robustness. Furthermore, employing the nine-crop approach for dataset augmentation improved the accuracy from 0.63 to 0.74 for DenseNet201 model without transfer learning. This research contributes to advancing food safety assessment practices and provides insights into the application of deep learning for preventing food adulteration. The proposed one-band mixed augmentation approach offers a novel strategy for handling band selection challenges in MSI data analysis.**

I. Introduction

FOOD safety has become a major issue in recent years, garnering significant attention from regulators and industry stakeholders alike. This issue is particularly critical when it comes to minced meat, which lacks distinctive morphological characteristics, making it more susceptible to intentional adulteration. Such fraudulent practices not only pose serious health risks to consumers but also undermine the integrity of the entire food supply chain, eroding public trust in the food industry. Consequently, it is imperative to adopt proactive measures for detecting and preventing food adulteration, ensuring the delivery of safe, reliable, and high-quality food to consumers.

Traditional methods for detecting meat adulteration typically involve destructive sample analysis, such as PCR analysis [1], are time-consuming and require specialized environments and trained professionals. Consequently, the need for effective and efficient techniques to detect food adulteration has become increasingly urgent. To address this challenge, researchers have investigated the use of non-contact technologies to address meat safety concerns, including the detection of fraud in processed meat using non-destructive spectroscopic methods [2]. Additionally, gas sensors have been employed for monitoring meat quality [3], while electronic noses have been utilized for monitoring meat spoilage [4]. These advanced technologies provide cost-effective and rapid alternatives to traditional methods, and their integration into food safety regulations reflects their increasing importance in ensuring the integrity of the food supply [5].

Multispectral imaging (MSI) has received considerable attention in recent years as a fast and non-destructive analytical approach to determining food quality and safety evaluation. MSI captures image data in specific wavelength ranges, providing spatial and spectral information of the object under analysis. Different meat qualities have different reflection intensities under different spectra [6], making it particularly useful for detecting food adulterants. It has been successfully used in various food safety applications, including the evaluation of microbial contamination in ready-to-eat vegetable salad [7], the assessment of cowpea seed health and differentiation of fungal species [8], and the evaluation of ready-to-eat pineapple quality [9]. Additionally, MSI has been used to estimate microbial spoilage in minced pork [10].

Machine learning models, such as partial least squares regression (PLSR) and support vector machines (SVM), have been applied to detect meat adulteration using MSI data [11]–[14]. However, current research on MSI for meat adulteration often utilize only limited attributes of the image data, such as mean and standard deviation, which can be a limitation in terms of accuracy and reliability. This limitation leaves room for improving the accuracy and reliability of meat quality control systems.

To address this limitation and further enhance meat quality control, the combination of MSI with deep learning techniques, such as convolutional neural networks (CNNs), has gained attention. We can improve the accuracy and reliability of meat quality control systems by using these models for image classification tasks in the food domain, specifically for meat adulteration. Although some research has explored the use of CNNs for image classification [15], there is still a gap in the literature on using these models for meat quality control systems.

A previous study developed a framework for coffee maturity classification with 15 bands of multispectral data based on CNNs and achieved a relevant high accuracy on five classes [16], achieved up to 98% accuracy on the dataset and 100% accuracy on cross-validation. However, this approach has not been applied to the problem of meat adulteration and spoilage in MSI data.

By leveraging the comprehensive information provided by MSI and harnessing the capabilities of deep learning, we seek to develop more effective methods for preventing and detecting meat adulteration. In order to facilitate the goals of our study, it was necessary to repreprocess data specifically for meat adulteration, as there was no readily available MSI image dataset for this purpose. We also adapt state-of-the-art CNN models and perform several optimizations to ensure their effectiveness in analyzing the acquired MSI data. Additionally, we explore the potential of leveraging the rich information contained in MSI data by experimenting with different preprocessing approaches.

Through our research, we aim to provide valuable information on the utilization of MSI and deep learning techniques, which can lead to the development of advanced approaches to ensure food safety and preserve the integrity of the meat supply chain. The findings of our study hold great promise for substantial advancements in current practices, leading to the development of more efficient and dependable methods for preventing and detecting food adulteration. As a result, these advancements will play a crucial role in safeguarding the safety and integrity of the food supply chain.

II. Methodology

In this study, we conducted experiments using 180 minced meat samples from 9 adulteration classes. We extracted multi spectral images in 18 bands and encoded and resized them into the required size by a deep learning model. We started with fine-tuning SOTA CNNs models to detect patterns and features indicative of meat adulteration, but the particularities of our image dataset indicated that training from scratch might be a better option for learning relevant features. The best-performing model was selected as the baseline. Additionally, we explored three different pre-processing modalities to assess their impact on the model's performance.

A. Datasets

The data acquisition process followed the pipeline illustrated in Fig. 1. Our study utilized a dataset consisting of MSI images depicting chicken and pork meat samples with varying levels of adulteration. The levels of adulteration spanned from 0% (indicating pure chicken) to 100% (representing pure pork), with nine intervals in between: 0%, 10%, 25%, 40%, 50%, 60%, 75%, 90%, and 100%. Chicken and pork were purchased from four different butcher shops (b_1, b_2, b_3, b_4) in Greece. Samples from each butcher shop contained five instances per adulteration level resulting in 45 samples per butcher shop. In total, the dataset contains 180 samples from four butcher shops.

The images were acquired using the Videometer lab system developed by the Technical University of Denmark and commercialized by "Videometer A/S" (http://www.videometer.com). The MSI images consist of 18 bands for each meat sample. The samples were kept at 4°C and captured after 24 h. There are a total of 180 sample image files of various temperatures and various adulteration levels. The final size of the dataset is 3240 (180x18) grey-scale images from 180 meat samples. The dataset includes nine classes, each representing a different level of adulteration.

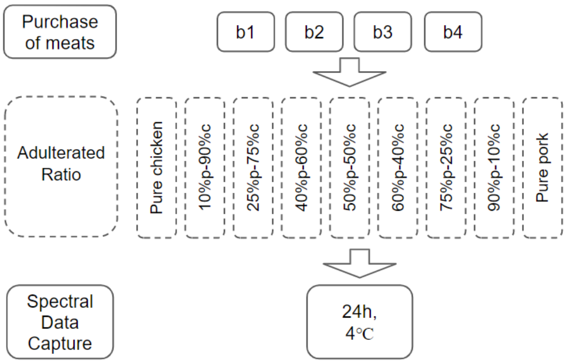

Fig. 1. Multispectral Imaging Acquisition pipeline

B. Data Preprocessing

Proper data preprocessing is crucial as it is the foundation for subsequent data analysis. By performing appropriate data preparation techniques, we can guarantee that the analysis results are reliable and carry significant implications. Additionally, it allows us to address any potential issues or biases in the data and optimize the performance of our machine learning model.

TABLE I
Details of Image Bands and Corresponding Wavelengths Used by Videometer Lab MSI Camera for Capturing MSI Dataset.

the band and wavelength details						
band	band1	band2	band3	band4	band5	band6
region	UV	Violet	Blue	Blue	Cyan	Green
wavelength	405nm	435nm	450nm	470nm	505nm	525nm
band	band7	band8	band9	band10	band11	band12
region	Green	Yellow	Red	Red	Red	Red
wavelength	570nm	590nm	630nm	645nm	660nm	700nm
band	band13	band14	band15	band16	band17	band18
region	NIR	NIR	NIR	NIR	NIR	NIR
wavelength	850nm	870nm	890nm	910nm	940nm	970nm

a) Image Preprocessing: Each sample in the dataset contains 18 grey-scale images of 18 non-uniformly distributed wavelengths with a size of 1200 by 1200 pixels. Each image represents a spectral feature of a sample in a particular band. Table I presents a detailed overview of the chosen wavelength bands utilized in our study. The selected wavelengths cover a spectrum ranging from 405nm to 970nm, comprising a total of 18 bands. Notably, this includes one band in the ultraviolet (UV) region and six bands within the near-infrared (NIR) region. This information provides a comprehensive understanding of the specific wavelengths employed in our research analysis. Fig. 2 shows all 18 bands of a sample which is 10%pork-90%chicken.

In order to accommodate the large extracted images within the proposed models, we first resize the images to a standardized size of 224 by 224 pixels. This resizing ensures uniformity and compatibility across the dataset. Following the resizing step, we employ min-max scaling to encode the images as values ranging from 0 to 1. This preprocessing technique effectively normalizes the pixel values, allowing for efficient handling and analysis of the data

b) Label Extraction: The images were labeled based on the information contained within their names, including the adulteration level, band number, sample name, and storage condition. We converted it into integers ranging from 0 to 8. Specifically, '0' denotes pure chicken, while '8' represents pure pork. For adulteration levels between 10% to 90%, we assigned integer values from 1 to 7 to represent varying ratios of pork and chicken: 10% pork - 90% chicken, 25% pork - 75% chicken, 40% pork - 60% chicken, 50% pork - 50% chicken, 60% pork - 40% chicken, 75% pork - 25% chicken and 90% pork - 10% chicken. This scale indicates the percentage of pork and chicken present in each sample, irrespective of which meat has adulterated the other. In the case of pork-adulterated chicken, a smaller scale number denotes a higher level of adulteration. We chose to utilize a single scale to simplify the paper, instead of employing separate scales for each meat species.

While it is important to label each image accurately, we also wanted to ensure that the labels were practical for the intended application. In this case, we use one-hot encoding to encode the image labels into a numerical format, which assigns a unique numerical value to each category. This approach enabled us to quickly generate statistics and analyze the model performance based on different adulteration levels.

C. Basic Adulteration Classification Pipeline

This study focuses on developing an automated method for detecting adulteration in meat samples using multispectral image analysis. The problem is approached as a classification task, where the performance of various deep-learning models is compared. To ensure consistency, we employ a standardized classification pipeline. This involves inputting an array with dimensions (224, 224, 18), representing the 18 bands of information in each sample, into the models. The models are then trained to predict the degree of adulteration based on the input image array.

To evaluate the effectiveness of different CNN-based models, we compare five models available in the Keras library [17]. The initial selection includes VGG16 and VGG19 [18], which serve as established benchmarks for image classification tasks. Additionally, Inception-ResNetV2 [19] and InceptionV3 [20] are chosen for their superior performance in computer vision tasks. Furthermore, we include DenseNet [21], known for its promising outcomes in similar studies.

To leverage pre-existing knowledge, transfer learning is applied to the selected CNN models. This allows us to explore if pre-trained models can enhance the performance of our task. Fig. 3 illustrates the basic experiment pipeline of the CNN models, providing an overview of the process.

We evaluate the performance of our models using two methods. Firstly, we perform a simple train/test split by partitioning the data into two sets, with the training set containing 80% of the data and the test set containing 20%. Given the limited number of samples in our dataset, we also use 5-fold stratified cross-validation (SCV) to evaluate the models more precisely.

The models are trained using the backpropagation algorithm. This algorithm works by calculating the loss function gradient concerning the network weights and using this gradient to update the weights in a direction that minimizes the loss function. This process is repeated iteratively until the network converges on a set of weights that minimizes the loss function. The specific methods and hyperparameters depend on each model. We evaluate the models using accuracy, precision, recall, and F1 score. We chose these metrics to understand the models' performance thoroughly.

D. Transfer Learning

To enhance the classification performance of our model, we opted to incorporate transfer learning into our training process and to evaluate its effectiveness. Given the limited nature of our dataset, transfer learning was considered a potential solution to optimize the model and improve its accuracy. The base model weights obtained from ImageNet [22], which consists of millions of images and 1000 labels, were used to initialize our model and provide a solid foundation for further training.

When dealing with datasets that contain more than three channels, such as our 18-channel multispectral data, transfer learning requires adjusting the pre-trained weights to accommodate the additional channels. Fine-tuning is performed on the first convolutional layer, configured to enable the neural network to read 18-channel images. In this process, the weights of the first convolutional layer are modified to accept the input of 18 channels. This is done by averaging the pre-trained weights of the first convolutional layer's three channels and replicating the resulting weights 18 times to accommodate all 18 input channels.

To align with our experiment's 9-class classification objective, we modified the fully connected output layer of all five models from 1000 to 9. Furthermore, to adapt transfer learning to our specific task, we made variations in the trainable layers of each utilized network. The trainable and non-trainable layers of the models are specified below.

- **VGG-16** consists of 16 trainable layers. While the first two layers remain fixed, the subsequent 14 layers are trainable. The original fully connected layers of 4096 and 4096 were replaced by adapted layers with sizes of 256 and 128, respectively.
- **VGG-19** comprises 19 trainable layers, where the first seven layers are untrained, while the remaining 12 layers are trainable. Similar modifications were made to the

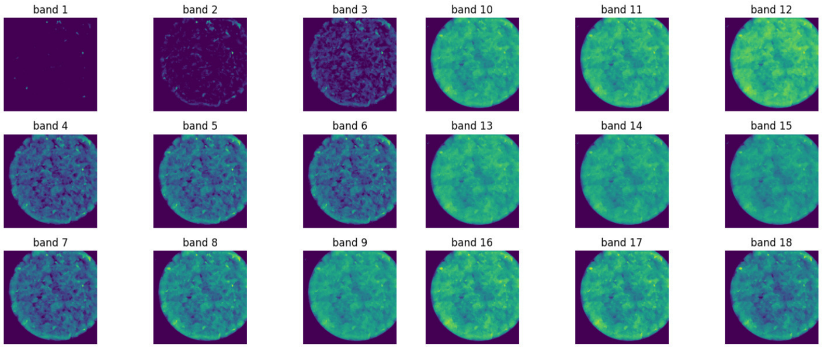

Fig. 2. The 18 bands for a 10% pork-90% chicken sample.

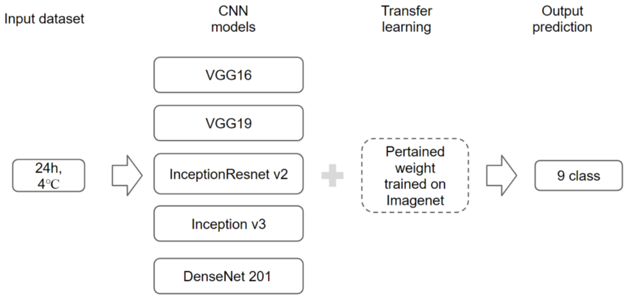

Fig. 3. Baseline CNN Classification Experiment Design

fully connected layers, adjusting their original sizes of 4096 and 4096 to sizes of 256 and 128.

- **InceptionV3** has 310 trainable layers. The first 150 layers are untrained, while the rest are made trainable. The original fully connected layer, initially sized of 2048, is replaced with two new fully connected layers sized of 256 and 128, respectively.
- **Inception-ResNetV2** The first 150 layers are untrained, while the remaining 578 are trainable. The original fully connected layers, sized of 1536, are substituted with two new fully connected layers sized of 256 and 128.
- **DenseNet201** has 706 trainable layers, with the first 150 layers left untrained and the remaining layers made trainable. Two new fully connected layers were introduced, having sizes of 256 and 128, respectively.

By adjusting the trainable layers in the specified way, the neural networks were fine-tuned to better suit our specific problem and data characteristics. The modified models were then used to conduct our experiments and to analyze their performance.

E. Hyperparameter Optimization

After experimenting with several optimizers, including Adam, Adamax, Adamgrad, and SGD, we selected the Adam optimizer for its superior performance. Then, we set the output layer with softmax activation function.

We utilized a learning rate scheduler function to optimize our model's performance. Our approach involved setting an initial learning rate of 0.0001 and employing an exponential decay function that reduced the learning rate by 0.095 at each epoch. The exponential decay scheme provided a smooth decay path, which was particularly effective during the initial stages of training. This strategy helped to improve the learning capacity of the model and yielded better results in our experiments.

F. Cross Validation

Cross-validation (CV) is a widely used technique in machine learning and data analysis to evaluate the predictive performance of models. It helps optimize hyperparameters, identify dataset issues, and prevent overfitting, ultimately improving the effectiveness of models in real-world applications. Stratified cross-validation is an essential variant of CV when working with imbalanced datasets. It ensures that each fold contains representative samples from all classes in the same proportion as the original dataset, mitigating the risk of biased assessments of model performance. By using stratified cross-validation, we can obtain more reliable estimates of the model's generalization capabilities and make better-informed decisions about its suitability for real-world applications.

For our experiments, we used a five-fold stratified cross-validation (5-SCV) approach. The data was divided into five folds, each containing an equal distribution of samples from all classes. The models were then trained on four folds and validated on the remaining one. This process was repeated five times, with each fold used as the validation set once. The stratified aspect of the cross-validation ensured that the class distribution was maintained across all folds, preventing bias in evaluating the models' performance. The final performance metrics were calculated as the average of the five iterations, providing a comprehensive and accurate assessment of the effectiveness of the models.

G. Model Improvements with Various Data Augmentation Configurations

To enhance the classification accuracy, we conducted various experiments on the dataset. We explored several techniques, such as removing uninformative bands, augmenting the training set, and cropping the original image to gather more information. Given the amount of conditions and considered models, we chose to focus on one model (e.g. DenseNet 201 model). Stratified sampling was applied so that 80%-20% of the dataset to be used for training and testing for all experiments. Specifically, for the basic adulteration classification and uninformative bands excluded experiments, the training set consisted of 144 images with 36 testing images. For one band augmentation experiment, the training set was extended to 288 images, while the test set remained at 36 images. The purpose of this was to determine whether augmentation could help the model learn more details about the features needed to classify the original images, rather than the augmented images. In the cropping experiments, the training set is increased to 576 images (for 4 crops) and 1296 (for 9 crops), while the test set size remains constant for consistency reasons.

1) Band Selection: Exclude Uninformative Bands using a Reflectance-based Method: To further refine the dataset and improve the classification performance of CNN models, we conducted a band exclusion approach based on previous research by L.-C. Fengou, P. Tsakanikas, and G.-J. E. Nychas [23]. This previous study compared the mean and standard deviation of the wavelength reflectance of pure chicken and pure pork at different storage times (0 h, 24 h, 48 h) and identified the wavelength from 700 to 940 nm as uninformative, which corresponds to bands 12 to 17 in our dataset. This exclusion was based on the overlap of wavelength reflectance. It is worth noting that the band exclusion approach has improved classification accuracy in previous studies on similar datasets. By excluding uninformative bands, the amount of noise in the data was reduced, and the signal-to-noise ratio was increased, factors which could improve the performance of the models.

To evaluate the impact of the band exclusion on classification performance, we trained the CNN models on a 12-band dataset, where the uninformative bands were excluded. We selected DenseNet201 as our base model without transfer learning and trained it on the 9-class classification task.

2) Optimizing Band Selection: Exclude Uninformative Bands using One-band Mixed Augmentation: Data augmentation is a widespread technique in deep learning used to increase the size and diversity of the training dataset. In our experiments, we applied mixed augmentation to enhance the diversity and size of our training dataset. This technique involves applying various transformations, such as zooming, rotating, shifting, and flipping, to the original data to create new and unique images while preserving the properties of the original data. Zooming allowed us to change the scale of the images, while rotation and shearing enabled us to modify the orientation and shape of the objects within the images. The width and height shifting helped to translate the objects in the images, while the horizontal flipping created a mirror image of the original one. The mixed augmentation method selects a random combination of transformations from the set specified in the augmentation pipeline. The chosen transformations include zooming between 40% and 80% of the original size, rotating the image up to 45 degrees, shifting the width and height of the image by up to 10%, shearing the image up to 20%, and flipping the image horizontally.

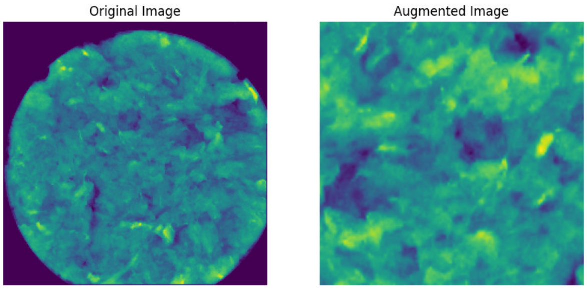

Fig. 4. Example of Augmentation

Fig. 4 shows one augmentation of one 25% pork-75% chicken sample in the dataset. The image underwent several augmentations. First, it was rotated at an angle of -34.97 degrees in a counterclockwise direction. Second, it was translated horizontally by -0.075 and vertically by 11.85 pixels. Third, it was sheared by -0.175, meaning that the object's shape in the image was distorted. Fourthly, the image was zoomed in by a factor of 0.74 along the x-axis and 0.50 along the y-axis. Finally, the image was flipped horizontally.

Multispectral images contain several bands of information, each of which may have varying contributions to the classification performance. In order to determine which bands are more informative for our models, we conduct data selection experiments. To do this, we first apply data augmentation techniques individually to each band in the dataset. Then, we combine the augmented bands and train models on each combination of bands. In this experiment, data augmentation was performed for each band in the dataset, by splitting the data into 144 samples for training and 36 for testing. We applied the described band augmentation process to the training set, which increased the training set size to 288 (for each sample, one band was augmented). Each sample had a shape of (224,224,18), where 224 represents the width and height of the image, and 18 represents the number of bands. Consequently, the final input training shape became (288, 224, 224, 18). Fig. 5 shows the augmentation pipeline of our data.

We evaluate the performance of each model and compare the results to a baseline model (DenseNet 201 without transfer learning) without augmentation. By comparing the performance of all combinations, we can identify the bands that have performed above the baseline and are therefore considered informative. This process allows us to identify the bands that provide the most useful information for classification and can help optimize the selection of bands for future experiments. Furthermore, this approach can be used to investigate the impact of data augmentation on individual bands and could help us understand the effect of each augmentation technique on the overall classification performance.

3) Augmentation by Applying Cropping to All Bands: To strike a balance between the amount of information conveyed

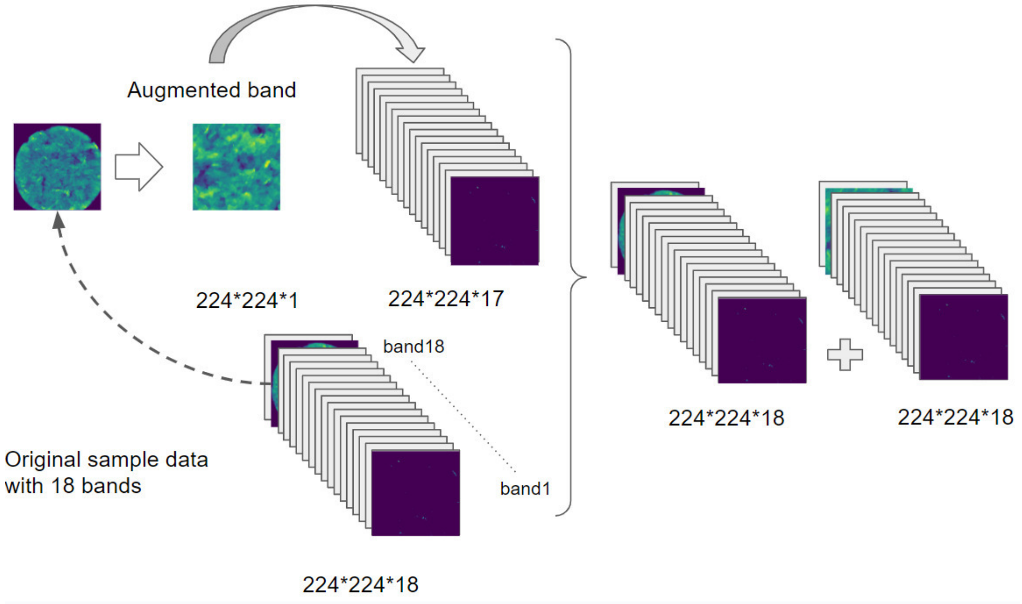

Fig. 5. Pipeline of One-band mixed Augmentation.One band of the original samples is augmented, replacing the original image. The augmented samples are combined with the original samples to form the training set.

by an image and the computational cost required for processing it, image cropping is a beneficial preprocessing technique. By cropping larger images into smaller clips, we can increase the dataset size without sacrificing crucial information, especially when obtaining additional datasets in the same field is challenging.

For the baseline classification, we resized the original images, which had dimensions of (1200 x 1200) pixels, to (224 x 224) pixels. However, this resizing process may result in a loss of information and potentially impact the accuracy of the classification results. To address this challenge, we propose an approach that involves cropping the raw images into four or nine clips. Through experimentation, we determined that four clips, each measuring (600 x 600 pixels), or nine clips, each measuring (400 x 400) pixels, were the most suitable sizes.

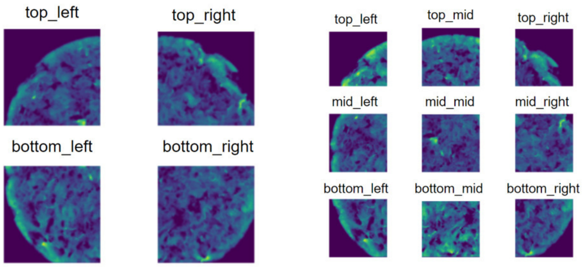

Fig. 6. Example of Image Cropping preprocessing. This image is randomly chosen from the MSI dataset and shows the 4-cropped and 9-cropped versions of the original image.

To maintain the spatial relationship between each cropped image and its original location, we incorporated position information into the extracted CSV file, alongside the corresponding label. This facilitated a clear understanding of the relative location of each cropped clip throughout the data preprocessing pipeline. For the four-cropped approach, we used position information such as lt (top left), lr (bottom left), lb (bottom right), and rb (top right). For the nine-cropped approach, position information included lt (top-left), mt (top-middle), rt (top-right), lm (middle-left), mm (middle-middle), rm (middle-right), lb (bottom-left), mb (bottom-middle), and rb (bottom-right). An example of the cropped images is shown in Fig. 6.

This approach effectively increases the dataset size while preserving the essential information from the original images. Additionally, the inclusion of position information provides valuable context for interpreting and analyzing the cropped clips. Overall, cropping and incorporating position information are effective preprocessing techniques for MSI data, enhancing the analysis quality and facilitating the utilization of these data in machine learning models. In our study, we performed cropping on the original image data, generating four and nine crops, respectively.

III. Results

In this study, we present a comprehensive evaluation of the efficacy of various deep learning models.

We used well-known CNN models including VGG16 and VGG19, Inception-Resnet v2, Inception v3, and DenseNet201 to explore their performance for 9-class adulteration classification task. To further optimize model performance, we leveraged transfer learning techniques.

Furthermore, we experimented with various data augmentation configurations such as rotation, shifting, schearing, flipping and zooming.

We also explored the impact of band selection on model performance, including the exclusion of non-informative bands based on reflectance and augmentation experiments in this study.

By evaluating the performance of various models, our objective was to provide insights into the selection of the most appropriate deep-learning architecture and preprocessing techniques for meat adulteration detection.

A. Best-performing model identification for meat adulteration classification

Table II shows the performance of different deep learning architectures on a 9-class classification task with and without transfer learning. The details of each model is explained in II-D. The results showed that DenseNet201 without transfer learning achieved the best accuracy of 0.63 and a precision of 0.64, while DenseNet201 with transfer learning achieved the best accuracy of 0.62 and the precision of 0.61 on all data sets and combinations.

B. Evaluation of baseline model performance for various data augmentation configurations

As DenseNet201 was the best-performing model, it was selected as a baseline for later experiments. The details of data augmentation are explained in section II-G2. The experiments focus on investigating the effects of band selection and augmentation techniques on the model performance. The results of these experiments are summarized in Table III, demonstrating that excluding non-informative bands improves model accuracy. Furthermore, excluding uninformative bands based on augmentation is shown to enhance model performance, with varying influences observed for different bands. Additionally, the use of all-band cropping augmentation, particularly employing the nine-crop approach, leads to the best results. These findings highlight the significance of band selection and augmentation methods in improving model performance for multispectral imaging data, contributing valuable insights to the field.

1) Band Selection: Exclude Uninformative Bands using a Reflectance-based Method: In this experiment, we trained the baseline model on a 12-band dataset for the 9-class classification task. The bands were selected based on the mean and standard deviation of reflectance for pure classes. The results showed that using 12 bands outperformed models using 18 bands in all metrics, which achieved an accuracy of 0.69 while using 18 bands achieved an accuracy of 0.63.

2) Optimizing Band Selection: Exclude Uninformative Bands using One-band Mixed Augmentation: A mixed band augmentation which is detailed in section II-G2 was applied to the baseline model. Table.IV shows the mean performance of the model under varying band augmentations. Our experimental findings indicate that preprocessing the input images with different band augmentations has a considerable impact on the model's learning capacity. In order to balance computational cost and experimental accuracy, we employed two different random seeds for conducting the experiments.

The average values of the evaluation metrics are presented as the experimental results. In particular, our comparison of the results with the best baseline model introduced in Table II (achieving 0.63 accuracy for the 9-class DenseNet model without augmentation) led to a decrease in performance, including bands: 1, 2, 5, 8, 12, 13, 15 and 16. In contrast, we found that some bands, such as bands: 3, 4, 6, 7, 9, 10, 14, 17, and 18, improved the model's performance.

Fig.7 shows that band 4 (470 nm, blue), band 14 (870 nm, NIR), and band 17 (940 nm, NIR) are the top 3 most informative bands for the dataset using the DenseNet201 model (without transfer learning). The augmentation on band 17 (940nm, NIR) increases the accuracy from 0.72 to 0.81. Therefore, the choice of performing band preprocessing is critical in optimizing the model's accuracy for this classification task.

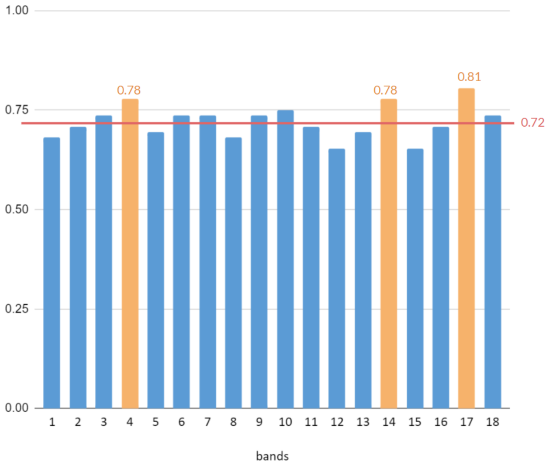

Fig. 7. Comparison of accuracies for various band augmentations on the dataset. The orange columns indicates the top 3 performing augmentation bands, the red line represents the baseline accuracy of the 9-class experiment without augmentation.

Based on the accuracies presented in Table IV, the six lowest performing bands (band1, band5, band8, band12, band13, and band15) were removed. The remaining 12 bands were stacked. The training process for this experiment adhered to the same settings as described in the baseline experiment. The 5-fold cross-validation produced average performance metrics, achieving 0.72 accuracy and 0.72 F1 score.

3) Augmentation by Applying Cropping to All Bands: In order to address the limitations posed by the limited size of the MSI dataset, we used the 4-crop and 9-crop approach to augment the entire 9-class data. Specifically, for the 4-cropped datasets, each class comprised 80 samples, and we used 80% of the dataset for training and 20% for testing, by making sure that none of the cropped versions of the original image would be found in both sets. We trained the baseline model in all these experiments. For the 4-cropped datasets, our experiment achieved 0.71 accuracy for 5-fold stratified cross validation. For the 9-cropped datasets, each class had 180 samples, resulting after augmentation in a total of 1620

TABLE II
PERFORMANCE OF VARIOUS MODELS WITH 5 FOLDS CROSS-VALIDATION WITHOUT AND WITH TRANSFER LEARNING USING 18-BAND 9-CLASS MSI DATA.

samples. We used the same train-test split procedure as above and achieved improved results, with an accuracy of 0.78. The confusion matrices of the three different inputs are visualized in Fig.8. 5-fold stratified cross validation is applied on the 9-crop case, achieving an average accuracy of 0.74.

IV. DISCUSSION

In this study, we examine the effects of various augmentations on the MSI dataset, using CNN based deep learning models for meat adulteration detection. We also inspect the effect of transfer learning and data preprocessing on their performance. The best configuration for the 18- Band, 9 class classification is found as DenseNet201 without transfer learning with an accuracy of 0.63 and F1 score of 0.64.

First we evaluated the performance of different CNN architectures on 9-class classification tasks with and without transfer learning. Our results showed that in the 9-class classification, DenseNet201 achieved the best accuracy with and without transfer learning.

Our findings suggest that the performance of CNN architectures can be influenced by their nature and design. For example, DenseNet201 is composed of densely connected layers, where each layer within a block receives the outputs from all preceding layers within the same block. This architecture promotes feature reuse and information flow, mitigating the vanishing gradient problem.

The number of trainable layers is important because it affects the depth and complexity of the network. A deeper network with more trainable layers has the potential to learn more complex features and patterns in the data. This may explain why Inception-Resnet v2 and DenseNet201 outperformed Inception v3 and VGG architectures in our study. The higher number of trainable layers in these architectures allows them to capture more intricate and nuanced information in the data, leading to improved performance in the classification tasks.

The achieved results indicated that transfer learning did not lead to a significant improvement in performance.This is consistent with the findings of a previous work[24] , they suggested that models trained from scratch can perform just as well as those that are pre-trained, even with substantially less data.

In addition to model architecture, the data configuration was found to have essential impact on the model performance. The experiment excluding uninformative bands chosen by reflectance revealed that the reflectance-based method improves classification performance. As shown in Fig.9, the reflectance of different adulterated samples in the dataset experienced slight changes as the adulteration level increased. By removing non-informative bands (700 to 970 nm), the model achieved better performance using only 12 bands compared to using all 18 bands for the MSI dataset.

Additionally, the experiment demonstrated that the performance improvement achieved by using 12 bands was consistent across different folds of the cross-validation, as indicated by the low standard deviation of the metrics. This consistency

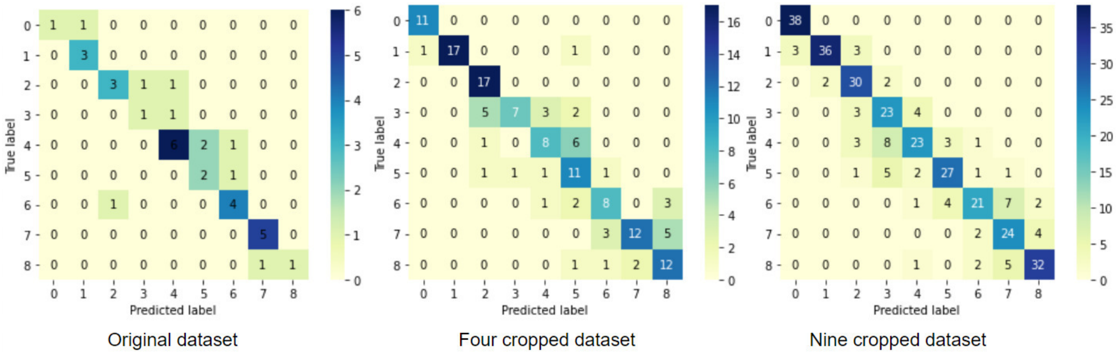

Fig. 8. Comparison of Confusion Matrices for Original, 4-Cropped, and 9-Cropped Images for the baseline model.

suggests that the exclusion of non-informative bands enhances the model's performance, and the results are not dependent on a specific fold.

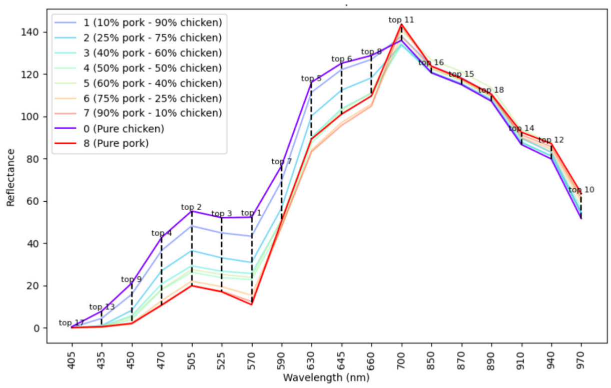

Fig. 9. Mean reflectance of samples of different adulteration level.

In the experiment on optimizing band selection using one-band mixed augmentation, the impact of different bands on the DenseNet201 model's performance without transfer learning was investigated. The results revealed that the choice of bands for augmentation significantly influenced the model's learning capabilities. Specifically, band 4 (470 nm, blue), band 14 (870 nm, NIR), and band 17 (940 nm, NIR) were identified as the most informative bands for the MSI dataset on the DenseNet201 model. Augmenting band 17 further improved the model's accuracy from 0.72 to 0.81, highlighting the importance of band selection and preprocessing in optimizing performance.

Comparing the two methods, one-band mixed augmentation proved to be a better approach for band selection compared to reflectance-based feature selection. Although the performance difference between the two methods was insignificant, the augmented-based 12-band approach slightly outperformed the reflectance-based 12-band approach for the MSI dataset. This finding suggests that one-band mixed augmentation enables a more comprehensive exploration of the feature space, leading to a more robust model.

Both experiments show promising results for selecting informative bands in multispectral image classification tasks. The reflectance-based method provides a straightforward and intuitive approach, while one-band mixed augmentation allows for a more exploratory analysis, potentially uncovering new features beyond spectral characteristics alone. Future research could explore combining these two approaches to leverage their respective advantages and further enhance classification performance.

The size of an original image file, amounting to 103 MB, is a pertinent consideration in the context of the present study, which seeks to identify and analyze meat adulteration in minced chicken-pork samples. Moreover, the extraction of a (224,224,18) numpy array from the original file raises concerns about the optimal utilization of the information contained within the multispectral data. To overcome these limitations, another experiment applied cropping based preprocessing to the original (1200 x 1200) pixels image.

By employing the four-crop and nine-crop approach to augment the entire dataset for the 9-class case, significant improvements were observed. The results indicate that the nine-cropped dataset achieved the highest accuracy of 0.74, outperforming both the uncropped and four-cropped datasets. These findings show the potential of crop augmentation as an effective approach to address the challenges posed by limited dataset sizes and for maximizing the utilization of multispectral data in classification tasks.

V. Conclusion

Our study highlights the potential of CNN models for detecting adulteration in minced meat samples. Among the evaluated models, DenseNet performed the best, showcasing its suitability for this task. We found that transfer learning did not significantly enhance model performance. Preprocessing data augmentation techniques, particularly our proposed one-band mixed augmentation approach, proved crucial in improving the model accuracy. Although our study had limitations, such as a small dataset and focus on a specific type of adulteration, it lays the groundwork for future research in this area. Further exploration of larger datasets and integration of additional data types are encouraged to advance food safety practices.

***Abstract*—The paper presents investigations concerning the decision rule filtering process controlled by the estimated relevance of available attributes. In the conducted study, two search directions were used, sequential forward selection and sequential backward elimination. The steps of sequential search were governed by three rankings obtained for variables, all related to characteristics of data and rules that can be induced, as follows, (i) a ranking based on the weighting factor referring to the occurrence of attributes in generated decision reducts, (ii) the OneR ranking exploiting short rule properties, and (iii) the proposed ranking defined through the operation of greedy algorithm for rule induction. The three rankings were confronted and compared from the perspective of their usefulness for the selection of rules performed in the two directions and with two strategies for rule selection. The resulting sets of rules were analysed with respect to the properties of the constituent decision rules and from the point of performance for all constructed rule-based classifiers. Substantial experiments were carried out in the stylometric domain, treating the task of authorship attribution as classification. The results obtained indicate that for all three rankings and search paths it was possible to obtain a noticeable reduction of attributes while at least maintaining the power of inducers, at the same time improving characteristics of rule sets.**

I. Introduction

ONE OF the main goals of data mining is the extraction of useful knowledge from large amounts of data or phenomena described by a high number of attributes. An important element of this process is the determination and selection of the most important attributes related to the described phenomenon [1]. The objective of this step, called feature selection, is to differentiate relevant variables from the entire set of features, while at the same time preserving the descriptive and representative qualities of the original set of attributes [2].

Feature selection can be accomplished by selecting a minimal subset of features that enables obtaining at least the same performance of a classifier as for the entire set of attributes [3]. In this case, feature subset selection requires assessing the quality of each discovered feature subset. Another way of proceeding is to construct a ranking of features based on a specific criterion. Then the variables are ordered from the most to the least important, and the top k features are selected based on a predefined threshold. Feature ranking is also known as feature weighting and involves evaluating individual attributes by assigning weights to them based on their relevance.

A technique used to search space of variables during the attribute selection process is an important factor. Since the problem of locating an optimal subset of features, taking into account all possible variable subsets, is NP-hard, greedy techniques, such as forward selection and backward elimination, are often used instead of exhaustive search. Forward selection begins with an empty set, which is gradually expanded by adding one feature (or a group of features) at a time until specific criteria are met. Sequential backward elimination involves starting with all attributes and progressively discarding them. Depending on the adopted criterion, added or rejected attributes can correspond to the highest positions in the ranking, or, they can be the lowest ranking elements.

One of the disadvantages of sequential selection is that interactions among features are not closely studied and dependencies can be missed when only one path of selection is investigated [4]. This problem can be remedied to some extent by varying the feature selection approach through patterns discovered in the data, such as decision rules, and discarding them only when they are dependant entirely on rejected variables, while keeping under consideration those that refer also to at least one attribute that is contained in the retained set. With this kind of processing, interactions among variables have more influence on the properties of recalled sets of rules.

The aim of the research presented in the paper and its contribution is the investigation and comparison of three influential factors, as follows: (i) two search strategies, i.e. sequential forward selection vs. sequential backward elimination, applied not directly to the variables in the dataset but through the filtering decision rules process, (ii) two approaches to rule selection, i.e., retaining rules that contain conditions only on the variables still in considerations vs. keeping the rules that include conditions on at least one of the attributes contained in the studied set, (iii) three ranking mechanisms, the OneR available in WEKA workbench [5], and two proposed, exploiting the properties of data and patterns discovered in them. One of those referred to the defined weighting factor, which takes into account the number of reducts in which a given attribute occurs and the cardinalities of these reducts [6], while the other was based on the properties of the greedy algorithm for the induction of decision rules, the number of occurrences in the rules and their support.

All experiments were performed on two datasets from the stylometry domain. The writing styles of the considered writers were learnt from available texts through the analysis of quantitative linguistic descriptors and advanced processing. To prevent bias on the observations, the datasets were prepared for the task of binary authorship attribution with balanced classes. The performance for induced rule-based classifiers was estimated with the help of test sets, over which the classification accuracy was averaged.

The results obtained allowed to conclude that all search paths led to increased performance for reduced sets of features while improving the characteristics of constructed rule sets. Backward elimination with keeping the rules referring to any attributes in the considered set allowed for reduction of more attributes than forward selection with limiting conditions in rules only to still present variables. The three investigated rankings produced close maximal predictions but for different numbers of attributes and rules. Greedy ranking held its ground when pitted against the other two, it even led to the one case of perfect recognition. These observations proved the merits of the described research works and again validated the methodology for ranking-driven rule selection.

The structure of the paper is organised as follows. Section II presents background information related to feature selection and induction of decision rules. Section III provides a description of stylometric analysis of texts, as the application domain. Section IV contains the explanation for the experiments performed and comments on the results obtained. Conclusions and future research plans are given in Section V.

II. Background information

In this section, aspects related to feature selection and decision rules are provided. Search strategies were described in the context of feature selection, and the main approaches for induction of rules were presented. Finally, the processing steps of rule filtering driven by feature selection were given.

A. Feature selection

During recent years, due to increasing demands for dimensionality reduction, extensive efforts in feature selection research have been made. It can be realised as a stage of data mining, related to data pre-processing, and then it affects such elements as visualisation, learning algorithms, and performance of classifiers. The main task of feature selection is to remove irrelevant or redundant variables so that their elimination from the set of attributes will not affect the performance of the learning algorithms [7]. The process of feature selection allows for data reduction and lowering of storage requirements. Furthermore, since the goal is to find the most relevant variables, it is possible to strive to improve data quality by enhancing data mining algorithms, that is, reducing learning time and improving predictive capabilities.

A feature selection procedure can be considered to contain three stages: (i) search for potential subsets of variables, (ii) evaluation of the subset of attributes based on some criteria, and (iii) setting the stop condition for the search. The final stage is closely linked to the initial one, as the search is repeated iteratively until the stopping criterion is met.

Due to the large search space, feature selection is also perceived as a combinatorial problem—for a dataset with N attributes, the search space is 2^N. Searching for an optimal subset of features taking into account all possible variable subsets is NP-hard problem [8]. An exhaustive search can be performed only if the number of attributes is relatively small. Instead, greedy [9] or meta-heuristics [10] approaches can be used.

To select a subset of variables from the input data, different search strategies can also be applied, including genetic algorithms, evolutionary computation techniques, heuristic search algorithms, and various hybrid strategies. Among greedy techniques, the sequential search performed as forward selection and backward elimination can be distinguished [11]. The sequential backward elimination method starts with all the variables, and then gradually features are removed from the set, either one by one, or in groups. In each step, the eliminated variable or variables contribute the least to the criterion function. Forward selection starts with the empty set to which sequentially features are added, again either one at a time or in groups, until certain criteria are met.

Both search strategies are heuristic and cannot guarantee the optimality of the selected features. Among the alternatives to these approaches, floating, branch-and-bound, and randomised can be mentioned [12]. Random search methods, for example, genetic algorithms, add some randomness to the search procedure to help escape from a local optimum. In certain cases, especially when dealing with high-dimensional datasets, an individual search is performed. Such methods evaluate each feature individually based on a specific criterion or condition. The branch-and-bound algorithm finds the optimal feature subset if the criterion function used is monotonic [3]. Floating search methods prevent the situation where the variable is deleted in backward elimination, and then it cannot be reselected, and also when a feature is added in forward selection and cannot be deleted once it was selected [11].

B. Ranking construction

Feature selection can be performed in two different ways, by selecting a subset of attributes or by creating a ranking of variables [13]. In the latter case, the variables are ordered according to the adopted criterion or evaluation function from the most important to the least important and the top k attributes are selected from the ranking, with k being some pre-selected threshold number. Feature ranking plays an important role in directing the search process in different machine learning tasks, especially when an exhaustive search is computationally unfeasible and a heuristic search approach is necessary. It determines the order in which the variables are explored by the algorithms within the feature space.

Feature ranking methods use different measures, for example, based on similarity score, statistics, information theory, or on some functions of the classifier's outputs [1]. Traditional ranking approaches evaluate variables without incorporating any learning algorithm. This category typically consists of filter-based feature selection methods, such as referring to information gain, correlation, or Relief algorithm. However, there are also some studies on wrapper techniques, which involve methods such as recursive feature elimination [14], and the classifier-aided feature ranking approach [15].

In the paper, three ranking mechanisms were studied, related to the properties of the data, and discovered patterns in the form of decision reducts and decision rules. One ranking was based on the defined weighting factor calculated through reducts, another was related to the OneR algorithm, and the third ranking was proposed by the authors and based on the properties of the greedy algorithm for rule induction. All the rankings obtained were used as filters for sets of induced rules.

1) Ranking of attributes based on reducts: Reduct is one of the key notions in rough sets theory [16] and refers to feature selection performed within the framework of rough sets. There are many definitions of a reduct because they deal with different criteria related to the selection of attributes and computing the most relevant sets of variables, for example, decision and local reducts for decision tables, reducts for information systems, reducts based on the generalised decision, or fuzzy decision reducts.

A reduct can be defined as a minimal set of attributes that preserves the degree of dependency of the entire set of attributes. Taking into account the performance, the reduct is such a minimal subset of attributes that has the same classification power as the complete set of available attributes [17].

The problem of calculating reducts is NP-hard, therefore, different heuristic approaches are used for its construction, for example finding reducts through sampling data from a decision table [18], heuristics based on discernibility matrix [19], greedy algorithms [9], Boolean reasoning, and many others [20]. In the investigation presented in the paper, the genetic algorithm [21], implemented in the Rough Sets Exploration System (RSES) [22], was used to construct the reducts. It is a binary genetic algorithm where every binary individual encodes one subset of attributes that is a potential reduct. The fitness function of a subset R has the form:

$$F(R) = \frac{n - L_R}{n} + \frac{2C_R}{m^2 - m}, \quad (1)$$

where n is the length of bit strings equal to a number of attributes, and m gives a number of objects. L_R denotes a number of "1"-s in the subset R, and C_R denotes the number of object pairs (with different decision values) discerned by the attribute subset R. Calculating C_R is the most time-consuming operation. It is accelerated by the "distinction table", a binary matrix of size $(n+1)\times(m^2-m)/2$. Each column corresponds to one attribute (the last column corresponds to the decision), and each row corresponds to one pair of different objects. The value "1" denotes an attribute with a different value on the pair of objects. Finding a reduct means finding the minimal subset of columns that cover the matrix.

The described genetic algorithm allows to generate a satisfactorily high number of reducts in relatively short time. The resulting reducts may contain different attributes and may also have different cardinalities. For the set of induced reducts, the weighting factor for features was proposed that takes into account the number of reducts in which a given attribute exists, and cardinalities of these reducts [6],

$$W_F(G_{Red}, a) = \sum_{i=k_{min}}^{k_{max}} \frac{card\,(RED(G_{Red}, a, i))}{card\,(G_{Red}) \cdot i}, \quad (2)$$

where k_{min} and k_{max} are respectively the minimal and the maximal reduct cardinalities detected for the group G_{Red}. $RED(G_{Red}, a)$ denotes the set of all reducts from the group G_{Red} that include the attribute a, and $RED(G_{Red}, a, k)$ is the set of reducts of length k that contain the attribute a. Then $card\,(RED(G_{Red}, a, k))$ returns for the group G_{Red} the number of reducts with specific length equal to k that contain the given attribute a. The values of W_F range from 0 (the attribute a is not included in any of the reducts in this group) to $1/k_{min}$, when the attribute is included in all the reducts and all the reducts have the same cardinality (then $k_{min} = k_{max}$).

A higher value of the weighting factor presented indicates that the attribute appears in more reducts with lower cardinalities, and low values of W_F are obtained for attributes that are included in fewer reducts containing more variables. All attributes included in a group can be ordered by the scores calculated for them, and a ranking is obtained as a result.

The described weighting factor promotes reducts with a small number of attributes. This way of reasoning follows from the fact that in a situation where we have two reducts and one of them has a smaller number of attributes, according to the definition of a reduct, this smaller number of attributes is sufficient to protect the performance of the system. Moreover, it complies with the Minimum Description Length principle [23]: "the best hypothesis for a given set of data is the one that leads to the largest compression of data". Additionally, reducts with smaller numbers of attributes are preferred from a knowledge representation perspective.

2) OneR algorithm: The OneR (One Rule) algorithm is a simple classification algorithm that is used in the field of machine learning. Its purpose is to select the most conclusive feature from all available features in the dataset, in order to create a simple classification model. This is done by calculating the number of occurrences of particular class labels for each value of a given attribute in the dataset. After this process, the OneR algorithm selects the feature for which the value is the most discriminating in the context of predicting class labels. In practice, for the selected feature, a single condition is created in a decision rule that is used to classify new instances. The algorithm generates one rule per unique attribute value of the selected best feature.

The main strength of the OneR algorithm is its ability to select the most relevant feature in the context of class prediction [24]. Although the OneR algorithm is simple and does not take into account interdependencies between features, it often allows to obtain satisfactory classification accuracy. In addition, this algorithm tends to choose the value of attribute that occurs the most frequently, and in this way it allows to ignore noise existing in the data. OneR is also called one-level decision tree algorithm. It selects attributes from a dataset one by one and generates a different set of rules based on the error rate from the training set. Finally, it chooses the attribute that offers rules with minimum error [25].

3) Ranking of attributes based on greedy algorithm properties: In the research, the authors propose a ranking mechanism exploiting the properties of the greedy algorithm for the induction of decision rules [26]. Such an algorithm constructs a decision rule for each row of a decision table. In each iteration, attributes are selected to form the conditions of the rules. The selected attribute separates the maximum number of rows from a set of rows with a different class label, so a decision table is divided into sub-tables as dictated by given attribute and corresponding value. The partitioning of a table is completed when all rows in the sub-table, corresponding to the selected attribute, have the same class labels.

As shown in previous research [27], given certain assumptions about the NP class, the greedy algorithm used to induce decision rules produces results that are not far from the best approximate polynomial algorithms for minimising the length of the rules, which is important for knowledge representation. Short rules can be considered as more general so they allow to reflect patterns hidden in the data and prevent overfitting, which is important for the classification process.

During research focused on the greedy algorithm, it was observed that in the majority of cases, when constructing decision rules, the greedy algorithm at each iteration selects an attribute that separates at least 50% of the remaining rows with different decisions.

The proposed ranking was based on the attributes contained in the decision rules, the percentage of separated rows with decisions different from the decision attached to a given rule, and the support of the rule. The latter element is an important factor in assessing the quality of decision rules. In order to construct the ranking, the decision rules were induced by the greedy algorithm and duplicate rules were removed from the entire set of rules. Then, for each attribute, the number of its occurrences in the rules was determined, assigning the highest positions in the ranking to the attributes with the highest number of occurrences. If the number of occurrences was the same for several attributes, then the percentage of rows separated by the given attribute was taken into account. The third factor that played a role in determining the score for each attribute was the support of the rule in which the attribute appeared, which led to the assignment of higher positions in the ranking to attributes from the rules with higher support.

C. Decision rules

Decision rules belong to popular forms used for data representation. They are induced from datasets very often presented as a decision table $T = (U, A \bigcup \{d\})$ [16], where U is a non-empty, finite set of objects, $A = \{a_1, \ldots, a_m\}$ is a set of condition attributes i.e., $a_i : U \to V_a$, where V_a is the set of values of attribute a_i called the domain of a_i, and $d \notin A$ is a distinguished attribute called a decision, with values $V_d = \{d_1, \ldots, d_{|V_d|}\}$. The decision rules take the form:

$$(a_{i_1} = v_1) \wedge \ldots \wedge (a_{i_k} = v_k) \to d = v_d,$$

where $a_{i_1}, \ldots, a_{i_k} \in \{a_1, \ldots, a_m\}$, $v_i \in V_{a_i}$, and $v_d \in V_d$. Pairs $(a_{i_1} = v_1)$ are called descriptors or conditions. The number of conditions in a premise part of a rule is its length. Short rules are preferred from the point of view of knowledge representation and with regard to the MDL principle. They are easier to understand and interpret. When assessing the quality of decision rules, support is another important factor. It is a number of such objects from the decision table whose attribute values satisfy the premise part of the rule, and they have the same decision as the one attached to the rule. This measure allows to discover major patterns present in the data.

There are a wide variety of approaches for induction of decision rules. Among the exact ones, Boolean reasoning and extensions of dynamic programming should be mentioned [28]. The construction of decision rules with maximum support or minimum length is considered an NP-hard problem, so different heuristics are used. They are based on modifications of exact approaches, different kinds of greedy algorithms, methods relying on sequential covering, genetic algorithms, and many others. In the rough set theory, the popular approach is also induction of rules based on a reduct. Then each rule has length equal to the cardinality of the reduct, and each object from a decision table has assigned values corresponding to condition attributes included only in this reduct.

Apart from using decision rules as a form of knowledge representation, they are very often used as classifiers. In this situation, the rule filtering process can be treated as a method of pruning the rule set to fine-tune the classifier by reducing the number of rules. The use of filtering rules in the framework of the feature selection process often leads to improved classification accuracy.

In the experiments performed, the decision rules were induced by the exhaustive algorithm implemented in the RSES system. It constructs all minimal decision rules, i.e. rules with minimal numbers of descriptors (pairs attribute = value) in their premise parts. Then, they were filtered sequentially, according to the search strategy added or removed, driven by the studied rankings of attributes.

III. Stylometric data

A writing style is an individual characteristic, based to some extent on social and cultural background, education, lifetime experiences, elements that are learnt, but also on personal linguistic preferences and habits. To obtain a definition of an authorial profile, access to some representative samples of writing is needed. Comparative analysis and stylometric data mining lead to the discovery of patterns specific to writers and the construction of approximating descriptions that can be applied to text samples of unknown or unconfirmed authorship to find the closest match. This way of carrying out the authorship attribution task means solving a classification problem [29], therefore, a dataset to be prepared needs to include some training and test samples, all relying on a set of selected efficient style-markers [30].

Stylometric descriptors that work best refer to common language elements as they are used almost subconsciously, so they are less prone to forgery or imitation. Lexical and syntactic markers are often employed for the task [31]. They provide quantitative characteristics through frequency of occurrence for function words and punctuation marks, which results in real-valued features. In the experiments reported, the set of markers contained 24 elements with values calculated over text samples obtained by partitioning long novels by four acclaimed writers into smaller chunks. The authors studied, Edith Wharton, Mary Johnston, Jack London, and James Oliver Curwood, were paired according to gender [32], in order to form two datasets with binary authorship attribution.

The division of long texts into smaller parts resulted in imposing a specific stratification of the input space [33]. To avoid bias when evaluating the performance of a classifier, the datasets (the male writer dataset and the female writer dataset) prepared included one train set and two test sets. The samples contained in sets of different types were based on separate novels. With binary classification, balanced data and the same importance of all classes, classification accuracy was used as a measure of performance, providing information on the average portion of correctly attributed text samples from test sets.

Among popular data mining approaches, those that involve induction of decision rules belong to the most advantageous. They not only enable assigning authors to samples, but also enhance understanding of the stylometric domain by providing an inside view on linguistic patterns detected for authors by the transparent form of discovered rules. Short rules, with a few conditions in their premises, are preferred over long rules [24]. The former are more general, while the latter with their too detailed definitions can cause over-fitting.

The datasets were discretised with the Fayyad and Irani algorithm [34]. It is one of the top-down supervised methods, which starts with assigning one large interval to represent in the discrete domain all the values of a transformed variable. Then, referring to the MDL principle and calculation of entropy [23], candidates for cut-points are evaluated to discover which are most supportive to distinction of classes. If further partitioning is disadvantageous to entropy, the processing stops. As a consequence, it is possible that some variables are removed from consideration in the discrete domain when they have a single categorical representation. In the experiments, for the female writer dataset 20 out of the total of 24 features received more than a single bin, and for the male writer dataset the set of attributes was reduced to 22.

IV. Performed experiments

The experimental process of the research works consisted of the following stages:

- Preparation of two datasets (female writers and male writers), which included discretisation by Fayyad and Irani algorithm applied to all condition attributes;
- Construction of three rankings of attributes:
  - *Reducts*—based on reducts and the proposed weighting factor;
    Using a genetic algorithm implemented in the RSES system, one group of 150 reducts was generated. Obtained reducts consisted of different attributes from the whole set of available features and had different cardinalities. The weighting factor defined in Eq. (2) took into account all these elements and returned scores for the variables. The ordering of attributes by their scores resulted in the ranking.
  - *OneR*—based on the OneR algorithm implemented in WEKA software [5];
  - *Greedy*—based on the properties of the greedy algorithm for induction of decision rules, that is, the number of rules in which a given attribute occurs, the percentage of separated rows with different decisions and the support of decision rules.
- Induction of decision rules by exhaustive algorithm, for the input datasets;
- Filtration of sets of rules accordingly to sequential forward selection and sequential backward elimination driven by attributes included in a given ranking;
- Evaluation of performance for rule-based classifiers with test sets;
- Assessment of the quality of rule sets from the point of view of knowledge representation, i.e., taking into account the number of rules, average length and average support;
- Comparative study of results, for two search directions, two rule selection strategies, and three rankings.

Details of all steps are provided below, along with comments on the results obtained.

A. Rankings

For the female and male writer datasets, the rankings obtained were presented in rows of Table I (where the letters F and M indicate the female and male writer datasets, respectively). The row *Position* denotes the position of the given attribute in a ranking, and 1 is considered the highest ranking position, assigned to the most important feature.

For the female writer dataset, in the case of the ranking constructed through reducts and the OneR algorithm, the entire set of attributes was used, with the exception of attr14, attr16, attr18, and attr21. It resulted from the situation that these attributes had only 1 bin allocated by the supervised discretisation process. For the male writer dataset, there was a similar situation, i.e. instead of 24 attributes, only 22 were used to create the ranking since attr11 and attr14 were the

Table I
RANKINGS OF ATTRIBUTES FOR FEMALE AND MALE WRITERS

Position	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20	21	22

attributes to which only 1 bin was assigned in the Fayyad and Irani discretisation process.

From the ranking created based on the accuracy of the greedy algorithm, in addition to the attributes with a single categorical representation, other variables were also excluded because they did not appear in the induced decision rules. Therefore, these rankings were shorter and contained 16 attributes for the female dataset and 17 for the male dataset.

It is worth noting that for the male writer dataset, all three rankings assigned the highest position to the same attribute: attr23. In the case of the female set, this attribute was ranked second only in the ranking related to the greedy algorithm. Furthermore, the features disregarded by the greedy ranking (attr9, attr12, attr15, and attr20 for female writers, and attr4, attr5, attr13, attr17, attr20 for male writers) were not recognised as irrelevant or close to irrelevant by other rankings, for example, for the male writers attr17 was found as the second ranking for the OneR algorithm.

B. *Strategies employed in decision rule filtering*

Forward selection was performed by sequentially filtering and increasing the set of decision rules. Starting with the highest ranking attribute, from the entire set of rules those were selected that contained conditions (in their premises) relating only to this attribute. Then, in the second step, a subset of recalled attributes was extended to the top two positions, and such rules were selected that relied only on these two variables as conditions. Next, three top ranking features were studied, and so on. In each step of the sequential search, the conditions in the rules were limited only to the currently selected subset. The forward rule filtering process continued until all available features and rules were included in the set considered.

The backward elimination was achieved by sequentially decreasing the set of decision rules. Starting with the attribute in the lowest ranking position, those rules were selected from the entire set of rules, which contained in their premises the condition referring to this very attribute. If a rule included some other attributes that worked as conditions, then that rule was not removed from the set of rules. The second step of backward reduction meant rejection of rules with conditions limited to the two lowest ranking variables, and so on, until the set of rules was exhausted. The difference between the two strategies involved is shown in the illustrative small example.

Let us assume a set of five condition attributes, for simplicity ranked as follows, where 1 is considered the top ranking position, and 5 the bottom of the ranking:

Position 1: attr1
Position 2: attr2
Position 3: attr3
Position 4: attr4
Position 5: attr5

The set of rules, subject to filtering driven by ranking, consists of eight elements.

Rule 1: with condition on attr1
Rule 2: with conditions on attr2 and attr3
Rule 3: with conditions on attr1 and attr5
Rule 4: with conditions on attr1 and attr4
Rule 5: with condition on attr3
Rule 6: with conditions on attr3 and attr5
Rule 7: with conditions on attr2 and attr5
Rule 8: with condition on attr4

For backward elimination, the processing starts with all rules included in the recalled set. Then, for the filtering steps, the resulting sets are as follows.

Step 1: Rejected attributes: attr5, recalled rules: all rules
Step 2: Rejected attributes: attr5, attr4, recalled rules: 1, 2, 3, 4, 5, 6, 7
Step 3: Rejected attributes: attr5, attr4, attr3, recalled rules: 1, 2, 3, 4, 7
Step 4: Rejected attributes: attr5, attr4, attr3, attr2, recalled rules: 1, 3, 4
Step 5: Rejected attributes: all, recalled rules: no rules

For forward selection at the starting point, the set of recalled rules is empty. It is next gradually expanded as listed below.

Step 1: Selected attributes: attr1, recalled rules: 1
Step 2: Selected attributes: attr1, attr2, recalled rules: 1
Step 3: Selected attributes: attr1, attr2, attr3, recalled rules: 1, 2, 5
Step 4: Selected attributes: attr1, attr2, attr3, attr4, recalled rules: 1, 2, 4, 5, 8
Step 5: Selected attributes: all, recalled rules: all rules

The process of rule filtering carried out for the greedy rankings was slightly different than for the other two rankings, because the rule sets induced by the exhaustive algorithm included rules with conditions on such features that were absent in the greedy ranking. Therefore, the first step of rule elimination was to remove rules containing only attributes that did not appear in these rankings, while the last step for forward selection was to add these rules.

C. *Performance of rule-based classifiers*

For all rule-based classifiers obtained in the decision rule filtering process, performance was evaluated with test sets. Fig. 1 presents the average classification accuracy obtained.

Decision rules induced by the exhaustive algorithm were selected through the backward elimination (column Back) and forward search (column Forw) strategies, with the conditions for recalling rules governed by the three rankings (groups of columns, Reduct, OneR, Greedy). The results shown in the bottom row provide the reference point, because they correspond to the case where the entire sets of attributes and rules were taken into account. The X mark denotes the situation where no rules were included in the set of recalled rules. The coloured cells indicate where the classification accuracy exceeded the reference point. The intensity of cell colour depends on how much the accuracy was improved. For each step of the rule filtering process, the columns Attr indicate the ranking position considered (which for forward search corresponds to the number of variables taken into account).

Figure 1. Accuracy of rule-based classifiers, for female and male writers

As can be observed in Fig. 1, in the case of the Greedy column and the backward elimination strategy, rejecting rules only with attributes not included in the ranking resulted in the same classification accuracy as for the entire set of attributes. For forward selection, the results for the last step of selecting features included in the rankings differed slightly from the ones given in the bottom row, after adding the rules with attributes that did not appear in this ranking. For female writers, a small improvement was noted, and for male writers, a small decrease was visible.

When the backward elimination strategy was combined with the Reduct and OneR rankings and applied to the female writer dataset, it should be noted that for all ranking positions considered the classification accuracy was always at least at the reference level, even in the last step of filtering for the attribute in the first position in the rankings. The highest value of the classification accuracy of 0.989 was obtained for the Greedy and OneR rankings, and was related to the third position in these rankings. For ranking based on reducts this value was slightly smaller (0.983) and happened in processing of the fourth position in the ranking.

In the case of forward selection executed for the female writer dataset, the highest possible classification quality equal to 1.0 existed for 11 attributes placed at top positions in the Greedy ranking. For the OneR algorithm the maximum was equal to 0.989 and for the Reduct ranking 0.978, and both were detected when the twelfth positions were processed.

For the male writer dataset for the top position in the three rankings, backward elimination obviously returned the same results. The highest classification accuracy of 0.967 was obtained for the Greedy ranking related to the sixth top position in the ranking. It was also the highest improvement noted for this dataset. Apart from the top two ranking positions, for all the rest of filtering steps, the classification was either the same or improved over the reference point. For the OneR ranker, the best performance (0.956) referenced the fifth top ranking position. With the exception of the top ranking position, for the OneR ranking in the entire rule filtering path, the reported performance was at least as good as for the entire sets of rules and attributes considered. The ranking based on reducts brought the worst results among the three rankings, however, even here they were still detected cases of maintaining or increasing performance for the reduced sets of rules.

In the forward search applied to the male dataset, the OneR ranking was most advantageous: for the fifteenth ranking position the maximal classification accuracy 0.961 was recorded. The second best level of predictions (0.956) was obtained for the nineteenth position of the Reduct ranking. The Greedy algorithm came last with the highest accuracy of 0.928, however, it resulted from processing the ninth ranking position, so more decision rules and features were discarded than for the other two cases.

D. Characteristic of rule-based models

The entire process of rule filtering driven by rankings involved two search directions, two strategies for rule selection, and three rankings. For all the sets and subsets of decision rules constructed, their characteristics were observed, as shown in Table II. These observations included the number of rules (NoR column), average rule length (Len column), and average rule support (Supp column). The column Attr points to the ranking position considered.

As could be expected, analysis of the rule sets showed that as the number of rules in the set decreased, their average lengths tended to decrease, and the average supports increased. This was particularly evident in the rows at the bottom or close to the bottom of the tables. The average values relating to the shortest rules with the highest support were marked in bold.

In the case of forward selection, the differences regarding the number of rules, their length, and support were more visible than in the case of backward elimination. It was due to the nature of how the strategies employed for rule selection in each case worked, as they were not the same.

With forward as a search direction, the processing started with the empty set of rules and then, gradually, in each step some recalled rules were added. These rules could include

conditions limited to the variables in the subset considered. In the first step only the top ranking attributes were taken into account, in the second step the top two were accepted, and so on. If a rule also contained conditions on other features (placed somewhere lower in the ranking), then it was not included in the recalled set. Therefore, always a ranking position that was processed directly gave the number of variables studied, and a subset of features present in the rules was explicitly visible.

The strategy applied in the backward elimination of decision rules started with the entire set of rules and then the groups of rules were gradually excluded, taking into account conditions on attributes from the lowest positions in a ranking. In this case, the assumption was that the eliminated rules should contain only attributes considered and discarded so far in the ranking. If a rule also included conditions on other features that were higher ranking, then such a rule was kept in the remaining set. This processing resulted in operation on higher numbers of rules for the same ranking position than when compared to the strategy applied in the forward selection. In fact, for each ranking position a set of rules recalled by forward selection was a subset of rules retained by backward elimination. It was especially striking in the case of the Greedy ranking and the number of rules obtained as characteristics for the constructed rule sets.

The advantage of this strategy was visible in the classification results, in particular for the female data set, where for almost every position of the ranking, the accuracy of rule-based classifiers was at least as good as the reference level considered for all variables from the set. Thus, this direction and the filtering rule strategy contributed to enhancing the power of the classifier. The drawback of such processing lies in keeping in considerations the higher numbers of attributes, and a lack of clear specification of their subset taken into account in each step. If there was a rule referring to all features, such rule would be kept to the very end, to the last step of filtering process, despite its significant length that indicates too close definition to be of any practical use, as the probability of exactly the same detailed pattern among test samples is low.

When the characteristics of the obtained rule sets were analysed, the classification accuracy of the constructed classifier was treated with extra attention. To provide the general look on the rule filtering process, over the entire run of feature and rule selection, the average performance was calculated, and the corresponding standard deviation (per sample), as shown in Table III. For both datasets and all rankings, backward elimination always brought better results than forward selection when combined with their strategies for rule selection. When the averaged performance is compared with the reference points of accuracy for the entire set of attributes available, it is clear that the backward search resulted in the improvement for all rankings for female writer dataset, while for male writers that was true for the OneR and Greedy rankings. For female writers the highest average classification accuracy was obtained for the Reduct-based ranking and for male writers for Greedy ranking. On the other hand, for female writers standard deviation reflected almost only direction and not ranking, yet for male writers the highest (but still rather small, only fractional) values were obtained for Greedy ranking.

Table III
SUMMARY OF OBTAINED ACCURACY OF RULE-BASED CLASSIFIERS

St.dev.	0.01	0.11	0.01	0.11	0.01	0.12
	Male					
Average	0.877	0.840	0.899	0.870	0.910	0.817
St.dev.	0.02	0.14	0.03	0.16	0.04	0.18

The rule characteristics can be treated as dimensions in an optimisation space. Among them, the performance and the ranking position for which undiminished performance was reported could also be included. Such a summarising look was given in Table IV, where the lowest values are preferred for: ranking position, number of rules, average rule length. The highest values are preferred for: classification accuracy and average rule support. No overall Pareto points were detected, but for each dimension, some maxima and minima can be observed, or groups of characteristics could be analysed. When the same values of the observed criterion were recorded more than once, the occurrence for the highest ranking position was selected as the best, since it corresponded to the most extensive reduction, as long as it happened while the observed performance was not lower than the reference point.

As the forward selection strategy quantitatively enlarged the set of rules, it can be noted that these were moderately short rules with relatively large supports, and the number of such rules was small. For the female writer dataset, the highest value of average rule support was 37.6 for an average length of 2.2 and the number of rules equal to 10. For the male writer dataset, the highest value of average rule support was 61.5 for an average length of 2.2 and the number of rules equal to 2.

In the case of the backward elimination strategy, the cut in the number of rules was generally smaller than for the forward search. The smallest reduction occurred for the Greedy ranking, for the female set. For the male set, the number of rules corresponding to the attribute in the highest ranking position was the same for all rankings, similarly the average rule length. Furthermore, for this dataset, the number of rules decreased about 10 times under this search strategy. For the Reduct and OneR rankings and female writers it was even greater.

The experiments carried out with varying search directions and strategies for rule selection enabled studying the effectiveness of the three rankings in the rule filtering process. The proposed Greedy ranking held its ground against the other two, leading to noticeably improved predictions for rule sets of decreased cardinalities, which is evidenced by the fact how often it led to the best results given in Table IV, and which clearly illustrates its merits.

V. CONCLUSIONS

The paper provides an illustrative example for the proposed research methodology dedicated to decision rule filtering governed by attribute rankings. The process of rule selection was executed with sequential backward reduction, where an entire set of induced rules is available at the beginning and then some elements from this set are discarded; and with sequential forward search, where the processing starts with the empty set to which recalled elements are added gradually. Along with two search directions, two strategies for rule selection were used, one with recalling rules including conditions only on variables from the currently considered subset, and the other with finding rules dependent on at least one of the attributes in the studied set.

In the investigations, three rankings of attributes were employed. The proposed ranking based on the percentage of separated rows and the properties of the greedy algorithm was confronted with the previously defined ranking referring to decision reducts, and the OneR ranker available in the popular WEKA environment. For the three rankings, the selection of rules was performed in the two directions, and the resulting rule sets were analysed with respect to the properties of constituent decision rules, such as their numbers, average length, and average support, but also from the point of evaluation of performance for all constructed rule-based classifiers when applied for labelling of samples from test sets.

The results from the experiments indicate that for all three rankings and search paths it was possible to obtain a noticeable reduction of attributes while at least maintaining the power of inducers, at the same time improving characteristics of rule sets. The special focus on Greedy ranking enabled to discover that it not only led to discarding some variables from the available sets, treating them as irrelevant, but also proved effective for rule filtering.

Future research will include application of the Greedy ranking in the feature selection process for other types of inducers, with different mathematical backgrounds and modes of operation. Also, the influence of discretisation step will be studied, as one of the factors greatly influencing representation of data and the patterns present in it.

***Abstract*—Re-colorization of images or movies is a challenging problem due to the infinite RGB solutions for a monochrome object. In general, the process is assisted by humans, either by providing colorization hints or relevant training data for ML/AI algorithms. Our intention is to develop a mechanism for fully unguided (and with no training data used) colorization of movies. In other words, we aim to create acceptable colored counterparts of movies in domains where only monochrome visualizations physically exist (e.g. IR, UV, MRI, etc. data). Following our past approach to image colorization, the method assumes arbitrary *rgb2gray* models and utilizes a few probabilistic heuristics. Additionally, we maintain the temporal stability of colorization by locally using *structural similarity* (SSIM) between adjacent frames. The paper explains the details of the method, presents exemplary results and compares them to the *state-of-the art* solutions.**

NOTE: ***All figures are best viewed in color and high resolution.***

I. Introduction and Motivation

COLORIZATION of monochrome objects is an ill-posed problem due to the infinite number of RGB solutions for given grayscale data. Nonetheless, this topic holds notable practical and commercial significance, particularly in the restoration of historical photos and movies, e.g. [1], [2].

In general, the development of colorization techniques involves incorporating more and more human knowledge and expectations into the algorithms [1]. To that end, earlier methods involved providing reference color images [3], [4] or manually *scribbling* important fragments [5], [6]. Recently, AI-based techniques have dominated, with architectures designed to learn color patterns suitable for specific domains, semantics, and/or contents, such as [7], [8].

Some works consider recognizing/learning the image domain (or specific objects within images) to further improve the results, e.g., [9], [10].

In other works, inter-domain transfer learning is considered [11], or multiple alternative colorizations are proposed by exploiting learned probability densities [12], [13].

Colorization methods for monochrome movies basically follow the same principles. In some works (for example, [2]), there is no distinction between the colorization of still images and movies. That is, each frame of a movie is considered a separate item and is re-colorized individually. However, such an approach may introduce temporal colorization discontinuities. Therefore, in recent works, including [14], [15] or [16], the issue of colorization continuity between adjacent frames is addressed, mainly by combining spatial and temporal consistencies of colors assigned to pixels with similar intensity levels.

Nevertheless, in all typical papers on re-colorization of monochrome objects, the algorithms are assisted by human knowledge/experience/expectations, even if the assistance is disguised as *training datasets* of relevant images/videos.

Therefore, the solution discussed in this paper may seem audacious. We propose a mechanism for fully automatic video colorization without additional metadata, manual assistance, learning processes, or domain identification. In other words, we aim to create plausible colored representations of *gray worlds* using only monochrome videos as the data source. By "plausible," we mean results that are visually attractive, statistically repeatable, and deliver convincingly rich sensations of colors.

It should be noted that we exclude simple pseudo-coloring techniques that use a limited number of colors corresponding to the number of intensity levels, resulting in a limited richness and diversity of coloristic effects.

The problem addressed appears to be relevant and practical because there are numerous domains, such as infrared, ultraviolet, ultrasound, MRI, X-ray, and others, where only single-channel visual data physically exist. Then, realistic-looking automatic colorizations can be synthesized for various reasons, even if it is just for aesthetic purposes (see examples in Fig. 1).

In our recent papers [17], [18], we overviewed the results obtained for unguided colorization of monochrome images, and the method for colorizing videos is a natural extension of those results. Therefore, Section II revisits a number of assumptions and techniques adopted in monochrome image colorization and repeated in video colorization.

Section III presents steps that are specific to the colorization of videos. A summary of the experimental results and corresponding comments is provided in Section IV. Finally, the concluding Section V discusses some supplementary details (mainly related to limiting the number of solutions) and outlines prospective directions for future research.

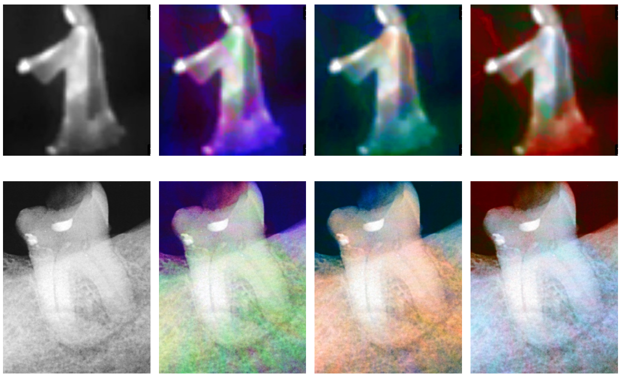

Fig. 1. Examples of monochrome images from non-visual domains (IR and X-ray), and their color-rich and visually plausible colorizations.

II. Principles of Automatic Colorization

A. Significance of Decolorization Models

Generally, colorization methods assume that the intensity of grayscale objects defines the luminance channel of the colored outputs, so only two channels of chrominance need to be reconstructed. It seems like a matter of arbitrary choice which chrominance models are used (e.g., CIELab in [8], [9] or YUV in [2], [5]). Sometimes, the model is not even specified, and only the final outcomes in RGB format are discussed.

However, almost no papers on re-colorization address the opposite question: **How was the original (real or hypothetical) RGB object decolorized to obtain a grayscale object?**

Typically applied decolorization (*rgb2gray*) models, i.e. YUV or YIQ, assume linear functions of primary colors:

$$I = k_R R + k_G G + k_B B \tag{1}$$

where $k_R = 0.299$, $k_G = 0.587$ and $k_B = 0.114$ (or, based on [19], $k_R = 0.2126$, $k_G = 0.7152$ and $k_B = 0.0722$).

Nevertheless, given that we assume that colored objects only exist hypothetically, any combinations of non-negative coefficients k_R, k_G, and k_B can be formally used (subject to the straightforward condition $k_R + k_G + k_B = 1$).

Therefore, as shown in Fig. 2, a colored object can be converted into a variety of its monochrome counterparts, which may significantly differ depending on the adopted *rgb2gray* model.

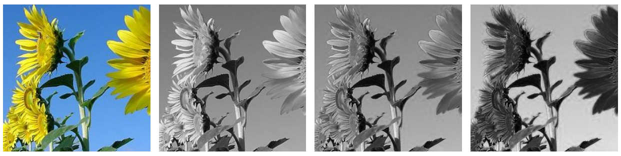

Fig. 2. A colored image and its three monochrome variants obtained using three different *rgb2gray* models, namely $[0.299, 0.587, 0.114]$, $[0.44, 0.14, 0.42]$ and $[0.14, 0.11, 0.75]$).

Correspondingly, by assuming a certain *rgb2gray* model, we can restrict the re-colorization results in a specific way. Any pixel with intensity I can only be assigned colors that satisfy Eq. 1 with the adopted $[k_R, k_G, k_B]$ values. Fig. 3 shows examples of the same image re-colorized using the same algorithm, but with different *rgb2gray* models adopted.

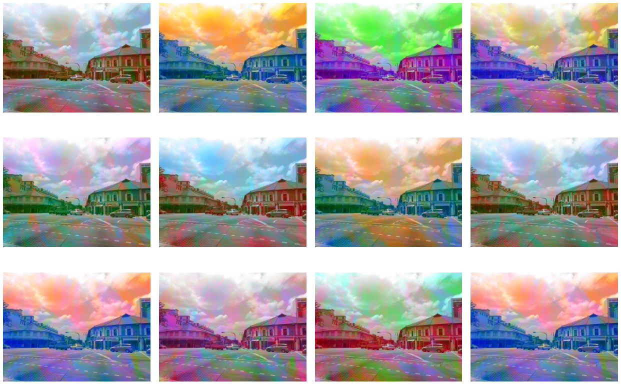

Fig. 3. The same monochrome image colorized (by the method discussed in [17], [18]) with different *rgb2gray* models adopted.

B. Colorization of Individual Pixels

In coloring monochrome objects depicting some non-existent *color worlds*, we are not restricted by the propertiess of YUV or YIQ models, which provide the best consistency between the brightness of the color and its monochrome counterpart, as perceived by human observers. Therefore, in the developed colorization scheme, we assume that:

Monochrome visual objects are derived from (only hypothetically existing) color counterparts by an *rgb2gray* model with arbitrarily selected k_R, k_G, and k_B coefficients.

If we assume that the coefficients are uniformly sampled into n values each (for example, $n = 101$ for a 0.01 stepsize), it can be easily obtained that the total number of available *rgb2gray* models is:

$$N = \frac{n(n+1)}{2} \quad or \quad N = \frac{(n-3)(n-2)}{2} \tag{2}$$

The first variant includes zero-coefficient models (e.g., $[0.4, 0, 0.6]$ or $[0, 1, 0]$). These models are excluded in the second variant, where each primary color must have a non-zero contribution to the intensity levels.

In the experiments, we use 0.05, 0.01 or 0.002 stepsizes, so that the total numbers of *rgb2gray* models are $231(171)$, $5151(4851)$ or $125,751(124,251)$. However, in the end, we only consider a limited number of $20 - 40$ models (see Sections IV and V for more details), resulting in the same number of alternative colorization outputs.

In rendering digital images, we adopt finite numbers of intensities and colors. Thus, given a monochrome intensity level I_p from the discrete range 0 to 255, it can only be assigned colors from a pool of colors that satisfy (subject to color discretization) Eq. 1. The size of those pools varies, depending on the intensity level. As an example, the numbers of colors assigned to intensity levels in two arbitrarily selected *rgb2gray* models are shown in Fig. 4.

The figure shows that the largest pools of colors are for mid-range intensities, with the number of colors gradually decreasing to a single choice for extremely dark or light intensities. (Monochrome white/black should remain white/black in color.)

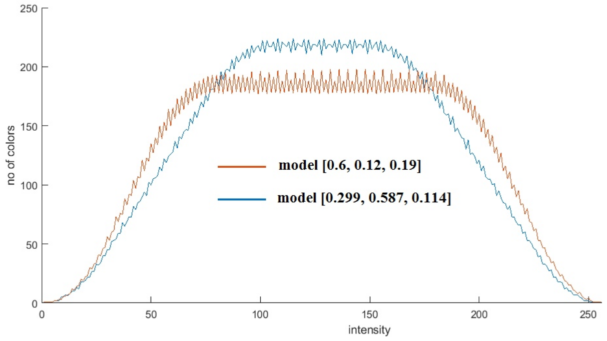

Fig. 4. Numbers of RGB colors assigned to intensities in two exemplary *rgb2gray* models.

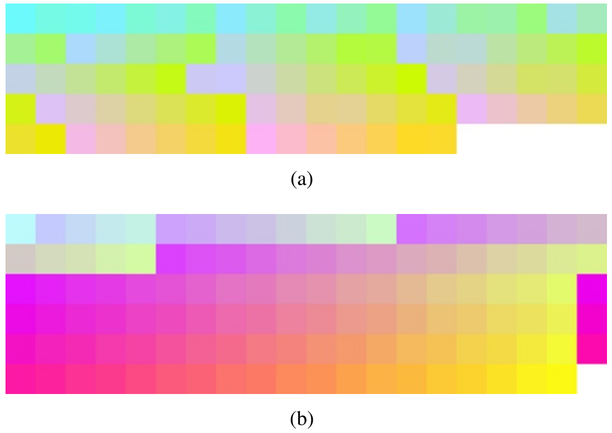
As an example, Fig. 5 displays the pool of colors for intensity level 208 under two *rgb2gray* models. Note that the first model is actually YUV, and all colors are perceived as having almost the same brightness. In contrast, the perceived brightness of colors varies significantly for the second model.



(a)

(b)

Fig. 5. Colors assigned to 208 intensity in (a) $[0.299, 0.587, 0.114]$ and (b) $[0.69, 0.12, 0.19]$ *rgb2gray* models.

With no prior information provided, all colors available to the I_p level can be assigned to a pixel of that intensity with the same probability. However, if the pixel has an adjacent pixel with an intensity I_1 and its already assigned color C_1, the probabilities of colors that could be assigned to I_p should be influenced by the intensity and color of the neighbor.

Therefore, we propose a simple but (as shown later) surprisingly effective heuristic rule:

The greater the difference in brightness between adjacent pixels, the higher the likelihood that their assigned colors will also differ significantly.

Under this rule, we prioritize colors from the pool available to the I_p level, which are at distances from the C_1 color proportional to the difference in intensity levels $\|I_p - I_1\|$.

Let's assume a pixel with I_p intensity, which has an already colored neighbor with I_1 value and C_1 color. Let $\mathbf{C} = \{C_{p_1}, ..., C_{p_N}\}$ be the list of colors assigned to I_p in the adopted *rgb2gray* model.

The neighbor (with I_1 value and C_1 color) contributes a color from the above **C** list. First, the list is ordered by the distances of its colors from C_1, i.e. $\mathbf{Cmod} = \{C_{p_{i1}}, ..., C_{p_{iN}}\}$, where

$$\|C_{p_{in}} - C_1\| \leq \left\|C_{p_{i(n+1)}} - C_1\right\| \tag{3}$$

It should be noted that inter-color distances are measured in the HSV space, as differences in this space are sufficiently close to represent perceived color similarities, e.g. [20].

Then, a uniform distribution is used to randomly select a color from a specific sub-range of the **Cmod** list. The location of this sub-range depends on the difference $\|I_p - I_1\|$. In general, for smaller differences, the sub-range is narrower and shifted to the left of **Cmod**, while for larger differences, it is wider and shifted towards the end of **Cmod**). Detailed description of this step can be found in [18].

In particular, if the neighboring pixel has the same intensity, i.e. $I_p = I_1$, the I_p intensity pixel would be (preliminarily) assigned the same color C_1.

Actually, images are colored incrementally (details in the following subsection), and it may happen that an uncolored pixel has several already-colored neighbors. Then, the color selection can be performed several times for that pixel, and the final choice is the mean of the colors obtained from all colored neighbors.

$$C_p = \frac{1}{K}\sum_{j=1}^{K} C_j \tag{4}$$

where $K = 1, 2, 3$ or 4.

This step allows us to generate a larger variety of colors than from the (possibly limited) pools of colors that are assigned to individual intensity levels.

C. Incremental Colorization

Colorization of monochrome images is performed incrementally, starting from the darkest and brightest pixels, for which the unique color choice exists (see Fig. 4). They are considered the initial list of already colorized pixels for the algorithm, which is actually a randomized variant of a popular *flood-fill* method.

Pseudo-code of the colorization algorithm is provided below.

Step 4 (which does not exist in the standard flood-fill method) is introduced to randomize the expansion of colorized patches, i.e. to avoid unnecessary regularities in the colorization process.

Algorithm 1 Monochrome image colorization

```
Require: Initial list $L$ of colored pixels
Ensure: Colorized images
remove from $L$ pixels which do not have uncolored neighbors;
copy $L$ to $Q$ queue
while $Q$ is not empty do
    move a random pixel from $Q$ to the front of $Q$;
    get the front pixel $p$ of $Q$;
    if $ps$ (south neighbor of $p$) exists and is uncolored then
        colorize $ps$ (Eq. 4);
        append $ps$ to the end of $Q$;
    end if
    repeat Steps 6-9 for $pn$, $pe$, $pw$ (north, east, west neighbors of $p$);
    remove $p$ from $Q$;
end while
```

D. Other Remarks

Despite the heavy presence of randomizing factors, the results produced by the outlined method are surprisingly repeatable, depending only (as expected) on the adopted *rgb2gray* model. Actually, all images shown in Figs 1 and 3 are generated by the method, and many more examples can be found in [17], [18].

The visual plausibility of the results can be further improved by projecting the colors of each pixel p onto the corresponding YUV plane $I_p = 0.299R + 0.587G + 0.114B$ (or $I_p = 0.2126R + 0.7152G + 0.0722B$). This is because colors assigned to the same intensity level can vary significantly in terms of their perceived brightness, see Fig. 5b. Projecting the colors on the YUV planes unifies the perceived brightness of colors with intensities of the original monochrome image, although it may alter the colors somewhat, as shown in Fig. 6.

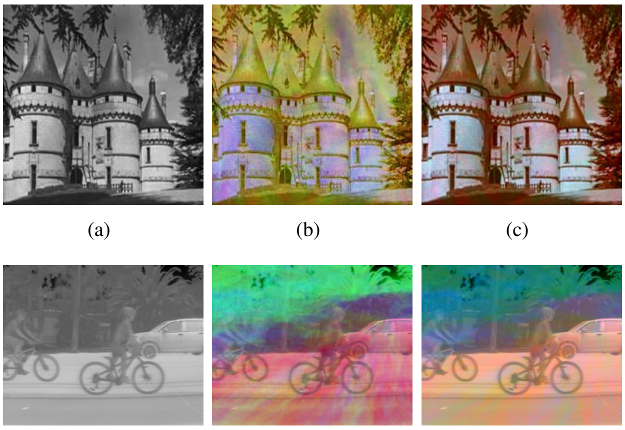


Fig. 6. Original monochrome images (a) and their colorizations before (b) and after (c) projections on the YUV planes.

III. From Images to Movies

Formally, the colorization of monochrome movies does not differ from the colorization of images, and both operations are often considered to be almost equivalent, e.g, [21]. Each frame can be independently colorized to provide the corresponding frame of the color movie. Such a simplified approach may be used if image colorization performs nearly flawlessly, which can only be achieved in specific and well-defined domains. Nevertheless, this method has been successful in a number of works, including the commercial system described in [2].

In our application, we cannot use this approach due to randomizing factors in the image colorization scheme. In such cases, even if the same *rgb2gray* model is used, adjacent frames with nearly identical content may have noticeably different colorization. An example is given in Fig. 7. Thus, the temporal continuity/stabilization of rendered colors over sequences of similar frames is particularly important for our problem.

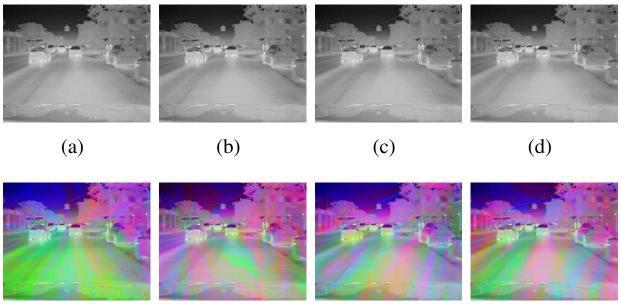

Fig. 7. Four subsequent monochrome frames individually colorized (using the same *rgb2gray* model) by the method outlined in Section II.

Recently, more attention has been paid to the temporal continuity of colors in the colorized movies. Several papers, e.g., [14], [15], [16], consider the regularization or stabilization of colors in adjacent video frames. In [22], a more general problem of stabilizing any visual properties in processed video files is considered.

Nonetheless, in all these papers, the results are obtained by training dedicated neural networks on sufficiently representative ground-truth data. Therefore, these approaches are not applicable to the considered problem of colorizing monochrome videos for which the color counterparts never existed.

In the proposed solution, we assume that the colorization continuity should reflect not only intensity similarities between adjacent frames but also content similarities, particularly the local ones.

After evaluating several popular metrics of image quality and similarity, e.g. [23], [24], the *structural similarity index measure* (SSIM) has been identified as the top candidate, [25]. SSIM is particularly suitable for monochrome images and is applicable to images of any content.

In general, the SSIM is defined by a weighted combination of three measures that broadly represent statistical similarities between the intensity, contrast, and structure of two image samples, X and Y:

$$SSIM(X,Y) = i(X,Y)^{\alpha} \times c(X,Y)^{\beta} \times s(X,Y)^{\gamma} \quad (5)$$

where $i(X,Y) = \frac{2\mu_X\mu_Y + c_1}{\mu_X^2 + \mu_Y^2 + c_1}$, $c(X,Y) = \frac{2\sigma_X\sigma_Y + c_2}{\sigma_X^2 + \sigma_Y^2 + c_2}$ and $s(X,Y) = \frac{\sigma_{XY} + c_3}{\sigma_X\sigma_Y + c_3}$.

Depending on the area over which means and standard deviations are computed, SSIM can indicate image similarities either globally (i.e., between whole images) or locally (i.e., between small neighborhoods of the same coordinates (m,n) in both images).

When coloring the current frame in the context of the previous one, we actually utilize both aspects of SSIM.

First, we calculate the global SSIM measure between the current monochrome frame (to be colored) and its monochrome predecessor (already colored). If the value is too low (the recommended threshold is 0.5), we assume no perceptual similarity between the frames, and the current frame is colorized independently.

In practice, such situations occur infrequently, mainly when assembling longer movies from shorter unrelated fragments, and high values of global SSIM similarity between adjacent frames can typically be expected. For example, the SSIM values between the neighboring pairs of monochrome frames in Fig. 7 are as follows: 0.9511 (frames *a,b*), 0.9756 (frames *b,c*), and 0.9508 (frames *c,d*).

Therefore, we normally define colors of the colorized frame I_k as weighted combinations of the independent colorization of I_k and colors of the previous frame I_{k-1}, i.e., for given pixel coordinates (m,n) we use the *local* values of SSIM:

$$Col_k(m,n) = sim \times Col_{k-1}(m,n) + (1 - sim) \times Col_k(m,n) \quad (6)$$

where $sim = SSIM(I_k(m,n), I_{k-1}(m,n))$.

Additionally, the colors computed by Eq. 6 are projected onto the corresponding YUV planes (defined by pixel intensities in frame I_k) as explained in Section II-D.

Fig. 8 provides exemplary effects of the proposed color regularization over neighboring frames. First, we display the local SSIM indexes between the monochrome frames from Fig. 7 in Figs 8(a-c). Then, the lower row of Fig. 8 shows the colored frames after the regularization.

IV. Experiments

The proposed method of monochrome movie colorization involves heuristic assumptions, arbitrary model selection, and probabilistic computational schemes. Furthermore, the obtained results cannot be objectively assessed since reference or ground-truth results are assumed to be non-existent.

Therefore, the performance of the method and quality of its outputs can only be evaluated through extensive experimentation. In particular, the final results are typically assessed using subjective criteria such as *visual plausibility*, *coloristic attractiveness*, *aesthetic value*, etc.

One of the main challenges in conducting such experiments is the large number of potential *rgb2gray* models, as discussed in Subsection II-B. The sheer quantity of alternative colorizations may be overwhelming for human evaluators. Therefore, it is necessary to reduce the number of effectively considered *rgb2gray* models.

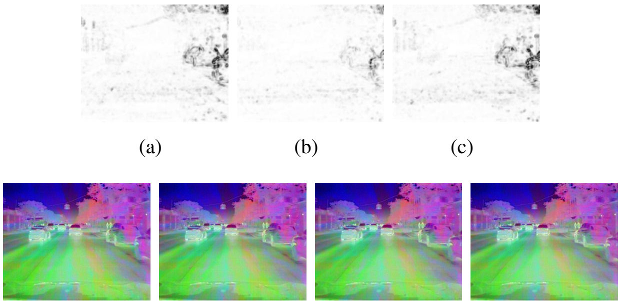

Fig. 8. SSIM maps (intensities proportional to the numerical values) for Fig. 7 pairs of monochrome frames: (a) for frames *a,b*, (b) for frames *b,c* and (c) for frames *c,d*. The bottom row displays the results after the color regularization.

For moderate numbers of adopted *rgb2gray* models, e.g., $231(171)$ models with 0.05 stepsize, we found that the most plausible solutions are normally obtained from the $10 - 15\%$ of results with the lowest value of *colorfulness* (details of this metric are provided in [1], [26]). Specifically, when the monochrome objects depict scenes from the real world, this subset typically includes solutions that vaguely align with human coloristic expectations (more information in [17]).

With a large number of models, e.g., $5151(4851)$ or $125,751(124,251)$, the models are preliminarily clustered into a recommended number of classes ($20 - 40$), and only the cluster medoids are used. Details of the clustering algorithm are outlined in Subsection V-A.

In any case, the users are presented with a limited number of suggested colorizations, from which they can select the most satisfactory option. Subject to the quality constraints of the original monochrome movies, the results always appear attractive and convincing, resembling scenes from 'fairytale lands'. Therefore, the preferred colorized version becomes a matter of personal choice.

In the experiments, the non-visual (IR) movies mainly come from FLIR ADAS[1] and CAMEL [27] datasets. The visual-frequency movies, which are used to better highlight the differences between our approach and the 'traditional' re-colorization expectations, primarily come from personal collections.

This section includes short representative frame sequences as illustrations. For example, Fig. 9 once again confirms that colorization supported by SSIM-based regularization provides a natural-looking continuity of colored frames, free of flickering and artifacts.

Fig. 10 showcases a rather unusual (but occasionally possible) result of re-colorization of a real-world movie. It can be observed that the selected colorization option appears even more natural than the original color movie!

[1] https://www.flir.eu/oem/adas/adas-dataset-form/

Similar effects can be observed in Fig. 11, where the re-colorized frames of an underwater movie appear more authentic than the original shots.

Nevertheless, in typical cases, even if the monochrome movie has ground-truth colors, there is no correspondence between the original colors and their re-colorized versions. In other words, there is no distinction between colorizing monochrome movies with or without existing color originals. The results appear visually plausible, but they may or may not meet the ground-truth coloristic expectations, with the latter being more typical (see examples in Fig. 12).

Finally, Fig. 13 provides exemplary colorization results (arbitrarily selected from a number of alternative results) for a sequence of frames extracted from an outdoor IR movie.

Overall, the experimental results confirm that plausible video colorization can be achieved fully automatically, without the need for learning from relevant training data, human assistance, or supplementary metadata. In other words, it appears possible to synthesize realistically-looking colorful immersion into the 'gray worlds' of monochrome visual data. With the mechanisms provided for pre-selecting the $20-40$ most promising *rgb*2*gray* models, users can choose their preferred colorization version from a limited yet sufficiently diverse number of alternative solutions.

However, considering that only subjective assessment criteria are currently utilized, presenting the actual video clips would be a more suitable approach to report the experimental results.

A. Comparing to SOTA

It is generally assumed that AI-based methods deliver *state-of-the-art* (SOTA) results for the colorization of monochrome objects. In particular, some works on video colorization, including [14], [16], use individual frame colorization by SOTA AI methods as benchmarks for the proposed algorithms.

Following the same approach, we colorized sequences of frames from the tested videos using the publicly available (at https://deepai.org/machine-learning-model/colorizer) tool which applies one of the most advanced re-colorization methods (outlined in [2]).

The results shown in Fig. 14 are utterly disappointing. While *visual plausibility* is basically unchanged compared to the monochrome images, the other subjective criteria, such as *coloristic attractiveness* or *aesthetic value* fall far below expectations. The color outputs are almost direct replicas of the grayscale values from the monochrome images. Apparently, when facing unfamiliar contents, the algorithm decides to keep the original monochrome colorization. In other words, satisfactory and visually attractive AI-based colorization is not possible for monochrome objects for which no coloristic knowledge or experiences are available. Therefore, the practicality of the proposed approach is somewhat boosted.

V. CONCLUDING REMARKS

A. Limiting the number of alternative solutions

The main practical obstacle in prospective applications of the proposed approach is (as highlighted in Subsection II-B and Section IV) the large number of available *rgb*2*gray* models. Human observers are unable to assess all possible colorization outputs, so limiting the number of models to a limited (but sufficiently diversified in terms of the produced results) is an important issue. This is the outline of the proposed remedy.

As an alternative to the representations given in Figs 4 and 5, the colors assigned to the selected intensity I can be visualized as the polygonal intersection of the $k_R R + k_G G + k_B B = I$ plane with the RGB color space cube. An example is provided in Fig. 15 (note locations of the centers of gravity of the depicted polygons).

Thus, the 256×3 matrix of gravity center coordinates of such polygons for $I = 0, ..., 255$ can be considered a compact representation of the adopted *rgb*2*gray* model. The matrix can be nicely visualized by a (discrete) curve winding from *black* to *white* in the RGB cube (see examples in Fig. 16). Those curves will be referred to as *mean-color curves*.

Then, the *rgb*2*gray* models can be clustered by clustering their *mean-color curves* (i.e. 256-dimensional arrays of $3D$ coordinates). Eventually, *medoids* of the obtained clusters are identified, and only the models corresponding to those medoids are used for colorization.

Therefore, we adopt a limited number of models (for example, only 32 clusters are built regardless the total number of models) which are as diversified as possible in terms of their statistical coloristic properties.

For the total number of 4851 *rgb*2*gray* models (i.e., 0.01 stepsize), the list of adopted model is given in Table I. It can be noted that one of the models, namely $[0.26, 0.58, 0.16]$, is quite similar to the standard YUV model with $[0.299, 0.587, 0.114]$ coefficients.

B. Summary

In this paper, we propose a method for addressing the ill-posed problem of colorizing monochrome movies without

any direct or indirect human assistance. Our method builds upon our recent results in colorization of monochrome images, where we assume the use of arbitrary decolorization (*rgb*2*gray*) models.

The movie colorization process involves two operations: image colorization and temporal stabilization of rendered colors. First, individual frames are colored using simple probabilistic heuristics and a randomized *flood-fill* technique, starting from the initial queue of darkest/brightest pixels with deterministic color choices. In the second operation, we utilize the SSIM similarity index to determine whether and to what extent color continuity should be maintained between adjacent frames.

While a large number of *rgb*2*gray* models can hypothetically be used, we can pre-select a limited number of sufficiently diverse variants. Users can then choose their preferred colorization from these options, typically based on personal preference.

The method is primarily designed for colorizing monochrome movies in domains where no actual color data exists, such as IR, UV, MRI, etc. In other words, our goal is to transform the monochrome data into convincingly realistic color versions of these *gray worlds*. This may be necessary for various reasons, including aesthetic considerations.

In future work, our intention is to focus on the following problems that have not yet been adequately addressed:

- Analysis of the mathematical properties of the method, which includes exploring alternative probability distributions used in the adopted heuristics, investigating the local (individual frames) and global (movies) convergence of colorization results, etc.
- Developing metrics for the objective evaluation of colorization results, including the selection of appropriate assessment criteria.
- Optimizing the code, including parallelization techniques, optimizing data structures, and other strategies. The ultimate objective may involve achieving real-time performance.
- Integrating the method with selected AI techniques to enhance its capabilities and explore potential synergies.

***Abstract*—The Internet of things (IoT) ecosystem provides a platform for the connectivity of interrelated smart devices to automate manual processes and reduce labor costs. IoT has brought significant benefits to all industries, including maritime, as various objects (e.g., ports, ships, agents, etc.) are connected to gather and share information within the maritime ecosystem. The innovative technological aspects of IoT are promoting the effective collaboration between the research community and the maritime industry, for enhancing the performance of maritime transportation systems. Therefore, this study discusses recent advances delivered by the IoT and other emerging technologies, like machine learning (ML) and computer vision (CV), for smart maritime transportation systems (SMTSs). In particular, this paper presents two specific use cases of SMTSs, namely, predictive maintenance and container damage/seal inspection. Moreover, the key benefits of integrating IoT with ML and CV are highlighted for the above-mentioned use cases. Finally, a discussion is presented to highlight key opportunities along with foreseeable future challenges in adopting these new technologies by the maritime industry.**

I. Introduction

MARITIME transportation is fundamental to the global supply chain. Conventional transportation systems are not inter- or intra-connected. However, with the advancements of information and communication technologies, the concept of connecting everything into smart maritime transportation systems (SMTSs) has emerged [1]. SMTSs use computing, telecommunication, radio-location, internet of things (IoT), and/or automation technologies to improve the performance, management, and safety of transportation systems [2]. In addition, SMTSs communicate information to maritime stakeholders about congestion levels, alternative modes of transportation, or alternate routes. Smart containers are also an essential component of SMTSs, as they enable fine-grained tracking of goods across continents [3]. A terminal is considered “digital” or “smart” if all of its objects are fully interconnected via different communication technologies, e.g., IoT, cloud, etc., to exchange information. A combination of smart sensors and actuators, wireless devices, data centers, and other IoT-based port services form the main infrastructure of smart ports, enabling port authorities to provide more reliable information and various new services to their customers.

A real-time smart port at Xiamen Ocean Gate has been implemented [4] as the first automated container terminal in China that follows the standards of a global automated terminal handling system. Furthermore, it is considered as the first terminal in the world to deploy 5G mobile networks and cloud technologies in its operations [5]. The authors of [6] also proposed several solutions for digitalization in global supply chains, connecting cities and ports via maritime informatics, and sustainable shipping. Furthermore, they also argue that the future of shipping relies on exploiting collaboration via digital data sharing. European ports have also taken initiatives to become smart ports [7]. For example, the Port of Rotterdam is using IoT-based sensors to enable advanced intelligence and create digital twins, the Port of Hamburg is using 5G-based networks to monitor the critical infrastructure by enabling virtual reality, while the Port of Seville is using mobile network technology to monitor goods and traffic in the port in real-time.

Moreover, the sustainability of short sea shipping (SSS) is central to a clean, safe, and efficient European Union (EU) transport system, researched by related Sea Traffic Management (STM) EU projects (such as STMV and STEAM). The study presented in [8] reports on key challenges for advancing reliability, quality, and safety, and removing unnecessary costs and delays at SSS hubs, with a particular focus on Eastern Mediterranean. Specifically, it considers the effect of port-2-port (P2P) communication on port efficiency by investigating the factors influencing the various waiting times at the Port of Limassol, Cyprus, both qualitatively and quantitatively. Finally, measures are proposed for improving agent performance based on the principles of Port Collaborative Decision Making, including P2P communication, data sharing, and transparency among all stakeholders involved in a port call process, and open dissemination of agent-specific key performance indicators (KPIs).

Cargo handling at the Port of Limassol is currently performed by several quay cranes and straddle carriers. These cranes are heavy machines that have multiple subsystems running internally that are managed by different programmable logic controllers (PLCs). The PLCs take input directly from

This research was funded by the European Union’s Horizon Europe program for Research and Innovation through the aerOS project under Grant No. 101069732.

the cranes, execute specific programmed logic, and produce output that allows terminal personnel to operate the crane. PLCs are therefore the most accurate representation of a port crane's status [9]. However, Big Data, artificial intelligence (AI)/ machine learning (ML), and IoT technologies, currently rely on remote servers and/or cloud technologies. So there is a gap between where the data is most accurate, and where the analysis and predictions are performed. This mismatch impacts real-time observability at the upper levels of the terminal system due to higher latency between the central server and the source from which the data originates. These constraints limit the efficiency of the terminal, as it cannot prevent possible unforeseen problems such as outages. Furthermore, there is a need to combine latest technologies with the IoT paradigm in order to enhance the performance of maritime ports. For instance, combination of IoT and ML/deep learning (DL) can enhance the lifetime of maritime equipment and reduce costs through accurate predictive maintenance (PdM). In another scenario, IoT with computer vision (CV) can help reduce human intervention in risky environments, e.g., security seal inspection and damage detection for containers during loading/unloading.

Therefore, this study focuses on how IoT can benefit the maritime industry, especially when combined with other emerging technologies. First, we highlight the research challenges and future directions for the adoption of IoT by the maritime industry. Then, we discuss two specific use cases of SMTSs, namely, PdM and container damage/seal inspection, where IoT is combined with ML/AI and computer vision technologies, respectively.

II. Challenges for IoT adoption

In the shipping industry, a huge amount of data is generated from various sources and formats. The various sources include traffic data, weather data, port call data, cargo data, water level data, and maritime equipment data. In this section, the main open issues related to the deployment of IoT in the maritime industry are presented below.

Real-time data collection and transfer: Data collection and transmission are considered two of the main issues in the use of IoT, ML, and CV technologies in the maritime industry. This is because the data collected by current technologies may be incorrect, unreliable, or incomplete in certain locations or at certain times due to the frequent movement of ships at sea. In addition, a ship is usually equipped with multiple sensors that generate a huge amount of data, and transmitting the data to data centers for further processing is inefficient, creating a major challenge and uncertainty. For example, each sensor requires a particular bandwidth to transmit the data to the database. Hence, new sensor technologies are needed to improve data quality, and high-tech IoT-based communication systems to speed up the data transmission speed [10]. Also, automating data acquisition instead of manual input will improve the quality of data.

Security and privacy concerns: Although modern maritime transportation systems benefit greatly from IoT and other communication technologies, security and reliability risks have increased significantly [11]. The involvement of various maritime stakeholders in planning and managing maritime traffic flows further exacerbates these challenges. Therefore, there is an urgent need to develop an IoT-based collaborative processing system that unifies the modular structure and integrates multiple modules involved in maritime transportation systems. In addition, a common and controlled access mechanism that cannot be manipulated or tampered with by unauthorized parties is also an essential requirement for SMTSs. Moreover, intercommunication and the integration of heterogeneous technologies into IoT-enabled SMTSs offer opportunities not only for the industries but also for cyber criminals. Cyber threat intelligence is an effective security strategy that uses AI models to understand cyber-attacks and can effectively protect IoT-enabled data [12]. In addition, the research community must take advantage of the latest technologies (e.g., ML, CV, blockchain, etc.) by combining them with IoT-assisted systems to find secure and reliable solutions for SMTSs at sea.

Big Data: In the maritime industry, huge amounts of data are generated from various sources every day. For example, Marine Traffic, an automatic identification system (AIS) vessel tracking website, reports collecting 520 million AIS messages daily involving 180 thousand distinct vessels from 3000 active AIS stations worldwide [13]. Port authorities and various port stakeholders (e.g., cargo terminals, tug operators) also collect data on the arrival, berthing, loading, unloading, relocation, anchoring, and departure of ships from ports [8], [14]. Various sensors are also deployed at sea to record data on various oceanographic, environmental, and meteorological parameters of interest, with data volumes reaching up to 5 GB per day [15]. Therefore, developing and designing a reliable and suitable storage architecture to meet the requirements of Big Data in the maritime industry has become a major challenge. Another challenge is the timeliness of processing maritime big data. In the maritime industry, fast and accurate decisions are needed to avoid hazards that relies on fast data processing. Hence, big data processing systems should be able to handle diverse and huge amounts of data, which are constantly increasing. There are several general big data frameworks for processing real-time data, such as Apache Kafka, Elasticsearch, OpenSearch, MongoDB, etc. So, developing an efficient big data framework that can process large maritime data sets is still an open challenge.

Emerging technologies: To ensure higher efficiency of SMTSs, new and emerging technologies must be adopted. In this regard, frugal AI, CV, ML, and IoT, especially when integrated with each other, can play a crucial role in reducing costs and increasing efficiency in smart ports. By using frugal AI models, the system can be lighter and less computationally intensive, which can be beneficial in situations where resources are limited. To prevent cyberattacks on SMTSs, satellite IoT and high-altitude platform solutions can be deployed. With increased GPS jamming and spoofing attacks on maritime systems, satellite IoT can serve as a complementary long-range

Fig. 1: A view of the container terminal at the Port of Limassol, Cyprus

solution and thus be beneficial in many ways [16].

III. IoT for Predictive Maintenance

Container handling equipment (such as ship-to-shore (STS) cranes, gantry cranes, straddle carriers, or reach stackers) require an optimal maintenance process due to the heavy loads, long operating times, and diverse weather conditions, motivating the need for a precise PdM system. Figure 1 shows the container terminal with several cranes and other equipment at the Port of Limassol, Cyprus. Preventive maintenance has traditionally been performed using supervisory control and data acquisition (SCADA) systems set up with human-coded thresholds, warning rules, and configurations to determine when a machine's condition requires repair or even replacement. However, this semi-manual approach does not take into account the more complex dynamic behavior of the machines, nor the contextual data that relates to the operational process as a whole. For this reason, and thanks to recent advances in AI and IoT, the implementation of ML-based solutions is seen as the next functional step that can lead to significant cost savings, higher predictability, and better availability. PdM results in up-to-the-minute knowledge of health status, which allows neither waiting for equipment to shut down (i.e., reactive maintenance) nor performing maintenance when it is not required (i.e., preventive maintenance). In PdM, the IoT can play an important role in predicting faults/failures at an early stage. For example, a number of appropriate sensors can be deployed in machinery/engines to minimize the risk of negligent failures of key components and increase their efficiency [17]. More comprehensive monitoring provides real-time information such as cargo temperature, gas emissions, and other important data that can help optimize operations, reduce maintenance costs, and increase the safety of the entire ecosystem [18].

Based on the current literature, a significant amount of work has already been carried out regarding ML and IoT approaches to solve PdM problems in various industrial environments. This, along with previous research on how the effectiveness of quay container cranes is affected by reduced speed and breakdowns [19] lies the basis for developing PdM approaches (proposed by combining IoT with ML models) applied to port machinery (such as STS cranes and straddle carriers). In addition, most ML projects require sufficient historical data to help understand past failures. This includes general characteristics such as mechanical properties, average usage, and operating conditions. However, even when sufficient data is available, the selection, training, and inference process of the most appropriate ML model for the computational capabilities of the pilot project's infrastructure elements is paramount. Although cloud computing can support predictive analytics solutions, running these models on a remote server introduces potential latency issues that can lead to delayed response times, depending on the quality of connectivity to send data from the device to the cloud over the internet. Edge technology can be considered as a way to optimize the speed and performance of predictive analytics by running ML models locally. Frugal AI models are seen as the optimum approach to (i) predict the remaining useful life of assets with regression models and (ii) predict failures within a given time window with classification models for STS cranes and straddle carriers. In the envisioned architecture, far-edge devices could be used for collecting data from sensors and the machine's PLC, and performing basic pre-processing of the data. Edge processing will be performed for local ML training and inferencing for identifying the need for PdM. Finally, cloud resources could be used for more intense ML training and testing.

IV. IoT for Container Seal Inspection

Containers play an important role in the maritime industry worldwide. Containerization has improved the way cargo is transported around the world by ensuring the safety of cargo in transit. To ensure the security of containers, they are sealed with security seals that prevent an unauthorized entry (a pictorial example of security seals is presented in Fig. 2). During transit, customs officers need to inspect security seals when containers pass through the container terminal gate. The current mechanism for checking the seals relies on visual inspection by humans, which can be time-consuming, labor-intensive, and potentially dangerous. Within the digitalization journey, CV is a rapidly growing field of AI that has many potential advantages in various industries [20], particularly in manufacturing and industrial settings, where visual inspections are critical to ensure product quality and safety. One significant advantage of CV is its ability to automate visual inspection processes. With the help of CV algorithms, it is possible to automate quality control, defect detection, and inspection processes, resulting in increased accuracy, speed, and cost-effectiveness.

One of the most important sources of data for the terminal is the camera system. Thanks to the explosion of customizable internet protocol television (IPTV) cameras, the captured video streams can be used in combination with CV to improve various aspects of the port. In particular, it is important to track the continuous flow of incoming and outgoing containers. Therefore, the development of CV and IoT-based systems will allow the terminal to automatically identify containers

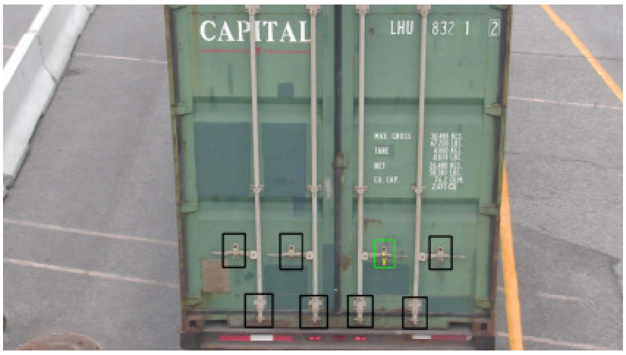

Fig. 2: A container with the security seal shown in a green square; the possible alternative positions for the security seals are shown in black squares.

with damage and verify the presence of proper container seals without requiring human intervention. These two features will be offered to container terminals' customers, providing added value from the quality checkpoint of view. In addition, frugal AI models can provide the automated and low-latency analyses of those video streams on the edge, avoiding human mistakes and at the same time reducing safety risks, thus achieving a secure, and trustable environment for workers.

Based on current literature, several studies exist that are employing IoT and CV for visual inspection processes in different industrial settings. However, we found only a few studies that deal with the maritime industry using CV, IoT, and edge computing based solutions. In the maritime industry, edge technology is considered the way of optimizing the speed and performance of CV analytics by performing ML locally, since despite cloud computing can support CV solutions, performing the inference process on a remote server may lead to potential latency issues, which may cause an unsafe environment for terminal workers. Therefore, an edge-based architecture of container damage/seal inspection via CV and ML technologies would be the most suitable solution. In the envisioned architecture, far-edge devices (i.e., IPTV customizable cameras) could be used for collecting video streams and performing basic pre-processing. Edge processing will be performed for local ML training and inference for identifying the presence of container damages or the absence of safety seals. Finally, cloud resources could be used for more intense ML training and testing.

V. Conclusion

This paper reviews the current status of IoT in SMTSs. The main research gaps identified in this study are: 1) the need to deploy IoT in the maritime industry, 2) the integration of IoT with other emerging technologies such as ML, edge computing, and CV, 3) data security and privacy, and 4) big data collection and storage, while the edge technology-based solution is proposed to optimize the speed and performance of predictive analytics by running ML and CV models locally. Furthermore, these challenges can also be addressed by combining emerging technologies, i.e. IoT, ML, edge computing, and CV, in the maritime industry. This paper explores two such use cases of SMTSs, while combining IoT with other emerging technologies; i.e., ML/DL for PdM, and CV for container damage/seal inspection.

***Abstract*—The automated process of determining the crop type carried on plots of land, leveraging data provided by earth observation satellites, represents a highly valuable ability that can serve as a foundation for subsequent analyses or as input for calibrating models, such as Decision Support Systems. This paper presents a study on the task of crop classification starting from indices derived from imagery data provided by ESA Satellites Sentinel 1 and 2. We create a valuable tool to verify farmers' claims, especially in relation to state subsidies for specific crops of interest. To this purpose, we focus on perfecting a binary classification for each of five crops of interest (Tomatoes, Soy, Sugar Beet, Rice, and Wheat), aimed to accurately discern the target crop against any other possible crop. The paper investigates various preprocessing techniques to create a dataset suitable for traditional machine learning methods, which presumes that each land plot to classify is represented by a fixed set of features. To deal with inevitable missing observations caused by clouds or other environmental factors, we investigate different imputation strategies (linear interpolation and constant value filling). Complementary, we study the impact of imbalanced classification labels and evaluate the effectiveness of standard balancing techniques. The findings offer practical implications for monitoring and optimizing agricultural practices in the context of precision farming and sustainable agriculture.**

I. Introduction

IN LINE with the objectives for the period 2023-2027 of the European Union's Common Agricultural Policy (CAP), Italy has allocated funds for the production of protein crops (€544 million per year). The aim is to incentivize local agricultural production of crops such as Tomatoes, Soy, Sugar Beet, Rice, and Wheat in local production through the granting of reimbursements by the state. Consequently, there is a pressing need for methods to verify the authenticity of indigenous crops. On-site inspections prove to be costly and inadequate given the scale of the problem, meanwhile satellite remote sensing is a promising technology to classify crops since it can provide periodically large-scale observations of ground objects [11], [13]. The objective of this study is to automate such verification procedures by using Machine Learning (ML) systems applied to satellite data of the relevant geographical areas. Specifically, we focus on the central area of region Emilia-Romagna (Italy) . The problem can be cast as a binary classification: given the data pertaining to a particular field and the farmer's statement regarding the crop, our goal is to verify the veracity of the information given.

The usage of machine learning algorithms for similar tasks is explored in many recent contributions. Among them, Random Forest [3], [7], [12] or decision tree-based [3], [9] classifiers are among the most commonly employed methods for handling this type of data. Data for this paper has been sourced from Sentinel satellites, deployed within the Copernicus program, managed by the European Space Agency (ESA). Sentinel-2 images, have already proven to be a valuable data source for crop mapping in different regions and countries like Central Europe [7], Spain [3], [10], Lebanon [9] and China [12].

The remainder of this paper is structured as follows. Section II, provides a description of the composition of the dataset, highlighting the type of utilized data, the characteristics of the satellite observations, and the distribution of the different crop types. Section III provides e a theoretical overview of the Machine Learning method employed: Random Forests

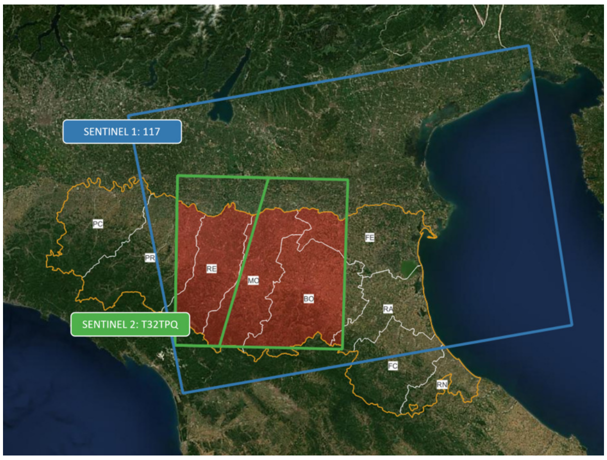

Fig. 1: Study area and locations of ground truth samples (red area). The analyzed fields are located in the central part of the region. This specific area of interest tends to prioritize the production of Wheat, Soy, and Sugar Beet over Rice and Tomatoes.

(RF) with an emphasis on the data pre-processing work, from handling missing dates due to adverse weather conditions to addressing the dataset's imbalance. Section IV presents the performance of the proposed pipeline for crop classification. The aim of this section to assess the accuracy of our model using the complete time frame of the planting process, from seeding to product harvest. In Section V we briefly go through the main result of this work to provide possible branches of further research on the topic.

II. Dataset and Preprocessing

All the data used for the remote sensing purpose in this work is acquired from the earth observation satellites deployed by ESA during the missions Sentinel-1 and Sentinel-2.[1]. Each of these missions deployed in a near-polar sun-synchronous orbit a twin pair of satellites (named Sentinel-1A and Sentinel-1B, Sentinel-2A and Sentinel-2B), which provide sensor observation capabilities depending on the objective of the mission. In particular, Sentinel-1 satellites are equipped with C-band synthetic-aperture radar (C-SAR), while Sentinel-2 satellites are instead equipped with passive Multi-spectral camera operating in 13 distinct bands spanning the spectrum of visible, near-infrared and short wave infrared. Sentinel-1A has a revolution period, hence a temporal revolution, of 12 days, whereas Sentinel-2A and Sentinel 2B of 3 to 5 days, depending on the area. Spatial resolution of Sentinel-1 observations is 10 meters, hence the crop field is discretized in squares of $100m^2$. Sentinel-2 data has a different spatial resolution according to the sensor by which they are collected, either 10 or 20 meters. From a qualitative standpoint, Sentinel-1 active radar sensors imply it always collects the data independently of atmospheric conditions, while Sentinel-2 satellites, relying on passive optical sensors, can produce missing or fragmentary observations due to clouds presence. Starting from the raw observations obtained from the Sentinel satellites, we leverage a total of 16 numerical indices, 12 of them are obtained by Sentinel-2A and Sentinel-2B, and 4 came from Sentinel-1A and Sentinel-1B. Sentinel-1B stopped working in December 2021 and is currently unavailable. Overall, the time frame of the whole dataset spans across 14 months.

A. Data Preparation

Each of the 2 indexes coming from Sentinel-1, named *backscatter* and *coherence*, is further divided in the two polarization VV (co-polarized) and VH (cross-polarized). Backscatter defines the portion of the radar signal that get reflected from the earth's surface straight to the radar antenna, while coherence is defined as the normalized value of the complex cross-correlation between a pair of SAR observation spaced by a period of 12 days. Intuitively, a very low value of the coherence, might indicate a big change in how the field presents itself in 12 days time-difference. To prioritize the number of available observations over the homogeneity of those observations, we also leverage the multiple observations of fields that are visible from partially overlapping orbits This is acceptable since we use pixel statistics (as detailed below), not raw observations, to analyze our data. The differences between observations from different orbits are therefore considered negligible.

The most popular index obtainable from Sentinel-2 observations is the NDVI (Normalized Difference Vegetation index), eq. (1), defined as the ratio of the difference and the sum of the reflected radiation in the near infrared and red, which is a good indicator of the amount of chlorophyll in a field.

$$NDVI := \frac{NIR - RED}{NIR + RED} \tag{1}$$

In order to produce a suitable time series representation for each field, we devise a simple yet effective post-processing strategy of the raw satellite observations. For each record, using its vector geometry, the corresponding patch is cut out for each available observation. Then, each patch is reduced to a set of five statistics (mean, mode, standard deviation, maximum and minimum). The full set of observation obtained over the growing season constitute the field time series that we aim to classify, and it's labeled with a single class identifying the crop being grown.

Our dataset consists of 49 different types of crops and 16,684 sample fields. Among those 49 crops only five are subject to crop-specific subsidies and only for them it is necessary to verify the truthfulness of the farmer's declarations. Getting more specific, the dataset consists of 12,496 samples with specific target crop, divided in: 743 Tomatoes, 63 Rice, 5,214 Wheat, 2,974 Sugar Beet and 3,502 Soy, and 4,188 samples with crops not subject to specific subsidies and therefore considered as ”OTHER” class.

[1] https://sentinel.esa.int/web/sentinel/missions

TABLE I: Amount of crop types for the available fields

Crop	**Amount**
Tomatos	*743*
Soy	*3502*
Sugar Beet	*2974*
Rice	*63*
Wheat	*5214*
Others	*4188*
Total	*16684*

B. Analysis of the used Dataset

Therefore, we propose a qualitative analysis of the available data, this is helpful in order to build an intuition for the possibility to accurately classify the observed crop based on the data gathered. The bar plots (Figure 2a-Figure 2e) depict the variation of the NDVI value across all the fields during the season. The black line represents the behavior of the NDVI average across the fields, while the green vertical bands represent one standard deviation above and one below the mean. The sowing and harvesting phases of the different crops (See Table II) are delimited by the dashed blue and red vertical lines, respectively. The behavior of the NDVI appears to be highly indicative of the growth trend: the blue area (sowing) is usually followed by an increase in the value of the index, whereas the red bands (harvesting) correspond to a steep decrease of the NDVI value. This has a straightforward interpretation given the meaning of the NDVI (indicative of the amount of chlorophyll in the field): after the sowing period, the amount of chlorophyll increases during the vegetative growth, and decreases rapidly with the harvesting. Looking at the width of the green error bars, we can also appreciate the variability changes during the different phases and among different crop types.

III. Method

Since ultimately the objective is to verify if the crop is the one declared by the farmer (among the 5 ones of interest) versus any other different crop type, we propose to train a binary classifier for each of the crop of interest. After the common data preparation steps detailed above, a binary classification dataset is prepared for each of the target crops, by assigning to the samples labeled as it the label positive (1) and to any other sample the label negative (0). At deployment stage, the binary classifier is fed a new unseen crop that should belong to a specific class and assess the truthfulness of the declared crop.

It is known in the literature that Random Forest has great performances in remote sensing classification tasks [1]. A Random Forest (RF) [2] is an ensemble method whose base estimators are decision trees. This method reduces bias and variance thanks to the introduction of multiple uncorrelated voters, because each of the trees has the chance to learn a different pattern in the data and then this knowledge is combined.

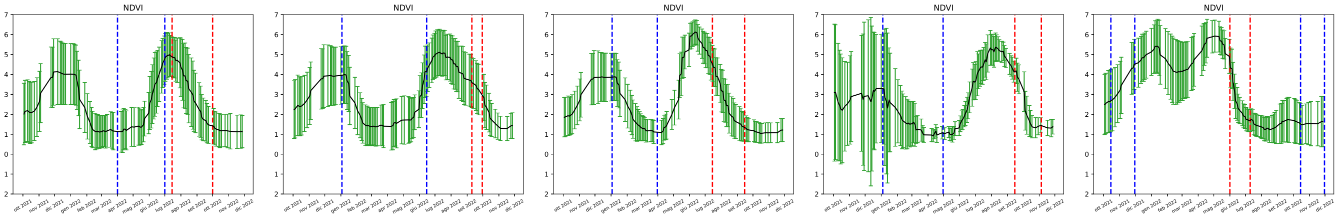
A. Missing data management

Due to variable atmospheric conditions and the nature of Sentinel-2 passive optical sensors, we have a lot of images that were totally or partially covered, hence we opted to disregard covered units up to a certain threshold during preprocessing. In order to represent each field as a fixed set of features, we define a common set of observation dates. While other strategies are possible, we prefer to preserve all the remaining observations by considering all the timestamps that corresponds to at least a single observation in the whole dataset, resulting in 110 valid timestamps. Complete observations of all the 16 indices are usually not available for all the 110 timestamps for each field, Figure 3 illustrates the approximate distribution of the amount of observations per field. We experiment with two standard techniques to fill the missing values. The first is to insert an out-of-scale value in all empty dates. The other technique we evaluate is linear interpolation [8]. For each field, we linearly interpolated all the statistics (mean, mode, minimum, maximum, standard deviation) in each of the empty dates.

B. Data imbalance management

The creation of the five binary classification dataset inherently causes large data imbalance that is of potential harm when training a classifier, as it could learn a bias towards the dominant class. To tackle this problem, we investigate 3 popular ways to obtain a balanced dataset before training the classifier: undersampling, random oversampling, SMOTE (Synthetic Minority Oversampling Technique) [5].

Undersampling consists in balancing the training set by randomly eliminating units from the majority class. The main drawback of this is the information loss, as the classifier may lose the chance to see some different and valuable examples of the adversary class. On the other hand, this approach leads to having a smaller dataset, which makes the training phase less time-consuming and energy-demanding, also reducing the environmental impact in the perspective of GreenAI. On a different note, random oversampling consists of balancing the training set by randomly sampling more units of the minority class.While this approach does not lose any information, it presents other drawbacks.The dataset becomes larger without actually adding new information: this translates in an increased computational cost and training time, without a corresponding increase in the algorithm performance. Furthermore, we run the risk to induce overfitting, reducing the classifier's ability to generalize with respect to undersampling, likely leading to many false positives [6]. Finally, SMOTE is a balancing technique that focus on generating synthetic samples for the minority class, this is achieved by interpolation in feature space between two neighbor samples from the minority class.This approach mitigates the risk of overfitting, but it is often unclear whether the newly generated units are actually realistic, therefore the risk is to create noise or introducing a bias in the training sample. For this reason, we refrain from leveraging SMOTE in the following experimental section.



(a) Tomato (b) Soy (c) Sugar Beet (d) Rice (e) Wheat

Fig. 2: Bar plots showing NDVI index across time for different crops. Vertical green error bars represent one standard deviation above and one below the average, computed among the fields. Vertical dashed blue lines enclose the sowing periods, red ones enclose the harvesting ones (See Table II)

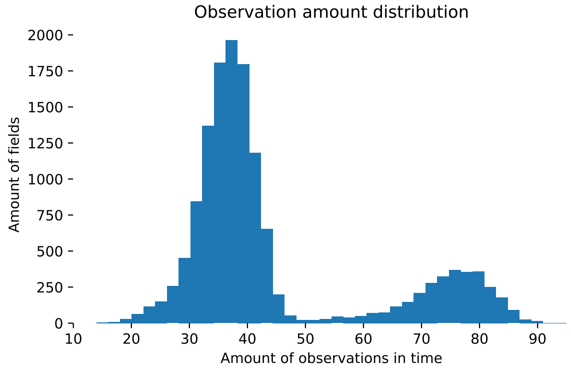


Fig. 3: Distribution of the amount of observations.

Intuitively, we could prospect that undersampling could be the best option for our case, given the dataset to be large enough for the model to see enough variability in the adversary class. Moreover, since false declarations are a rare occurrence (<5%), we could foresee that among the units flagged as suspicious (classified as negative for the class of interest), there would be a predominance of false positive. False positive could trigger and unnecessary verification, while false negatives could mean a false declaration going undetected, hence the trade-off should be carefully evaluated in the deployment scenario.

IV. Experiments

In this section, we present and discuss the results of the methodology detailed in the first part of this manuscript. To restate, the goal of our research is to leverage the observations provided by the ESA Copernicus satellites in order to provide the regulatory agency with feedback on the truthfulness of the stated crop for a given plot of land. A negative outcome of the automatic classification might trigger an on-site inspection, hence it is crucial to be able to provide a reliable classification.

A. Experimental Setup

For the purpose of this work, five crops have been considered, which are reported in Table II along with the most relevant information of the production's life cycle. Our training data include all the available observation for the 2022 season (completed), we train a binary classifier for each of the five crops of interest, leveraging the datapoints labeled with the target class as positive examples (class 1), and the remaining datapoints as negative examples (class 0), those include the remaining 4 classes along with other crop classes. In this evaluation, we use as training data all the data available between the beginning of the sowing phase to the end of the harvesting for the target crop. This analysis is relevant for two aspects: (a) It allows for a controlled setup to experiment with multiple options for dealing with the problems of extremely unbalance between positive and negative examples (Section III-B) and to evaluate the two options for dealing with missing observations (Section III-A). (b) It allows defining a baseline for the classifier's performance in a best-case scenario.

TABLE II: Start and end of sowing and harvesting operations for the crops of interest, along with the minimum and maximum observed days of duration of the crop cycle. The information is obtained from the data for the 2022 growth season. Dates are expressed in (mm/dd) format.

Crop	**Sowing**		**Harvesting**		**Cycle duration (d)**	
	start	end	start	end	min	max.
Tomato	04/01	07/01	07/15	10/01	95	110
Soy	01/03	06/15	09/10	09/30	120	150
Sugar Beet	01/03	03/31	07/15	09/15	60	90
Rice	01/04	04/30	09/15	11/05	160	180
Wheat	10/15	11/30	06/01	07/10	210	230

To assess the effectiveness and reliability of the classification models we use the standard metrics in the literature for binary classification: Precision, Recall and F1-Score, defined below.

$$\text{Precision} = \frac{\text{True Positives}}{\text{True Positives} + \text{False Positives}} \tag{2}$$

$$\text{Recall} = \frac{\text{True Positives}}{\text{True Positives} + \text{False Negatives}} \tag{3}$$

$$\text{F1-score} = 2 \times \frac{\text{Precision} \times \text{Recall}}{\text{Precision} + \text{Recall}} \tag{4}$$

Given the extreme unbalance of the dataset uses for testing, it is best to avoid relying on the Accuracy, since a high accuracy may be achieved by simply predicting the majority class.

For each binary classifier, we isolate a uniformly sampled 25% of the available data for evaluation, while the remaining 75% is used for training. The very same train-test subset have been used for all the experiments, to ensure a fair comparison.

Before training each classifier, we further refine the training data by narrowing the observation window to only include observations between the start of the sowing season to the end of the harvesting season for the target crop. This is especially important since the same field might be grown with different crops through the year, which might induce a bias in the classifiers.

B. Results

TABLE III: Comparison of Interpolation with out-of-range placing for filling statistics of missing observation dates.

Crop	***Strategy***	**Precision**	**Recall**	**F1-Score**
Tomato	*Interp.*	0.89	0.59	0.71
	Fill	0.89	0.62	0.73
Soy	*Interp*	0.915	0.86	0.89
	FIll	0.92	0.86	0.89
Sugar Beet	*Interp*	0.99	0.93	0.96
	Fill	0.99	0.92	0.96
Rice	*Interp*	1.0	0.75	0.85
	Fill	1.0	0.375	**0.54**
Wheat	*Interp*	0.93	0.93	0.93
	Fill	0.93	0.93	0.93

a) Management of missing observations: The first fundamental experiment involves comparing different strategies for filling missing observations in the statistics, as introduced in Section III-A. The results obtained with two strategies, linear interpolation and filling missing values with an out-of-scale value (-1000), are presented in Table III. The choice of these strategies appears to have minimal impact on the evaluated metrics, except for the *Rice* crop, which exhibits a significantly low recall when using the constant value strategy. However, it is challenging to precisely attribute this result solely to the interpolation strategy, due to the crop's extreme under-representation across the dataset. For the above reasons, in the remainder of this analysis, we opted to use the Interpolation strategy.

b) Dataset balancing: The second part of the experimental evaluation focuses on determining the optimal strategy for handling the highly unbalanced dataset used to train the binary classifier. We compare the performance of the baseline classifier trained on the original imbalanced training set with the same model trained using two different resampling techniques: undersampling and oversampling. Undersampling involves reducing the number of instances from the majority class to achieve a more balanced representation of the classes, conversely oversampling involves increasing the number of instances in the minority class to address the class imbalance. These and other resampling strategies are further described in Section III-B.

By analyzing the results presented in Table IV, noteworthy observations can be made regarding the two resampling techniques. The application of the undersampling strategy resulted in an increase in the number of false positives, where crops are mistakenly classified as the target crop. Consequently, this led to a notable decrease in the Precision metric, reaching drastic levels for certain cases as highlighted in the results table. This issue can be attributed to the significant reduction in the training data caused by the undersampling procedure. As a result, the negative effect is particularly pronounced for the most underrepresented crops, such as Rice and Tomato. It's worth noticing that False positive are possibly the least desirable outcome in our application scenario, while a false negative leads to further investigations on the effective crop being carried out, a false negative means that bogus declaration are more likely to be undetected.

TABLE IV: Effects of training data balancing on the unbalanced test data.

Crop	***Train Data***	**Precision**	**Recall**	**F1-Score**
Tomato	Unbalanced	**0.89**	**0.59**	0.71
	Undersampling	**0.39**	**0.92**	0.54
	Oversampling	0.83	0.72	0.77
Soy	Unbalanced	0.915	0.86	0.89
	Undersampling	0.832	0.93	0.88
	Oversampling	0.9	0.91	0.91
Sugar Beet	Unbalanced	0.9	0.93	0.96
	Undersampling	0.95	0.96	0.95
	Oversampling	0.99	0.99	0.99
Rice	Unbalanced	1.0	0.75	0.85
	Undersampling	**0.12**	0.87	0.22
	Oversampling	**1.0**	0.75	0.86
Wheat	Unbalanced	0.93	0.93	0.93
	Undersampling	0.88	0.97	0.92
	Oversampling	0.92	0.95	0.93

On the other end the oversampling strategy shown promising results, with a noticeable reduction in false negatives with respect to the baseline with only a manageable increase in false positive, the overall superiority of this approach is hence validated by an increase in F1 score for all the crops. To conclude, while we can't recommend relying on an undersampling strategy, we are confident in suggesting the oversampling approach in order to reduce the number of occurrences of an investigation being triggered by mistake.

c) Choice of the classifier: The previous results were all obtained with a Random Forest classifier, to demonstrate the validity of our choice, therefore hereafter we evaluate the alternative usage of the very powerful and popular binary classifier SVM [4] This classifier builds a separation hyperplane by choosing support vectors, those are the defined as the harder to classify points. For a simple yet meaningful comparison, we compare the results obtained without train dataset balancing, using the interpolation strategy for the management of the missing observation.

In Table V we report the results. It's clear that RF slightly outperforms SVM for all the crops, of particular interest it is the Rice crop, that never gets correctly classified, hence scoring zero in all the metrics. The reason lies in the very small number of fields labeled as Rice (Table I), with SVM clearly requiring a larger training set. Another advantage of RF is its superior interpretability compared to SVM. With each decision

TABLE V: Comparison of the results obtained with Random Forest and SVM.

Crop	*Classifier*	**Precision**	**Recall**	**F1-Score**
Tomato	**RF**	0.89	0.59	0.71
	SVM	0.876	0.55	0.68
Soy	**RF**	0.915	0.86	0.89
	SVM	0.87	0.87	0.87
Sugar Beet	**RF**	0.99	0.93	0.96
	SVM	0.97	0.93	0.95
Rice	**RF**	1.0	0.75	0.85
	SVM	0.0	0.0	0.0
Wheat	**RF**	0.93	0.93	0.93
	SVM	0.9	0.94	0.92

tree acting as a transparent flowchart, it becomes easier to comprehend how the model classifies data points. The consensus-based decision-making further enhances stability and improves generalization abilities. In contrast, SVM's optimal hyperplane may lack clear interpretability.

V. Conclusion and future works

In conclusion, this work provides a significant contribution to agricultural research by demonstrating the applicability of machine learning techniques and the utility of satellite data for crop classification. The proposed methodology can be applied to verify the authenticity of farmers' claims, especially regarding state subsidies for specific crops of interest.

Our work lays the foundation for further research in the field of agricultural field classification using satellite imagery and ML techniques. Several avenues for future work can be explored to enhance and extend the findings presented in this paper.

1) Multi-class classification could provide a more comprehensive understanding of crop distribution and facilitate more accurate crop monitoring and yield estimation.
2) Incorporating additional data sources, such as weather data, soil composition, or historical crop records, could improve the accuracy and robustness of the classification models.
3) Investigating the development of dynamic classification models that can adapt to changing environmental conditions and crop phenology could enable real-time monitoring and detection of crop changes, disease outbreaks, or other significant events that affect agricultural fields.

By pursuing these future research directions, we can advance the field of agricultural field classification and contribute to the development of more accurate, efficient, and sustainable agricultural practices.

***Abstract*—Machine learning algorithms are widely used in the assessment of error-proneness in software. We conducted several experiments with error prediction on public PROMISE repository. We used Decision Tree and Random Forest algorithms. We also examined techniques aiming at the improvement of performance and accuracy of the model – such as oversampling, hyperparameter optimization or threshold adjustment. The outcome of our experiments suggests that Random Forest algorithm, with 100 – 1000 trees, can be used to obtain high values of evaluation parameters such as accuracy and balanced accuracy. However, it has to be implemented with a set of techniques countering imbalance of the datasets used to assure high values of precision and recall that correspond with correct detection of erroneous software. Additionally, it was shown that the oversampling and hyperparameter optimization could be reliably applied to the algorithm, while threshold adjustment technique was not found to be consistent.**

***Index Terms*—error prediction, error proneness, decision tree, random forest, PROMISE repository, machine learning.**

I. Introduction

HIGH quality of software is essential in software production. Software testing is a key part of the software development process, especially for quality assurance, but it requires a lot of time and resources. It is estimated that testing activities consume more than half of the cost of the whole software development process [1], [2]. Application of software error prediction is almost 30% cheaper than testing, according to recent studies [3]. Ability to predict faulty components in the early phase may highly increase cost-effectiveness. There is abundant literature on software defect prediction, some works are mentioned in section II. There are also several systematic literature reviews on this subject eq. [4], [5], [6].

Contemporary solutions put strong emphasis on the usage of machine learning algorithms in software defect prediction. However there are many papers on software error prediction we decided to conduct some experiments on the usage of machine learning algorithms – Decision Tree and Random Forest on public PROMISE repository. We wanted to examine the relationship between computational effort and accuracy of obtained results. Techniques aiming at the improvement of performance and accuracy of the model – such as oversampling, hyperparameter optimization or threshold adjustment were also analyzed and addressed.

Paper is structured as follows. Section II introduces related work. Methodology is stated in section III. The experiment and its analysis are presented in section IV. Section V concludes the paper, highlighting some issues.

II. Related Work

Lately various studies have been conducted in order to compare algorithms used to determine error-proneness. Many of them were based on wide variety of machine learning algorithms [7] and used formerly mentioned PROMISE [8] repository as its dataset.

Random Forest, Naive Bayes, J48, Immunos 1 & 2, CLONALG, AIRS (Artificial Immune Recognition System algorithm) 1 & 2 and AIRS 2 Parallel were algorithms studied by Catal et al. [9],[10]. When AIRS algorithm was taken into consideration the researchers concluded that the best results were obtained when CK metrics and LOC metric were combined.

AIRS is a system inspired by human's immunological system with B-cells and T-cells as our guardians. In the past the main application was supervised learning, however, in 2001 it was demonstrated that algorithms based on this system can be also used for classification domain [9]. Other slightly different algorithms using AIS include CLONALG [11] and Immunos [12].

As previously mentioned, Catal et al. [9] have also directed their research towards Random Forests (RF). This algorithm is based on existence of high number of so called "trees". Each tree is independent, but at the end the majority voting result of all the trees in the forest is taken as a final result. Model can be trained with various performance enhancing techniques. One of them is bootstrap sampling or bagging (bootstrap aggregating), which means randomly taking only small part of the dataset for each training process and repeating it multiple times. In case of singular trees one may also consider pruning – technique based on removal of some of the nodes that are not essential and could result in overfitting. Nonetheless, as it was stated in study by L. Breiman [13] that procedure is not needed in case of RF algorithm when bagging is applied. According to the study by Mundada et al. [14] RF is the best algorithm for NASA datasets, which are a part of the PROMISE repository.

J48 is an algorithm that implements C4.5 decision tree learning [9], [15].

Mundada et al. [14] directed their study towards Artificial Neural Network (ANN) and Resilient Back Propagation (RBP) using JM1 dataset. As a result of this experiment, researchers concluded that the better accuracy of ANN algorithm was reached, when compared with already existing analytical models.

Bishnu et al. [16] studied performance of QUAD Tree-Based K-Means Clustering Algorithm using AR3, AR4 and AR5 datasets. It was concluded that error rates of this algorithm are comparable to the ones obtained with other algorithms. In order to obtain the best values, data sets partitioning has to ensure that the sum of distances within the clusters is properly reduced [17].

Okutan and Taner [18] used 9 datasets from PROMISE dataset to research Bayesian Networks. The results of the study stated that the LOC, RFC and LOCQ metrics are the best choice due to their effectiveness when this algorithm is considered. An important advantage of this network is the fact that it can be used even when the metrics are incomplete for some sets.

Kumudha et al. [19] have introduced a significant development in the field. Their research focused on conventional Radial Basis Function Neural Network (RBFNN) and the novel Adaptive Dimensional Biogeography Based Optimization Model (ADBBO). Having based the research in CM1, JM1, KC1, KC2, and PC1 datasets, results obtained during this study showed that newly proposed method is more effective when compared with already existing algorithms.

Gupta and Gupta. [20] have used derived metrics from PROMISE repository datasets to determine fault classification. In this study, the emphasis was put on the data distribution and skewness rather than the algorithms itself.

Erturk and Akcapinar [21] have used projects from PROMISE repository to conduct research on Fuzzy Inference Systems (FIS) [22] and Adaptive Neuro Fuzzy Inference System (ANFIS). Those new methods deploy iterative software error-proneness prediction to automatically detect fault prone sections.

Alighardashi et al. [23] have used ten PROMISE and NASA datasets to test feature selection method. Five filter methods were used during this study. Weighted filter (WF) method was determined to be able to detect best features that would allow the fault prediction accuracy to be the increased in the fastest way possible.

After preparation of the above related work recent publications in this domain appeared e.g. [24], [25], [26], [27]. These works are not included in the above text.

III. Methodology

For the purpose of the experiment Decision Tree and Random Forest algorithms [9] were selected. Random Forest, being composed of Decision Trees, is a flexible algorithm that can be applied both in classification and regression problems. As the purpose of the experiment is to assess error-proneness of the samples within the datasets, one can consider the problem primarily as classification problem. One can also assume that there are two classes of results - code either is correct or incorrect. However, as it is possible to apply regression version of Random Forest algorithm in this particular scenario and to some extend treat its values as a probability of existence of an error, it was used and compared against its classification counterpart.

Python [28] was used for implementation and functions from NumPy [29], Pandas [30], scikit-learn [31] and imbalanced-learn [32] libraries were a basis for the implementation of the algorithm and the evaluation of performance such as accuracy, recall, precision, etc.

Hyperparameter optimization was not initially performed as some hyperparameters, such as forest size, were the focus of the study and in order to better understand what are the disadvantages of the basic model. Optimization of multiple hyperparameters would result in largely extended training times, especially if larger forests were to be considered. In further parts optimization techniques were used in order to increase the performance and assess the full potential of Random Forest in error-prediction field.

Similarly, SMOTE [33] oversampling was another technique that was not used initially, but was introduced later in order to improve the performance of the model. By default bootstrapping was enabled throughout the whole experiment and pruning was not performed as recommended by Breiman [13]. The order of processes is presented in Fig1.

Threshold adjustment

Fig 1. Phases of experiment

IV. Experiments

Public NASA datasets were used, including those available within the PROMISE repository. The scope of the tests includes CM1, KC1, KC2, PC1, PC2 and PC3 sets.

Experiments were conducted on two devices: personal laptop and virtual machine provided by the Warsaw University of Technology.

A. Experiment results

Experiment was divided into a series of incremental steps. Each step introduced new technique or method, or combined those previously assessed. The final outcome was the process presented in Fig 1.

Initially the datasets were analyzed and some results of analysis are presented in Table I. It can be seen that datasets are highly imbalanced.

Table I.
Dataset properties

Dataset	Dataset size	Error-free software in dataset [%]	Number of metrics
CM1	498	90.2	22
KC2	522	79.5	22
PC1	1109	93.1	22
PC3	1563	89.8	38
KC1	2109	84.6	22
PC2	5589	99.6	37

Before introduction of any enhancement mechanism, it was assumed that the optimal number of trees for the experiment should be in the range from 100 to 1000. This observation was confirmed throughout the experiment. Above 1000 trees any substantial improvement to the evaluation metrics was not observed as shown in Table II. It is worth noting that the training time grows almost linearly with the forest size, therefore lower forest sizes are generally preferred when training time is limited. Even though, all experiments were performed for forest sizes of 1 (decision tree), 10, 100, 1000, 10000, 25000 and 50000, results provided in this paper were obtained for forests with 1000 trees unless stated otherwise.

Table II.
Basic classification accuracy

Number of trees	1	10	100	1000	10000
Dataset	Accuracy				
CM1	0.81	0.87	0.86	0.86	0.86
KC1	0.81	0.84	0.85	0.85	0.85
KC2	0.74	0.82	0.82	0.80	0.82
PC1	0.90	0.91	0.92	0.92	0.92
PC2	0.99	0.99	0.99	0.99	0.99
PC3	0.85	0.90	0.90	0.90	0.90

Even though, accuracy score is rather high, it is usually very close to the percentage of error-free samples in the dataset. Analyzing metrics such as recall, precision, and balanced accuracy it was clearly visible that model tends to classify vast majority of samples as error-free, thus making from few to even no useful detections (true positive values) as in case of dataset CM1, as shown in Table III.

Table III.
Basic classification for CM1 dataset

Accuracy	0.86
Recall	0.00
Precision	0.00
Balanced accuracy	0.49
F1 score	0.00

First technique aiming to improve error-prone software detection that was assessed was threshold adjustment. As this problem deals with two classes – erroneous software and error-free software it is primarily a classification problem. However, one may take a regression approach with the 0.5 threshold as a default one. Adjustment of that selection threshold, either its lowering or increasing, could potentially lead to better classification. Exemplary outcome of the experiment for CM1 dataset is presented in Fig 2.

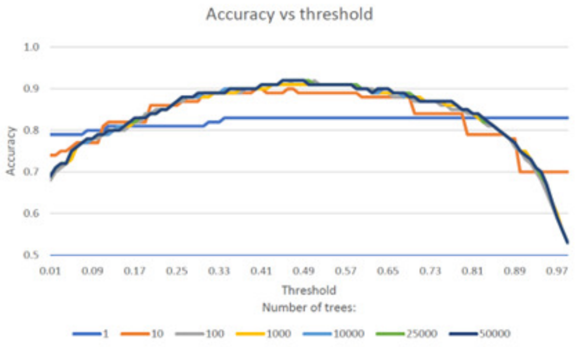

Fig 2. Threshold adjustment for CM1 dataset

Slight change of the threshold around the 0.5 mark in some cases, provided some minor improvements. Nonetheless, no direct pattern could be established observing various datasets and forest sizes. Moreover, it did not help in any way to tackle the problem of datasets imbalance, still being strongly biased towards error-free classes. Given method was also combined with subsequently described methods, however, at each step it was too unpredictable and, as a result, it was discarded.

Further studies were done on SMOTE oversampling technique. As presented in Table IV, it aimed to reduce the learning bias resulting from dataset imbalance by equalizing proportions via creating artificial samples.

Table IV.
Dataset sizes before and after oversampling

	Before SMOTE		After SMOTE	
	Faulty	Not faulty	Faulty	Not faulty
CM1	45	428	428	428
KC1	307	1696	1696	1696
KC2	96	399	399	399
PC1	73	980	980	980
PC2	21	5288	5288	5288
PC3	151	1333	1333	1333

As presented in Table V and Table VI, significant improvements could be noticed. Not only, was the accuracy improved, but more importantly precision and recall values also, which indicate that the true error-free software was now properly detected and classified.

TABLE V.
DATASET SIZES BEFORE AND AFTER OVERSAMPLING

	Accuracy	
	Before	After
CM1	0.86	0.94
KC1	0.85	0.91
KC2	0.80	0.85
PC1	0.92	0.96
PC2	0.99	1.00
PC3	0.90	0.93

TABLE VI.
OVERSAMPLED CLASSIFICATION FOR CM1 DATASET

Accuracy	0.94
Recall	0.98
Precision	0.88
Balanced accuracy	0.91
F1 score	0.93

In the final part of the experiment hyperparameter optimization for the previously analyzed oversampling technique was added. Similarly to the forest size selection, this step becomes more and more computationally intensive with the increase in number of the combinations that have to be considered. Performing grid search and cross-validation proved to be successful in improving results, as can be seen in Table VII. Comparison of balanced accuracies obtained throughout the experiment was presented in Fig 3.

TABLE VII.
RESULTS AFTER HYPERPARAMETER OPTIMIZATION

	Dataset					
	CM1	KC1	KC2	PC1	PC2	PC3
Accuracy	0.95	0.91	0.87	0.98	1.00	0.94
Recall	0.98	0.91	0.89	0.98	1.00	0.95
Precision	0.91	0.91	0.86	0.97	0.99	0.93
F1 score	0.95	0.91	0.87	0.98	1.00	0.94
Balanced accuracy	0.95	0.91	0.86	0.98	1.00	0.94

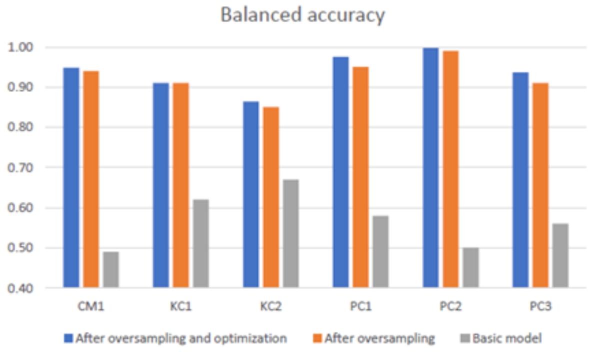

Fig 3. Balanced accuracy comparison

B. *Comparison with other studies*

Comparing obtained results with other studies within the domain, one can reference AUC obtained in a study by Catal et al. [10]. As presented in Fig. 4, results for all of the datasets that were covered by both experiments have significantly improved.

Nonetheless, when comparing the results with studies based on neural networks, such as the ones obtained via implementation of ADBBO by P. Kumudha et al. [19], presented in Fig. 5, it can be observed that the Random Forest provided better results for PC1 and CM1 datasets, while it was outperformed by Neural Network in case of KC1 and KC2 datasets.

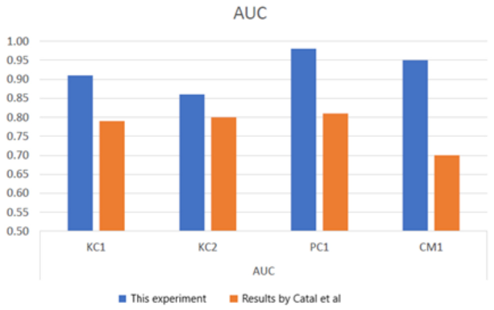

Fig 4. AUC comparison with prior study

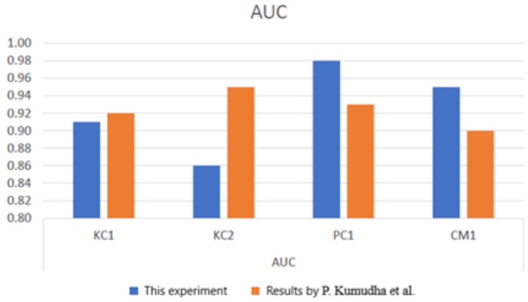

Fig 5. AUC comparison with prior study

A recent study by T.F. Husin et al. [26] was analyzing Least Square Support Vector Machine (LSSVM) combined with the use of SMOTE technique. Even though, it was concluded that SMOTE significantly improved obtained results, as presented in Fig. 6, those results were not close to the results obtain in this or any of two previously mentioned studies.

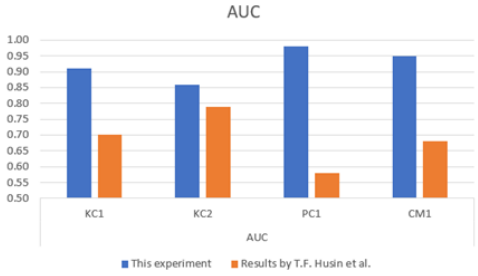

Fig 6. AUC comparison with new study

V. CONCLUSIONS

The aim of our study was to assess the viability of application of Decision Tree and Random Forest algorithms within the scope of error-proneness detection field. The series of experiments was conducted for six different datasets and total algorithm training time was approximately 150 hours with the majority of this time spent on the final version. Therefore, due to vastness of collected data detailed results presented in section IV focused only one of them – CM1. Study was performed on the data acquired from PROMISE repositories started with the analysis of the most basic models, which turned out to be insufficient due to the bias towards error-free classification resulting from dataset imbalance. Subsequently, a set of techniques was deployed in order to improve its performance. They included hyperparameter optimization, basic feature selection, threshold adjustment and SMOTE oversampling technique.

As a result it was possible to observe that implementation of mechanisms aiming at improvement of performance of algorithms resulted in models being able to quite accurately classify samples present within PROMISE repository. High values of precision and recall, in most cases above 90%, may assure one that software errors can be well detected using Random Forest algorithm. It was also shown that usually random forests of sizes between 100 and 1000 are the most appropriate as above that values accuracy does not seem to improve, while computation time does. Nonetheless, it is also worth mentioning that single decision trees also provided useful results, however, they cannot quite compete with the anti-overfitting properties of the forest. Further, if predictions trained on PROMISE datasets are to be reasonable, one shall counter negative effects of imbalanced dataset – oversampling was proved to be a viable solution that significantly increased values of evaluation parameters such as balanced accuracy. Additionally, if training time is not limited, hyperparameter optimization may further improve obtained results. Finally, there has not been found any reason to use regression instead of classification it this particular classification problem. Throughout the study, it was found that threshold adjustment technique could result in slight improvements, however, it could not be reliably used.

In order to further improve results obtained by Random Forest, one may consider application of more advanced feature selection methods. Similarly, it would be reasonable to use MOOD and QMOOD object metrics. Further, one could consider creation of their own datasets, based on publicly available repositories. Performing a training on data gathered from projects in the same language, technology or domain as the target test set could also make prediction algorithm more sensitive to crucial aspects of assessing error-proneness for a given case.

***Abstract*—The proliferation of digital artifacts with various computing capabilities, along with the emergence of edge computing, offers new possibilities for the development of Machine Learning solutions. These new possibilities have led to the popularity of Federated Learning (FL). While there are many existing works focusing on various aspects of the FL process, the issue of the effective problem diagnosis in FL systems remains largely unexplored. In this work, we have set out to artificially simulate the training process of four selected approaches to FL topology and compare their resulting performance. After noticing concerning disturbances throughout their training process, we have successfully identified their source as the problem of exploding gradients. We have then made modifications to the model structure and analyzed the new results. Finally, we have proposed continuous monitoring of the FL training process through the local computation of a selected metric.**

I. Introduction

FEDERATED Learning (FL, [1], [2]) is a relatively novel approach to Distributed Machine Learning (DML). It allows a system to take full advantage of the data locality and computing power of distributed devices. In a standard scenario, the goal is to train a global model using local models trained by the clients on their local data. Clients periodically send parameter updates to an aggregator node. The new version of the global model is established, communicated back to clients and the process repeats until stopping criteria are met.

Currently, a common way to prepare for an FL training process begins with the centralized construction and training of an initial ML model. This preliminary phase allows the developer to utilize a plethora of already established techniques in order to develop the best ML solution possible. The data preprocessing steps, architecture and hyperparameters from that solution are then used as a basis for the local models trained by the FL clients. However, this approach also relies on the existence of a global dataset with a distribution and format that sufficiently resembles that of the client data. This global dataset may sometimes be impossible to create due to the client data being very localized, client-specific and inaccessible because of privacy concerns. Of course, such a model can also be developed as an FL model from scratch by conducting multiple FL training runs and selecting the best performing training parameters and architectures. Unfortunately, the diagnosis of problems such as vanishing or exploding gradients based on the learning curve would necessarily be hindered by the existence of other destructive factors, like client dropout and differing local data distributions. The development of the final model would therefore necessitate a large number of completed FL training processes and as such be both very resource and time consuming.

Additionally, many current research trends in FL result in solutions that may undergo a very different training process from the centralized baseline. For example, a common goal of trying to achieve scalability while preserving the stability of the training is often mitigated through the appropriate choice of topology. Here, topology refers to the network topology of the FL system, which indicates how clients communicate with the server and with each other [3]. The additional communication on the global and local level may cause the training curve to undergo periodic spikes and drops in accuracy, which can then be hard to distinguish from other ML problems.

We have encountered the problems mentioned above throughout our work on the Assist-IoT project [1]. We were conducting tests in order to select the FL topology best suited to use in the Assist-IoT project in the pilots focusing on: (1) construction workers' health and safety assurance, (2) vehicle exterior condition inspection [4]. The purpose of the FL solution was effective fall detection of construction workers in the case of (1) and automatic vehicle damage detection in the case of (2). In an effort to determine the best topology for the aforementioned use cases, we have analyzed different approaches to the problem [5] and selected 4 most "promising" and representative to further test their behaviour. Our experiments have revealed concerning instabilities in the training processes of some of them. Through additional trials and further examination of the existing result, we have identified the source of the problem as exploding gradients. The problem of exploding gradients here describes a situation in which the gradient backpropagated through a neural network grows exponentially during training, causing the neural network performance to stall or even deteriorate [6].

The work of Karolina Bogacka and Anastasiya Danilenka was funded in part by the Centre for Priority Research Area Artificial Intelligence and Robotics of Warsaw University of Technology within the Excellence Initiative: Research University (IDUB) programme.

[1] https://assist-iot.eu

We have then modified the hyperparameters to avoid this problem and achieve better results. We would like to share our process as a case study, finishing it with a proposal of an additional procedure that could enable easier identification of the exploding gradient problem in FL systems.

II. Related works

A. The state of FL diagnostic tools

There are few existing works concerning the design and development of FL diagnostic tools. Some of them focus on system monitoring through the identification of badly-performing clients while maintaining security and privacy [7] [8]. This approach to diagnostics is appropriate for FL systems, however, it is often unable to sufficiently recognize any problems stemming from the model architecture or training configuration. The most comprehensive attempt at providing systematic problem diagnosis for FL, FedDebug, offers the possibility of setting breakpoints and replaying previous rounds through a continuous collection of metrics, such as response time, training and validation loss as well as other performance indicators. Those metrics are then used to construct a simulation of the training, which enables easier identification of a faulty client. Despite the narrow focus of this solution, the broad functionalities of the system should be easily extended to other problems [9].

One of the rare works to not focus on finding underperforming clients but on mitigating issues concerning FL models is Fed-DNN-Debugger [10]. It consists of two modules: one is responsible for nonintrusive metadata capture (NIMC), which produces data that is then used for automated neural network model debugging (ANNMD). Local models are then repaired through retraining on specially selected samples. However, its main focus lies in training bugs, which are caused by misconducted training processes, such as biased data, noisy data or insufficient training. It does not enable easy identification of structure bugs, which stem from inappropriate model architecture or hyperparameters.

B. The exploding gradient problem

The exploding gradient problem describes a phenomenon in which the gradient backpropagated through a neural network grows exponentially from layer to layer [6]. Unfortunately, the maximal depth of many popular ML architectures is limited by the existence of this phenomenon. There are existing techniques such as weight scaling or batch normalization which can be used to mitigate these problems. However, they are not always effective [6]. It is possible to use architectures that avoid the exploding gradient problem [11] such as fully connected ReLU networks. Nevertheless, due to the limited functionality of those architectures, it is not a commonly employed practice.

C. Advances in research on Topology of Federated Learning

Although a typical FL system follows a simple centralized topology, with a single server node, often located in the cloud, communicating directly with a federation of clients, this is not necessarily the most optimal, or efficient, solution for many use cases [3]. Interest in network topology in the context of FL stems from the evidence that its impact can be extremely effective in mitigating data heterogeneity. Some types of topologies can also either fully eliminate the need for a central cloud server or greatly reduce its importance [12]. This is significant since the main roadblock for the full production deployment of many FL systems involves communication inefficiency. Other works try to balance these two approaches, by combining nodes in various ways, for example by organizing the clients into groups [13].

A broad classification of current trends in FL topology-related research can be found in [3], which classifies FL topology types into centralized (referred to also as star) [2], tree [14], hybrid [15], gossip [16], grid [17], mesh [3], clique [12] and ring [18]. Classic Federated Averaging [2], can be counted as an example of the centralized topology, involving only a single server independently communicating with each FL-participating client.

The TornadoAggregate algorithm, described in [15], combines star and ring topologies to form STAR-rings and RING-stars. One involves a central server performing periodic federated averaging combined with ring-based groups, while the other consists of a ring with star-based groups. Surprisingly, the first approach is significantly more successful, outperforming the RING-stars with regard to performance, while maintaining the same scalability as described in the aforementioned paper. This process does not require the setup of additional devices and so seems suitable for later reuse.

Many of the above-mentioned topologies use client grouping to manage the problems with heterogenous data. Moreover, this kind of mitigation method can also be used in combination with a centralized topology, in the form of centralized training with dynamic clustering implemented as IFCA in [19]. IFCA involves the simultaneous training of a given number of clusters, allowing for the dynamic creation of client clusters and models personalized for that cluster. However, some of the reported results were subpar due to the necessity of beginning the training with a warm start and accurate knowledge on the number of clusters present in the dataset [20]. In order to limit the occurrence of these issues, an improved version was developed. The new algorithm, SR-FCA, periodically reclusters the clients in a manner that leads it to be both more robust and less resource-intensive for edge clients.

In summary, there are many approaches to FL topology which result in different benefits and drawbacks. Some solutions focus on providing additional robustness to the system at the expense of decreased privacy and a more cumbersome setup. Others accept a communicational and computational overhead in exchange for the ability to use FL without selecting a single centralized server.

D. Scalability in FL

In our experiments, we have concentrated on the systems that are potentially easy to set up, scalable and able to withstand perturbations present in edge environments. Here, a scalable FL system should be able to maintain high and effective performance in an massively distributed environment, that is, one with a very large number of clients [21]. Many topologies achieve scalability through the creation of local groups, which minimize the necessary frequency of the global aggregation rounds and, by extension, the communicational strain on the server [15].

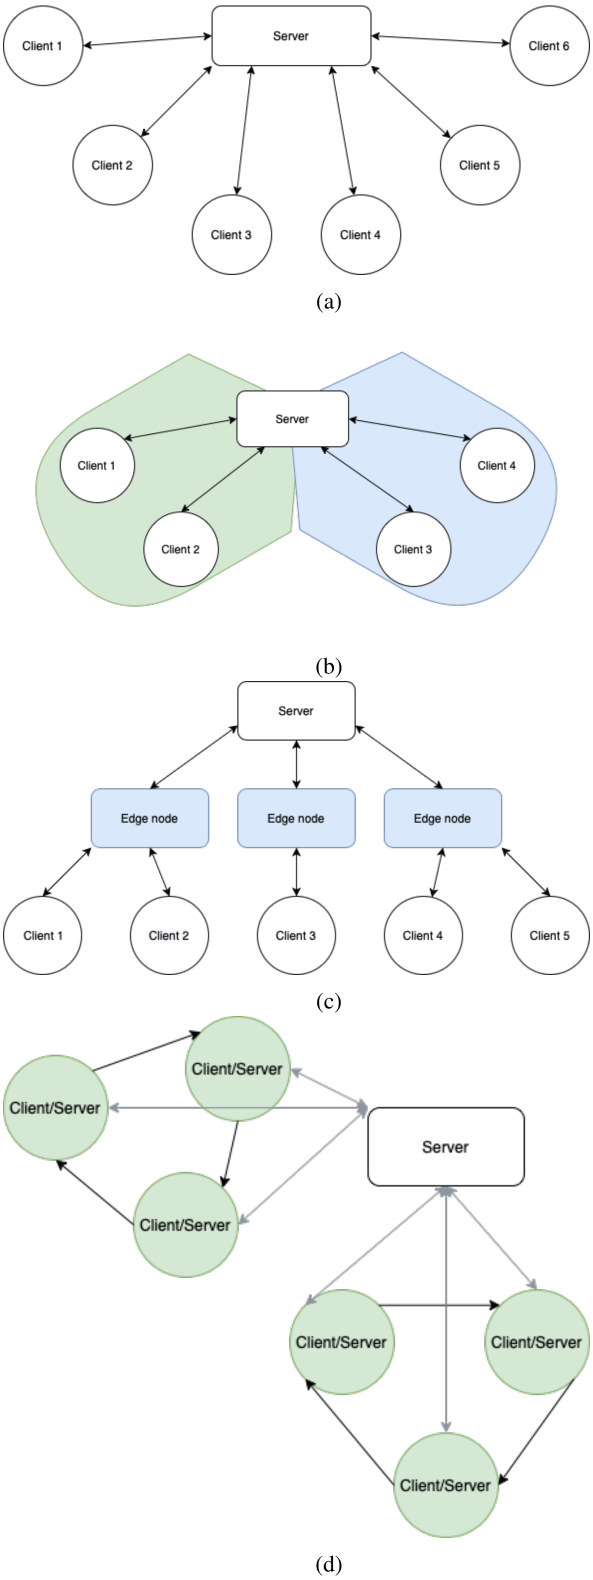
III. Experimental Setup

In order to determine the best topology (both in terms of achieving the best possible performance and maintaining robustness to issues such as heterogenous data or client dropout) for the Assist-IoT pilots, our tests have been conducted on four potential solutions representative of the general trends. Those solutions are described visually in Figure 1. Their short summations can be found below.

1) Centralized: The centralized topology closely adheres to the original process of FL training from [2]. The server sends the model parameters to the clients, where they are trained for multiple iterations and subsequently aggregated on the server. We have decided to include this topology as a baseline for comparison with other, more sophisticated methods.

2) Centralized with dynamic clusters: The structure involves a server communicating with multiple clients. The main difference between this approach and a classic, centralized topology lies in the existence of multiple models (each of which is meant to be suitable just for a subset of the clients). After a given amount of training rounds, the server reclusters the clients based on the similarity of their weights (here estimated using Euclidean distance). The models are then aggregated separately for a given cluster [20]. Importantly, this implementation of SR-FCA (which stands for Successive Refine Federated Clustering Algorithm) aggregates the models using TrimmedMeanGD [22] instead of FedAvg, which provides additional robustness to the training process by removing outlier weights before aggregation. This method does not necessitate any previous knowledge about the number of clusters in the dataset nor additional computation on the client. The dynamic nature of its clustering algorithm causes this method to easily adapt to changes in client number and distribution. Unfortunately, SR-FCA does not necessarily increase the scalability of the solution in its current form.

3) Hierarchical: A hierarchical topology, known also as a tree topology [23], introduces a third type of node, apart from the client and server node to a centralized system: an intermediate (edge) node. In this case, the FL process begins with the server sending the model parameters to the edge nodes, which in turn send them to their clients. The clients train the model for a single iteration and send the results to the edge node, which aggregates those intermediate results. After this process repeats a set number of times, all the aggregated parameters from all of the edge nodes are once again aggregated on the main server [24]. As for the grouping of the clients to a given edge node, this simulation follows the heuristic introduced in [14] by spreading out groups of clients with similar data distribution between various clients.



(a)

(b)

(c)

(d)

Fig. 1: A visualization of the FL system topologies investigated in this work

We have decided to test it as a more sophisticated and scalable FL topology, that nevertheless does not need computationally-intensive client clustering and does not introduce additional aggregation algorithms to Federated Averaging.

4) Hybrid: Tornadoes, or STAR-rings, is an especially promising approach presented in [15]. It combines a centralized solution with the existence of local, ring-based client groups. After the global server supplies the clients with starting parameters, the clients train the model and pass it on to the next client in their ring. In the next iteration, they accept an appropriate model from the previous client in the chain, train it for a given iteration on their own data and pass it on to the next client. After a set amount of inter-node iterations, all the model parameters from all of the clients are aggregated by the centralized server. Interestingly, since ring-based groups can be very susceptible to catastrophic forgetting in groups with high variance [15], a specialized clustering algorithm has been proposed by the authors. This algorithm requires access to client data distributions to compute the most optimal arrangement of ring groups, which may not be suitable for more private use cases. Additionally, it tends to be quite resource-intensive and frequently returns rings with significantly unequal numbers of nodes, which in some cases may complicate system maintenance. Although this FL topology requires using both an exhaustive client grouping algorithm and a more elaborate communication schema, the reported scalability of this method in environments with a large number of nodes is promising enough that we have decided to examine it further in our research.

A. Experiment Design

The experiments were conducted using the German Traffic Sign Recognition Benchmark Dataset [25], developed for a multi-class, single-image classification challenge held at the International Joint Conference on Neural Networks in 2011. The dataset incorporates 43 distinct classes divided into batches of size 16. The data was thoroughly shuffled and divided equally between the clients. Later, 80% of that dataset was used as the training data and 20% as the testing data. Independently of the local datasets, a global test set was placed on the server containing 12630 out of all the examples, with the remaining 39209 being divided between all the clients. In order to minimize the computations necessary for the simulation, the dataset has been rescaled to the size of 32 by 32 pixels.

The model used for the experiments consisted of 2 convolutional layers and a single dense layer. It was initially trained using the Adam optimizer with categorical cross-entropy loss without any gradient clipping. After the analysis of first experiments, gradient clipping was introduced for weights exceeding the value of 1.0. The clients were trained for 25 global rounds with 20 local iterations (the exact manner of conducting local iterations differed from topology to topology).

1) Client Grouping and Communication Schema: For the centralized training, no grouping of the clients was involved. Instead, the clients locally trained the model for one epoch on their own data and then sent those models to the server for aggregation, which constituted a full round. 25 of such training rounds have been conducted, with metrics such as aggregated loss, aggregated accuracy, global test set loss, and global test set accuracy being gathered after each of those rounds.

In the case of the centralized topology with dynamic clusters, the threshold λ of 5, size parameter t of 3 and β of 0.1 have been used. The Euclidean distance served as a metric to compute the differences between local weights. The clients have trained for 20 local iterations before each global round, and every 4 global rounds the clients were reclustered.

For the training of hierarchical FL a total of 5 intermediate nodes have been simulated, each managing 20 clients assigned to it. To sum up, the training was conducted on a 100 FL clients. Hierarchical FL involves a more intense communication protocol in the relation between the clients and the intermediate nodes: FedSGD [14]. For this reason, while the global communication schema between the edge nodes and the server has been maintained, the communication between the clients and edge nodes was much more frequent. Although this schema does increase the intensity of communication between nodes, it does not additionally overwhelm the server and, instead, maintains constant contact with edge nodes, which are presupposed to be much closer geographically located to the clients than the server.

Finally, for the hybrid topology, the number of 33 clusters was determined to be the most appropriate. This decision was influenced mainly by the suggestion placed in the original paper, highlighting the importance of small rings [15]. The original paper was also the source of the algorithm used for grouping the clients into clusters. The lengths of the resulting clusters vary from 1 to 8 clients per cluster. Additionally, the decision to conduct the experiments using a larger number of clusters did not influence the computational intensity of the process for the clients. It also did not add any overhead to the necessary communications between the clients and the server. Similarly to the hierarchical FL, the schema used here maintained a set number of global rounds with a set number of local rounds of training in between, here involving the clients accepting a new model, training it for one batch, and then passing it down the chain.

IV. Results and the diagnostic process

First tests conducted on IID data can be seen in Figure 2. Each one was conducted three times and averaged in order to obtain a smoother, more informative curve. Although two topologies, centralized (yellow) and centralized with dynamic clusters (blue), seem to be converging smoothly, there are suspicious perturbations that can be spotted both in the case of the hybrid topology (green) and hierarchical topology (purple). A potential explanation of the similar results of the centralized topology and centralized with dynamic clustering may stem from the fact, that in highly IID environments centralized topologies with dynamic clustering form just a single cluster and therefore are reduced to a simple centralized topology. Further examination reveals that each drop in the aggregated accuracy for the hierarchical topology happened in a different run.

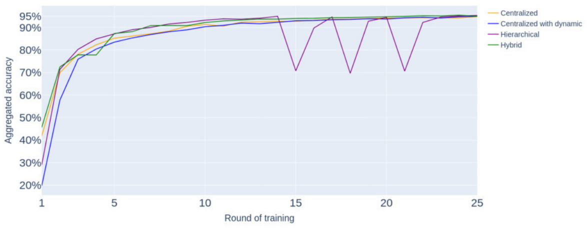


Fig. 2: The accuracy training curves for initial experiments

The issue has been further investigated in Figure 3a. The figure shows the mean aggregated loss measured for the clients belonging to a given cluster (differentiated with a color) after each local iteration and shown on a logarithmic scale. A cluster in our implementation of hierarchical FL includes all the clients performing their local aggregation on the same edge node, which means that all of the clients involved in the simulation are divided into 5 clusters with 20 clients each. The rise in aggregated test loss starts in iteration 201 with a global aggregation round (marked as a pink cross on the figure), and begins to drop after 221, so after another global aggregation round. It can be then observed that the sudden rise in aggregated was correlated with the adherence to a given cluster. Perhaps the frequent local aggregation rounds in hierarchical FL minimize the effectiveness of the Adam optimizer and cause gradient explosions to spread more effectively.

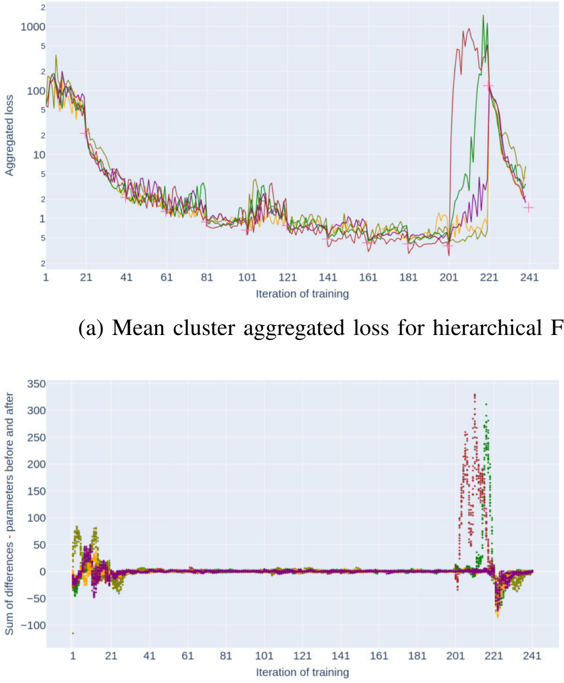
Figure 3b shows a makeshift metric, measuring the sum of the differences between obtained and trained weights for each client after each local iteration. The colors differentiating the adherence to a given node are maintained. The sudden increases in the weight differences correlate with the rise in aggregated loss both in the cluster affiliation and the iteration. These results confirm the existence of a gradient explosion problem.

After diagnosing the issue, an additional precaution of gradient clipping was applied to the model. New trials were then conducted to see if the learning curve improved. Figure 4a shows improvement in the form of a significantly smoother training process. Analogously, the difference in weights as shown on Figure 4b has stabilized and decreased significantly.

Repeating the first trial yields on Figure 5 slightly better, significantly smoother performance for all of the already mentioned FL topologies. An especially significant difference is visible for the hierarchical FL performance (purple), which suggests it to be an especially vulnerable topology to gradient explosions.

V. Discussions

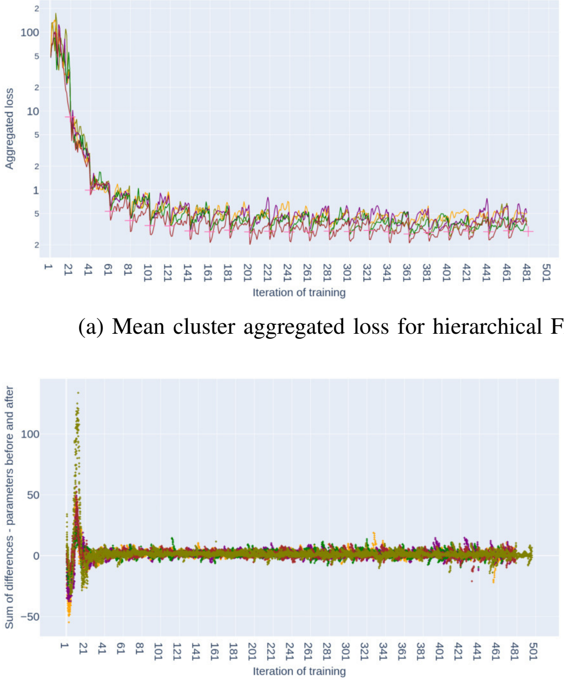
Based on the usefulness of the additional metrics collected throughout the training in the diagnostic process, we propose continuous monitoring of the gradient scale of the local



(a) Mean cluster aggregated loss for hierarchical FL

(b) Client weight differences for hierarchical FL

Fig. 3: Initial experiments



(a) Mean cluster aggregated loss for hierarchical FL

(b) Client weight differences for hierarchical FL

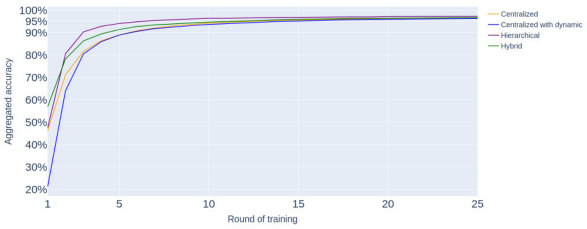

Fig. 5: The accuracy training curves for improved experiments

models through the regular computation of the gradient scale coefficient on the clients. The gradient scale coefficient is defined as follows.

$$GSC(k,l,f,\theta,x,y) = \frac{||J_k^l||_{qm}||f_k||_2}{||f_l||_2} \tag{1}$$

It measures the relative sensitivity of layer l with regards to random changes in layer k, measuring the size of the gradient flowing background relative to the size of the activations growing forward. A detailed explanation of this metric and how to use it to can be found in [6]. Its usefulness stems from robustness to network scaling, which introduces the possibility of result standardization.

We would like to measure the GSC of each of the client models after every iteration in order to use it to detect large, sudden shifts on the global level. These sudden shifts could then indicate the possibility of gradient explosion and prompt the developer to quickly recognize the problem without wasting needless resources for unsuccessful ML training.

VI. Conclusions

Although FL system and algorithm design remain popular research areas, the question on how to effectively enable the debug and maintenance of those systems is still largely unanswered. Our case study presents how a problem commonly encountered in classical ML may present in more complex FL topologies. We have also proposed a potential monitoring method for the early detection of such problems. All in all, we would like to stress the importance of the inclusion of such tools in distributed environments, where issues like client dropout or diverging distributions may be masking more fundamental problems.

***Abstract*—Currently, anomaly detection is an increasingly important issue in terms of research work and applications in production systems. Information about system malfunction allows the implementation of precise diagnostic and corrective actions. Two main approaches based on statistical analysis and machine learning techniques are used in anomaly detection systems, which are computationally complex, especially when dealing with high traffic volumes in computer network. In this paper, the limitation of the sampling frequency for network traffic parameters is proposed as a technique to reduce the computational complexity of anomaly detection methods. The proposed approach has been verified in a real network link monitoring system for a medium-sized ISP. The results obtained are promising and can be used to build a production system that enables the development of early warning systems in the area of security incident detection dedicated to high-speed access links.**

I. Introduction

DISTRIBUTED information systems are becoming increasingly prevalent in critical areas of human life. For instance, they are used to control traffic in the city [1], [2], monitor patients' vital signs [3], or manage technological processes in smart factories [4]. This information systems are exposed to a number of new types of cyber security threats. The market offers ready-made tools for executing attacks, which affects the constant increase in the number of security incidents. During the pandemic period alone, cybercrime increased by 600% [5], and the average cost of a data security breach in the U.S. in 2022 was 4.35 million [6]. There is no single effective system of protection against these threats. Nowadays threat detection and elimination systems have a cascade structure. In other words, we have many interconnected layers in which IDS, IPS, ACL, etc. function. Each type of layer is sensitive to different types of attacks. In the case of carrier access links, such as those used for Internet Service Provider (ISP) companies, simple Access Control List (ACL) rules that filter network traffic based on source and destination addresses are generally applicable. Even in the case of such a simple mechanism, the implementation of a larger number of ACLs, or the implementation of a mechanism for logging information (what flow and by what ACL was blocked) can bring significant delays in the transmission path. Therefore, the authors posed the question during their research: is it possible to detect anomalous behavior without introducing additional delay while reducing the computational complexity of detecting process? Anomaly detection is an important data analysis task that detects anomalous or abnormal data from a given data set. Preliminary research has shown that a conducted cyberattack can affect the change of statistical characteristics of network traffic in the access link. Therefore, the analysis of descriptive link parameters, statistical techniques or artificial intelligence can be used in the area of an access link on the border of the protected network to detect the threat. Anomaly detection is widely used in myriad fields such as medical, public health, fraud detection, intrusion detection, industrial damage, image processing, sensor networks, robot behavior and astronomical data [7]. Current research is concerted around speeding up the detection process reducing the computational complexity of the entire process and identifying not only the occurrence of a given anomaly but also eliminating its causes.

At present, there is a clear trend related to identifying the best AI models for anomaly detection in ISP links in order to achieve the best possible detection performance. Applications in this area include both supervised and unsupervised methods [8], [9], [10], [11]. Of course, previously, network traffic sampling methods [12] were used for anomaly detection using traditional IDS probes. Such methods were applied, for example, in the work [9], and the obtained results look promising. Their applications allow for preliminary verification in terms of detecting anomalies in large volumes of network traffic. However, it should be noted that a large body of work in this field is based on previously prepared test datasets [13], [14], [15] or on data obtained from real links with low throughputs [16]. Preliminary results of conducted research have shown that, in addition to data sampling, the proper preparation of acquired data and flow aggregation have a positive impact on detection outcomes. Of course, data preprocessing can also be computationally complex, but it can be easily parallelized and computed distributed among system nodess [17], [18]. The analysis of available literature clearly demonstrates the pursuit of increasing the accuracy of predictive models, but we must not forget about their applicability in real computer networks. In this study, the authors decided to investigate the impact of data set impoverishment (sampling) on the sensitivity of the anomaly detection model and whether it is possible to limit the number of processed traffic samples while maintaining the detection level. The entire study was conducted in a production network of an ISP (Enf sp. z o.o). The developed detection layer at the ISP access link can serve as an additional layer of protection against cyber-attacks in cascade anomaly detection systems [19]. If the detection effectiveness of the model slightly decreases with decreasing traffic sampling frequency, it will positively contribute to reducing the amount of necessary measurement data to be transmitted and the processing time required, thus increasing the applicability of the solution in real networks.

The article has the following structure: Chapter 2 presents the network structure of the ISP access node and the architecture of the data acquisition and processing system. In Chapter 3, the data aggregation and sampling process are discussed in detail. Chapter 4 describes the model used for anomaly detection. Chapter 5 presents the obtained results, including the accuracy of detection in relation to the sampling frequency. In Chapter 6, the obtained results were summarized, and directions for further research were indicated.

II. ISP EDGE NODE TOPOLOGY

As mentioned earlier, the research was conducted in the environment of a medium-sized ISP. Real network traffic from end customers was analyzed. In order to carry out the research, it was necessary to modify the structure of the access node used in the system. The system structure is shown in Figure 1. The access router (Extreme MLX-4) connect the entire network segment to the Internet using the BGP protocol. The core of the access network was built based on two switches: Extreme 690 (CORE switch) and Extreme 670 (S1 switch). Policy shaping and NAT for the LAN segment were implemented through a software router (TC + IPTables) built on a Dell R710 server. Two additional hosts, PC1 and PC2, were introduced into the network. PC1 was connected to the LAN network using a Dasan switch, while PC2 was connected through a TP-Link switch in the demilitarized zone of the access node. Its task was to emulate an attack on PC1. All traffic transmitted to the LAN is directed through port P1. Using the port mirroring mechanism, the traffic from port P1 is copied to the Dell PowerEdge R940 server, where calculations related to anomaly detection are performed. This server had the following specifications: Intel(R) Xeon(R) Gold 624 CPU @ 2.60GHz processor; 128 GB of RAM; NVIDIA Tesla V100-PCIE-16GB GPU; HDD 4.5 TB. The 'PowerEdge R940' server hosted a virtual machine based on the Debian OS, which collected traffic (bidirectional) using tcpdump. The laboratory setup allowed for data collection in the infrastructure from the layer 1 to layer 7 of the ISO/OSI model, capturing individual packets for specific network flows using the tcpdump sniffer. Such an environment allowed for testing various data processing techniques and AI algorithms to determine the optimal sampling frequency at which the created models would effectively detect abnormal periods in the packet flow in the investigated network.

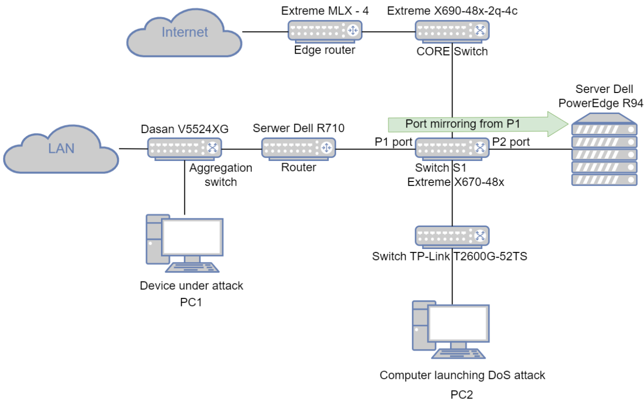

Fig. 1. ISP network edge node architecture with testbed elements

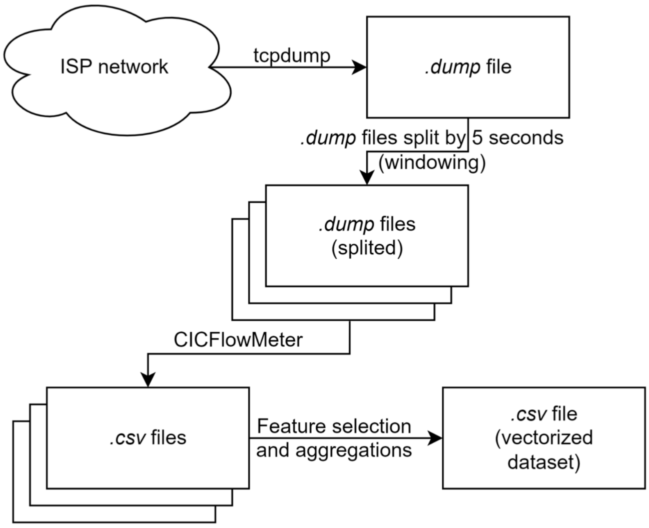
In the next step, a system was built to allow smooth frequency sampling changes. It should be noted that during the conducted research, the entire traffic from port P1 was collected. The entire sampling process was performed on the PowerEdge R940 server, enabling repeated tests for different sampling frequencies. Ultimately, in production systems, the sampling frequency can be set on a specific probe installed in the network. This not only reduces the amount of processed data but also limits the amount of data transmitted between the probe and the detection system. Additionally, initial data preprocessing can also be performed on the measurement probe (in the test system port P1 acts as the probe). Sequential packet selection with a fixed period between consecutive samples was used in the sampling process. In other words, all collected packets were labeled with consecutive natural numbers, and only those packets whose indexes were multiples of a selected natural number s, such as $s = 2$ (sampling every other packet), were chosen for further analysis. Of course, it is possible to apply a different statistical distribution of samples, which will be the subject of further research. The data received from the ISP network was saved in .dump file format. Subsequently, it was divided into equal time intervals (windows). Each window represents a short time of network operation that is evaluated by the machine learning model to classify the entire window as either anomalous or not. The order of the sampling and windowing processes is interchangeable. In the next step, CICFlowMeter software [20] was used for feature extraction. As a result of its operation, CSV files containing feature vectors describing each analyzed packet were obtained. These files were used in further analysis for feature selection and aggregation, which will be described in detail in the subsequent part of the article. The data processing process is described in Figure 2.

In order to describe the process of windowing, i.e., to divide packets into windows depending on the time of their capture, let us make the following assumptions:

$$T = \{t_0, t_1, t_2, \ldots, t_z\}$$
$$t_k = k \cdot f, \quad k \in \mathbb{N}_0, \quad k \leq z$$



ISP network
tcpdump
.dump file
.dump files split by 5 seconds (windowing)
.dump files (splited)
CICFlowMeter
.csv files
Feature selection and aggregations
.csv file (vectorized dataset)

Fig. 2. Data processing scheme

$$z = \left\lfloor \frac{t_{test}}{f} \right\rfloor,$$

where: t_{test} – total duration of the test; k – the number of the given window; P - set of all packages; T – set of all the moments of time in which the windows begin; f – the length of the window within which the packages will be aggregated.

In view of this, we can assume that the set of packages contained in a given window can be described as follows:

$$O_u = \{p \in P : t_u \leq p^{(t)} < t_{u+1}\}$$

$$u = 0, 1, \ldots, z-1$$

where: O – set of all windows; $p^{(t)}$ - packet capture time p.

The data was divided into two sets:

1) The training set represented normal network traffic and was collected for one hour under standard network operating conditions. It consisted of traffic from LAN clients and PC2 (see Figure 1). These data will be used to train a model for the purpose of identifying normal traffic. The anomaly detection model used in the further part of this work will be based on a set of unsupervised algorithms. This approach was chosen because in case of supervised learning model, staff would have to label which packets belonged to normal traffic and which were considered anomalous. This process is extremely time-consuming. Naturally, in the case of unsupervised learning, during the training period, it is essential to ensure that the network is not under attack. Therefore, the training time of the models must be closely monitored by the technical personnel. After training the model on attack-free traffic, it should be able to determine whether incoming packets grouped in windows O_u will contain flows characterized by parameter values deviating from the characteristics of normal traffic. The training dataset contained information on 1,182,566,238 packets.
2) The test set aimed to verify the performance of the model based on the training set. The packets in the windows represented network traffic in two states: normal and anomalous. The anomaly was a 5-minute long Denial-of-Service (DoS) attack. The test dataset contained information on packets captured over a period of 45 minutes, out of which 20 minutes represented normal traffic, the next 5 minutes included the anomaly, and the remainder consisted of normal traffic again. For this dataset, window labeling was performed to mark them as either anomalous or non-anomalous in order to assess the quality of the trained model. The test set contained information on 697,871,782 packets.

It should be noted that during the conducted research, a series of experiments related to DoS and DDoS attacks were carried out, and repeatability of the obtained results was achieved. The DoS attack was identified by the ISP operator as the most common type of attack that the network encounters during its normal operation. Of course, the model shows sensitivity to other types of anomalies not related to DoS attacks, but research in this area needs to be continued.

III. Pre-processing of data

The data collected during the experiments were continuously subjected to the process of cleaning and preparation for further stages of processing related to model training and anomaly detection. According to the scheme presented in Figure 2, all extracted windows O_u had to undergo a vectorization process, so that each window represented independent feature vectors. The vectorization method used in this work is an aggregation approach of selected flow features obtained through feature extraction using the CICFlowMeter software for unique source and destination IP address pairs. A flow represents the packet flow between two network devices, defined by source and destination IP addresses, as well as used ports and network protocols. For the purpose of this work, the notations $p^{(s)}$ and $p^{(r)}$ were adopted to denote the source and destination IP addresses of a given packet, respectively. Therefore, the vectorization process can be described as follows:

$$D^{(u)} = \left\{ F_2\left(F_1\left(R_i^{(u)}\right)\right) : i = 0, 1, \ldots, \left|R^{(u)}\right| \right\},$$

$$R^{(u)} = \left\{ \left\{ p \in O_u : \left\{p^{(s)}, p^{(r)}\right\} = \bar{U}_j^{(u)} \right\}, \right.$$
$$\left. j = 0, 1, \ldots, \left|\bar{U}^{(k)}\right| \right\},$$

$$U^{(k)} = \left\{ \left\{p^{(s)}, p^{(r)}\right\} : p \in O_k \right\},$$

where: $D^{(u)}$ - the aggregated feature vectors of window flows u; $R^{(u)}$ - a set of packet collections with unique destination and recipient IP addresses; $U^{(u)}$ - a set of all destination and source IP address pairs in the window k; $\bar{U}^{(u)}$ - a subset contained in $U^{(u)}$ composed only of its unique elements; F_1 - the first aggregation function, its task is to aggregate packet features for each unique flow; F_2 - the second aggregation function, its task is to aggregate flow features for each unique destination and recipient IP address pair.

In the first stage (aggregation F_1), the characteristics of each flow occurring in the processed window were aggregated. The set of packets in the window is divided into subsets, where each subset contains the set of packets responsible for the creation of a particular flow. In the second stage, the aggregated characteristics obtained in stage F_1 were further aggregated for each unique destination and recipient IP address pair $p^{(s)}, p^{(r)}$ in the processed window O_u. Additionally one dimension describing the number of flows for unique destination and recipient IP address pairs was added to the final vectors $D^{(u)}$. This type of aggregation allows for a complete vector representation of flow data for a given window, which directly translates into reducing the computational complexity of the detection process by reducing the number of features to 25. These features were selected through experimental work aimed at identifying characteristics that maximize the effectiveness of anomaly detection. The list of all used features is presented in Table I, which also indicates the actions performed in the individual aggregation stages F_1 and F_2.

TABLE I
FEATURES USED IN FEATURE EXTRACTION PROCESS

ID	Feature Description	Aggregation F_1	Aggregation F_2
0	Number of flows		Count

IV. MODEL DESCRIPTION

To test the performance of the sampling frequency's impact on anomaly detection accuracy, a densely connected neural network based on an autoencoder architecture was used [21]. The application of this model for anomaly detection is well-known in the literature, and its effectiveness for the complete dataset was experimentally confirmed in the initial stage of the conducted research. The operation of the adopted model can be divided into two main stages:

1) The forward propagation stage of the neural network, which consists of two key components:
   a) Compression of the input feature vector into fewer dimensions (encoding).
   b) Reconstruction of the compressed feature input vector (decoding).
2) The stage of calculating the reconstruction error based on the comparison of the input vector with the output of the neural network. Based on the reconstruction error, a decision is made to classify the sample into normal or containing an anomaly.

Let M denote the reconstruction error for a single vector w. It can be observed that as a result of applying aggregation F_2, we obtain a set of vectors describing the features of all unique sender and receiver IP address pairs. Therefore, the reconstruction error for a single vector w can be expressed as follows:

$$M_w^{(u)} = \frac{\sum_{i=0}^{24} (D_i^{(u,w)} - m(D^{(u,w)})_i)^2}{25}$$

To calculate the reconstruction errors for all vectors in a given window O_u, the above formula should be applied to each $w = 0, 1, \ldots, \left|D^{(u)}\right|$.

The classification of a window can be expressed as follows:

$$a_u = \begin{cases} \text{anomaly} & \text{if } \max(M^{(u)}) > y \\ \text{no anomalies} & \text{otherwise,} \end{cases}$$

where: y – classification threshold; a_u – window classification decision u; $m(D^{(u,w)})$ - vector reconstructed using autoencoder.

Table II presents the detailed architecture of the utilized autoencoder, which was developed based on conducted experiments aiming to maximize the effectiveness of anomaly detection. The dimensions of the input data to each of the layers is marked as follows: the first dimension marked "-" is the number of feature vectors, which can be arbitrary. The second dimension is the size of the input vectors. The output dimension column describes the dimension of the vectors after calculating the total excitation of each neuron and applying the activation function.

The model was trained using windows from the training dataset. It was trained for 30 epochs using the ADAM[22] optimization method and mean squared error (MSE)[23] as the

TABLE II
AUTOENCODER ARCHITECTURE

Layer	Input dimension	Number of neurons	Output dimension	Activation function.
densely connected densely connected	(-, 25) (-, 13)	13 6	(-, 13) (-, 6)	RELU RELU
densely connected densely connected	(-, 6) (-, 13)	13 25	(-, 13) (-, 25)	RELU no activation function

reconstruction loss for window characteristics. Additionally, to improve the weight fitting process, the data underwent standardization[24] using the mean and standard deviation of the features from the windows in the training dataset.

V. RESULTS

The combination of processing data using aggregation of unique sender and receiver IP address pairs, along with a model based on maximum reconstruction error of processed feature vectors in each pair's window, yielded good results in anomaly detection task. The windows where anomalies occurred showed significantly higher maximum reconstruction error compared to those characterized by normal traffic. Table III presents the results of anomaly detection quality on the test dataset. The performance of the developed model was evaluated on the test dataset for different sampling frequencies $s = 10, 25, 50$. The obtained results are presented in Figures 3 to 5. The maximum reconstruction error for the non-anomalous sender and receiver IP address pair is indicated in blue color, while the reconstruction error for the attacking device's IP address and the target IP address is shown in red color.

TABLE III
RESULTS OF MODEL EVALUATION ON THE TEST SET

Sampling frequency (s)	Window size in seconds	Detection accuracy
1	5	100.0%
2	5	100.0%
5	5	100.0%
10	5	100.0%
25	5	99.8%
50	5	87.6%

The results show that satisfactory performance is achieved even in the case of $s = 25$, which means checking every 25th network traffic sample. It is important to note that in the experiments, the window length was 5 seconds and the entire attack lasted 5 minutes. It is assumed that for longer-lasting attacks with higher network traffic intensity, such as DDoS attacks, the sampling frequency can be further reduced. The sampling threshold should be determined individually based on the characteristics of the specific network and the sensitivity of the system expected by the ISP operator.

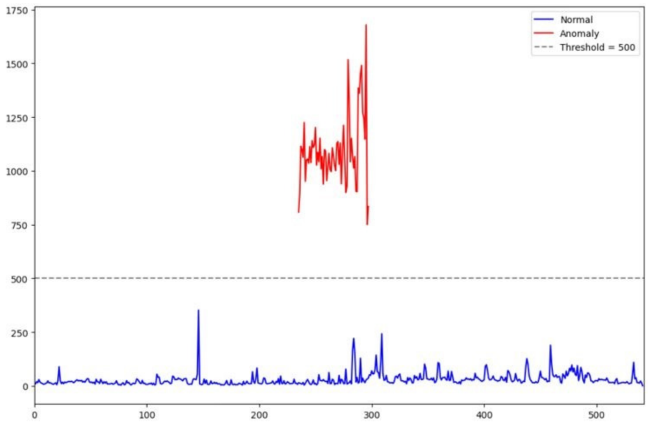

Fig. 3. Model evaluation on test set for sampling every 10 packet

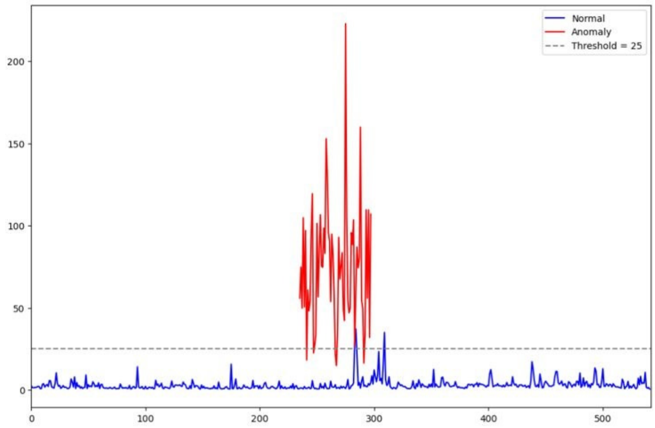

Fig. 4. Model evaluation on test set for sampling every 25 packet

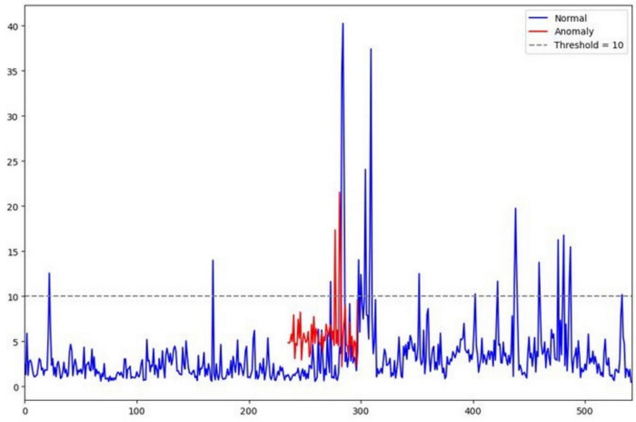

Fig. 5. Model evaluation on test set for sampling every 50 packet

VI. Summary

The paper presents the results of research related to the possibilities of applying a data sampling mechanism for anomaly detection on high bandwidth network links. The research work was carried out in a medium ISP environment in a production infrastructure. The anomaly detection approach proposed in the work taking into account windowing and data sampling allowed to reduce the data needed for anomaly detection (DoS Attack) by 25 times. This makes it possible to reduce the bandwidth of IDS and IPS probes detecting threats, which will directly translate into the cost of implementing cybersecurity systems. Further research concert around the use of non-uniform sequential sampling of traffic, e.g. by using different frequencies and statistical distributions depending on the time of day or network activity. In addition, preliminary studies have shown that the designed system is also effective in detecting other types of anomalies, e.g. data generated by faulty network interfaces. It should be noted that the proposed approach makes it possible to monitor high-throughput access links of ISPs and thus introduce another layer of protection for the entire ICT system against cyber attacks. Thanks to the use of traffic copies, the proposed architecture itself does not bring delays to the end user traffic forwarding process, and once a threat is detected, a given flow can be redirected for further inspection using policy-based routing mechanisms.

Acknowledgment

Work of Marek Bolanowski and Andrzej Paszkiewicz is financed by the Minister of Education and Science of the Republic of Poland within the "Regional Initiative of Excellence" program for years 2019–2023. Project number 027/RID/2018/19, amount granted 11 999 900 PLN. The research was carried out in cooperation with "Centrum Badawczo-Rozwojowym Inteligentnych Sieci CBRIS" Enf Sp. z o.o.

***Abstract*—Principal component analysis (PCA) based on L1-norm has drawn growing interest in recent years. It is especially popular in the machine learning and pattern recognition communities for its robustness to outliers. Although optimal algorithms for L1-norm maximization exist, they have very high computational complexity and can be used for evaluation purposes only. In practice, only approximate techniques have been considered so far. Currently, the most popular method is the bit-flipping technique, where the L1-norm maximization is viewed as a combinatorial problem over the binary field. Recently, we proposed exhaustive, but faster algorithm [1] based on two-dimensional Jacobi rotations that also offer high accuracy. In this paper, we develop a novel variant of this method that uses three-dimensional rotations and quaternion algebra. Our experiments show that the proposed approach offers higher accuracy than other approximate algorithms, but at the expense of the additional computational cost. However, for large datasets, the cost is still lower than that of the bit-flipping technique.**

I. Introduction

PRINCIPAL component analysis (PCA) is a method for multivariate data analysis with various uses, including dimensionality reduction, feature extraction and noise reduction [2]. The PCA tries to identify orthogonal directions, along which the data exhibit the greatest variability. The projections of the data on these directions are viewed as principal components. This technique is also referred as L2-PCA, because the data variability is measured using Frobenius norm (L2-norm on matrices). It can be easily implemented using, for example, singular value decomposition (SVD) of the observation data matrix [3]. However, it is also sensitive to the presence of outliers, i.e., data points that differ significantly from the other observations. In order to mitigate this drawback, several PCA techniques have been proposed that are based on L1-norm [4], [5], [6], [7]. Interestingly, the L1-norm criterion can also be used to perform independent component analysis (ICA) after data whitening [8], [9]. The L1-norm optimization problem can be formulated in several ways [5], but unlike in the case of the L2-PCA, these formulations are not equivalent. In this paper, we consider the following maximization:

$$\mathbf{Q}_{\text{L1}} = \underset{\substack{\mathbf{Q}=[\mathbf{q}_1,\ldots,\mathbf{q}_k]\in\mathbb{R}^{d\times k}\\ \mathbf{Q}^T\mathbf{Q}=\mathbf{I}_k}}{\operatorname{argmax}} \sum_{i=1}^{k} \|\mathbf{X}^T\mathbf{q}_i\|_1, \tag{1}$$

where $\mathbf{X} = [\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_n] \in \mathbb{R}^{d\times n}$ is a data matrix of rank $r_x \leq \min\{d, n\}$, consisting a sequence of observation vectors $(\mathbf{x}_i)_{i=1}^n$, and $\|.\|_1$ denotes L1-norm that return the sum of the absolute values of the individual entries. The parameter k denotes the number of the L1 principal components. Please note that the problem (1) is not scalable, i.e. it can not be translated into a sequence of the one-unit problems simply by projecting the data-matrix onto the null-space of the previous solution as in the L2-PCA algorithms. Furthermore, absolute value function is non-differentiable. For these reasons, obtaining the exact solution is a rather challenging task. In [5] it was shown that, if $\mathbf{X}\mathbf{B}_{\text{opt}} \overset{\text{SVD}}{=} \mathbf{U}\mathbf{\Sigma}\mathbf{V}^T$, and

$$\mathbf{B}_{\text{opt}} = \underset{\mathbf{B}\in\{\pm 1\}^{n\times k}}{\operatorname{argmax}} \|\mathbf{X}\mathbf{B}\|_*, \tag{2}$$

where $\|.\|_*$ denotes nuclear norm, then $\mathbf{Q}_{\text{L1}} = \mathbf{U}\mathbf{V}^T$ is the optimal solution to (1). Therefore, the L1-norm maximization can be viewed as a combinatorial problem over the binary field. Unfortunately, the exhaustive search algorithm [5] has complexity $\mathcal{O}(n^{dk-k+1})$ and is difficult to use in practice. A faster, yet suboptimal, version of this approach is based on consecutive bit-flipping operations [6]. Its time complexity is of order $\mathcal{O}(nd\min\{n,d\} + n^2(k^4 + dk^2) + ndk^3)$, which can still be prohibitive for large data sizes. The most computationally efficient algorithm based on the fixed-point (FP) iterations was developed earlier in [4]. Unfortunately, it is rather inaccurate.

Recently, we proposed two L1-PCA algorithms [1] based on the Jacobi estimation framework. This framework is commonly used for diagonalizing symmetric matrices [3], [10] through the two-dimensional (plane) rotations. It also found applications in data-driven algorithms [11], [12] for iterative transformations of multi-dimensional data. It was shown in [1] that the Jacobi-based L1-PCA approaches provide high accuracy as compared to the existing suboptimal algorithms. They are also considerably faster than currently the most accurate method based on bit-flipping. In this paper, we propose to replace the conventional Jacobi rotations with higher-dimensional quaternion-based rotations. It is expected that, in this way, the convergence properties of an algorithm can be improved. A similar approach has been proposed in work [13] where we used quaternionic factorization of the 4×4 orthogonal matrices and Newton-Raphson iterative

This work was supported by Bialystok University of Technology under the grant WZ/WI-IIT/5/2023

scheme to solve the ICA problem. Here, we present a simpler approach based on three-dimensional rotations to solve the L1-norm maximization problem. When compared to our previous method [1], a novel algorithm offers a higher probability of finding a solution that is closer to the optimal one at the expense of the additional computational cost. However, our experiments show that for large datasets, this cost is still lower than that of the bit-flipping method.

II. Preliminaries on quaternions

A quaternion $Q \in \mathbb{H}$ can be represented using the rectangular form as follows [14]:

$$Q = q_0 + \boldsymbol{i}q_1 + \boldsymbol{j}q_2 + \boldsymbol{k}q_3, \quad q_0, q_1, q_2, q_3 \in \mathbb{R}, \tag{3}$$

where $\boldsymbol{i}$, $\boldsymbol{j}$, $\boldsymbol{k}$ denote imaginary units. The real part of Q is q_0 and the pure quaternion part is $\boldsymbol{i}q_1 + \boldsymbol{j}q_2 + \boldsymbol{k}q_3$. The multiplication of quaternions is determined by the following rules:

$$\boldsymbol{i}^2 = \boldsymbol{j}^2 = \boldsymbol{k}^2 = \boldsymbol{ijk} = -1. \tag{4}$$

It is associative and distributes over vector addition, but it is not commutative.

When describing properties of the quaternions it is convenient to express them as the combination of a scalar part, $q_0 \in \mathbb{R}$, and a vector part, $\mathbf{q} = [q_1, q_2, q_3]^T \in \mathbb{R}^3$: $Q = [\![q_0, \mathbf{q}]\!]$. For example, the conjugate of Q can be written as $\bar{Q} = [\![q_0, -\mathbf{q}]\!]$, and the norm (modulus), is given by:

$$|Q| = \sqrt{q_0^2 + \|\mathbf{q}\|^2}. \tag{5}$$

For non-null quaternion, the inverse is defined as follows:

$$Q^{-1} = \bar{Q}|Q|^{-2}, \quad QQ^{-1} = Q^{-1}Q = 1. \tag{6}$$

Since

$$e^Q = \sum_{k=0}^{\infty} \frac{Q^k}{k!} = e^{q_0} \left[\!\!\left[\cos\|\mathbf{q}\|, \frac{\mathbf{q}}{\|\mathbf{q}\|} \sin\|\mathbf{q}\| \right]\!\!\right] \tag{7}$$

every quaternion Q can also be expressed in an exponential (polar) form:

$$Q = |Q|e^{\theta\mathbf{q}/\|\mathbf{q}\|} = |Q| \left[\!\!\left[\cos\theta, \frac{\mathbf{q}}{\|\mathbf{q}\|} \sin\theta \right]\!\!\right], \tag{8}$$

where $0 \leq \theta < 2\pi$ is an angle such that:

$$\cos\theta = \frac{q_0}{|Q|}, \quad \sin\theta = \frac{\|\mathbf{q}\|}{|Q|}. \tag{9}$$

This form is especially useful, because it allows us to express rotation in SO(3), The notation SO(d) denotes special orthogonal group in a d-dimensional Euclidean space, consisting all orthogonal matrices of determinant 1. Let $P = [\![0, \mathbf{p}]\!]$ be a pure quaternion that corresponds to a vector $\mathbf{p} \in \mathbb{R}^3$ and

$$U = u_0 + \boldsymbol{i}u_1 + \boldsymbol{j}u_2 + \boldsymbol{k}u_3 = \left[\!\!\left[\cos\frac{\theta}{2}, \mathbf{u}\sin\frac{\theta}{2} \right]\!\!\right], \tag{10}$$

be a unit-norm quaternion, where $\mathbf{u} = [u_1, u_2, u_3]^T \in \mathbb{R}^3$ is a unit vector indicating the direction of an axis of rotation, and an angle $0 \leq \theta < 2\pi$ is the magnitude of the rotation about the axis. Then the rotation of the vector $\mathbf{p}$ with an angle θ around a vector $\mathbf{u}$ can be expressed as follows:

$$P' = [\![0, \mathbf{p}']\!] = UPU^{-1} = UP\bar{U}. \tag{11}$$

Above operation can be expressed equivalently using matrix/vector multiplication by $\mathbf{p}' = \mathbf{R}(U)\mathbf{p}$, where:

$$\mathbf{R}(U) = \tag{12}$$

$$\begin{bmatrix} 1-2u_2^2-2u_3^2 & 2u_1u_2+2u_0u_3 & 2u_1u_3-2u_0u_2 \\ 2u_1u_2-2u_0u_3 & 1-2u_1^2-2u_3^2 & 2u_2u_3+2u_0u_1 \\ 2u_1u_3+2u_0u_2 & 2u_2u_3-2u_0u_1 & 1-2u_1^2-2u_2^2 \end{bmatrix},$$

is a rotation matrix. Theoretically, any rotation matrix can also be constructed using Euler angles, as a product of the three rotation matrices about the axes of the fixed coordinate system. Unfortunately, the Euler angles differing in many ways can give the same rotation matrix. In our case, this leads to multiple cost function calculations for the same point. Since the representation (10) corresponds almost uniquely to a given rotation matrix, such ambiguities can easily be avoided when working with quaternions.

III. Methods

A. Jacobi-based estimation framework

In the conventional Jacobi estimation framework [11], [1] the solution matrix is considered to be a product of the rotations in SO(2). These rotations are applied successively to the data matrix so that some objective function is optimized. For instance, in our previous work [1], the L1-norm metric is maximized as follows:

$$\mathbf{X}^{(t)} = \mathbf{G}(p_t, q_t, \theta_t)\mathbf{X}^{(t-1)}, \quad t = 1, 2, ..., \tag{13}$$

with $\mathbf{X}^{(0)} = \mathbf{W}\mathbf{X}$, where $\mathbf{W} \in \mathbb{R}^{d \times d}$ is an arbitrary orthonormal matrix defining initialization point. The matrix $\mathbf{G}(p, q, \theta)$ represents Jacobi/Givens rotation [3] by the θ angle in the (p, q) plane, i.e.:

$$\mathbf{G}(p,q,\theta) = \begin{bmatrix} \mathbf{I}_{p-1} & \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \cos\theta & \mathbf{0} & \sin\theta & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{I}_{q-p-1} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & -\sin\theta & \mathbf{0} & \cos\theta & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{I}_{d-q-1} \end{bmatrix}, \tag{14}$$

where p, q are two integers such that such $1 \leq p < q \leq d$. Thus, the solution matrix $\hat{\mathbf{Q}}_{\mathrm{L1}} \in \mathbb{R}^{d \times k}$ is given by:

$$\hat{\mathbf{Q}}_{\mathrm{L1}} = \mathbf{W}^T \left[\overset{\curvearrowright}{\prod_t} \mathbf{G}(p_t, q_t, \theta_t)^T \right]_{*1:k}, \tag{15}$$

where $[\,.\,]_{*1:k}$ denotes the first k columns of an argument matrix. All possible rotations represented by pairs (p_t, q_t) are arranged in so-called sweeps. These sweeps are repeated cyclically until the maximum number of iterations is reached or when, for all rotations in the current sweep, we have $|\theta_t| \approx 0$. In fact, any rotation order is allowed [12], [15], but most frequently a row-cycling ordering is used as presented in Tab. I. For a fixed arrangement of the plane rotations, each

TABLE I: Row-cycling ordering for $d = 3$.

sweep no.	1			2			...
t	1	2	3	4	5	6	...
(p_t, q_t)	(1,2)	(1,3)	(2,3)	(1,2)	(1,3)	(2,3)	...

transformation in (13) depends on a single parameter θ_t, and hence d-dimensional optimization problem can be reduced to the sequence of $d(d-1)/2$ simpler one-dimensional subproblems per sweep. Let us denote by $\hat{x}_{ij}^{(t)}(\theta)$ the (i, j)-th entry of the data matrix (13) evaluated for the angle $\theta_t = \theta$. Then, the 'local' L1-norm maximization problem at tth rotation can be defined as follows:

$$\theta_t = \underset{-\pi/2 \le \theta < \pi/2}{\operatorname{argmax}} \sum_{\substack{i \in \{p_t, q_t\} \\ i \le k}} \sum_{j=1}^{n} \left| \hat{x}_{ij}^{(t)}(\theta) \right| . \tag{16}$$

Since we are interested in finding only the first k principal components, the outer summation range in (16) covers only indices less than or equal to k. In this way, the rotations that would have to be performed entirely in the null-space can simply be omitted. Also note that, the matrix (14) modifies only the rows p_t, q_t of the data matrix $\mathbf{X}^{(t-1)}$, so that the summation coefficients can be computed directly as

$$\hat{x}_{p_t j}^{(t)}(\theta) = x_{p_t j}^{(t-1)} \cos\theta + x_{q_t j}^{(t-1)} \sin\theta, \tag{17}$$

$$\hat{x}_{q_t j}^{(t)}(\theta) = x_{q_t j}^{(t-1)} \cos\theta - x_{p_t j}^{(t-1)} \sin\theta. \tag{18}$$

In work [1], we proposed two methods for solving (16). The first one performs exhaustive angle search, and the second one uses a differentiable approximation for absolute value function and calculates the rotation angles using the simplified Newton method. In this paper, we consider only the exhaustive algorithm due to its simplicity and high accuracy. Namely, the objective function in (16) is evaluated at the set of equidistant points, i.e.: $\{-\pi/2 + i\pi/m : i = 0, 1, ..., m-1\}$. We call this set the dictionary. The parameter m is an integer value controlling an angular resolution, i.e., the smallest non-zero angle that is used to represent rotation. Theoretically, greater the value of m, the higher angular resolution and better accuracy of the optimization. However, by increasing this value, we do not prevent the method from falling into local optima.

B. Proposed method

Key idea of the proposed method is to modify the Jacobi estimation framework by replacing rotations in SO(2) with rotations in SO(3). Please note that the conventional approach can guarantee a global convergence only for $d = 2$. For higher-dimensional problems, the Jacobi rotations are performed sequentially. Therefore, we may easily get trapped in local maximum due to non-convexity of the cost function. Similarly, rotations in SO(3) do not guarantee finding a global optimum for $d > 3$, however, such replacement can increase frequency with which the method finds an optimal solution. Furthermore, with the higher-dimensional rotations, more data samples are used when computing the local objective functions, and thus these functions should be smoother, which may result in a faster convergence. Namely, we propose to replace (14) with a quaternion based matrix:

$$\mathbf{R}(p, q, r, U) = \tag{19}$$

$$\begin{bmatrix} \mathbf{I}_{p-1} & \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & u_{11} & \mathbf{0} & u_{12} & \mathbf{0} & u_{13} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{I}_{q-p-1} & \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & u_{21} & \mathbf{0} & u_{22} & \mathbf{0} & u_{23} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{I}_{r-q-1} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & u_{31} & \mathbf{0} & u_{32} & \mathbf{0} & u_{33} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{I}_{d-r-1} \end{bmatrix},$$

where $1 \le p < q < r \le d$ and the coefficient u_{ij} is (i, j)-th entry of the matrix (12) computed for the quaternion:

$$U(\lambda, \phi, \theta) = \left[\!\left[\cos\frac{\theta}{2}, \sin\frac{\theta}{2}\mathbf{u}(\lambda, \phi) \right]\!\right]. \tag{20}$$

Since the matrix (12) is orthogonal, the matrix (19) is also orthogonal. For convenience, the rotation axis is factorized using spherical coordinates, i.e.:

$$\mathbf{u}(\lambda, \phi) = [\cos\lambda \sin\phi,\ \sin\lambda \sin\phi,\ \cos\phi]^T, \tag{21}$$

where $0 \le \lambda < 2\pi$ and $0 \le \phi \le \pi$ denotes azimuthal and polar angle, respectively. More formally, our optimization problem can be stated as follows:

$$(\lambda_t, \phi_t, \theta_t) = \underset{\substack{0 \le \lambda < 2\pi \\ 0 \le \phi \le \pi \\ 0 \le \theta < 2\pi}}{\operatorname{argmax}} \sum_{\substack{i \in \{p_t, q_t, r_t\} \\ i \le k}} \sum_{j=1}^{n} \left| \hat{x}_{ij}^{(t)}(\lambda, \phi, \theta) \right|, \tag{22}$$

where $\hat{x}_{ij}^{(t)}(\lambda, \phi, \theta)$ denotes the (i, j)-th entry of transformed data matrix $\mathbf{R}(p_t, q_t, r_t, U)\mathbf{X}^{(t-1)}$. The coefficients $\hat{x}_{ij}^{(t)}(\lambda, \phi, \theta)$ for $i \in \{p_t, q_t, r_t\}$ can be stacked in the vector representing imaginary part of the following quaternion:

$$[\![0, \mathbf{x}_j^{(t)}(\lambda, \phi, \theta)]\!] = U(\lambda, \phi, \theta) X_j^{(t-1)} U(\lambda, \phi, \theta)^{-1}, \tag{23}$$

$$X_j^{(t-1)} = \left[\!\left[0, [x_{p_t j}^{(t-1)}, x_{q_t j}^{(t-1)}, x_{r_t j}^{(t-1)}]^T \right]\!\right]. \tag{24}$$

As before, the simplest solution to (22) is to use an exhaustive search method. Please note that there is not necessary to discretize the entire sphere because for a given vector (21) and an angle θ there is an opposite vector $-\mathbf{u}(\lambda, \phi)$ that generates the same rotation matrix for the angle $2\pi - \theta$. Let us denote by $\mathbb{A} = \{i\pi/m : i = 0, 1, ..., m-1\}$ and $\mathbb{B} = \{j\pi/m : j = 0, 1, ..., 2m-1\}$ the sets of equidistant points on interval $[0; \pi)$ and $[0; 2\pi)$, respectively. Then our spherical coordinate search dictionary can be defined as the following set:

$$\begin{aligned} \mathbb{D} = \{(\lambda, \phi, \theta) :\ & (\lambda, \phi, \theta) \in \mathbb{A} \times \mathbb{A} \times \mathbb{B} \wedge \\ & (\phi > 0 \vee \lambda = 0) \wedge (\phi = 0 \vee \theta > 0)\}, \end{aligned} \tag{25}$$

where × denotes Cartesian product. The condition in the second line removes from the set redundant coordinates and those for which the rotation matrix is equal to the identity matrix (for $\theta = 0$), except the point at the north pole.

TABLE II: Arrangements of rotation subspaces for various signal dimensionalities.

	$d=4$	
t	(p_t, q_t)	(p_t, q_t, r_t)
1	(1, 2)	(1, 2, 3)
2	(1, 3)	(1, 2, 4)
3	(1, 4)	(2, 3, 4)
4	(2, 3)	...
5	(2, 4)	...
6	(3, 4)	...

	$d=5$	
t	(p_t, q_t)	(p_t, q_t, r_t)
1	(1, 2)	(1, 2, 3)
2	(1, 3)	(1, 4, 5)
3	(1, 4)	(2, 4, 5)
4	(1, 5)	(3, 4, 5)
5	(2, 3)	...
6	(2, 4)	...
7	(2, 5)	...
8	(3, 4)	...
9	(3, 5)	...
10	(4, 5)	...

It can be verified that the cardinality of the set (25) is $l = 2m^3 - 3m^2 + 3m$. Obviously, for large m searching for the solution exhaustively may be unpractical, as the sequence length l grows rapidly with m. However, as we will show in the experimental section, the rotations in SO(3) can be represented with a much lower resolution than rotations in SO(2). In other words, the parameter m can be much smaller than that of the conventional Jacobi-based framework. Therefore, we can still use the exhaustive method at reasonable runtime.

Similarly to the conventional method, the consecutive rotations are organized in sweeps and repeated cyclically until convergence. However, since we deal with rotations in SO(3), a three-dimensional subspace must be defined for each rotation. Theoretically, for $d > 3$, the rotations can be performed in all possible subspaces defined as the 3-combinations of the row indices. However, we observed that to have convergence, not all combinations are needed. Namely, any combination (x, y, z) can be removed if all three pairs (x, y), (x, z) and (y, z) can also be found in other combinations. As presented in Tab. II, for $d = 4$ the combination $(1, 3, 4)$ was removed because there are the combinations $(1, 2, 3)$, $(1, 2, 4)$ and $(2, 3, 4)$ containing the pairs $(1, 3)$, $(1, 4)$ and $(3, 4)$, respectively. Such subsets of the combinations can also be obtained by joining plane rotations sharing the same dimensions. For example, two pairs (1,2) and (1,3) can be joined in the triple $(1, 2, 3)$, and the pair $(2, 3)$ can be removed as it is already present in the triple. In our simulations, we use this algorithm to generate arrangements presented in Tab. II for $d = 4, 5$. It can be verified that for $d \geq 3$ we have $n_r = \lceil d(d-2)/4 - \mathrm{mod}(d, 2) + 1 \rceil$ 3D rotations per sweep, where $\lceil . \rceil$ denotes ceiling operation. Similarly to Jacobi-based framework, there may exist other arrangements of the rotation subspaces, and some of them may be better than others. However, this issue is out of scope of this paper, and will be studied in a future work.

The pseudo-code of the proposed method is presented in Alg. 1. The sequence of triples defined in line 5 is defined according to the Tab. II. Please note that, at tth rotation, the matrix (19) modifies only the rows p, q, r. Therefore it is not necessary to compute it explicitly. In fact, only the matrices (12) are needed. Furthermore, they can be pre-computed for a given dictionary $\mathbb{D}$ once and used in subsequent iterations.

Algorithm 1 Pseudo-code of the proposed algorithm

Require:
$\mathbf{X} \in \mathbb{R}^{d\times n}, \mathbf{W} \in \mathbb{R}^{d\times d}, \mathbf{W}\mathbf{W}^T = \mathbf{I}_d, k \leq \mathrm{rank}(\mathbf{X}), \mathbb{D}$

Ensure: $\mathbf{Q} \in \mathbb{R}^{d\times k}, \mathbf{Q}^T\mathbf{Q} = \mathbf{I}_k$

```
1:  $\mathbf{X}^{(0)} \leftarrow \mathbf{W}\mathbf{X}$
2:  $t \leftarrow 1$
3:  for $sweepNum = 1 : maxSweepNum$ do
4:      $encore \leftarrow 0$
5:      for $(p, q, r) = \{(1, 2, 3), ...\}$ do
6:          $(\lambda_t, \phi_t, \theta_t) = \underset{(\lambda,\phi,\theta)\in\mathbb{D}}{\mathrm{argmax}} \sum_{\substack{i\in\{p,q,r\} \\ i\leq k}} \sum_{j=1}^{n} \left|\hat{x}_{ij}^{(t)}(\lambda, \phi, \theta)\right|$
7:          $\mathbf{R}_{\text{opt}} \leftarrow \mathbf{R}(p, q, r, U(\lambda_t, \phi_t, \theta_t))$
8:          $\mathbf{W} \leftarrow \mathbf{R}_{\text{opt}}\mathbf{W}$
9:          $\mathbf{X}^{(t)} \leftarrow \mathbf{R}_{\text{opt}}\mathbf{X}^{(t-1)}$
10:         $t \leftarrow t + 1$
11:         if $\mathbf{R}_{\text{opt}} \neq \mathbf{I}$ then $encore \leftarrow 1$
12:     if $encore = 0$ then break
13: $\mathbf{Q} \leftarrow [\mathbf{W}^T]_{*1:k}$
```

IV. Experiments

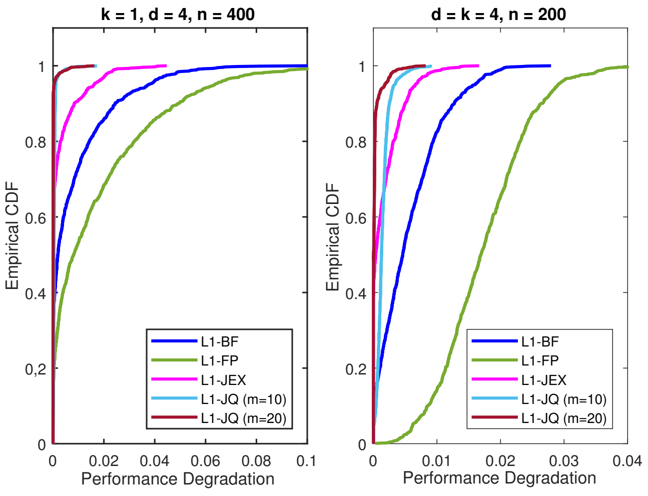
The proposed method has been implemented and evaluated in the Matlab environment. For convenience, it was denoted as L1-JQ, which stands for Jacobi method with quaternion rotations. For comparative purposes we also evaluated three other approximate methods for maximization of the L1-norm: bit-flipping algorithm [6] (L1-BF), fixed-point iterations [4] (L1-FP), and Jacobi exhaustive method with SO(2) rotations [1] (L1-JEX). In the case of the L1-JEX method, the parameter m was set to 512. We verified empirically that, for this method, rotations at a smaller angle than $\pi/512$ are not statistically significant. In order to explore how the estimation error is affected by the angular resolution, the algorithm L1-JQ was evaluated for two different values of the parameter $m \in \{10, 20\}$. For all approaches, the identity matrix was used as the initialisation point.

A. Accuracy

The performance degradation ratio attained by the algorithms was measured using a similar procedure to that in [6]. Namely, the following metric was considered:

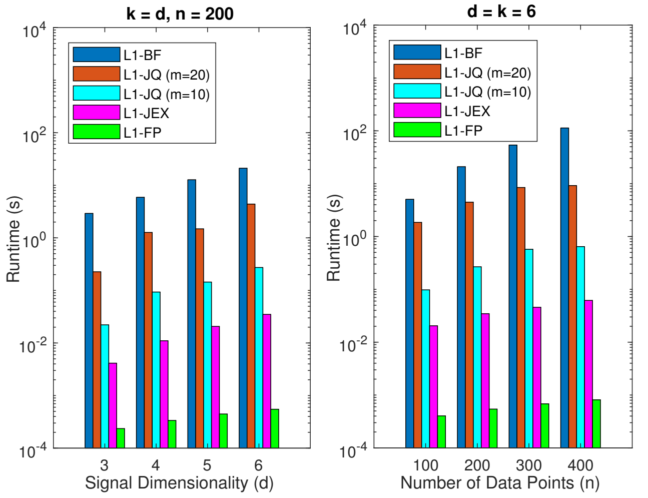
$$\Delta(\mathbf{Q}, \mathbf{X}) = \frac{\|\mathbf{X}^T\mathbf{Q}_{\text{L1}}\|_1 - \|\mathbf{X}^T\mathbf{Q}\|_1}{\|\mathbf{X}^T\mathbf{Q}_{\text{L1}}\|_1}, \tag{26}$$

where $\mathbf{Q}$ is the orthonormal matrix estimated using an evaluated method. Ideally, the matrix $\mathbf{Q}_{\text{L1}}$ should be the matrix obtained by an optimal L1-PCA algorithm [5], for the same data matrix. Unfortunately, the computational complexity of the optimal method is extremely high. Thus, such an approach is possible only for very small data sizes ($n \ll 100$). The presented method is intended for larger data sets. For these reasons, in this experiment, we replaced the matrix $\mathbf{Q}_{\text{L1}}$ with the matrix representing the best solution among all methods. In order to measure which method gives the best result most



(a) (b)

Fig. 1: Empirical CDF of performance degradation ratio estimated for various L1-PCA algorithms



(a) (b)

Fig. 2: Comparison of average runtimes (in seconds) measured for all methods and various data sizes across 100 Monte Carlo runs. (a) Runtime vs signal dimensionality. (b) Runtime vs number of observation samples.

frequently, the empirical cumulative distribution functions (ECDFs) were computed. The ECDFs are the fractions of the measurements (26) that are less than or equal to the specified values. Thus, the higher the value of the ECDF, the better accuracy. We considered two scenarios: the first one with $d = 4$, $k = 1$, $n = 400$, and the second one with $d = k = 4$, $n = 200$. In both scenarios, 1000 random data matrices were randomly generated with entries drawn independently from a Gaussian distribution $\mathcal{N}(0, 1)$ as in [6], [1]. The results are presented in Fig. 1. In the first scenario (on the left), the proposed approach with $m = 20$ gives a zero or close to zero value of the degradation ratio in about 95 percent of runs. This is the best score among all methods. In the case of the L1-JEX, L1-BF and L1-FP methods, these fractions are 65, 30, and 15 percent, respectively. The performance loss due to smaller dictionary size is rather not noticeable in this scenario. Both versions of the proposed method perform equally well regardless of the value of the parameter m. In the second scenario (Fig. 1b), we see that each method attains the best result less frequently. However, once again, the L1-JQ algorithm for $m = 20$ achieves lower values of the metric (26) more frequently than any other method. It gives the best or close to best result in about 75 percent of runs, while for the L1-JEX and L1-BF methods, these frequencies are 40 and 10 percent, respectively. The most significant performance loss can be seen for the L1-FP method. It comes from the fact that the L1-FP method for $k > 1$ is based on successive null-space projections that violate the non-scalability principle of the L1-PCA. We also see that the reduction in accuracy of the L1-JQ method due to the decrease in a value of the parameter m is more prominent. This reduction is especially noticeable in a frequency with which the method obtains the best solution. Please note that even if the proposed approach does not give the best solution most frequently, the metric (26) usually takes relatively small values. Namely, the degradation ratio attained by L1-JQ method with $m = 10$, computed with respect to the best solution, is with empirical probability 1 less than 0.008. Other methods attain significantly greater values of the degradation ratio. For example, the largest values of the metric (26) returned by the L1-JEX and L1-FB methods were 0.016 and 0.027 respectively.

B. Execution time

In order to compare the computational performance of the proposed algorithm with other methods, we measured their average execution times for various data sizes. The experiments were carried out on the system with AMD Ryzen 5 3550H processor. Once again, two scenarios have been considered. In the first one (Fig. 2a), we examined how the dimensionality of the signal affects the computation time. Here, we assumed that the number of data samples $n = 200$ and $k = d$. It can be seen that even for the higher angular resolution ($m = 20$), the proposed method is a faster than L1-BF algorithm. On the other hand, it is slower than the method based on SO(2) rotations, even when the angular resolution is low ($m = 10$). None of the methods can compete with the L1-FP method, which turns out to be the fastest approach. Also note that the execution time of the all rotational methods increases quite fast with the dimension number. It is not surprising, as the number of rotations per sweep increases quadratically with d.

In the second scenario (see Fig. 2b), we assumed that $k = d = 6$ and checked how the computation time is affected by the number of samples n. The results are similar to that of the previous case. It can be seen that all rotational methods are generally faster than the L1-BF algorithm. In addition their execution times increase linearly with the number of samples. This is serious improvement compared to the L1-BF algorithm, where the execution time increases quadratically with n. Our experiments clearly show that the precision of the

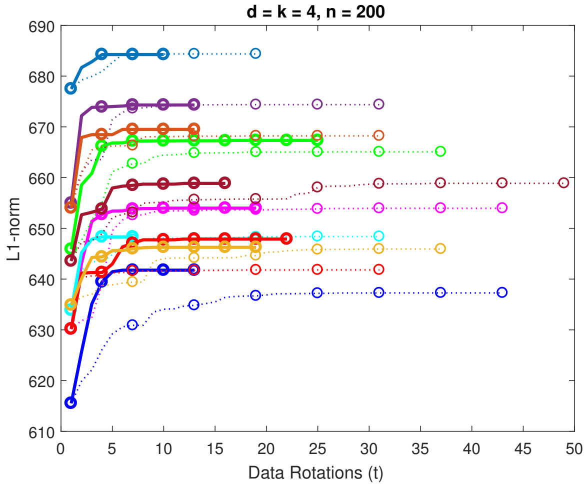


Fig. 3: Convergence curves obtained during 10 Monte Carlo runs for the L1-JQ method with $m = 20$ (solid lines) and the L1-JEX algorithm (dotted lines). Each Monte Carlo run is presented using different colour. The first data rotation in each sweep is depicted by circle.

L1-JQ method is paid for by increased computational burden. Nonetheless, its computational complexity can be still smaller than or at least comparable to that of the L1-BF algorithm. Also note that the rotational algorithms, including the proposed one, may not be the best choice for large d. For instance, when $d > n$, the L1-BF algorithm may offer better performance. However, a such scenario is rarely encountered in practice and thus less interesting.

In Fig. 3, we also show the convergence curves obtained for L1-JQ ($m = 20$) and L1-JEX methods. The L1-norm was measured after each data rotation for 10 independent Monte Carlo runs. The maximum number of sweeps was limited to 100, but none of the methods reached this limit. As we see, both methods converge in a relatively small number of sweeps (from 2 to 8), but the proposed method offers higher convergence rates. It also achieves higher values of the L1-norm more frequently, which is consistent with our previous findings. On the other hand, the computational cost of the single rotation of the proposed method is higher than that of the L1-JEX method. Thus, in overall, the L1-JEX method remains computationally more efficient.

V. Conclusion

In this paper, we proposed a novel version of the exhaustive Jacobi-based algorithm for maximization of the L1-norm. It was shown that the Jacobi rotations can be replaced by the quaternion-based rotations in SO(3). In this way, it is possible to increase the accuracy of the estimation at the expense of additional computational cost. Indeed, the simulation results show that the proposed method gives the best solution more frequently than other approximate methods. Although the algorithm was implemented using exhaustive search, the improvement in the accuracy was obtained for relatively small dictionary size. The results suggest that precision of angular representation of the rotations in higher-dimensions can be substantially lower than that of the two-dimensional rotations. Thus, a solution can be found exhaustively at a reasonable computational cost. Furthermore, for large datasets, the execution time of the proposed method is still smaller than that of the bit-flipping technique.

Future works include implementation optimizations, practical applications and more rigorous estimation error analysis. It could be especially interesting to establish the theoretical bounds of estimation error with respect to the precision of angular representation of the rotations.

***Abstract*—From ancient times olive tree cultivation has been one of the most crucial agricultural activities for Mediterranean countries. In recent years, the role of Artificial Intelligence in agriculture is increasing: its use ranges from monitoring of cultivated soil, to irrigation management, to yield prediction, to autonomous agricultural robots, to weed and pest classification and management, for example, by taking pictures using a standard smartphone or an unmanned aerial vehicle , and all this eases human work and makes it even more accessible.**

In this work, a method is proposed for olive disease classification, based on an adaptive ensemble of two EfficientNet-b0 models, that improves the state-of-the-art accuracy on a publicly available dataset by 1.6-2.6%. Both in terms of the number of parameters and the number of operations, our method reduces complexity roughly by 50% and 80%, respectively, that is a level not seen in at least a decade. Due to its efficiency, this method is also embeddable into a smartphone application for real-time processing.

I. Introduction

OLIVE tree cultivation represents one of the most important activities of agriculture for the civilizations of the Mediterranean area. Indeed the countries of this area produced roughly 65% of the world's olive oils in the last years [1]. Olive-derived products have shown health benefits due to their compounds [2]. In addition, olive trees are known to adapt to environmental stresses such as salinity, drought, heat and high levels of ultraviolet B rays [3], [4], [5] generating, during the millennia, 600 species within 25 genera [6]. However, even olive trees are affected by diseases: some of them are visible on their fruits and can happen only during specific periods of the year, while others have visible signs on the leaves [7]. The signs of a disease can be different in different hosts and can evolve over time.

Although olive cultivation techniques have been perfected over the centuries, artificial intelligence has only recently entered the olive industry, bringing a series of significant innovations and improving the management of many issues, like as predicting crop yields, plant health monitoring, disease prevention, identification and classification, irrigation management, monitoring and management of agricultural activities [8], [9], [10] (e.g. sowing, harvesting, pruning,...), even for olive disease [11], [12]. We propose here a highly efficient solution that allows to classify olive diseases affecting leaves directly from images taken by standard smartphone cameras. This paper is organized as follows: in Sec. II, the dataset used for experiments is described; in Sec. III, the solutions and the experimental setup are described, while results are shown in Sec. IV. The paper ends with a discussion and conclusion in Sec. VI.

II. Dataset description

To test our solution, the largest publicly available dataset [13] has been used: it is composed of 3400 images representing olive leaves affected by *Alucus olearius* or *Olive peacock spot* or *healthy*. Tab. I shows the distribution of the classes, while a sample of images for each class is shown in Fig. 1.

TABLE I: Data distribution of the dataset used.

Class	Size
Aculus olearius	890
Healthy	1050
Olive peacock Spot	1460

III. Design description

A. *EfficientNet*

We selected EfficientNet-b0 [14] as the core model because, according to its structure and the obtained results, it has the best accuracy/complexity trade-off. Two main factors give the efficiency of this architecture: the first is the compound scaling (Fig. 2) by which input scaling (i.e. input size), width scaling (i.e. convolutional kernel size) and depth scaling (i.e. the number of layers) are performed in conjunction since, by observation, they are dependent; the second is the use of the inverted bottleneck MBConv (first introduced in MobileNetV2, an efficient model designed to run on smartphones) as a main module, reducing the complexity of convolution by expanding and compressing the channels.

B. *Ensembling*

The most significant contribution to this work is given by ensembling: it is a technique of combining several models, called *weak* models, in order to provide produce a model

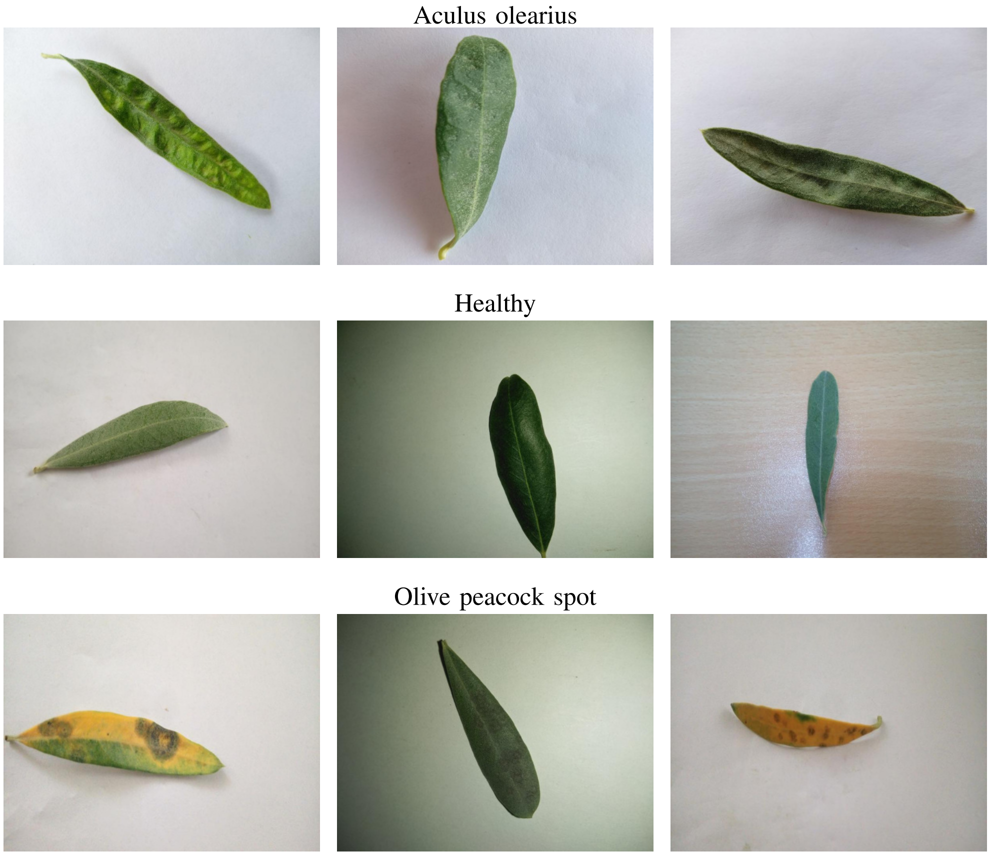

Fig. 1: Samples from the dataset for Aculus olearius (first row), Healthy (second row) and Olive peacock spot (third row)

having better results than a single one [15]. Ensembling is also known to reduce errors and improve the model's generalization capabilities. Due to its resource-consuming nature and the exponential growth of model complexity, however, ensembling is scarcely used in computer vision. By contrast, our method allows performing ensembling in an adaptive and efficient way (Fig. 3):

- we use only two weak models (achieving minimality and efficiency);
- the ensemble is not a typical aggregation function, but it is performed using a linear combination layer, trainable by gradient descent (obtaining adaptivity);
- the ensemble is performed using the deep features instead of the output, excluding redundant operations (for efficiency).

C. *Validation pipeline*

The validation pipeline can be split into two main phases:

1) 5-fold cross-validation with end-to-end EfficientNet-b0 training, using transfer learning [16] from ImageNet pretrained models [17], because transfer learning provides faster convergence;
2) 5-fold cross-validation with fine-tuning of the ensemble, using the two best models from the previous phase.

The design choices used during the validation are:

Input size: set to 512×512 because, after a preliminary investigation, it gives the best trade-off between image quality and computational costs.

Batch size: set to the maximum available using our GPU (32GB RAM), which is 50 for the end-to-end and 200 for the fine-tuning.

Regularization: early-stopping with patience of 10 epochs is used, helping to prevent overfitting.

Optimizer: AdaBelief [18] with learning rate $5 \cdot 10^{-4}$, betas (0.9, 0.999), eps 10^{-16}, using weight decoupling without rectifying, in order to have both fast convergence and generalization.

Validation metric: Weighted F1-score which better takes into account both errors and data imbalance.

Dataset split: training and test subsets are preset, in every run of the 5-fold cross-validation, the training set is split 80/20 in train/valid.

Standardization: data are processed in order to belong to a distribution with values around the average and the unit standard deviation, improving stability and convergence of the training.

Obviously, each run of the cross-validation of both phases is associated with a different initialization of the random model

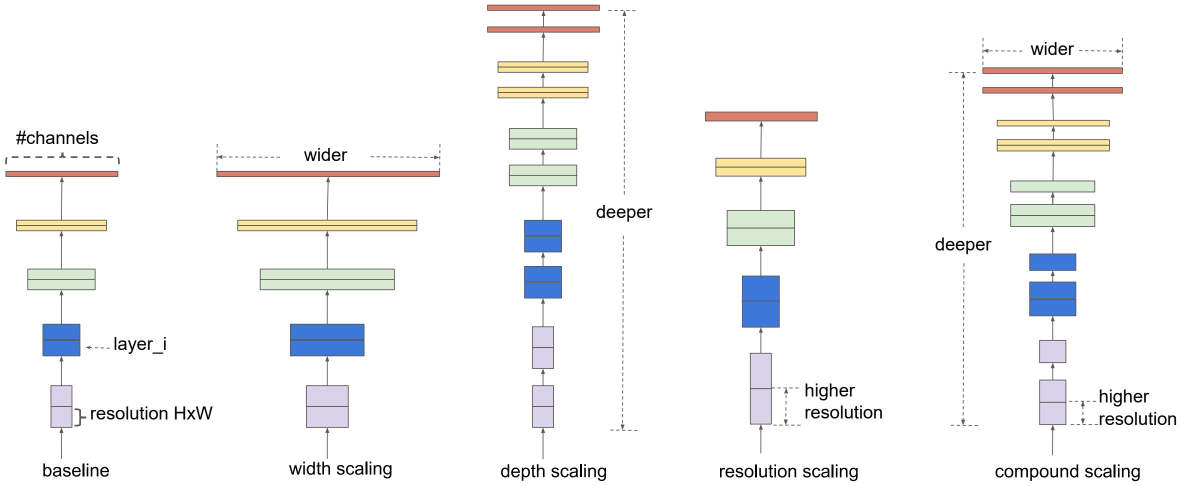

Fig. 2: Example of scaling types, from left to right: a baseline network example, conventional scaling methods that only increase one network dimension (width, depth, resolution) and, at the end, the EfficientNet compound scaling method. Image taken from the original paper [14].

parameters.

IV. Experimental results

According to Tab. II, the EfficientNet-b0 with the selected design choices already provides a good starting point with an average F1-score of 0.969, 0.983 and 0.999 for test, valid and train set, respectively, with high robustness (i.e. low variance). The ensemble further reduces the variance and improves the generalization power (i.e. performance on valid and test) by an average of +1.5% and +1.4% on test and valid, respectively. The final errors are 12 (test: 9; valid: 2; train: 1) and in Fig. 4 the confusion matrix for the test set is shown.

The strength of the proposed solution is even more significant when compared with the State of the Art (SOTA) Tabs. III-IV, indeed the EfficientNet-b0 has the values of the same metric as the best performing SOTA model, and it uses only 52% of parameters and 21% of FLOPs, while considering the Ensemble the complexity (both parameters and FLOPs) is roughly doubled, but it is still lower than the SOTA, for a +1.6% on all the metrics.

V. Discussion

In order to stress our method, we tested an ensemble of five weak models: while using other datasets, generally this improves the results a little at the expense of complexity, as Tab. V shows, in this case, the results don't improve, the errors remain exactly on the same 12 images even if distributed among the different splits.

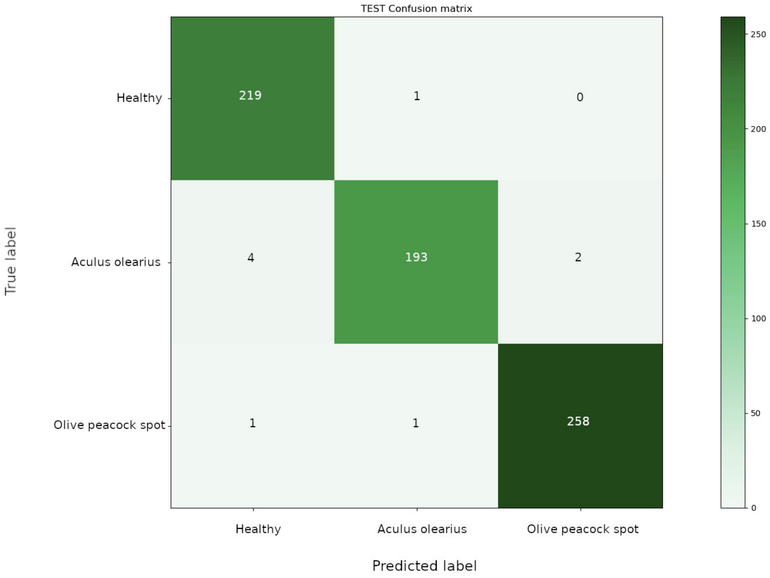

Fig. 4: The confusion matrix on the test split of the best ensemble model.

TABLE II: Metrics (F1-score) on the subset of 5-fold cross-validation runs of both end-to-end weak (left) and fine-tuning ensemble models (right). The ensemble has a twofold contribution: improving generalization performances (+1.5% on test, +1.4% on valid, on average) and robustness (halving the deviation). Data is organized best-to-worst fold (top-to-bottom), and then the models corresponding to the first two rows in the left table are used as weak models for the ensemble.

[2] authors did not specify the version they used, metrics are about the lightest one (DenseNet-121).

[3] authors did not specify the version they used, metrics are about the lightest one (ResNet-18).

[4] the actual trainable parameters are 0.1M (the parameters of the combination layer) and the gradient backward propagation stops at this layer.

[5] the forward pass can be parallelized, having the same execution time of a weak model.

TABLE V: Metrics (F1-score) related to the best ensembles of five weak models.

Test	Valid	Train
0.98529	1.00000	0.99908
0.98529	1.00000	0.99908
0.98235	1.00000	0.99908
0.98235	1.00000	0.99908
0.98235	1.00000	0.99908

This approach to ensembling has been recently introduced and discussed in [21], [22]; it has already proved excellent applicability to AI-based methods for agriculture [23].

Specifically in [21], we tested our method on seven benchmarking datasets, that are: CIFAR-10 [24], CIFAR-100 [24], Stanford Cars [25], Food-101 [26], Oxford 102 Flower [27], CINIC-10 [28] and Oxford-IIIT Pet [26]. The results demonstrated that our novelties improve the SOTA for each dataset by an average of 0.5%, using different kinds of images, reducing complexity in terms of the number of parameters up to sixty times and of FLOPs up to one hundred times. This results in a considerable saving of time and costs compared to most recent models (i.e. Vision Transformers [29]).

In [30], our method was also tested on images of plants taken on the field, in different environments, backgrounds, light conditions and at different stages of growth of the weeds. This defined the baseline for an in-progress work, in which, with the help of farmers taking pictures directly on the field using a mobile app [31], a set of models trained and being continuously extended, are contributing to significantly improving the classification of about a hundred of the main stressors that can interfere with wheat cultivation, such as weeds, pests, diseases and damages.

Another real-world application using this solution on a different domain was presented and discussed in [22]: using a public database of lung ultrasound, the SOTA was reached with 100% of accuracy in classifying healthy from Covid-19 from pneumonia cases.

VI. Conclusions

In this paper, we presented an efficient adaptive ensemble method to classify olive leaf diseases using two EfficientNet-b0 as weak models. The ensemble is performed by a linear layer that combines the features of the weak models. Our method increased the generalization strenghtby about 1.5% and reduced the variance. Moreover, by parallelizing the independent weak models, the complexity is comparable to a single weak model, having 52% of parameters and 21% of FLOPs of the best SOTA solution.

Due to its efficiency, given a significantly smaller architecture in terms of the number of tunable parameters and floating point operations comparable to those of a decade ago, this solution can also be embedded into a smartphone application for real-time classifications.

Further studies will be performed to investigate the use of the efficient adaptive ensemble method with a greater number of weak models.

***Abstract*—Scalability is an important aspect related to time and energy savings on modern multicore architectures. In this paper, we investigate and analyze scalability in terms of time and energy. We compare the execution time and consumption energy of the LU factorization (without pivoting) and Cholesky, both with Math Kernel Library (MKL) on a multicore machine. In order to save the energy of these multithreaded factorizations, the dynamic voltage and frequency scaling (DVFS) technique was used. This technique allows the clock frequency to be scaled without changing the implementation. An experimental scalability evaluation was performed on an Intel Xeon Gold multicore machine, depending on the number of threads and the clock frequency. Our test results show that scalability in terms of the execution time expressed by the Speedup metric has values close to a linear function with an increase in the number of threads. In contrast, scalability in terms of the energy consumed expressed by the Greenup metric has values close to a logarithmic function with an increase in the number of threads. Both kinds of scalability depend on the clock frequency settings and the number of threads.**

I. Introduction

SCALABILITY is one of the main requirements to be taken into account when implementing parallel software on multicore machines, in particular for numerical algorithms involving many matrix calculations. The scalability feature allows an increasing number of threads to be used on a multicore machine in the hope that both time and energy efficiency will increase rather than degrade. The classical approach to scalability in parallel processing focuses on performance in terms of runtime. In this work, we want to study scalability in terms of two criteria, both the running time of the numerical algorithm and the energy consumption. The importance and need to consider multiple criteria in relation to scalability in parallel processing is shown in the work [8].

A distinction is made between two basic concepts related to scalability: scalability in the strong sense and scalability in the weak sense. In this paper we will only study scalability in the strong sense, that is, for a given problem size we will increase the number of threads. We focus on strong scalability because the parallelism available on modern machines will continue to increase.

An in-depth understanding of scalability in terms of execution time and energy consumption and the correlation between the two can allow the design of specific optimizations to reduce runtime and energy consumption for applications in different domains. In particular, it is important to study applications that make deliberate use of cache. Such applications usually come from the field of numerical linear algebra and involve matrix computations. Linear algebra is an important component of many numerical algorithms for various scientific and engineering problems. Over the years, BLAS (Basic Linear Algebra Subroutines) [6] has become the standard interface for linear algebra operations. One of the most popular BLAS packages is Math Kernel Library (MKL) [1]. The MKL library also contains implementations of matrix factorizations such as the LU factorization and the Cholesky factorization. The implementations of all factorizations are based on the BLAS library. The classical approach implemented in the MKL library for parallel matrix factorizations in cache-based systems uses fixed-size blocks that fit in the cache to evenly distribute the workload between threads. Currently, the MKL library tends to optimize runtime and does not take into account energy consumption savings. It is a well-known fact that reducing computation time usually implies energy savings, and is not the only reason for energy saving. Therefore, in order to improve the saving of energy of the algorithms from the MKL library without changing their implementation on multicore architectures, this work uses the dynamic voltage and frequency scaling technique DVFS [9].

The main contributions of this paper:

- a thorough empirical study of the runtime and energy consumption of multithreaded matrix factorizations (LU and Cholesky) concerning changing clock frequency and a selected number of threads;
- a scalability study using Speedup and Greenup metrics for varying numbers of threads for different clock frequencies;

IEEE Catalog Number: CFP2385N-ART ©2023, PTI

The remainder of this article is organized as follows. In Section II, we discuss metrics such as Speedup and Greenup used to measure scalability in terms of the time and energy of parallel applications on multicore machines. In Section III we briefly review the LU and Cholesky algorithms. In Section IV, we present the test methodologies and experimental evaluation. Finally, in Section V, we conclude and make suggestions for future work.

II. Metrics

Energy consumption is the product of runtime and power consumed. Energy can be saved in various ways, e.g. by shortening runtime, reducing power consumption, or both, extending time but reducing power consumption more or vice versa.

The Speedup metric is known in the literature and used to analyze performance in parallel programming between different code implementations. It is assumed that we have two implementations of the algorithm, one non-optimized (basic) code running in time T_B and the other optimized code running in time T_O. Speedup is defined as follows:

$$Speedup = \frac{T_B}{T_O}$$

In [2] Greenup is defined analogously to Speedup only in terms of energy consumption:

$$Greenup = \frac{E_B}{E_O}$$

where E_B is the total energy consumption of the non-optimized code and E_O is the total energy consumption of the optimized code.

III. Algorithms

We will briefly introduce the LU and Cholesky algorithms used to solve systems of linear equations. The LU factorization transform square nonsingular matrix A into a product of two matrices:

$$A = LU$$

where L and U are lower and upper triangular matrices respectively.

The Cholesky factorization is defined only for A being Hermitian and positive-definite and has a form:

$$A = LL^T$$

where L is a lower triangular matrix. In this article, we investigate the LAPACK [3] implementation of the LU factorization from MKL library, namely `dgetrfnpi` (LU) [5], `dpotrf` (Cholesky) routines. These implementations are based on BLAS and arise from the use of a multithreaded BLAS.

The total number of floating-point operations (add, multiply, divide) for the LU factorizations is equal approximately $\frac{2}{3}n^3$. The number of floating point comparisons for the LU factorization is equals 0. The number of floating-point operations in the Cholesky factorization is $\frac{1}{3}n^3$. The number n is the size of the factoring matrix A.

IV. Numerical experiment – methodology and results analysis

A. Methodology

We tested two versions of matrix factorization: LU and Cholesky. We tested all algorithms without parallelization (1 thread) and in parallelized versions for 10, 20, 30, and 40 threads.

TABLE I: LU factorization at 1.7GHz

Threads/ Frequency	Time[s]	Energy[J]	Performance	Efficiency
1/1.7	889.07	57216.78	26.426	0.411
10/1.7	90.72	10560.03	258.989	2.225
20/1.7	46.35	7724.50	506.902	3.042
30/1.7	32.65	6716.32	719.517	3.498
40/1.7	26.53	6169.10	885.598	**3.808**

TABLE II: Cholesky factorization at 2.0GHz

Threads/ Frequency	Time[s]	Energy[J]	Performance	Efficiency
1/2.0	403.73	26795.84	29.098	0.438
10/2.0	40.35	4570.90	291.150	2.570
20/2.0	21.24	3653.45	553.140	3.215
30/2.0	14.67	3375.74	801.009	**3.480**
40/2.0	13.26	3412.81	886.171	3.442

Our test dataset consists of a square matrix filled with double-precision values. The matrix has dimensions of nxn, where $n = 32786$. In other words, our test dataset comprises 1073741824 cells, amounting to a total data size of 8 GB. For all algorithm versions, we have adhered to a row-wise data arrangement. These algorithms have been implemented in C++, incorporating vectorization and parallel processing techniques.

In our experimental configuration, we utilized a computing platform featuring a contemporary multicore Intel(R) Xeon(R) Gold 5218R processor, boasting 40 cores and a clock speed of 2.1 GHz. Our system was powered by the Linux 4.18.0 kernel and ran on the AlmaLinux 8.4 operating system, with the Intel ICC version 2021.5.0 compiler.

The Linux kernel facilitates CPU performance scaling through the `CPUFreq` subsystem, comprising three layers: core, scaling drivers, and governors. The core of `CPUFreq` offers a universal code infrastructure and user interfaces for all platforms supporting CPU performance scaling. It establishes the foundational framework for the other components. Scaling drivers communicate with hardware, supplying scale managers with data on available P-states (or P-state ranges in some cases) and accessing platform-specific hardware interfaces to modify processor P-states as directed by scale masters. Governors execute algorithms for estimating the necessary CPU capacity, typically each manager employing a single, optionally customized scaling algorithm.

The default scaling driver and governor are automatically chosen, but advanced configurations can still utilize userspace tools like `cpupower`, `acpid`, laptop mode tools, or desktop GUI tools.

To modify clock frequencies, we employed `CPUfreq` with the `acpi_cpufreq` driver. By default, this driver follows the

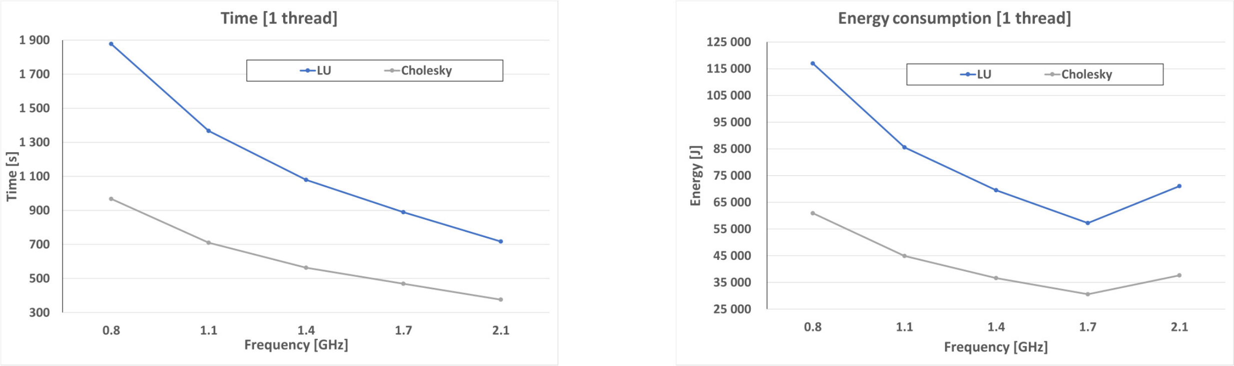

Fig. 1: Time execution for LU and Cholesky for 1 thread – left; Energy consumption of LU and Cholesky for 1 thread – right.

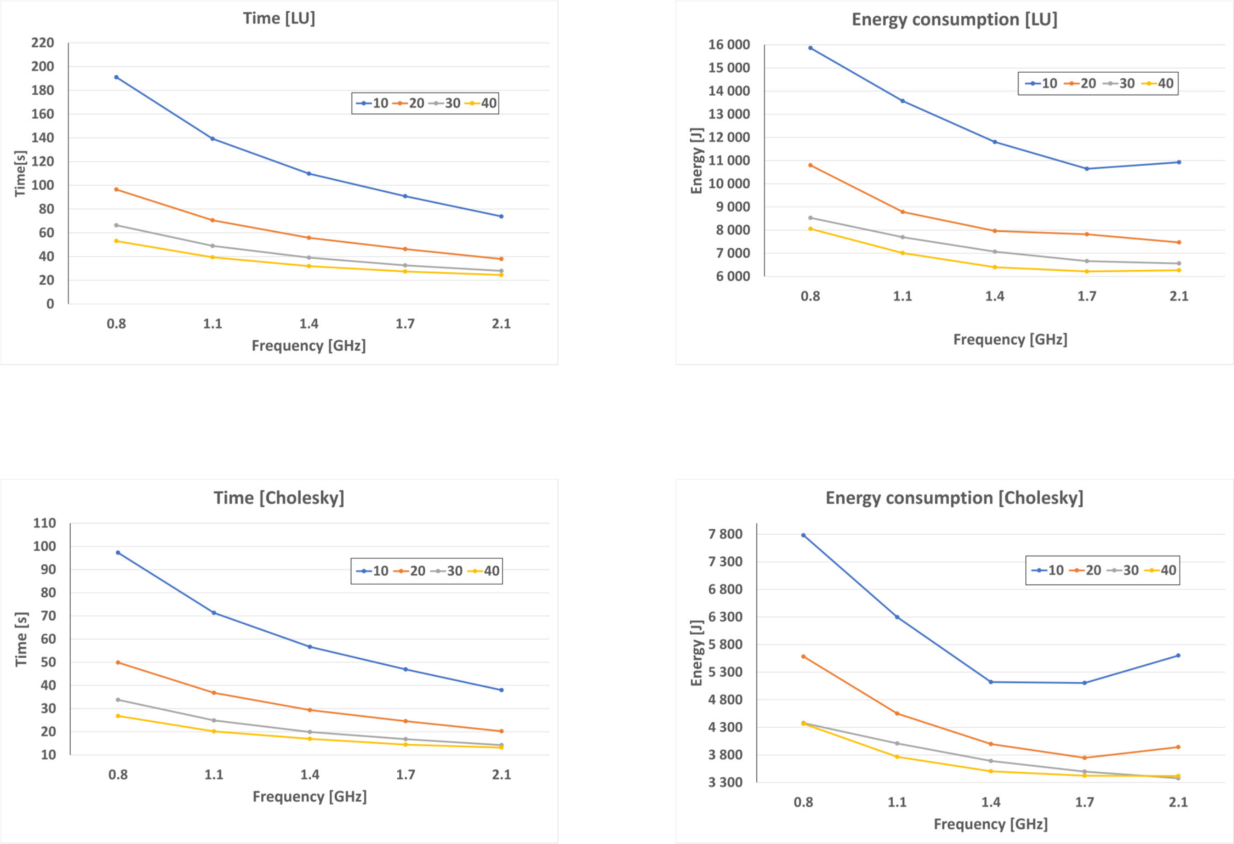

Fig. 2: Time execution for LU and Cholesky – left; Energy consumption of LU and Cholesky – right.

TABLE III: The most energy saving versions of algorithms

version of algorithm	energy consumption [J]	time [s]	waste of time [%]	energy saving [%]
LU ǀ 40 threads ǀ 1,7 GHz	6169.10	26.53	7.9	1.6
Cholesky ǀ 30 threads ǀ 2.0 GHz	3375.74	14.67	10.1	1.3

"conservative" governor, adjusting clock frequencies based on core load, selecting from available frequencies ranging from the minimum to the maximum supported by the processor.

We utilize the `cpupower` program to adjust the processor frequency limit's minimum and maximum values at a specific level, using the following commands:

```
cpupower frequency-set -d 1400000
cpupower frequency-set -u 1400000
```

for setting the minimum and maximum frequency limit values to 1.4 GHz. Executing these commands automatically switches the governor to `userspace`, enabling the configuration of a specific frequency. This frequency adjustment applies uniformly to all cores.

We do tests for the frequencies (P-states) available on our platform from 0.8 GHz to 2.1 GHz with step 0.1 GHz. We test first the following frequencies: 2.1 GHz, 1.7 GHz, 1.4 GHz, 1.1 GHz, and 0.8 GHz.

To assess the impact of algorithm optimizations on energy usage, we relied on data collected via the RAPL (Running Average Power Limit) interface, specifically designed for Intel processors. RAPL utilizes machine-specific records to continually monitor and regulate real-time energy consumption. In multi-socket systems, RAPL provides individual results for each socket or package, while also offering separate measurements for the memory modules (DRAM) linked to each socket. Starting with Haswell processors featuring fully integrated voltage regulators, RAPL's measurement accuracy has notably improved and meets acceptable standards [7]. Throughout our tests, we conducted measurements at 1-second intervals, considering the combined energy consumption of all sockets and their associated memory modules for analysis.

B. Time and energy consumption

In Fig. 1, we present the runtime and energy usage of individual algorithms when using a single thread. In Fig. 2, we display the same for parallel versions, i.e., for 10, 20, 30, and 40 threads. Notably, in the case of a single thread, the Cholesky factorization outperforms the LU factorization in terms of both time and energy consumption. This disproportion in performance is evident in Fig. 2, where we have different the y-axis scales to accommodate the dissimilarities.

In Fig. 2, we observe that reducing the clock frequency leads to an increase in runtime across all scenarios, while increasing the number of threads consistently reduces runtime. Thus, for our architecture, utilizing 40 threads at a frequency of 2.1 GHz proves to be the optimal choice in terms of time efficiency.

However, when considering energy consumption, a lower clock frequency, such as 1.7 GHz, can be advantageous in certain instances. This reduction in energy usage is evident for non-parallelized algorithm versions (approximately 19%) and for parallelized versions across all cases with 10 threads (3% for LU and 9% for Cholesky). Additionally, for 20 threads, a decrease in energy consumption is noticeable when employing 1.7 GHz with the Cholesky factorization (5%) and even for 40 threads with the LU factorization (1.6%). Lowering the clock frequency beyond 1.4 GHz does not yield any significant energy benefits.

Furthermore, we observe that energy consumption decreases as the number of threads used for calculations increases, with one exception: the Cholesky algorithm at 2.1 GHz. In this particular case, the algorithm is 1.2% more energy-efficient at 30 threads compared to 40 threads. A similar situation is observed at 2.0 GHz and 1.9 GHz (Fig. 3).

In response to the observed energy reduction when transitioning to a clock frequency of 1.7 GHz, we conducted additional experiments to explore the behavior of other frequencies within the range of 1.4 GHz to 2.1 GHz. The outcomes are depicted in Fig. 3. Subsequent tests indeed validated the presence of a localized energy consumption minimum at the 1.7 GHz frequency even for the LU algorithm executed with 40 threads.

The Table I and Table II show the test results for the frequencies at which we observe decreases in energy consumption for LU and Cholesky factorizations, respectively. The highest efficiency is achieved with LU at 1.7 GHz (Table I) running on 40 threads and in the case of Cholesky at 2.0 GHz (Table II) on 30 threads. Table III displays a compilation of algorithm versions and clock frequencies that resulted in the lowest energy consumption across both factorizations. In the table, the first column outlines the algorithm and the chosen configurations, the second column presents energy consumption in Joules, and the third column indicates the algorithm's runtime. The fourth and fifth columns reveal the percentage increase in runtime and the percentage reduction in energy consumption, respectively, relative to the configuration that achieved the shortest runtime — which, for both factorizations, was 40 threads and a 2.1 GHz clock frequency. Traditionally, optimizing for both time and energy efficiency involves increasing the number of threads and elevating the clock frequency. However, the two factorizations examined here demonstrate exceptions to this rule. If prioritizing energy savings over runtime, alternative thread and clock settings can be considered. Our tests have identified that the most energy-efficient configuration is achieved with 40 threads and a reduced clock frequency of 1,7 GHz for LU, while for Cholesky, it is with 30 threads and a clock frequency reduced to 2.0 GHz.

C. Speedup and Greenup

The figures in Fig. 4 illustrate the Speedup (left column) and Greenup (right column) values for different clock frequencies,

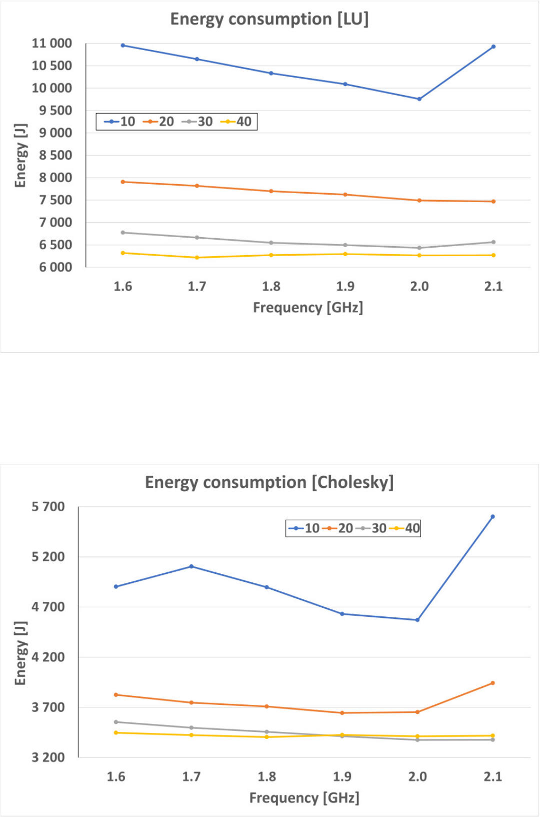

Fig. 3: Energy consumption of LU and Cholesky for frequencies from 1.6 GHz to 2.1 GHz.

derived from our experimental measurements. Each chart corresponds to one algorithm, either LU or Cholesky. The x-axis represents the number of active threads, while the y-axis displays the Speedup or Greenup values. To enhance reference, we've indicated the maximum expected Speedup (linear with the number of threads p) and Greenup (logarithmic with the number of threads p) with a dashed black line in the charts.

Across all two algorithms, it's evident that as the number of threads increases, irrespective of the clock frequency, the runtime improvement outpaces the reduction in energy consumption (time decreases more rapidly than energy consumption). For LU, Speedup approaches linearity for all frequencies, with deviations from the maximum expected value increasing as the thread count rises. Regarding Speedup, the 0.8 GHz frequency yields the most favorable results, while 2.1 GHz performs the poorest.

In general, the Greenup plot deviates further from the maximum expected value compared to Speedup, confirming our observations. For the algorithms we tested, similar to Speedup, the highest Greenup values are achieved at 0.8 GHz, while the lowest values, differing from the Speedup scenario, occur at 2.0 GHz. Notably, the 2.1 GHz frequency, which yielded the lowest Speedup values, still results in relatively high Greenup values (as seen in the purple line in the chart).

In our architecture, we observed the relationship:

$$Greenup \leq \alpha \log_2(Speedup)$$

where $\alpha > \beta$, and in our specific case, β falls within the interval $(2.84; 2.85)$. This leads to a research question: What is the value of α for other architectures?

V. Conclusion

This study explores scalability in relation to execution time and energy consumption for two matrix factorizations (LU and Cholesky) derived from the MKL library. To minimize energy consumption in these factorizations, we employed the DVFS technique. This approach allowed us to adjust clock frequency settings at the operating system level without modifying the implementation code.

We examined the impact of two parameters, clock frequency, and the number of threads, on execution time and energy consumption on a multicore machine. Execution time consistently decreases when using the highest clock frequency and the maximum number of threads for both factorizations. However, the same cannot be said for energy savings, as it varies based on the number of threads and clock frequency less regularly (see Table III).

Speedup and Greenup values increase with an expanding number of threads and typically decrease with a lower clock frequency. Experimental results reveal that Speedup values consistently surpass Greenup values, sometimes reaching up to 74% higher for specific combinations of clock frequency and thread count.

A deeper analysis of the research results, extended by tests of the LU factorization algorithm with pivoting and a study of the correlation between operation time and energy consumption using the Powerup and EDP metrics, is presented in [4]. Future research will address poor scalability by examining its impact on execution time and energy consumption in various multi-core machines and applications. Poor scalability entails keeping the problem size per processor constant while adding more computational units. Additionally, a key aspect to investigate is the correlation between strong and weak scalability regarding energy consumption.

Abstract—**This paper presents research involving the selection of floating photovoltaics (FPV) system constructions under Polish conditions using a multi-criteria method incorporating criteria compensation reduction following the strong sustainability paradigm. The applied method is called SSP-COPRAS (Strong Sustainability Paradigm based Complex Proportional Assessment). The selection was carried out among four FPV designs and one reference conventional ground-mounted PV (GMPV) system. Data were obtained from the reference research paper. The results proved that the FPV system has a noticeable potential for making it competitive with GMPV, especially when technical criteria and criteria compensation reduction play an important role. However, GMPV's higher ratings, especially in terms of economics, show that FPV would have to reach a higher product maturity to become realistically competitive.**

I. Introduction

THE DEVELOPMENT of renewable energy sources (RES) has been an important element of energy and climate policy in European countries for many years. The objectives of the adopted policy oblige European Union member countries to increase the share of energy obtained from RES both in total energy consumption and in individual branches of the economy [1]. Poland's energy system is mainly based on coal [2]. However, the coal-based energy economy is one of the most important causes of climate change caused by carbon dioxide emissions into the atmosphere [3]. It implies that Poland is facing an urgent transition to energy systems using renewable energy sources [4]. Floating photovoltaics (FPV) can contribute to fulfilling this challenge [5]. Due to forecasts of rapid development of FPV in Europe [6], [7], it was decided to focus on applying this technology in Poland. FPV is currently a new and as yet immature technology [8]. However, factors such as the lack of available space for conventional photovoltaic systems, the increase in the number of producers, and financial encouragement in the form of fixed prices for FPV installations will stimulate the intensive development of this technology [9], [10].

This paper presents the assessment results concerning the technical and economic criteria of four different constructions for a designed FPV system. The data for the alternatives considered were derived from the reference paper, in which the analysis was carried out based on simulations performed on the PVsyst system [10]. The main objective of the analysis carried out in this article, which serves as a reference for this research work, was to investigate whether the application of FPV could be profitable in Polish conditions. The FPV under consideration has a capacity of 1 MWp. Such installed capacity was chosen because the auction mechanism provides the most cost-effective prices for PV systems under 1 MWp. The artificially created upper reservoir of the Porąbka-Żar pumped storage power plant was adopted as the target site for the considered structures. This reservoir has a limited usable area due to its rounded walls. In this article, the considered constructions were evaluated separately for each criterion with the performance values of each criterion. Simulations at PVsyst showed that FPV systems showed a slight advantage over ground-mounted PV (GMPV) for specific constructions.

Since FPV in Poland are new, this work provides a comprehensive source of knowledge on how such systems can work in Polish conditions, highlighting the novel character of the investigated topic. However, the manner of evaluation in the discussed article is complicated because it forces the analyst to consider the following criteria without considering them simultaneously. The present method also does not allow to assign of relevance to the evaluation criteria, which is essential from the decision-makers point of view. Finally, such a way of evaluation does not provide an opportunity to take into account the strong sustainability paradigm, which is important in terms of sustainable development of FPV systems [11]. Its consideration is justified by the fact that one system may have an extremely good value within one criterion that will compensate for less favorable values for other criteria. Preventing the phenomenon of criteria compensation is, therefore, one of the elements of the strong sustainability paradigm that should be considered in the field of RES. The limitations mentioned above in the discussed research became the motivation for presenting in this paper results of research using the new SSP-

COPRAS (Strong Sustainability Paradigm based Complex Proportional Assessment) multi-criteria method [12], [13], [14] for selecting the best construction of a floating solar farm from among four FPV variants and one reference system installed on the ground. MCDM methods have proven useful in FPV-related selection problems involving site selection [15], [16] and construction assessment [17].

The paper adopts nine evaluation criteria from a reference research paper: five are technical, and four are economic. The use of the MCDA method is justified by the fact that the MCDA results allow considering multiple criteria simultaneously and analyzing various scenarios, which is important from the decision-makers point of view [18], [19]. In addition, SSP-COPRAS makes it possible to reduce the compensation of criteria according to a strong sustainability paradigm [20], [21].

II. Methodology

This section presents the following steps of the SSP-COPRAS method, including basic assumptions and mathematical formulas. SSP-COPRAS implemented in Python is available at GitHub repository, along with a dataset of FPV constructions under consideration at link https://github.com/energyinpython/SSP-COPRAS-FPV.

Step 1. Create the decision matrix $X = [x_{ij}]_{m \times n}$ as Equation (1) shows. This matrix includes performance values x_{ij} collected for m alternatives, where $i = 1, 2, \ldots, m$ regarding n evaluation criteria, where $j = 1, 2, \ldots, n$.

$$X = [x_{ij}]_{m \times n} = \begin{bmatrix} x_{11} & x_{12} & \cdots & x_{1n} \\ x_{21} & x_{22} & \cdots & x_{2n} \\ \vdots & \vdots & \vdots & \vdots \\ x_{m1} & x_{m2} & \cdots & x_{mn} \end{bmatrix} \tag{1}$$

Step 2. Calculate the Mean Deviation MD for each performance value x_{ij} by subtracting the mean value of each alternative's performance $\overline{x_j}$ for each criterion C_j. Multiply the resulting value by the sustainability coefficient s_j defined for each criterion as a real number in the range between 0 and 1. Equation (2) presents the complete procedure performed in this step.

$$MD_{ij} = (x_{ij} - \overline{x_j})s_j \tag{2}$$

Step 3. Assign 0 value to these MD values that for profit criteria C_j are lower than 0 (when x_{ij} is less than $\overline{x_j}$) and to these MD values that for cost criteria C_j are higher than 0 (when x_{ij} is higher than $\overline{x_j}$), as Equation (3) shows,

$$MD_{ij} = 0 \, \forall \, MD_{+ij} < 0 \, \vee \, MD_{-ij} > 0 \tag{3}$$

where MD_{+ij} represent MD values for profit criteria and MD_{-ij} define MD values for cost criteria. This step prevents unintended enhancement of performance values that are outliers from the average toward the worse.

The rest of the steps are the same as the classic COPRAS method.

Step 4. Normalize the decision matrix X using sum normalization method presented in Equation (4)

$$R = [r_{ij}]_{m \times n} = \frac{x_{ij} - MD_{ij}}{\sum_{i=1}^{m}(x_{ij} - MD_{ij})} \tag{4}$$

where $i = 1, 2, \ldots, m$ denotes ith alternative and $j = 1, 2, \ldots, n$ represents jth criterion

Step 5. This step involves calculating the weighted normalized decision matrix by multiplying values r_{ij} in normalized decision matrix R by the weights w_j determined for particular criteria, as Equation (5) demonstrates.

$$V = v_{ij} = r_{ij} w_j \tag{5}$$

Step 6. Calculate the sums of weighted normalized outcomes individual for profit criteria which have to be maximized (S_{+i}) and for cost criteria which have to be minimized (S_{-i}) as Equation (6) demonstrates,

$$S_{+i} = \sum_{j=1}^{n} v_{+ij}, \; S_{-i} = \sum_{j=1}^{n} v_{-ij} \tag{6}$$

where v_{+ij} are related to profit criteria which have to be maximized, and v_{-ij} are related to cost criteria which have to be minimized.

Step 7. Calculate the relative priority Q_i of evaluated options using Equation (7),

$$Q_i = S_{+i} + \frac{\sum_{i=1}^{m} S_{-i}}{S_{-i} \sum_{i=1}^{m} \frac{1}{S_{-i}}} \tag{7}$$

where an alternative with the highest value of Q_i is considered as the best option.

Step 8. Calculate the quantitative utility value U_i for each alternative,

$$U_i = \frac{Q_i}{Q_{max}} \tag{8}$$

where Q_{max} defines the highest relative importance score. The alternative with the highest U_i value is the best scored option.

III. Results

In this paper, a multi-criteria evaluation was performed using the SSP-COPRAS method considering the criteria compensation reduction for the four variants of FPV constructions and one corresponding ground-mounted PV system (GMPV) equivalent considered as a reference point for the FPV project assessment. Four FPV variants include two systems produced by Ciel&Terre: C&T S12 and C&T EW12 and two by Solaris Synergy: SolSyn S12 and SolSyn S25. Five technical parameters and four economic indexes serving as evaluation criteria are provided in Table I, together with units and objectives. Cost type represents criteria with the aim of minimizing performance values. On the other hand, Profit type defines criteria with the aim of maximizing performance values. The performance values of each FPV and reference GMPV construction collected for evaluation criteria are provided in Table II.

The investigation was conducted in two stages. Stage one involves an evaluation using SSP-COPRAS for the different relevance of the two criteria groups considered: technical parameters and economic indexes. When the significance of the technical criteria group was incremented from 0.25 to 0.75 with a step of 0.05, the significance of the economic group was reduced accordingly. Obtained values were then divided by 5 for the technical criteria and 4 for the economic criteria, and the resulting values were assigned to each criterion. Thus, an equal distribution of weights within the two criteria groups was applied. Sustainability coefficient s values were set as standard deviation values calculated from the normalized decision matrix for each criterion.

TABLE I
TECHNICAL PARAMETERS AND ECONOMIC INDICATORS OF DIFFERENT FPV SCENARIOS AND REFERENCE GMPV SYSTEM.

Criteria		Unit	Type
Technical parameters			
C_1	Area	[m^2]	Cost
C_2	Y$_f$ (Final PV system yield)	[kWh/kWp]	Profit
C_3	PR (Performance ratio)	[%]	Profit
C_4	AED (Annual Energy Density)	[kWh/m^2]	Profit
C_5	T$_{IWA}$ (Irradiance-weighted average temperature)	[$^\circ C$]	Cost
Economic indicators			
C_6	NPV (Net Present Value)	[€]	Profit
C_7	IRR (Internal Rate of Return)	[%]	Profit
C_8	LCOE (Levelized Cost of Energy)	[€/MWh]	Cost
C_9	Minimum Auction price for which NPV = 0	[€/MWh]	Cost

TABLE II
DECISION MATRIX WITH PERFORMANCE VALUES OF TECHNICAL PARAMETERS AND ECONOMIC INDICATORS OF DIFFERENT FPV SCENARIOS AND REFERENCE GMPV SYSTEM.

Technology	C_1	C_2	C_3	C_4	C_5	C_6	C_7	C_8	C_9
GMPV S25	10982	1079	86.92	96.5	25.5	82645	13.3	73.2	46.7
SolSyn S25	15220	1104	89.52	71.3	19.1	82426	12.9	74.5	46.9
SolSyn S12	9901	1046	89.26	103.8	19	44062	10.63	79	51.1
C&T S12	9901	1027	87.67	102	22.2	-26787	8	88.8	57.2
C&T EW12	8514	936	87.99	108	21.4	-83161	3.3	96	63.5

The SSP-COPRAS evaluation was then conducted sequentially for different scenarios of criteria relevance. SSP-COPRAS preference values obtained for this part of the study are contained in Table III.

In turn, rankings of the evaluated systems were built by sorting the preference values in descending order, as in the SSP-COPRAS evaluation, the alternative that received the highest preference value is considered the best scored. Rankings obtained for different weighting of technical and economic criteria groups are visualized in Figure 1. It can be observed that when economic criteria are more important and account for up to 60% of relevance, the leader of the ranking of evaluated systems is the reference system, namely the GMPV S25. This result coincides with the analysis of the authors of the reference article. However, when the relevance of the technical criteria group begins to dominate (from 65%), the ranking leader becomes SolSyn S12. This system receives the most significant promotion of all the alternatives when increasing the relevance of the technical criteria group.

SolSyn S12 has favorable performances in Annual Energy Density, T$_{IWA}$, performance ratio, and area. The C&T S12 and C&T EW 12 systems remain at the bottom of the ranking regardless of the change in the significance of the criteria groups. It is worth noting the two FPV systems, which are SolSyn S12 and SolSyn S25. SolSyn S25 has an advantage over SolSyn S12 when economic criteria are more relevant. When their relevance is aligned, SolSyn S12 gains an advantage over SolSyn S25. It is justified by the fact that SolSyn S25 has superiority over SolSyn S12 in terms of all economic criteria: NPV, IRR, LCOE, and minimum auction price. However, considering technical criteria, SolSyn S12 has an advantage over SolSyn S25 in terms of area, Annual Energy Density (significant advantage), and T$_{IWA}$.

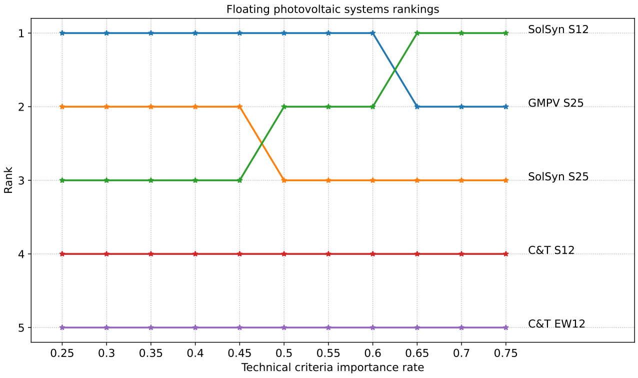

Fig. 1. SSP-COPRAS ranks of evaluated FPV and GMPV systems for different criteria weights.

In the case of FPV design, the desire for the smallest possible area is justified because the area of the power plant tank for which the study was conducted is limited, reducing the usable area for the floating system. In addition, a sufficient distance from the edge of the reservoir is required. Besides, a larger surface area requires more photovoltaic modules, which increases the cost of purchasing, installing, and maintaining the system. Annual Energy Density is an important profit criterion, as its high value increases the amount of electricity produced by the system during the year, which raises profits from system performance. Low irradiance-weighted average temperature (T$_{IWA}$) values increase the water cooling effect. The advantage of FPV systems over GMPV is partly due to the water-cooling effect, which enhances the efficiency of the solar farm.

In the following research stage, an analogous analysis was performed for modified values of the sustainability coefficient. Criteria weights were set as equal. Table IV provides performance values obtained for this analysis. Rankings of evaluated systems are displayed in Figure 2. In the case of sustainability coefficient modification, which was the subject of the second stage of the study, it turned out that all studied alternatives are stable in terms of the phenomenon of criteria compensation.

TABLE IV
SSP-COPRAS PREFERENCE VALUES OF EVALUATED FPV AND GMPV SYSTEMS FOR DIFFERENT SUSTAINABILITY COEFFICIENTS.

Technology / Sustainability coeff.	0	0.1	0.2	0.3	0.4	0.5	0.6	0.7	0.8	0.9	1
GMPV S25	1.0000	1.0000	1.0000	1.0000	1.0000	1.0000	1.0000	0.9983	0.9921	0.9854	0.9783
SolSyn S25	0.9641	0.9632	0.9624	0.9615	0.9606	0.9597	0.9589	0.9564	0.9496	0.9424	0.9348
SolSyn S12	0.9690	0.9727	0.9767	0.9810	0.9856	0.9906	0.9959	1.0000	1.0000	1.0000	1.0000
C&T S12	0.8278	0.8346	0.8417	0.8492	0.8569	0.8651	0.8737	0.8813	0.8854	0.8895	0.8938
C&T EW12	0.7187	0.7209	0.7232	0.7257	0.7284	0.7312	0.7342	0.7362	0.7350	0.7337	0.7323

In the case of a significant degree of compensation reduction, we observe an advancement to the leading position of SolSyn S12, which, with a sustainability coefficient value of 0.7, outperforms the reference system GMPV S25.

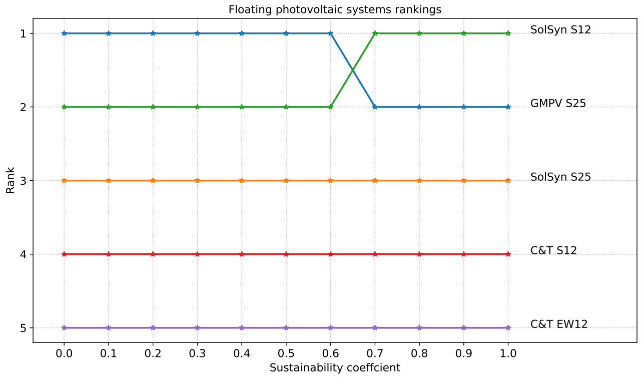

Fig. 2. SSP-COPRAS ranks of evaluated FPV and GMPV systems for different sustainability coefficients.

IV. Conclusion

Research results proved that the alternative that is robust in terms of technical criteria and sustainability and has the most potential to be a real competitor to the reference GMPV S25 design is the SolSyn S12. The potential of FPV systems in technical terms was also noted in the background paper [10] referenced in this research work, where a slight advantage of FPV systems over GMPV in terms of power generation capability was found. On the other hand, if economic factors play the most important role, the conventional reference PV design called GMPV S25 is the unquestionable leader. This result confirms the conclusions of the analysis carried out by the authors of the article [10], who found that FPV systems are currently less favorable from an economic point of view, especially in the auction system. It is because of the need for high capital expenditures, which currently cannot be compensated for even by a floating system with the best performance. FPV would have to reach a higher product maturity to become realistically competitive, especially from an economic point of view. In contrast, the results show promising potential in technical terms.

***Abstract*—Vision-based semantic segmentation of complex urban street scenes is a very important function during autonomous driving (AD), which will become an important technology in industrialized countries in the near future. Today, advanced driver assistance systems (ADAS) improve traffic safety thanks to the application of solutions that enable detecting objects, recognising road signs, segmenting the road, etc. The basis for these functionalities is the adoption of various classifiers. This publication presents solutions utilising convolutional neural networks, such as MobileNet and ResNet50, which were used as encoders in the U-Net model to semantically segment images of complex urban scenes taken from the publicly available Cityscapes dataset. Some modifications of the encoder/decoder architecture of the U-Net model were also proposed and the result was named the MU-Net. During tests carried out on 500 images, the MU-Net model produced slightly better segmentation results than the universal MobileNet and ResNet networks, as measured by the Jaccard index, which amounted to 88.85%. The experiments showed that the MobileNet network had the best ratio of accuracy to the number of parameters used and at the same time was the least sensitive to unusual phenomena occurring in images.**

I. Introduction

SEMANTIC segmentation of images is a very important topic in computer vision, and its purpose is to divide the image into regions of different semantic categories. This division is connected with the classification of the image in the sense that it produces per-pixel category prediction instead of image-level prediction [1]. This means that semantic segmentation can be seen as extending image classification from the image level to the pixel level. However, the training data intended for semantic segmentation requires manual labelling at the pixel level, which is much harder and more time-consuming than other vision tasks, such as image classification or object detection.

Much effort has gone into research on image segmentation in recent years and great progress has been made [2], [3], [4], [5], [6]. Despite this, segmentation still remains a difficult problem because of rich intra-class variation, context variation and ambiguities resulting from the low resolution of images.

State-of-the-art approaches used in semantic segmentation adopt a fully convolutional network (FCN) with an encoder/decoder architecture [7], [8]. The encoder generates low-resolution image features and then the decoder upsamples features to segmentation maps and is used for pixel-level classification of the feature representations.

Semantic segmentation has many different applications, notably including: augmented reality, autonomous driving, image editing, medical imaging, robotics, smart cities, and many others [9], [10].

The visual understanding of complex urban street scenes is crucial for problems concerning the smart city, in which autonomous vehicles can drive and certain infrastructure elements can communicate to ensure the greatest comfort of people and reduce the time lost. The use of various large-scale datasets contributed to a great development of research on object detection and a popularisation of methods using deep learning techniques [11], [12]. To use artificial neural networks (ANN) for the semantic segmentation of complex urban scenes, researchers can utilise Cityscapes [13], a benchmark suite and a large-scale dataset to train and test approaches for pixel-level and instance-level semantic labelling. Figure 1 shows example images available in the training subset of the Cityscapes dataset [13]. Images from the training set which can be semantically segmented using specific colours contain 30 different classes describing defined objects found in the city.

This paper presents research on the semantic segmentation of urban scenes using several different convolutional neural networks with an encoder/decoder architecture. For this purpose, MobileNet [14], [15] and ResNet50 [16], [17] were used as encoders in the U-Net model [18]. During the studies, some modifications to the U-Net model were also proposed based on the experiments carried out. The research work was done using the Cityscapes dataset [13]. The purpose of this research was to obtain improved segmentation results, and to assess the proposed solutions in detail, including their advantages and disadvantages.

II. Materials and methods

A. Data

Research work was carried out using the Cityscapes dataset [13]. This is a collection of 3,475 images from cities in Germany that were recorded during vehicle driving. They are saved in the *png* format and have a resolution of 2048×1024 pixels. This set was divided into a subset designed for training,

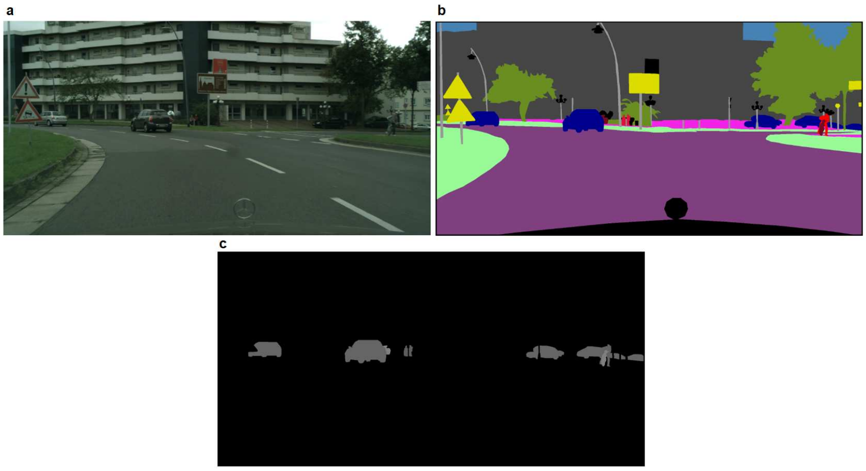

Fig. 1. Sample images from the training subset from the city of Stuttgart. (a) Source image. (b) Semantic segmentation in colour. (c) Segmentation with only vehicles and people marked.

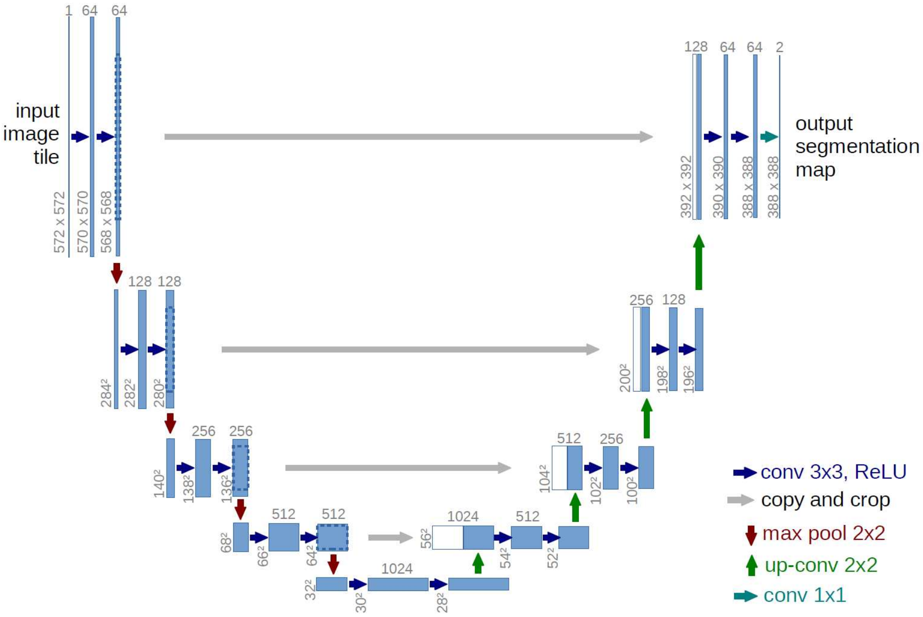

Fig. 2. Diagram of the U-Net model, in which the characteristic letter "U" is visible. Blue rectangles represent multi-channel feature maps. The current size of the maps is written on the left. The current number of channels is written above each rectangle. White rectangles are maps transferred to the decoding part of the model. Blue arrows are convolutional layers, red ones are pooling layers, and green arrows are layers that increase the resolution. Gray arrows connect feature maps obtained during encoding to their counterparts during decoding [18].

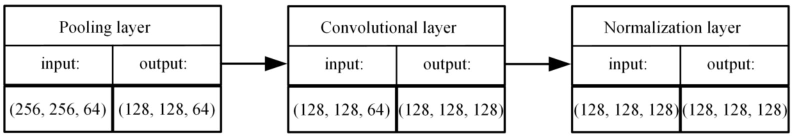

Fig. 3. Proposed encoder block. The first two numerical values are the height and the width of feature maps, and the third is the number of channels. The pooling layer reduces the resolution of feature maps. Then, the convolution layer uses filters to increase the number of channels. At the end, normalization is performed.

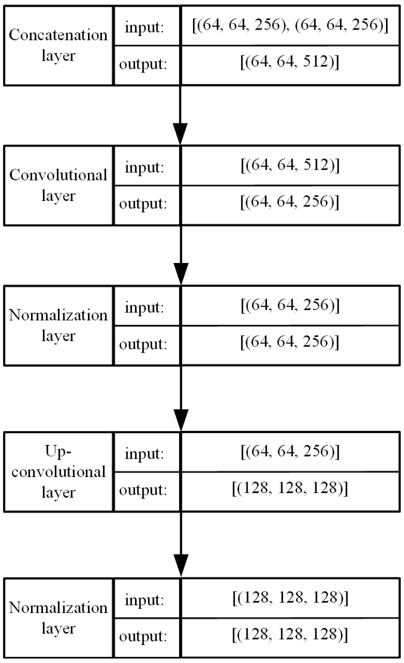

Fig. 4. Proposed decoder block. The first two numerical values are the height and width, the third is the number of channels. The concatenation layer connects the feature maps of the encoder and the decoder that have the same resolution, and then the convolutional layer reduces the number of channels. The next steps are: data normalization and the use of an up-convolutional layer which increases the resolution of feature maps. The last element of the block is the normalization layer whose output forms one of the inputs of the next concatenation layer that begins the next decoder block.

comprising 2975 images, and a subset for testing machine learning models, containing 500 images.

B. Preprocessing

Pre-processing is to shorten the network training time and to properly prepare the images so that the learning process is efficient and the highest possible results of semantic segmentation are obtained on the test set. For this purpose, image resolution change, random cropping and normalization were applied.

1) Resolution change: To improve the training time of ANNs, the original resolution of source images was reduced from 2048 × 1024 pixels to 600 × 300 pixels using the nearest neighbour method [19]. Apart from RGB channels, the rescaled images also contained a channel representing the segmentation of individual images.

2) Random cropping: In the next step, random cropping [20] was used to obtain images with the size of 256× 256 pixels. In addition, every image was mirrored with a probability of 1/2. This produces more diverse input data and reduces the risk that the network will analyse the general features of all images.

3) Normalization: The next step is data normalization. This means changing the value range of image RGB channels to the interval of [0, 1]. The last channel, which contains values representing the semantic segmentation, remains unchanged.

C. Convolutional network models used

During the study, an attempt was made to evaluate two convolutional networks, i.e. MobileNet [14], [15] and ResNet50 [16], [17], used as the encoder in the U-Net [18] model to perform semantic segmentation. Some modifications to the U-Net model were also proposed based on experiments carried out on the training set.

1) U-Net model: U-Net is a neural network model whose original purpose was the semantic segmentation of medical images [18]. The U-Net model consists of two paths which make the model diagram resemble the letter "U", namely the contraction and expansion paths representing the encoder and the decoder, respectively. Both paths are shown in Figure 2.

2) Modified U-Net model: A modified network model based on the standard U-Net model with added normalization layers, abbreviated as MU-Net, was proposed for performing the semantic segmentation. The Rectified Linear Unit (ReLU) [21] was used as the activation function. Example network encoder and decoder blocks are shown in Figures 3 and 4. Convolutional layers use 3×3 filters. A 1×1 filter is used for concatenation layers and at the resolution of 256×256 pixels, when transition to pixel classification occurs. During the convolution, there is a descent to feature maps with the size of 8×8 pixels. This network is configured only for performing the semantic segmentation. This is why the appropriate parameters were selected during many trials to train the network and the possible decrease of the accuracy during the classification of the entire image or the detection of individual objects was not taken into account.

Therefore, during many attempts to teach the network on the training set, appropriate parameters were selected

3) MobileNet: The Mobilenet [14] is a convolutional network that can be used on mobile devices. It is characterized by fewer parameters and a shorter training time than other models of convolutional networks. It has a high ratio of accuracy to the parameter number. The MobileNetV2 network [15] is an extension of the Mobilenet network. The authors mention semantic segmentation as one of the applications of this network. The main changes compared to the previous version are the use of the ReLU6 activation function instead of ReLU, and of the so-called bottleneck [22]. According to the authors' calculations, this network is more accurate than the original version, while the number of parameters is significantly reduced.

4) ResNet50: ResNet50 is a network belonging to the group of so-called residual neural networks [16] introduced in 2015, where the 50 in the name represents the number of network layers. They are characterized by the possibility of skipping some layers during the analysis. The ResNet network has a block-skipping mechanism which transfers to the next layer the parameter value processed only by the activation function. Network blocks use the bottleneck method just like in MobileNetV2. The ResNet50V2 network has a small block consisting of a normalization layer followed by a ReLU activation function. Pre-activation, i.e. the use of blocks before fully convolutional layers, speeds up the training of the network and improves its accuracy.

5) Decoders used: A decoding part was added to each neural network used to encode image features so that the numbers of encoder and decoder parameters are similar. In addition, in the case of Mobilenet and ResNet50, the same decoder was used for v1 and v2. Because of the similar number of parameters in the MU-Net and ResNet50 encoders, the MU-Net model uses the same decoder as the ResNet50 model.

Data from Table I shows that regardless of using one decoder for the MobileNet network and another for the remaining networks, every U-Net model has a different number of decoder parameters. This is due to the different number of channels in specific encoder layers. The consequence of this is that concatenation layers that follow these layers and have these layers as input also have a different number of channels, resulting in a different number of parameters.

TABLE I
THE NUMBER OF PARAMETERS IN THE ENCODING AND DECODING PARTS OF NETWORKS BASED ON THE U-NET MODEL.

	Number of parameters		
Network	Encoder	Decoder	Entire U-Net model
MobileNet	3 228 864	2 788 834	6 017 698
MobileNetV2	2 257 984	2 288 610	4 546 594
ResNet50	23 587 712	19 483 426	43 071 138
ResNet50V2	23 564 800	15 698 722	39 263 522
MU-Net	25 163 136	19 554 850	44 717 986

III. EXPERIMENTS COMPLETED AND THEIR RESULTS

The accuracy of segmentation performed with CNNs was measured using the Jaccard index. This is the most widespread method of evaluating semantic segmentation. It allows calculating the similarity of the obtained segmentation to the manually labelled by experts. After the process of training on a set of 2,975 images, the results obtained were evaluated on a set of 500 images 256×256 pixels in size, produced by the random cropping of the original test set. It can be said that all ANNs achieved very similar results, as shown in Table II and in Figure 5.

TABLE II
TABLE SHOWING THE ACCURACY OF THE U-NET MODEL NETWORK USING SPECIFIC ENCODERS. THE RESULTS TURNED OUT TO BE VERY SIMILAR DESPITE VERY LARGE DIFFERENCES IN THE NUMBER OF PARAMETERS.

Encoding network	Jaccard index values
MobileNet	86.19%
MobileNetV2	86.20%
ResNet50	86.23%
ResNet50V2	86.27%
MU-Net	88.85%

It is worth noting that the improvements in the new versions of both MobileNet and ResNet50 led to a slight increase in the Jaccard index values of the semantic segmentation, while the number of parameters was reduced by, respectively: 24.4% and 8.9%. For this reason, only the newer versions of both networks were used in subsequent experiments that checked the accuracy of segmentation using the Jaccard index. It can be concluded that increase of performance is not caused by reducing the number of parameters, it is the result of improving the network architecture. The difference in Jaccard index values between the most and least accurate ANNs amounts to 2.7%.

A. Noise in images

The impact of noise on the accuracy of the segmentations performed was checked for 59 images from the test set from the city of Lindau. Noise was introduced in the images using the Hue, Saturation, Value (HSV) colour space and an additional Holdness parameter. The channel values of Hue vary from 0 to 180, and of Saturation and Value from 0 to 255. The Holdness parameter has values from the interval [1, 8] and is inversely proportional to the hue variation. Table III shows the segmentation results measured with the Jaccard index. Figure 6 shows an example source image before and after noise was added, and Table III shows the segmentation results measured with the Jaccard index. Noise with the values of (Hue, Saturation, Value, Holdness) = (10, 22, 22, 1) was added to all images from the test set from the city of Lindau. Even though the noise had been selected so that it would not hinder humans from recognizing any image elements, ANNs encountered a problem and Jaccard index values fell by about 20%.

TABLE III
DIFFERENCE IN ACCURACY OF U-NET MODELS BEFORE AND AFTER NOISE WAS ADDED TO IMAGES.

Encoding network	Original set	Noisy set
MobileNetV2	75.81%	51.90%
ResNet50V2	74.46%	56.52%
MU-Net	79.36%	59.48%

B. Non-standard lighting – shaded images

The 7 most shaded examples were selected from the test image set to test the impact of low light on segmentation accuracy. The results are presented in Table IV.

TABLE IV
A TABLE SHOWING THE ACCURACY OF THE U-NET NETWORK MODEL CHECKED ON IMAGES WITH POOR LIGHTING CAUSED BY SHADE.

Encoding network	Jaccard index value
MobileNetV2	84.22%
ResNet50V2	83.52%
MU-Net	86.39%

The results show that strong image shading does not hinder obtaining positive segmentation results. The approximately 2% drop in accuracy may be due to other features of the selected images.

C. Class imbalance

Class imbalance is a phenomenon in which the analysed classes are not equally represented. A dominant number of pixels belonging to one or several classes may occur in the

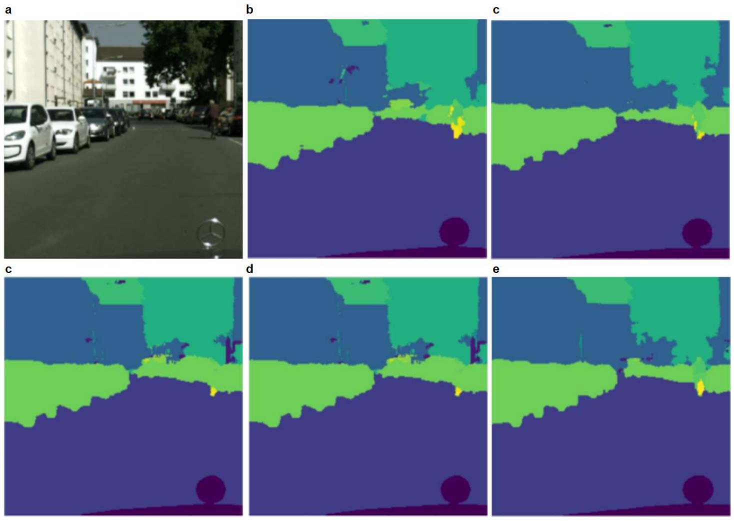

Fig. 5. Example results of a semantic segmentation on a sample image from the test set. (a) Original image (b) MobileNet (c) MobileNetV2 (d) ResNet50 (e) ResNet50V2 (f) MU-Net.

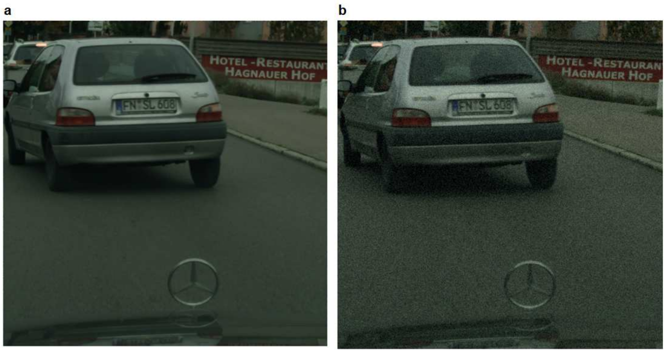

Fig. 6. Example test images from the city of Lindau (a) Original source image (b) Image with added noise with values of (Hue, Saturation, Value, Holdness) =(10, 22, 22, 1).

semantic segmentation. An example is shown in Figure 7, in which the road and vegetation are darker, and bright sunlight penetrates only to a small extent. As a result, two dominant classes are visible, namely the road and vegetation. ANNs frequently do not receive images with strongly dominant classes during training, or receive too few such images to later produce correct results when the classifier is tested. To check the segmentation results, 20 images with strongly dominating classes were selected from the test set, and the results obtained are presented in Table V. The results from Table V demonstrate a certain advantage of the ResNetV2 network in this test. The MobileNetV2 network also achieved a better result than the proposed MU-Net model, which may indicate some overtraining of this network, which produced the worst result this time.

TABLE V
A TABLE SHOWING THE ACCURACY OF THE U-NET MODEL NETWORK USING SPECIFIC ENCODERS, CHECKED ON 20 IMAGES WITH DOMINANT CLASSES.

Encoding network	Jaccard index value
MobileNetV2	76.67%
ResNet50V2	79.36%
MU-Net	74.99%

IV. Conclusions

This paper describes the practical properties of neural network models, namely MobileNet, ResNet, U-Net, and the MU-Net model, used for the semantic segmentation of images from the Cityscapes dataset [13]. The U-Net model is a very interesting approach to the problem of semantic segmentation, which is an extremely difficult area of digital image analysis. However, this model has some accuracy limitations and the constant increase of the number of parameters will not ensure satisfactory results, which is one of the conclusions. During the research, the author was able to propose an MU-Net model, i.e. an ANN dedicated to semantic segmentation, which produced results slightly better than universal networks like MobileNet or ResNet. However, the MobileNetV2 network turned out to be the most interesting and promising ANN used. It has a

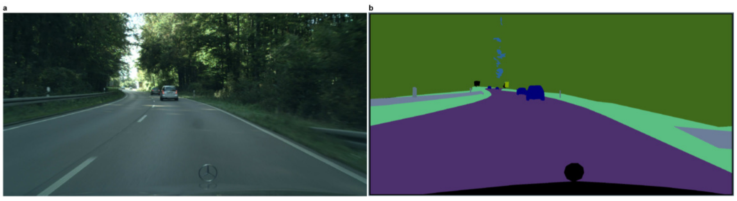

Fig. 7. Example image with semantic segmentation showing non-standard lighting and class imbalance. Most of the image is covered by the road and vegetation, while bright sunlight and moving cars occupy a small fragment of the image. (a) Original image. (b) Semantic segmentation containing mainly two classes.

very good ratio of accuracy to the number of parameters and, at the same time, is less affected by non-standard phenomena in images. Due to the constantly increasing computing power of mobile devices, neural networks designed for analysing images on mobile devices with even better parameters can be expected in the near future. In future research, it is definitely worth investigating improving the accuracy of the semantic segmentation of noisy images and the issue of class imbalance. There are also other interesting directions of research, e.g. performing a semantic segmentation that simulates autonomous vehicle driving using recorded videos, and carrying out a three-dimensional semantic segmentation of urban scenes. It is also worth trying to supplement training sets using various augmentation methods, but keeping in mind the need to prevent learning the wrong patterns.

***Abstract*—[Context and motivation] More and more often software development projects involve participants of diverse nationalities and languages. Thus, software companies tend to use English as their business language. Moreover, to better prepare for future jobs, students consciously choose university courses in English. [Question/problem] As a result there is an increasing number of software engineers who are working or studying in a language which is not their native language. The question arises whether native language has an effect on the quality of natural language requirements. [Principal ideas/results] From the analysis of the requirements formulated by 44 participants of our empirical study, it follows that native language may have a negative effect on requirements quality, e.g., ambiguity, variability, and grammar issues. Furthermore, different native languages might drive to different quality issues. [Contribution] In order to prevent quality issues, our findings might be used by educators to adjust their materials to cater to different language groups, while practitioners might use them to improve their requirements review process.**

I. Introduction

SOFTWARE engineering is a diverse field, both in terms of research areas and worker backgrounds. This diversity is present in the industry, and companies are increasingly using English as their business language, no matter what country they are based in. University students are also globally mobile, with many who have the means often choosing to study all or part of their higher education abroad in English. This means that there is an increasing number of software engineers who are working or studying in a language that is not their native language.

Software engineers often use requirements specifications, either writing or developing systems from them, where the quality of the specification could determine the quality of the end product. The success of a software development project is said to depend on the quality of its requirements specification [1], [2]. Requirements are often written in natural language and, thus, the language used in that requirement could also have an effect on the quality of the specification.

The purpose of this study is to analyze natural language requirements written in English to determine (1) whether a author's native language has an effect on the quality of these requirements, and (2) which qualities are affected. In this paper, the term "native language" is defined as being the language of the country in which a person is born, raised, and receives early years of education. In an agile context, natural language requirements can either be written in the Software Requirements Specification (SRS) style or as user stories.

The findings from this study could support industry practitioners, research, and requirements engineering education. Targeted teaching and training could be developed to improve not only the overall quality of requirements but also to focus on the qualities that native speakers frequently have problems with. The study outcome could also help companies with requirements review processes, and quality checklists definition to identify or avoid requirements issues early on in development.

II. Background and Related Work

The IEEE Recommended Practice for Software Requirements Specifications [3] presents guidelines on how to produce "good" natural language SRS-style requirements. The guidelines detail eight characteristics that individual requirements should possess and five characteristics that a set of requirements should have. The recommended practice states that individual requirements should be: necessary; appropriate; unambiguous; complete; singular; feasible; verifiable; correct; and conforming (when applicable). A set of requirements should be: complete; consistent; feasible; comprehensible; and able to be validated. If an individual requirement or set of requirements violates one or more of these qualities, then it is not considered to be "good".

The INVEST criteria, originally discussed by Wake in 2003 [4], are specifically for evaluating the quality of user stories, rather than SRS-style requirements. According to the criteria, a user story should be: independent, negotiable, valuable, estimable, small, and testable [5]. If the story does not meet one or more of these criteria, then it is not of good quality.

There is a large body of work on requirements quality, with some focusing on specific qualities of a requirements specification and others giving a broader overview of what quality might be. Kiyavitskaya et al. [1] and Fabbrini et al. [6] take a detailed linguistic approach to identify ambiguity in requirements specifications. Antinyan et al. [7] focus on different requirements quality and developed a metric to measure the complexity of a requirement. With a broader look at all of the potential qualities of a requirements specification, Knauss et al. [8] developed a GQM approach to improving requirements quality. Genova et al. [2] also had a wider view of which requirements qualities to consider when creating the framework and tool for improving the quality of a requirements specification. However, while these studies were conducted in English, none of them looked at the linguistic background of the participants.

III. Research Methodology

Research Questions. Our study aims to answer the following research questions:
RQ1: Does the native language have an effect on the quality of natural language requirements?

- RQ1.1: Which requirements qualities are affected?
- RQ1.2: Do any particular languages have greater effects on requirements quality?

Participants and Data Collection. We aimed to find participants who had a software engineering background, and who could potentially be asked to write requirements. The participants were selected on the basis of convenience sampling. Survey participants were reached via the REFSQ 2022 conference, LinkedIn, Facebook, Twitter, Discord, and email, and via sharing the survey link with the students studying software engineering at the Universities the authors work for. Thus, the participants were a mix of students, researchers, and industry practitioners within software engineering. We created an online survey hosted on sosci.de. The survey was piloted by two representatives of the study participants. We decided to ask two students (those who might have the lowest experience with requirements) who gave feedback which was used to refine the survey questions. The first five questions in the survey were demographic questions. The sixth question was a simple domain description after which the participant was asked to write five natural language requirements (either SRS style or user stories) for the example domain. The survey questions and study material are available online [9].

Data Analysis. The qualitative data was analyzed using thematic coding as per Saldana [10] with two coding iterations. The thematic coding process used a coding dictionary that we created, which covered violations of any of a selected subset of the IEEE characteristics of individual requirements [3] or four of the INVEST criteria for user stories [4], [5]. When analyzing SRS-style requirements, we used the 2018 IEEE guidelines [3] that detail what good individual requirements should possess: correct; ambiguous; verifiable; necessary; appropriate; complete; singular; and feasible. The characteristic of "conforming" was not included in the analysis as the participants in the case study were not given a set template or writing style to follow. We chose to exclude the five characteristics for a set of requirements as we only asked participants to provide a sample of requirements rather than a complete requirements specification, and we did the analysis on each individual requirement. We also looked at whether a requirement is vague because we felt that being imprecise might not necessarily mean the requirement is ambiguous or unverifiable – it may just need more details or explanation.

For user story analysis, we used the INVEST criteria [4], [5]. "Independent" was excluded as it would require evaluation of the user stories as a set, while analysis was conducted on individual user stories. We also made note of whether the user story was correctly formed according to the Agile Alliance user story template [5]. As SRS-style requirements and user stories have different purposes and quality criteria, we did not use the SRS-style characteristics to analyze user stories, and the INVEST criteria were not applied to SRS-style requirements. The requirements in this study are in written form, and so we also considered language quality as a contributor to the overall requirements quality. Therefore, we applied codes for typos and grammar issues.

After the first author completed the first analysis pass, a sample of 10 randomly-chosen responses (a total of 50 requirements) was analyzed by the second author. Then, we came together to discuss any differences and how to improve the coding book. Coding was redone by the first author based on these discussions. Tab. I shows three examples of requirements received in the survey and the final codes that were applied. The final coding book with examples is available online [9]. Fig. 1 gives an overview of the thematic codes.

IV. Results

47 people answered the survey. However, three respondents did not complete the requirements writing task sufficiently; therefore, 44 survey responses were considered for the analysis with 220 requirements in total. For simplicity, and to aid comparison, we report percentages over all collected requirements (user stories and SRS-style ones), even though not all errors are applicable to all requirements.

Respondent Demographics. Fig 2 shows the native languages of our respondents. The majority of respondents had Polish as a native language, due to the third author sharing the survey link with the Master students of software engineering specialty. Swedish, Chinese, and English were the next most common native languages of respondents. Although there are many dialects and languages, the participants are known as students of Beijing University of Technology where the language of instruction is Beijing Mandarin.

In terms of roles within software engineering, 22/44 respondents were students of master-level studies who might be treated as novice requirements engineers. Industry practitioners were the next largest group with 8 participants, and there were also 5 Researchers. 9/44 respondents had multiple roles within software engineering: 6 were both a student and an industry practitioner; 2 were both a student and researcher; one person was an industry practitioner and a researcher.

Among the 14 respondents who selected the industry practitioner role as either their only role or as one of their multiple job roles, 4 stated their roles as "Developer" and 3 "Software Developer". There was one answer each for the following roles: "Senior Software Engineer"; "software engineer"; "System Architect"; "Technical project manager";

the 44 participants) given in the online survey, 233 codes were applied. This means that multiple codes were applied to some requirements. The four codes that were applied the most were: unverifiable (25.91% of all codes); ambiguous (21.82%); grammar issue (18.64%); and incorrect format (11.82%). The codes with the fewest applications (but more than 0) were: incorrect (0.45% of codes); unfeasible (also 0.45%); and inappropriate (0.91%).

Looking at Table II, the native Chinese speakers had by far the highest percentage of occurrence of unverifiable codes (46.67%). The native Arabic speakers had the second highest percentage (30%), and the native Polish speakers had the third highest percentage of unverifiable requirements with 28.24%. Native Arabic speakers had the highest percentage of ambiguity occurrences with 50% of the requirements given being coded as ambiguous. The Polish native speakers had the second highest percentage of ambiguous code occurrences with 28.24%.

Observation 2: There are four requirements qualities that were affected the most that are: verifiability, unambiguity, grammar correctness, and correct format.

Observation 3: Native speakers of Polish, Arabic, and Chinese introduced the highest number of errors.

Other Factors. In our survey, we collected data on other factors such as level of education, number of languages spoken, and mother tongue. We found that holding a Bachelor's degree as the highest level of education and speaking four or more languages had a negative effect on requirements quality. This data is omitted for space reasons, but results are available online [9].

V. Discussion

All participants in the study did make requirements quality errors, regardless of their native language. However, being a native speaker of Chinese, Arabic or Polish may have a negative influence on the quality of requirements that are written by those speakers. Two of these three languages have a writing system that is entirely different from English, which uses the Roman alphabet.

Unverifiability was the most common error made by the study participants and is a quality that often concerns Non-Functional Requirements (NFRs). The second most common error was Ambiguity. Althouth, as mentioned in Section II, ambiguity is a widely-researched topic within software engineering [11], [12], [1], [13], [14], the results from the study in the present paper suggest that continuing research and education in this area seems still needed.

The third most common error—grammar issues—could also be considered to be connected to ambiguity in some cases. Introducing grammar-checking tools and proofreading into the requirements writing process might help in preventing these errors. Then, there was the incorrect format error type as the survey participants did not use what is considered to be the standard user story format [5], [4]. Thus, using such frameworks and tools for improving user story quality [15], [16] might be valuable.

Chinese, Arabic and Polish appeared to have a greater negative effect on requirements quality than the rest of the languages in our studies. However, we cannot claim what is the root cause of this observation. It is necessary to investigate whether requirements quality is affected by the native language itself (linguistic differences), the level of English education, education within software engineering, or other factors. Future studies that discover the root causes might deliver guidelines for requirements for engineers and educators.

VI. Threats to Validity

Internal: Thematic coding brings threats to validity due to being subjective in its nature and subject to the bias and experience of the person doing the analysis. In order to mitigate this and minimize the threat, the second author received the coding dictionary that we created and independently coded a sample of 20% of the requirements obtained in the study. The English level of participants was not taken as the variable in the study, but we had an inclusion criterion– the participants need to have enough knowledge and skills so that they are able to either study or work in English.

External: The study may not have a large scope of generalisability as even though the survey was shared with non-students, a large portion of the data collection was reliant on students. However, it could be argued that the results from student data could be indicative of the software engineering industry as they frequently work and might be treated as novice employees.

VII. Conclusion

This study investigates whether native language has an effect on the quality of requirements. The results from the analysis of the online survey data suggest that native language may indeed have an effect on requirements quality as well as on the type of error introduced by the requirements writer. It follows from our study that more work and education need to be carried out on improving verifiability and ambiguity within requirements. Moreover, more training is needed also on how to write user stories so that they are well-formed. Grammar issues were also quite prevalent across all requirements. Our results might be used by practitioners to include quality checks of the errors in their review process and by educators to draw the attention of students to errors they might introduce and teach them how to prevent making those errors. Moreover, researchers might use our results to investigate the root causes of why native speakers of some languages make more errors than native speakers of other languages.

***Abstract*—Federated learning (FL) is a decentralized approach that aims at training a global model with the help of multiple devices, without collecting or revealing individual clients' data. The training of a federated model is conducted in communication rounds. Still, in certain scenarios, numerous communication rounds are impossible to perform. In such cases, a one-shot FL is utilized, where the number of communication rounds is limited to one. In this article, the idea of one-shot FL is enhanced with the usage of adversarial data, exploring and illustrating the possibilities to improve the performance of resulting global models, including scenarios with non-IID data, for image classification datasets: MNIST and CIFAR-10.**

I. Introduction

FEDERATED learning [1] is a popular research field that attracts thousands of researchers due to its simple, yet, open for improvements idea that is inline with current trends in distributed computing infrastructures. The core of federated learning lies in its collaborative nature, which allows multiple devices (clients) to use their own private data to jointly train one global model, managed by the centralized server. In general, the federated learning workflow can be summarized as follows: (1) a global model is initialized (during the first round) or aggregated (for subsequent rounds) on a server and sent to the set of client devices, (2) client devices receive the current version of the global model and use their private data to train the model for a set number of epochs, (3) each client returns resulting updates/weights/whole model back to the server, (4) server receives updates from clients and aggregates them into the new version of the global model. The client-based training round happens multiple times and is referred to as a communication round. At the end of each communication round the updated models are aggregated into the new version of the global model utilizing the federated averaging (FedAvg [1]) algorithm, which averages the updated models' weights. The federated averaging can also be easily combined with a weighting technique, for instance, its first version [1] weighted individual client's update based on the size of the local dataset this client possessed and used during training.

Communication between the centralized server and client devices is a well-known bottleneck for the federated learning pipelines [2], therefore, techniques for improving the convergence time [3], minimizing energy consumption [4] or improving network resource management scheme [5] were studied. One of the ways to mitigate the communication burden between the server and the client is to utilize the concept of few-shot learning.

Few-shot learning [6] is usually referred to as a learning technique where during training a model only sees a small portion of data (for instance, a few examples of each class in a classification task instead of a full dataset) and then is considered ready for performing testing/inference. In the case of federated learning, the few-shot learning idea restricts the number of communication rounds that happen between clients and centralized servers, e.g. one-shot federated learning implies only one communication round [7].

Despite few-shot learning techniques being able to drastically reduce the number of communication rounds needed to train the model, new questions arise, concerning the performance of the resulting models, since machine learning models usually require numerous epochs to reach the best possible accuracy. The problem of few-shot FL is further complicated by the privacy-preserving nature of the FL, which does not allow revealing any information about the local data that clients used during local training. In some cases, the problem of non-IID data can materialize, which can further damage the performance of the resulting global model [8], [9], [10]. Non-IID data can manifest itself in many ways. One of the possible classifications can be described as follows [9]: (1) quantity skew (different sizes of the local datasets that clients possess), (2) attribute skew (local datasets have unique distinct features for the same event/object they are describing, e.g. writing style), (3) label skew (only a subset of labels is present in local data, leaving some labels with no samples), (4) temporal skew (local datasets have time-dependent nature, e.g. were collected in different moments of time), (5) preference skew (same

The work of Anastasiya Danilenka and Karolina Bogacka was supported by the Centre for Priority Research Area Artificial Intelligence and Robotics of Warsaw University of Technology within the Excellence Initiative: Research University (IDUB) programme.

event/object in different local datasets has a different target value due to subjective preference, e.g. ratings). Combinations of the different skews can also be present inside one scenario.

In this article, one-shot federated learning is researched in the context of aggregation of the clients' updated models and the possibility of using adversarial images as a source of client-picking guidance and performance improvement in the presence of label skew non-IID data.

II. Related works

As was stated in section I, the decision to drastically limit the number of communication rounds increases the importance of the aggregation algorithm, which can significantly influence the best possible performance on the test dataset. One of the first approaches to one-shot FL was to utilize ensemble learning, where each updated client model was treated as a part of the ensemble [7]. It was acknowledged, that in FL scenarios, the size of the ensemble of models depends on the number of participating clients, which can reach millions of devices. Moreover, not all clients are equally "useful" in terms of the data they have. Therefore, the ensemble of the models was restricted to a subset of models depending on the selection criteria. For example, models for the ensemble could be chosen randomly, or based on some indicator. One of the possible indicators for best candidates is the local test performance of the model, which requires the model to save a portion of its local data as a test set to measure the performance of the updated global model after local training on the remaining local data. Another similar technique uses a local cross-validation performance as a performance indicator for ensemble model picking.

Distillation technique was also researched with respect to one-shot FL. Data distillation was studied as an alternative to communicating whole models/model updates from clients back to the server [11]. Instead, each client, after receiving the global model used it to distill its own local data and sent the resulting set of distilled data and targets back to the server. Although communicating clients' data even in a distilled form that cannot be directly interpreted by the human eyes may be considered a violation of the clients' privacy, the authors state, that acquiring distilled data will not let the adversary replicate the resulting global model. After receiving the resulting datasets from all clients, the server uses them to train its own global model. Some enhancements were also presented in the process of data distillation, for instance, soft labels. Another distillation technique is proposed to treat clients' models as teachers and use them for training a student model on the server side. For instance, client devices can use their data to train conditional variational autoencoder (CVAE [12]). Moreover, the ensemble of these decoders is further distilled on the server into one decoder that can further be used as a data generator for training a global model on the server side [13].

The presented approaches to one-shot FL are capable of reaching a good final accuracy while preserving the benefits of the reduced number of communication rounds. Nevertheless, they may still require training additional models (e.g. encoders) or be prone to suffering from non-IID data (cross-validation ensembles). Therefore, a new way of performing one-shot FL can be of interest. This article presents an algorithm that can acknowledge the presence of label skew non-IID data and mitigate its effect on the final model, without requesting any additional data from the clients or imposing any additional computation on the client devices by using adversarial data.

III. Adversarial attack

Neural networks are susceptible to various kinds of adversarial attacks [14]. The attacks aim at misleading the trained models into incorrect predictions, by altering the perfectly correct source data sample in a way that is unrecognizable by the human eye. This changed source sample is referred to as an adversarial sample.

There are several methods for generating adversarial samples. The method that the adversary prefers can depend on how much information about the source model the adversary has. The attack methods that require full access to the target model gradients are called 'white-box" attacks, while attacks that can operate on a limited set of information from the source model, e.g. the predictions from the target model, are called "black-box" attacks. Among the most popular attack methods, one can name: the fast gradient sign method (FGSM) [15], its iterative version I-FGSM [16], momentum-enhanced MI-FGSM [17], Carlini and Wagner (C&W) [18] attacks, and more.

Moreover, with respect to image classifiers, attacks can also be divided into two categories based on the precise intention of the attack. The attack which aims solely to mislead the trained model into misclassifying an image into any class that is not the right one is called a non-target adversarial attack, while the attack that aims at making the classifier make a mistake by predicting a certain class, set by the adversary, is called a targeted attack.

One of the fascinating properties of the adversarial samples is their transferability [19] – adversarial samples generated for one target model can also mislead models which were trained to solve similar tasks. In other words, models with similar architectures that were trained on non-intersecting subsets of the dataset will most likely be successfully attacked by the same adversarial sample. The reason behind this phenomenon is that models that have similar tasks tend to come up with similar decision boundaries. This behavior can be valuable in terms of federated learning scenarios, where clients with similar datasets are training a set of individual models with respect to the same task objective.

To sum up, during the targeted adversarial attack, the adversary creates an adversarial sample by modifying the source sample based on the selected attack method (e.g. by using gradient-based algorithms like FGSM-family methods). These changes applied to the source sample force it to cross the decision boundary estimated by the target model [20], resulting in misclassification.

IV. Proposed approach

As discussed in section II, one of the possible approaches to one-shot FL is an estimation of the most successful client models and using them for making an ensemble of models instead of combining all clients' models into one global model version. The proposed approach described in this paper uses the knowledge retrieved from the adversarial samples to find the most promising clients to be included in the ensemble of models. A more complex algorithm based on the idea of adversarial data was described in a previous article [21] and is referred to as AdFL (Adversarial FL). Although the AdFL algorithm implies training in epochs, in this article the algorithm is adapted to a one-shot FL scenario and further extended to be used in an ensemble of models. The description of the algorithm is given in Algorithm 1.

Algorithm 1 Server-side of proposed one-shot FL, where n – positive size of the model ensemble, w_0 – initialized global model

```
Ensure: $\mathrm{w}_0$; clients are ready;
Require: n > 0;
for client in Clients do
    $\mathrm{w}_0^{client}$ ← run training on client($\mathrm{w}_0$)
end for
adv data ← create adversarial data($\mathrm{w}^{[0,...,Clients]}$)
$\mathrm{CS}^{[0,...,Clients]}$ ← calculate CS(adv data, $\mathrm{w}_0^{[0,...,Clients]}$])
$\mathrm{w}_0^{[0,...,Clients]}$ ← sort desc($\mathrm{w}_0^{[0,...,Clients]}$, $\mathrm{CS}^{[0,...,Clients]}$)
model ensemble ← $\mathrm{w}_0^{[0,...,n-1]}$
```

1) The server initializes the global model and sends it to all clients, participating in training.
2) Clients perform local training with the whole data they possess for the specified number of epochs.
3) Clients send the resulting updated models back to the server.
4) After collecting all updated models, the server uses them to generate $C \times N$ adversarial samples, where C – is the number of classes in the classification task and N – is the number of updated models returned from the clients as described in section IV-A.
5) Based on the generated adversarial samples, for each updated client model, a *coherence score* (*CS*) is calculated as described in section IV-B.
6) *CS* is further used as a performance indicator to identify the top-performing models and use them as an ensemble.

A. Adversarial samples generation

In order to identify clients that can potentially be useful for the ensemble, the proposed algorithm exploits the transferability property of adversarial samples that was described in section III. Still, per definition, adversarial samples are created on the basis of existing samples drawn from the source data. This condition is generally unacceptable for strictly privacy-preserving FL. Therefore, considering the absence of the source data on the server side where the creation of the adversarial samples happens, a random noise image is considered the starting point for adversarial sample generation.

The targeted MI-FGSM method is used in this article to generate adversarial samples [17]. The algorithm can be summarised in a few steps as described in formulas listing (1), where t is the current iteration of the method, x states for the input noise image, y – target class, to which the resulting image should eventually be attributed, g_t – accumulated gradients through previous t iterations, θ – source model (in case of presented algorithm, one of the updated clients' models), and J – loss function (e.g. cross-entropy).

$$g_{t+1} = \mu * g_t + \frac{\nabla_x J(\theta, x_t^*, y))}{||\nabla_x J(\theta, x_t^*, y))||_1} \quad (1)$$

$$x_{t+1}^* = x_t^* + \alpha * sign(g_{t+1}) \quad (2)$$

The algorithm is parameterized by a number of parameters, namely, μ – decay factor, α – step size. Moreover, the resulting x_{t+1}^* image is further clipped at the end of each iteration in the clipping range e. The parameters used in this paper are different from those presented in the referenced paper, due to the different intentions for the resulting adversarial samples. Initially, adversarial samples are created to perform an attack on trained classifiers during inference time, but in the case of the one-shot FL algorithm described in this paper, the target is the transferability measure of the samples. Therefore, the constraints on the amount of the changes applied to the source image were loosened to allow more gradient information to be added to the adversarial sample. For instance, the number of MI-FGSM iterations was increased to 30, and step size α was increased to 1.

B. Coherence score

After local training, clients return the resulting updated models back to the server, where each model is used to generate one adversarial sample per class in the classification task. These samples are further used to estimate their transferability across all models. The idea behind this action is to find models that can generate transferable samples and are susceptible to samples, generated by other models. This two-side transferability might come from the similar decision boundaries that were learned during the local training step as noted in section III. Therefore, it can be assumed that such models learned somehow in a similar way.

The two-sided transferability measure is called a coherence score (CS) and is calculated out of two separate measures, each of which summarizes either the ability to create or the ability to identify adversarial samples.

The ability of a certain model to produce adversarial samples that are being recognized by other models participating in training is measured according to equation (3), where k stands for the model that was predicting adversarial samples generated by the source model, c stands for a target class that the adversarial sample was made to represent. The measure is calculated across all models from the training set with respect to the adversarial data, generated by the source model for which the measure is computed. The predictions of this source model for its own data are omitted.

$$\text{was predicted} = \sum_{k=1}^{K} \sum_{c=0}^{C-1} \text{is correct}_{k,c} \cdot \text{returned prob.}_{k,c} \quad (3)$$

This equation uses a binary feature to identify if the prediction of the adversarial sample was correct or not. This binary flag is then multiplied by the confidence of the prediction. Therefore, no punishment is done due to the wrong prediction and less certain predictions will accumulate less significance.

The ability of the model to correctly predict classes of adversarial data generated by other models is measured according to equation (4), where k stands for the model that generated the adversarial data and c stands for the target class of the adversarial sample.

$$\text{predicted others} = \sum_{k=1}^{K} \sum_{c=0}^{C-1} \text{is correct}_{k,c} \times \\ \times \text{returned prob.}_{k,c} \quad (4)$$

Again, the results of the model predicting its own adversarial data are omitted.

The resulting coherence score is a simple summation of the two previously described measures (equation (5)).

$$\text{coherence score} = \text{predicted others} + \text{was predicted} \quad (5)$$

Each of the models returned by the clients, participating in training, acquires its own coherence score and the list of models can then be easily sorted based on the resulting measure. The models that scored higher in CS are treated as those that provide more value to the model ensemble and are picked first. On the other hand, the coherence score can also be used for weighted federated averaging to create one global model instead of an ensemble.

V. Experimental section

To illustrate the efficiency of the presented adversarial-based method in one-shot federated scenarios, a series of experiments were performed on two datasets for image classification tasks: MNIST and CIFAR-10.

The results of the presented approach are compared to three algorithms: classic federated learning (FedAvg), and two ensembles – an ensemble of random models and a cross-validation ensemble.

In all experiments, only 10% of models were included in the ensemble, making the number of models per ensemble equal to 5. For cross-validation, during the local training part, 5 validation folds were performed, with train/validation data division being 80/20 respectively. The validation performance during cross-validation was collected. After that, the model was trained once again with the whole local data and sent back to the server together with validation metrics.

A. Data partition

Each of the experiments featured 50 federated clients that had approximately 400 images from the training dataset as their local data. The local datasets were created in a non-intersecting manner. Moreover, all classes inside the local dataset had the same number of instances (locally balanced dataset). The local training round consisted of 15 epochs, with the optimizer set to Adam, with starting learning rate of 0.001. For the test performance estimation, test sets provided by the datasets were used.

As was mentioned in section I, non-IID data can create additional challenges to federated pipelines. Therefore, during the experiments, both IID and non-IID data partition scenarios were examined. In the case of IID data, all classes were equally presented in the local datasets of clients. The label-skewed non-IID data partition was emulated by constructing each client's local dataset only from the limited number of classes. In both MNIST and CIFAR-10 experiments, the number of unique classes presented in the local dataset was limited to 4. So, before starting the FL pipeline, each client's class set was constructed individually by sampling 4 classes from the set of all classes. For each class, a probability of its occurrence in the local dataset is drawn from a normal distribution. The example of probability distribution used for CIFAR-10 experiments is showed in Figure 1.

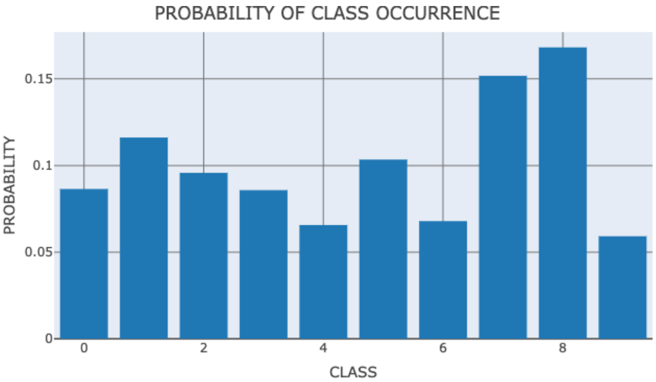

Fig. 1. Class occurrence probability for CIFAR-10 label skew experiments

Due to the custom distribution of the probabilities of class occurrence, some classes were less represented globally across client devices, while others – more.

B. Model configuration

For the MNIST classification task, a simple LeNet5 [22] configuration was used for all the experiments. As for the CIFAR-10, a custom configuration of a Convolution Neural Network was implemented, featuring 6 convolution layers, each pair followed by a maximum pooling layer, at the end followed by three dense layers.

C. Results

All experiments were performed at least 15 times to better capture the statistical significance of the results. As the training process consists only of one epoch, the final performance of the models was summarised across multiple runs. For the MNIST dataset and IID data partition, the result is showed in Figure 2.

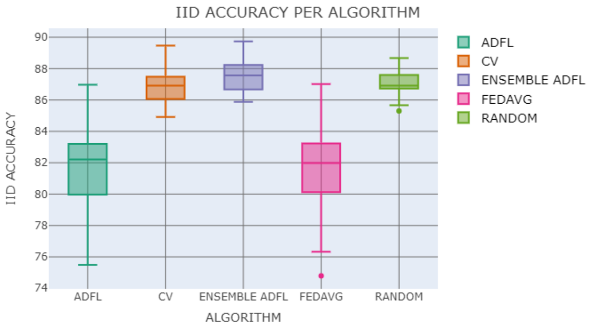

Fig. 2. Test accuracy comparison for IID MNIST experiment

It is seen, that, in general, all algorithms managed to get more than 80% of accuracy, while centralized models on the MNIST dataset reach up to 98% of accuracy. Still, some algorithms scored higher than others: ensembles of models performed better than aggregated global models – with median accuracy for AdFL, cross-validation and random ensembles being 87.6%, 86.9%, and 86.9% respectively, while aggregated FedAvg and AdFL achieved 82% and 82.2%, respectively.

In contrast, the non-IID scenario shows a different behavior, as showed in Figure 3 in addition to a way smaller resulting accuracy across all algorithms.

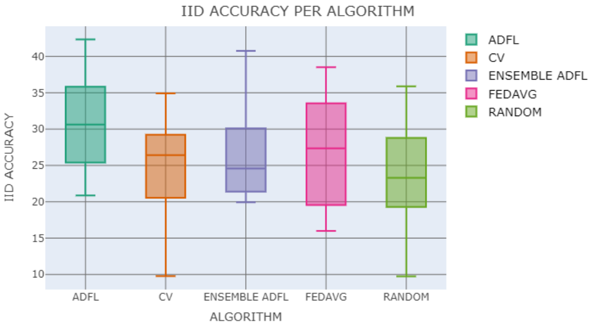

Fig. 3. Test accuracy comparison for non-IID MNIST experiment

Here, aggregated versions of the models perform better than the ensembles, with AdFL and FedAvg reaching 30.6% and 27.4%, and AdFL, cross-validation, and random ensembles reaching 24.6%, 26.4%, 23.3%, respectively.

This difference in behavior on varying datasets depending on either presence or absence of non-IIDness, may come from the fact that individual model evaluation cannot spot the non-IID clients. Therefore, it is not guaranteed that models which were exposed to heterogeneous data during training will appear in the ensemble.

To identify if this behavior can be replicated, the same experiment was performed on the CIFAR-10 dataset. The results for the IID data partition are showed in Figure 4.

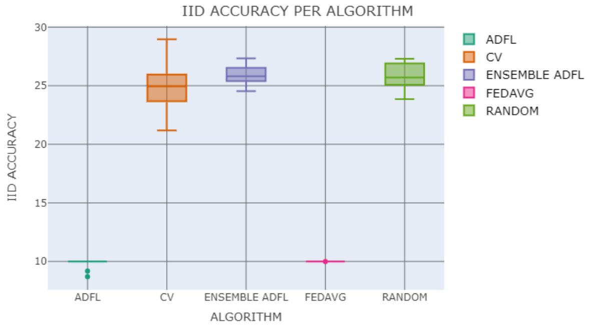

Fig. 4. Test accuracy comparison for IID CIFAR-10 experiment

In this case, again, ensemble versions perform better than aggregated models in the presence of IID data. AdFL, cross-validation, and random ensembles reached 25.8%, 24.9%, and 25.6%, respectively, while aggregated versions could not manage to achieve any meaningful results in the provided scenarios.

However, when examining the results for the CIFAR-10 non-IID scenario (Figure 5), the results differ from those observed on the MNIST dataset with non-IID data.

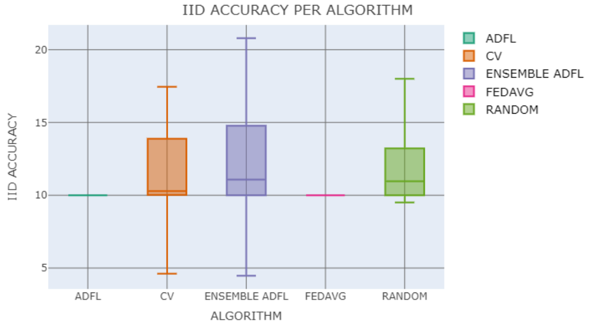

Fig. 5. Test accuracy comparison for non-IID CIFAR-10 experiment

In the CIFAR-10 non-IID scenario, contrary to MNIST, aggregated models (AdFL and FedAvg) still could not get any meaningful performance, while ensemble methods showed low, but, somehow diverse across experiments, accuracy with AdFL, cross-validation, and random ensembles achieving 11.1%, 10.3%, and 10.9% median accuracy, respectively. Although median accuracy is low, maximum accuracy for AdFL, cross-validation and random ensemble reached 20.8%, 17.5%, and 18%. This low performance may be a sign that the proposed task was overly complex and, therefore, may need more experiments with bigger local datasets or require some knowledge transfer techniques.

VI. Conclusion

In this work, a new approach to building a model ensemble for one-shot federated learning was introduced and compared with other ensembling techniques for both IID and non-IID scenarios. It was observed, that, for the MNIST dataset, in the presence of IID data, presented ensembling techniques achieve better performance than the aggregated models, but for non-IID data the situation is opposite. For the CIFAR-10 dataset, the studied non-IID scenario presented a complicated scenario and did not replicate the results of the MNIST dataset. Still, the described technique utilizing adversarial data shows similar or better performance when compared to other algorithms with respect to test accuracy for both MNIST and CIFAR-10 image classification tasks. Further research may inspect other non-IID data scenarios, use more sophisticated model architectures and datasets, and improve the ensemble construction technique.

***Abstract*—Federated learning (FL) allows multiple devices to jointly train a global model without sharing local data. One of its problems is dealing with unbalanced data. Hence, a novel technique, designed to deal with label-skewed non-IID data, using adversarial inputs is proposed. Application of the proposed algorithm results in faster, and more stable, global model performance at the beginning of the training. It also delivers better final accuracy and decreases the discrepancy between the performance of individual classes. Experimental results, obtained for MNIST, EMNIST, and CIFAR-10 datasets, are reported and analyzed.**

I. Introduction

FEDERATED learning (FL) was introduced in [1]. It aims at creating a shared model, combining information from multiple sources, without sharing local data. In standard FL, training proceeds in rounds. Here: (1) global model is initialized, (2) current version of the global model is sent to selected clients, (3) they complete training, using their local data, (4) model updates are gathered on the server and used to generate a new version of the global model [1]. In this work, complete models are communicated (in (2) and (4)).

How to aggregate updates is a subject of intensive research. The basic approach is to average updates (using the FedAvg algorithm). A natural extension to FedAvg is weighting, i.e. assigning individual importance to each client, based on additional knowledge. For example, clients with more local data receive larger weights for their updates [1].

In FL, the complete dataset is never "known". Hence, the statistical properties of local and global datasets are unknown. Therefore, it cannot be established if data is identically independently distributed (IID). However, it has been established that non-IID datasets negatively affect the quality of the FL-trained model [2]. Non-IID data can be classified on the basis of the source of heterogeneity [2], i.e.: (1) data quantity skew (local datasets differ in size), (2) label distribution skew (different devices have different subsets of labels inside local dataset), (3) attribute skew (local data has unique characteristic features, noise, perturbations, etc.), (4) temporal skew (local data distributions differ over time, or data was collected in different time periods). Obviously, combinations of skews can materialize. This work concentrates on non-IID datasets with the label distribution skew. Depending on how many labels are represented in the local dataset, the skew can be extreme, with only 1 label in each dataset, to a $(C-1)$-label skew, where C is the number of labels in the set. Here, each local dataset lacks data for exactly one label. In research experiments, the data partition strategy determines, which label(s) is(are) missing.

In this context, a novel method, to overcome the problems caused by the label distribution skew, called *Adversarial Federated Learning* (AdFL), is proposed. It is inspired by adversarial attacks and is applicable, primarily, to neural networks applied to image data. To the best of our knowledge, it is the first attempt to recover local data distribution information, from the clients, using adversarial inputs and to use adversarial images to coordinate the training process.

In what follows, in Section II, related research is outlined. Section III, introduces adversarial attacks followed, in Section IV, with the description of the AdFL algorithm. Section V, presents the experimental setup and results, obtained with MNIST [3], EMNIST [4] and CIFAR-10 [5]. Conclusions and directions for future research complete this work.

II. Related work

When the problem of data heterogeneity was acknowledged, the quantity skew was mitigated by weighting the updates, based on the number of data samples in local datasets. In other approaches, to deal with the problem of non-IID data, FedProx [6] and SCAFFOLD [7], tackled the problem by restricting local model updates using proxy terms and control variates. Moreover, use of gradient correction [8], utilization of knowledge distillation [9], applied client picking [10], data sharing [11] and adapted loss functions in presence of data imbalance [12] have been explored.

While many methods reported improvements on standard datasets (MNIST, CIFAR-10, CIFAR-100), still, (i) some required additional information from clients (e.g. distribution information, averaged data), (ii) others rely on external datasets (representative of the local data), or (iii) involve training of additional, data generator, models. This may not be feasible in the real world or may introduce new privacy risks. Hence, the proposal is articulated in what follows.

III. Adversarial federated learning

In FL, in the past, adversarial techniques were used to generate data (a) to improve resistance to adversarial attacks [13], or (b) to increase the amount of locally available data [14].

Here, a different way of integrating adversarial data into FL is proposed.

A. Adversarial attack

Adversarial attacks make it possible to alter a sample from the training data, in a way that is undetectable to humans, so that the network will misclassify such (previously classified) sample [15]. In other words, when the attack is performed on a trained model then, by modifying the target sample, the adversary tries to make a valid target sample cross the decision boundary of the classifier [16], and be misclassified.

Depending on the applied changes, one can distinguish *non-targeted* and *targeted* attacks. A non-target attack aims at making the model deliver incorrect predictions. Targeted attacks set the class, to which the misclassification should be attributed. Separately, *white-box* attacks can access the model's architecture and parameters, while *black-box* can access only the model's output. Among the most famous attacks are: one-step Fast Gradient Sign Method (FGSM) [17], its iterative version I-FGSM [18], and its version enhanced with momentum MI-FGSM [19].

B. Transferability of adversarial inputs

An important property of adversarial inputs is their transferability, i.e. adversarial inputs generated for one model will mislead also other model(s) trained on similar datasets, to solve similar tasks. Note that in FL clients share the same task, model architecture, and data space. Hence, adversarial samples, generated by all clients, should be transferrable. To establish this, a series of experiments, to measure the attack success rate (ASR) – a common metric for qualifying the performance for adversarial attacks [19] – was performed. In these experiments, and in what follows, MI-FGSM was used to create targeted adversarial attacks [19]. Overall, data was IID distributed among 40 clients (all clients had samples of all classes in local datasets). During each server-side epoch, 10 clients were selected, according to the strategy described in Section IV, and performed local training. Next, clients' models (returned to the server) were used to generate one adversarial sample per class (see, Section IV-A). Hence, $10{*}C$ adversarial images were generated, where C is the number of classes. Next, updated clients' models classified the adversarial samples, and if the predicted class was equal to the target, the attack was qualified as successful. Table I shows the transferability metric for standard datasets (MNIST, EMNIST, and CIFAR-10) during the 5th, 25th, and 50th epochs.

TABLE I
ATTACK SUCCESS RATE (ASR) STUDY INSIDE A FEDERATED SCENARIO

	Epochs		
Dataset	5	25	50
MNIST	1	1	1
EMNIST	0.98	1	1
CIFAR-10	0.5	0.99	1

As can be seen, ASR is high, therefore, due to the high transferability of adversarial data and its connection with the decision boundaries, it is possible to derive insights about the local data, by asking clients' models to produce adversarial images, while "keeping private information private". This observation became the foundation of the AdFL algorithm.

IV. AdFL ALGORITHM

The AdFL algorithm uses adversarial images as a source of additional knowledge about FL training. To do so, the adversarial data is generated first. Here, there are two places where adversarial images can be generated. (1) Clients can produce them, as they have access to all necessary data. (2) Server can use the updated models to generate them. In AdFL, adversarial data is generated on the server, using a random noise image as a starting point. The server-side part of the AdFL algorithm is summarized in Algorithm 1.

Algorithm 1 AdFL algorithm (Server); Cl states for client; Cl_e – subset of clients picked for training on epoch e; *global distribution* tracks distribution of classes during FL training; $distr_{all}$ – estimated classes presence in clients' local datasets

```
Ensure: global model $w_0$, global distribution, clients ready
  for $e$ in $epochs$ do
    if $e == 0$ then
      $Cl_e \leftarrow$ all clients
    else
      $Cl_e$, global distribution $\leftarrow$ pick clients($distr_{all}$, global distribution)
    end if
    for $Cl$ in $Cl_e$ do
      $w_e^{Cl} \leftarrow$ run training($w_e$)
    end for
    adv data $\leftarrow$ create adversarial data([$w_e^0$, ..., $w_e^{Cl_e}$])
    if $e == 0$ then
      $distr_{all} \leftarrow$ estimate distribution(adv data)
    end if
    $CS_{[0-Cl_e]} \leftarrow$ calculate coherence(adv data, $w_e^{[0,..,Cl_e]}$)
    $w_e \leftarrow$ FedAvg([$w_e^{[0,..,Cl_e]}$], $CS_{[0-Cl_e]}$)
  end for
```

Overall, there are 6 steps that define the AdFL algorithm. Note that all AdFL-specific steps take part on the server, with no additional Client-side computations.

1) During "warm-up", round **all** clients perform local training, and return models to the server. In subsequent rounds, local training is completed by a subset of clients on the received version of the global model.
2) On the server, updated clients' models generate adversarial samples, as described in Section IV-A
3) Generated adversarial samples are used to estimate the distribution of classes across clients (see, Section IV-B).
4) Coherence scores (CS) are calculated, based on updated models and adversarial samples (see, Section IV-D).
5) CS are used as weights during aggregation, resulting in the next global model, sent to the clients.

6) From there on, the subset of clients that participate in the training is defined by the client-picking strategy (Section IV-C) and the process repeats.

A. Adversarial inputs creation

To create adversarial data, the data-free approach has been selected, to protect clients' data. Hence, the initial data source is a random noise image that, by default, is not classifiable. Starting from this image, a targeted adversarial attack is performed, using the MI-FGSM. Here, the adversarial image creation lacks malicious intent, becoming less sensitive to the amount of allowed changes. Hence, the MI-FGSM parameters have been aligned with the pursued goal. Overall, each updated client model generates C images representing classes that are present in the task. The steps of adversarial input generation are presented in Algorithm 2, with the default federated steps omitted.

Algorithm 2 Adversarial data generation

```
Ensure: $targets \leftarrow [0, ..., C-1]$
Ensure: $w_e^{[0,..,Cl_e]}$ {Clients' updated models during epoch $e$}
  for $target$ in $targets$ do
    for $w_e^i$ in $w_e^{[0,..,Cl_e]}$ do
      $adv\ img \leftarrow$ rand noise[$Ch$, $H$, $W$]{Random sample}
      for $step$ in $num\ steps$ do
        $adv\ img^i_{target} \leftarrow$ step($w_e^i$, $adv\ img^i_{target}$, $target$)
      end for
    end for
  end for
```

B. Local distribution estimation

Based on generated adversarial data, it is possible to estimate the class distribution among the clients. Here, it was established that predictions of adversarial samples, returned by the clients' updated models, are illustrative of the presence of certain classes in the local dataset (of this client). Therefore, uncovering class presence within clients' data can be used for balancing the label-skew. It is also the reason why adversarial sample generation runs for a set number of steps (30). If the target class is missing from the client's local dataset, the model will fail to generate an adversarial sample of that class. Moreover, using this knowledge, AdFL performs a warm-up epoch, by initiating training on all clients. This allows capturing a meta-level picture of class presence across clients, gathering the data needed for the client-picking routine that will occur in each training round.

After the updated models return to the server, adversarial data generation occurs, and the results of all models' predictions are used to estimate class distributions. Here, all updated models generate adversarial samples and predict the resulting samples. Next, for each model, its predictions are summarised and classes that appeared in the predictions are treated as signs of these classes being present in the client's dataset.

A set of experiments was performed to establish how precise the estimation of classes' presence in local datasets is. The experiments were performed for two extreme cases: IID setup (all classes are present), and $\leq$20% of classes setup, i.e. two classes per client for MNIST and CIFAR-10 datasets, and 12 classes for the EMNIST dataset. The effectiveness was measured as the percent of classes detected from the adversarial data in total, across all clients during the warm-up FL training round, against the average number of classes detected per client. The results are listed in Table II.

TABLE II
DETECTED CLASSES (DC) METRICS FROM ADVERSARIAL DATA

	MNIST		CIFAR-10		EMNIST	
Metric	IID	2	IID	2	IID	12
DC (%)	100	100	100	100	100	97.1
Avg. DC	10	2	10	2	62	11.4

Although the experiments show that class detection can be performed quite accurately, it remains only an estimation of the actual classes' presence. Moreover, the quality of the adversarial samples depends on the number of local training epochs. Thus, tuning this parameter is important for obtaining a proper class distribution prediction. Hence, for the reported experiments, the number of local epochs is set to 10 for MNIST and EMNIST and 2 for CIFAR-10.

C. Client-picking strategy

After predicting classes that are present in the local datasets, a client-picking strategy that will mitigate the presence of local label-skew can be proposed. Based on the estimation of classes' presence in local datasets obtained during the "warm-up" round, a simple approach to balance the training process was designed. Specifically, the balance of classes during the training process is maintained by the global label frequency vector of size C, where C is the number of unique classes in the classification task. This vector is updated in each FL training epoch after a client is selected to be involved in the current training epoch. It reflects the frequency of a particular class being picked for training. To ensure equal exposure for all classes, the clients for each FL round are selected to make the values in C close to a uniform distribution. Here, a Kullback–Leibler (KL) divergence is used (for details, see [20]). This allows each FL round to include clients with rare classes in their data, by computing the KL-divergence of the global classes frequency, with respect to the uniform distribution, if a client (its data classes) is to be added to the training round. In each round, clients with the smallest KL divergence are picked. Here, note that several clients may have the same KL divergence (possibly, a minimum for the current set of clients). In this case, random client selection is applied.

D. Clients coherence measurement

Another outcome of the transferability of adversarial samples is an ability to identify "problematic clients", i.e. clients, whose models are not able to produce or identify transferable adversarial samples. In order to measure the "two-side transferability", the coherence score (CS) measure was defined.

CS calculation can be described as follows: (1) at the end of the training round, all updated models create adversarial samples for each target class, (2) each updated model predicts all adversarial samples produced by models participating in the round, (3) for each updated model the CS consists of two parts: (i) describing how good this model recognized adversarial samples from other models, and (ii) how successfully other models recognized this models samples. Therefore, models with high CS excel in both creating transferable samples and correctly classifying those created by others.

Here, the ability of the updated model to predict adversarial images produced by other models is measured according to Equation 1, where each multiplication consists of a binary flag indicating whether or not the prediction for class c generated by model k was correct, and the probability returned by the model. Predicting own inputs is omitted.

$$\text{predicted others} = \sum_{k=1}^{K} \sum_{c=0}^{C-1} \text{is correct}_{k,c} * \text{returned prob.}_{k,c} \tag{1}$$

A similar measure was applied to evaluate the ability, of the updated model, to produce adversarial images that are recognized by the other models. The individual CS is a result of a simple summation of the two scores. After the coherence scores, for all clients, are calculated, they are normalized and used as weights for the FedAvg aggregation.

V. Experimental setup, results, and their analysis

A. Data partitioning

During experiments, label-skew was simulated using three parameters: (1) number of unique classes in dataset, (2) total number of data samples in dataset, and (3) probability of class appearing in data. The number of unique classes inside the local dataset is fixed for an experiment, and all clients have the same number of unique classes. However, the set of local labels differs between clients. Total number of samples is also fixed, and all clients have the same amount of data. Moreover, local data is equally divided among classes, e.g. for 2 classes, 50% of data will be of class 1, and 50% of class 2. The probability of all classes appearing in a local dataset is defined, by drawing a sample from the normal distribution for each of the classes. Next, the resulting values are normalized to represent the probability vector. To determine the classes of a specific client, a random subset of the set size is drawn. Since the normal distribution was used, borderline cases may materialize, when few classes have a high probability of appearing. Therefore, they will be overrepresented, while a few other classes may be left out, because of their extremely low probability of occurrence. Here, random seeds were used to ensure robustness. An example of the probability of occurrence for 10 classes is presented in Figure 1.

Note that this data partitioning scheme introduces a challenging label-skew scenario, as it allows some classes to be "common" in the clients' population, while others are rare, therefore, producing a global class imbalance.

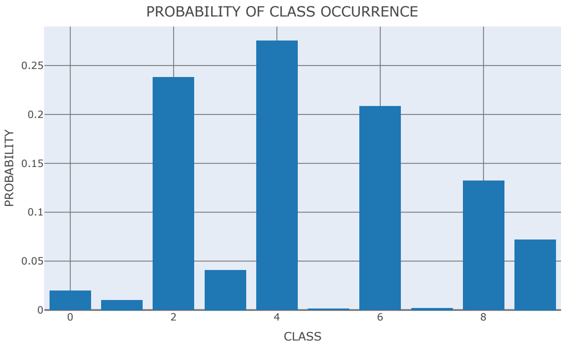

Fig. 1. Probability of occurrence for 10 classes

B. Models and hyperparameters

In the experiments, Convolutional Neural Networks (CNN) were used. For MNIST and EMNIST, a LeNet-5 architecture was used [21]. For CIFAR-10, the pre-trained version of the mobilenetv2 [22] model was used, provided by the torchvision package, with weights coming from Imagenet dataset [23]. The pre-trained version of the mobilenetv2 model was chosen to verify the applicability of the algorithm to more complex datasets and architectures that are not trained from scratch. If not stated otherwise, the cross-entropy loss function was used. The Stochastic Gradient Descent (SGD) was used as the optimizer. Model and algorithm-specific hyperparameters are presented in Table III.

TABLE III
Hyperparameters used in the experiments

Parameter	MNIST	EMNIST	CIFAR-10
Num. classes per client	2	12	2
Total classes	10	62	10
Clients per training round	10	10	10
Total clients	40	40	40
Data samples per client	400	1200	400
Learning rate	0.001	0.001	0.001
Batch size	10	10	10
Num fed epochs	10	10	2
FedProx μ	0.1	0.1	0.1
FedMix M	400	1200	400
FedMix λ	0.2	0.2	0.05
Num of adv. steps	30	30	30

C. Experimental setup

The performance of AdFL was tested on three datasets: MNIST, EMNIST, and CIFAR-10. The project, including both AdFL and other algorithms, was implemented in Python (3.7.9), using PyTorch (1.10.0). Moreover, for ready model architectures and datasets, torchvision (0.11.1) was used.

D. Experimental results and their analysis

AdFL performance is compared to FedAvg, FedProx, and FedMix algorithms (Section II). The parameters for FedProx and FedMix were as in [11]. The experiments were performed 10 times for MNIST and 6 times for EMNIST and CIFAR-10, with different random seeds, while preserving data partition. For MNIST, the resulting median test accuracy, over a set of experiments, is presented in Figure 2.

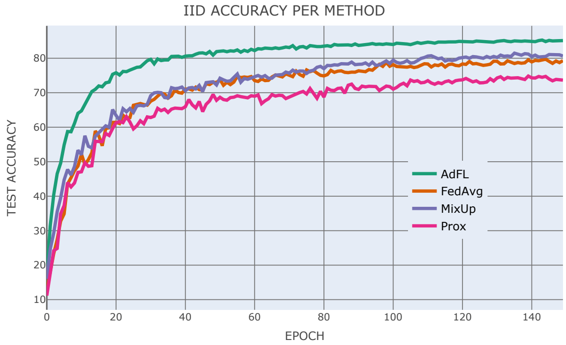

Fig. 2. Test accuracy for MNIST

AdFL improves model performance at the beginning of the training, and ensures stable performance, with slight accuracy improvement, later. This can be valuable in the case of the limitation of client-server communication rounds. The minimum accuracy improvement is about 3.3%.

For EMNIST, the median test accuracy of different algorithms is presented in Figure 3. Again, AdFL is more stable at the beginning and shows gradual improvement without significant peaks. It also results in test accuracy improvement of around 2% (compared to FedAvg).

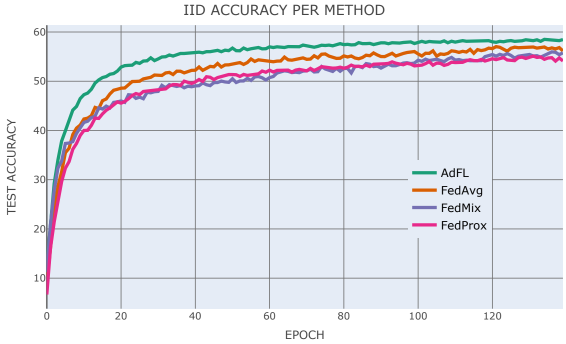

Fig. 3. Test accuracy for EMNIST

Note that, with a very challenging label-skew scenario, the performance of the models depends directly on the probabilities of class occurrence and how they are distributed among clients. Here, an additional set of 7 EMNIST experiments was performed, where the random seeds were changed each time before generating probabilities of classes occurrence and classes distribution, while preserving other parameters listed in Table III. The EMNIST dataset was chosen for testing, as it has 62 classes (as opposed to 10 classes in the remaining datasets). The average accuracy improvement and the Wilcoxon signed-rank test [24] results are presented in Table IV. As can be seen, the accuracy improvement remains for varying data partitions, with respect to FedAvg, FedProx, and FedMix algorithms.

TABLE IV
AdFL PERFORMANCE STUDY ON VARYING EMNIST DATA PARTITIONS

	FedAvg	FedProx	FedMix
Acc. impr.	1.70%	3.87%	1.88%
Std	1.11	1.61	2.91
p-value	0.0469	0.0156	0.0313

For CIFAR-10, the median accuracy is shown in Figure 4. It can be seen that, compared to previous datasets, training was less stable and the results show accuracy fluctuations even for a median of results. Still, on average, AdFL shows better accuracy from the very start of the training, resulting in a final accuracy improvement of around 2%.

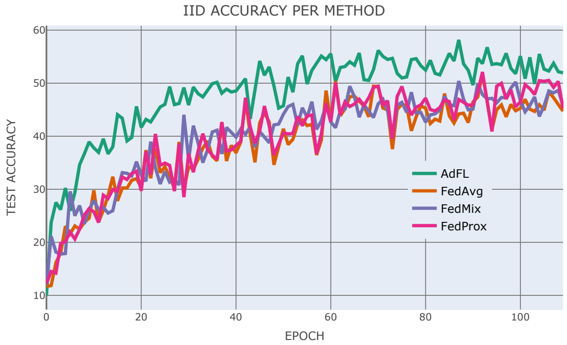

Fig. 4. Test accuracy for CIFAR-10

The summary of all experiments is presented in Table V together with the standard deviation of the final accuracy. The statistical accuracy improvement, related to AdFL, was measured with the Wilcoxon signed-rank test, on results presented in Table V and is depicted in Table VI.

TABLE V
EXPERIMENTS SUMMARY

	MNIST		CIFAR-10		EMNIST	
	ACC	STD	ACC	STD	ACC	STD
AdFL	56.44	0.51	51.77	2.36	56.67	0.41
FedAvg	53.71	1.75	47.70	2.53	53.39	1.38
FedProx	52.28	1.39	48.42	3.21	51.99	1.09
FedMix	51.03	1.53	49.13	2.30	50.81	1.47

TABLE VI
WILCOXON SIGNED-RANK TEST P-VALUE

	MNIST	EMNIST	CIFAR-10
FedAvg	0.0039	0.0313	0.0313
FedProx	0.0039	0.0313	0.0313
FedMix	0.0039	0.0313	0.0313

The results of the Wilcoxon signed-rank test show that the difference in accuracy achieved by AdFL is statistically significant. To better encapsulate the unstable performance on the CIFAR-10, the median over the last 10 epochs was taken as the final accuracy. AdFL improves the accuracy of the global model and, moreover, reduces the gap in performance between individual classes, despite their uneven distribution across local datasets. It can be measured as a standard deviation between accuracy among all classes (see, Table VII).

TABLE VII
TEST ACCURACY DEVIATION AMONG INDIVIDUAL CLASSES PER METHOD

Dataset	FedAvg	FedProx	FedMix	AdFL
MNIST	0.095	0.179	0.112	**0.025**
EMNIST	0.34	0.33	0.39	**0.26**
CIFAR-10	0.35	0.34	0.37	**0.23**

For all datasets, the standard deviation within the classes is significantly lower for the AdFL algorithm, therefore, illustrating the benefits of balanced training. Finally, the Wilcoxon signed-rank test was applied and it was found that the obtained results are statistically significant.

VI. CONCLUDING REMARKS

In this work, it was shown that utilizing adversarial data on the server side, during FL training, can reveal data distribution information. Use of this information results in more balanced performance in all classes, in the case of label-skewed data. Future research can concentrate on (1) exploring properties of adversarial samples, and (2) applicability of AdFL to more complex datasets, models, and label-skew scenarios. Improvements can also be made to the client-picking strategy and the adversarial data generation process. Additional research can also explore AdFL's potential to battle other non-IID scenarios, e.g., by locating clients with corrupted data.

***Abstract*—Internet of Things solutions typically involve interaction between sensors, actuators, the cloud, embedded systems and user applications. Often in such cases, there are time constraints specifying the maximum response time to a request. This time depends on the calculation time and transmission time. Existing Internet communication solutions do not ensure the implementation of transmissions in a way that guarantees meeting the set time constraints. This paper proposes a new model of Internet communication dedicated to real-time Internet of Things systems, which includes a communication protocol, as well as a transmission scheduling and routing method. The protocol takes into account information about transmission time constraints, which is used for packet scheduling by routers, allowing to increase quality of service. In addition, the proposed static routing mechanism makes it possible to parallelize transmissions if time constraints are still exceeded. Also presented are preliminary results of experiments showing to what extent the proposed methods allow improving the quality of service in real-time Internet of Things systems.**

***Index Terms*— real time routing, tasks scheduling, IoT, communication protocols.**

I. Introduction

The rapid development of the Internet of things (IoT) concept has led to a very large increase in interest in these solutions in almost all areas of our lives [1-3]. In the age of accelerating solutions in this area, there is a steadily increasing demand for IoT systems that, using various communication technologies, will also meet real-time requirements [4]. An important challenge of this research direction is to ensure that time requirements can be met optimally. The need to design real-time IoT (RTIoT) systems was recognized more than 10 years ago [5], when the first technologies and standards to support these solutions began to emerge (e.g.: Time Coordinated Computing (TCC) [6, 7], or the IEEE 802.1 standard – Time Sensitive Network (TSN) [8]). Usually, however, the solutions known today do not guarantee a satisfactory level of Quality of Service (QoS), which in most cases is crucial for the correct operation of the designed system. Therefore, it is necessary to undertake research work to develop methods and technologies to build IoT applications that meet real-time requirements. The first stage of this work was the development of the RTIoT system design methodology by the authors [9].

The key elements of the aforementioned methodology are to propose efficient scheduling and routing methods dedicated directly to RTIoT systems. The primary task of implementing such solutions will be to obtain better QoS performance values relative to standard scheduling methods, especially routing. In this case, the QoS value should be calculated for the worst case, i.e. for conditions that determine the maximum expected load on the system.

Thus, the research problem can be formulated as follows: given is a set of *N* endpoint devices and computing nodes of an IoT network that can send and/or receive transmitted data. The individual devices are interconnected using the network infrastructure that includes, among other things, va.rious communication links of a certain bandwidth and active devices, including routers. Given are also *M* different types of transmission between endpoint devices. In addition, there are strict time requirements associated with selected transmissions. Thus, it is necessary to find a solution for organizing the transmission in order to achieve the best QoS parameters (such as the average QoS of all real-time transmissions), that is, to minimize the average violation of time constraints. For this purpose, transmission scheduling algorithms (determining the order in which data is transmitted) as well as routing algorithms (optimizing routing for individual transmissions) can be used. This work assumes that the above problem will be optimized using static routing. This will ensure the predictability of the developed solutions, enabling the design of RTIoT systems based on small and medium-sized networks, such as a metropolitan area network.

The subsequent part of the article is organized as follows. Section II analyses the current state of the art of communication protocols currently used in IoT systems. Section III describes the assumptions that define the specification of the proposed system and the QoS optimization assumptions. Section IV proposes a transmission scheduling algorithm and an algorithm for selecting optimal routes. Section V contains the results of the experiments conducted, while Section VI presents conclusions and directions for further research.

II. Related work

In real-time IoT systems, the use of appropriate types of transmission media and the implementation of proper communication protocols, with particular emphasis on routing methods, plays an important role. Known communication protocols that are worth considering when designing RTIoT solutions include: RTSP (Real Time Streaming Protocol) [10], WebRTC (Web Real Time Communication), XMPP (Extensible Messaging and Presence Protocol) [11], MQTT (Message Queue Telemetry Transport) [12], CoAP (Constrained Application Protocol) [13], WebSocket [14], 6LoWPAN (IPv6 over Low-Power Wireless Personal Area Networks) [15].

The most well-known routing protocols used in IoT systems include:

- RPL (Routing Protocol for Low Power and Lossy Network – LLNs). LLNs are devices characterized by low power consumption, memory, and reduced resource engagement for processes. This protocol belongs to the family of distance vector protocols, which has been designed to work on multiple links [16].
- CTP (Collection Tree Protocol), which is a distance vector routing protocol and was developed for packet routing in WSNs (Wireless Sensor Networks). This protocol assumes the construction of a network topology tree taking into account routes for potential data packets [17].
- LOADng (Lightweight On-Demand Ad hoc Distance Vector Routing Protocol – next generation), is a lighter version of the AODV (Ad hoc On-Demand Distance Vector) protocol for LLNs. It was designed on the premise that LLNs are unoccupied for most of their time. This protocol follows an approach in which routes are determined in the direction of the packet's destination only when there is data to be sent [18].
- CORPL (Cognitive Radio RPL routing protocol), which is based on the RPL routing protocol and, with the modifications made, enables its use in Cognitive Radio environments [19].
- CARP (Channel-Aware Routing Protocol) – a protocol that uses a multi-hop approach to deliver data packets for WSNs. CARP has the advantage of taking link quality into account in the node selection process for next-hop [20].
- E-CARP (Enhanced CARP) – it is characterized by energy efficiency in the process of transmitting packets from the transmitter to the destination. In addition, this protocol does not differentiate the priority of attributes [21].

When it comes to designing real-time IoT networks, it is important to consider the issues of routing protocols and aim to achieve the best QoS transmission parameters. Based on their ability to deliver packets at specific/set deadline values, these protocols can be divided into two major groups: hard real-time and soft real-time [22]. Real-time routing protocols include:

- QoSR (Quality-of-Service Routing) – its greatest asset is its low energy consumption in determining the path for delivering data packets from source to destination. Unfortunately, the protocol exhibits poor support for scalable networks [23].
- QoSAM (QoS Aware Multi-Hop) – similarly to the QoSR protocol, it solves the problem of excessive energy consumption in determining the path for a packet from source to destination. Unfortunately, this protocol has much room for improvement in terms of reliability [24].
- MIMO (Multiple Inputs and Multiple Output) – a protocol that is dedicated to widely scaled WSNs. The implementation of this routing protocol offers the benefits of better energy utilization, lower transmission delays, packet loss and better bandwidth utilization of the transmission link [25].
- PRTR (Potential-based Real-Time Routing) – similarly to the MIMO routing protocol, it is characterized by scalability and a reduced probability of packet loss during transmission – resulting in the protocol requiring additional power, energy [26].
- QEMPAR (QoS and Energy Aware Multi-Path Routing Algorithm) – increases the lifetime of the network, unfortunately at the cost of increased delays [27].
- PT (Pheromone Termite) – features very good packet transmission performance by using a termite-based approach for routing. The protocol specifically focuses on finding the shortest route while maintaining QoS requirements. The PT protocol provides two new properties: pheromone sensitivity, which helps determine the link throughput, and packet generation rate, which helps update nodes in relation to the number of generated packets. One of the disadvantages of this protocol is that it is dedicated to large-scale networks [28].

A lack of an approach that takes into account proper packet scheduling (using appropriate scheduling methods) with deadline values, which can translate into improved QoS performance values, can be noticed in all of the above-mentioned communication protocols.

III. Assumptions

IoT systems usually have predefined functions, i.e. they can be specified in the form of a set of communicating tasks. In most cases, it is possible to estimate task execution times (e.g. for the worst case) and transmission volumes. Thus, for RTIoT systems, a design methodology analogous to that used for distributed embedded systems can be proposed [29].

According to our RTIoT system design methodology, the system specification is represented by a set of annotated task graphs (ATGs) [30]. Each ATG can be activated at a certain maximum frequency. The maximum number of instances of a given graph is also given. Designing an RTIoT system involves mapping the specifications to a target architecture consisting of 4 layers (Fig. 1): the Sensor Layer (SL), the Edge Layer (EL), the Cloud Layer (CL) and the User Layer (UL)

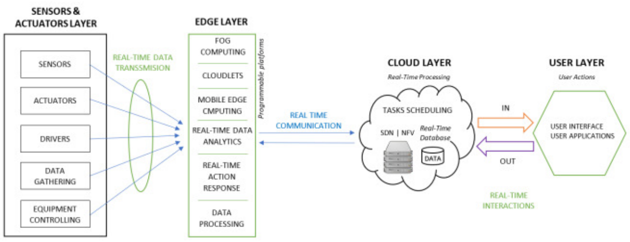

Fig. 1. General architecture of a real-time IoT system

A. System specification

A task graph is a directed acyclic graph $G=\{V,E\}$ in which nodes $v_i \in V$ represent tasks and edges $e_{i,j} \in E$ describe relationships between tasks, usually related to communication. The attributes of the graph describe the assignment of tasks to the layers of the RTIoT architecture and transmission volumes between tasks. Sample annotated task graph is shown in Fig. 2. Attributes that define layers are represented by colours. Attributes describing transmissions are represented by edge labels. From the perspective of network communication, only the transmissions between layers are relevant.

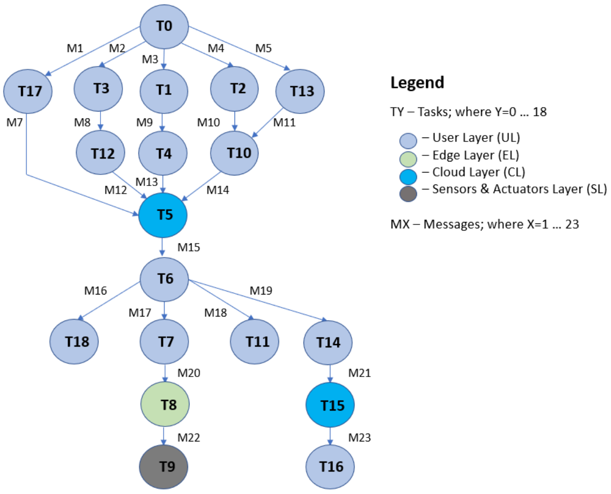

Fig. 2. Sample annotated task graph

Graph given in Fig. 2 describes the main function of a smart city system for managing parking spaces [9]. The user activated task graph specifies the following system functionalities: searching for the parking space closest to the user's current location, the function of finding the user's car in the parking lot based on their license plate number, the function of reserving any free parking space based on the entered search criteria, the function of charging a parking fee for the used parking lot, and the function of retrieving information on weather conditions.

In the example presented in Fig. 2, one task graph activation can cause the following transmissions: M7, M12, M13, M14, M15, M20, M21, M22, M23, where successive numbers indicate individual transmission types. Multiple instances of a given task graph can be activated at any given time, caused by the occurrence of multiple simultaneous events activating given function. For example, multiple users can run an application that sends requests to an IoT system. Thus, there may be a large number of simultaneous transmissions causing a significant load on communication links, leading to the violation of the time constraints.

B. QoS optimisation

A d_{max} time constraint can be associated with any v_i task. This constraint determines the time in which the task should be completed. Soft real-time systems are considered in the paper. In such systems, two types of restrictions are defined: d^h_{max} and d^s_{max}, The d^s_{max} constraint can be exceeded but then the quality of service (QoS) is lower. The d^h_{max} constraint specifies the maximum time that can no longer be exceeded. Violation of the d^h_{max} constraint means packet lost.

The goal of optimizing RTIoT systems is to achieve the highest possible QoS. QoS for a single constraint can be defined as:

$$QoS_i = \begin{cases} 0 \text{ when } t_i > d^h_{max} \\ 1 \text{ when } t_i < d^s_{max} \\ 1 - \frac{t_i - d^s_{max}}{d^h_{max} - d^s_{max}} \textit{ in other cases} \end{cases} \tag{1}$$

where: t_i – is the current finish time of task covered by the i-th constraint.

Then the total QoS for the system can be determined as the average value of all QoS_i:

$$QoS = \sum_{i=0}^{n} \frac{QoS_i}{n} \tag{2}$$

where: n – is the number of all constraints in all instances of task graphs.

If for task v_i constraints d^h_{max} and d^s_{max} are specified then time constraints for all transmissions represented by edges $e_{x,i}$ entering node v_i can also be specified as follows:

$$\text{ex}d^h_{max} = d^h_{max} \text{ - } te_i \tag{3}$$

$$\text{ex}d^s_{max} = d^s_{max} \text{- } te_i \tag{4}$$

where: te_i – is the expected execution time of task v_i, usually determined by WCET (Worst Case Execution Time) estimation.

Time constraints for all transmissions can be determined in an analogous way. Thus, the goal of transmission optimization will be to organize the transmission of messages in such a way that each transmission ends before $\text{ex}d^s_{max}$ or exceeds this time as little as possible while not exceeding $\text{ex}d^h_{max}$. This can be achieved by appropriate transmissions scheduling and/or the use of routing that minimizes collisions of simultaneous transmissions.

IV. Real-time Routing

Existing methods of Internet communication are mainly based on ensuring the most efficient transmission. They do not take into account time constraints or the issue of predictability of transmission time. For these reasons, these methods are not suitable for RTIoT systems.

In order to take into account time constraints, the routing method should use transmission scheduling mechanisms in such a way as to minimize delays and not use overly time-consuming route determination algorithms.

A. Transmission scheduling

It is assumed that individual packets contain information identifying real-time transmissions. Real-time transmissions are processed in the first step, in the order determined by the scheduling algorithm. The remaining transmissions are processed in FIFO order when the list of real-time transmissions is empty. The real-time transmission scheduling algorithm is based on the Least Laxity First (LLF) algorithm [31], which provides optimal task scheduling in real-time systems. Associated with each such packet is information specifying the deadline exd^{s}_{max} and the expected transmission time tt_i estimated based on the length of transmission and the average bandwidth of communication links. Draft scheduling algorithm is shown in Fig. 3.

```
Schedule ($e_i$, RTList){
if RTList[0]=Φ
    TList[0]=$e_i$
else {
    pos=0;
    while RTlist[pos]!= Φ
        if (Laxity(Tlist[pos])<Laxity($e_i$)) pos++;
        else {
            Insert($e_i$, RTList, pos);
            break;
        }
 }
return RTList;
}
```

Fig. 3. Draft transmission scheduling algorithm

The *Laxity(e$_i$)* function computes the transmission time reserve as follows:

$$L_i=exd^{s}_{max}-tt_i \tag{5}$$

The *Insert(ei, RTList, pos)* function inserts the transmission e_i into the *RTList* at the *pos* position. Thus, the scheduling algorithm creates a list of transmissions ordered from the smallest value of L_i.

B. Choice of routes

The choice of transmission routes for transmitting individual packets affects both transmission time and collision-related delays. Thus, the main goals of optimization should be to find the shortest routes and avoid collisions for simultaneous transmissions. Collisions cannot be avoided for transmissions using the same transceivers or receivers.

In the case of real-time systems, it is crucial to implement the transmission such that the violation of time constraints is eliminated or minimized. In addition, the real-time system should be predictable, only then can adequate QoS be guaranteed under a set system load. Predictability can only be achieved with static routing. Then, assuming that the network topology is fixed and the network load is known, the assumed minimum QoS level will be guaranteed. We also assume that all non-colliding paths between given nodes may be found using existing methods e.g. as in the NoC systems [30].

The problem of optimizing real-time transmission for a given network topology can be defined as the problem of allocating communication routes for worst-case scenarios. Suppose that at any given time, m transmissions of data M_1, ..., M_m need to be made between S_i and D_i nodes. Then, if after scheduling the transmissions according to the algorithm from Fig. 3, the transmission delay, for any transmission, resulting the position in the list will cause the deadline to be exceeded, it means that it is necessary to send packets through different routes in order to parallelize the transmissions. Otherwise, all packets can be sent via a single route.

The algorithm for allocating transmissions to routes is shown in Fig. 4. The input to the algorithm is a list of non-colliding *PList* routes and an ordered list of *RTList* transmissions. The algorithm then sequentially schedules transmissions for the next paths in a loop. Transmissions allocated to routes are removed from the *RTList*. The *Time* counter adds up the times of consecutive transmissions allocated to a given path. If the allocation of the next transmission to a particular path results in exceeding the deadline for that transmission then the transmission remains in the list and the algorithm will try to allocate it to the next path in the next loop run. The algorithm returns the number of routes required to complete all transmissions, or an ERROR value if it fails to ensure that all transmissions complete within the required time. In that case, either the network topology needs to be modified to create more routes, or the remaining ones need to be allocated with a minimal violation of the time constraint in order to achieve the lowest QoS drop.

```
AssignPath(Plist, RTList) {
   PathNo=0;
   do {
        Path=Plist[PathNo];
        Time=0;
        For (Pos=0; Length(RTList); Pos++)
          if (Laxity[RTList[Pos]-Time >=0) {
             Assign(RTList[Pos], Path);
             Time+=RTList[Pos].tt;
             Remove(RTList[Pos]);
          }
         if (RTList==Φ) return PathNo;
        PathNo++;
     }
    while PList[PathNo]<>Φ;
     return ERROR;
}
```

Fig. 4. Draft route assignment algorithm

When transmissions involve different destination nodes, routes and ordered *RTLists* should be determined for each node and the algorithm shown in Fig. 4 should be performed independently for each pair of lists *(RTList*, *PList*).

V. Experimental results

The work performed included four experiments. Each of them was performed with given initial conditions such as: equal bandwidth of transmission links; no other type of data packets in the network; 100 different packet transmissions were assumed in the same period, with transmission time for a single packet not exceeding 50ms. Soft deadline (ranging from 1000ms to 5000ms) and hard deadline (ranging from

2000ms to 7000ms) values were also set randomly. The experiments may correspond to any transmission from Fig. 2, between 2 layers (e.g. M20), assuming simultaneous activation of this transmission by 100 users.

The first experiment was conducted for a network in which communication over a single transmission link is assumed. Packet handling by a router with an implemented static routing mechanism is done according to a random packet queue. With this type of approach, it is observed that QoS requirements are not met for a lot of transmitted packets. For 40% of all transmissions the QoS were lower than 1 and 13% of transmissions failed i.e. the hard deadlines were not fulfilled.

The second experiment is an extension of the first approach, which was extended to include the implementation of the LLF-based packet scheduling algorithm (described in Section IV.A of this paper). The results of this experiment clearly show the benefits of using packet scheduling. With appropriate transmission scheduling using the LLF-based algorithm, transmission quality improvement is achieved by obtaining better QoS parameter values with respect to the original values. Only 9% of transmissions exceeded the soft deadline. Thus, this approach is closer to meeting the conditions for real-time transmission.

The third experiment assumed the existence of two independent routes through which packets can be sent using routing mechanisms. In addition, for the purposes of the experiment, it was assumed that the distribution of packets between the previously mentioned routes is even, i.e. half of the previously assumed 100 packets are routed through one link and the remainder through the other link. The results of this experiment showed that, despite the existence of a second, alternative communication link, not all individual transmissions were able to achieve satisfactory QoS results – not all packets (only 87%) were delivered while maintaining the QoS parameter at the level specified by the soft deadline.

The last experiment is an extension of the approach tested in the third experiment. In this case, as in the second experiment, the LLF algorithm that schedules data packets was used. The results of this experiment showed that the existence of two routes in combination with the implementation of a packet data scheduling algorithm allows for the best results in terms of QoS parameters. In this case, all individual transmissions achieved the highest value of the QoS parameter equal to 1. Table I presents a summary of the results obtained for all four experiments conducted. The first column (PAR) defines the parameter name. The following rows contains values of: Average transmission time (ATT), soft deadlines (SD), hard deadlines (HD), number of messages (NM), the number of transmissions that exceeded the soft deadline (NM<SD), the number of transmissions that exceeded the hard deadline (NM<HD), Quality of Service (QoS) obtained for each experiment.

Fig. 5-8 illustrate the dependence of subsequent data transmissions on QoS parameters. Transmissions that did not meet any QoS requirements in the experiments were marked in red, transmissions that only met the requirements of the soft deadline were marked in blue, and those that met all requirements were marked in green.

Analysing the results of the research, it can be seen that for the first experiment, 27 different transmissions did not meet the requirements of the soft deadline, while 13 did not meet the requirements of the hard deadline. In the second and third experiments 9 and 12 different transmissions, respectively, did not meet the requirements of the soft deadline. In the last experiment, all QoS requirements for all types of transmissions were met.

TABLE I. SUMMARY OF EKSPERIMENTAL RESULTS

PAR	Random Singe route	LLF Singe route	Random Double route	LLF Double route
ATT	3434ms			
SD	1000ms, 3000ms, 5000ms			
HD	2000ms, 5000ms, 7000ms			
NM	100			
NM < SD	27	9	13	0
NM < HD	13	0	0	0
QoS	**0,81**	**0,97**	**0,95**	**1**

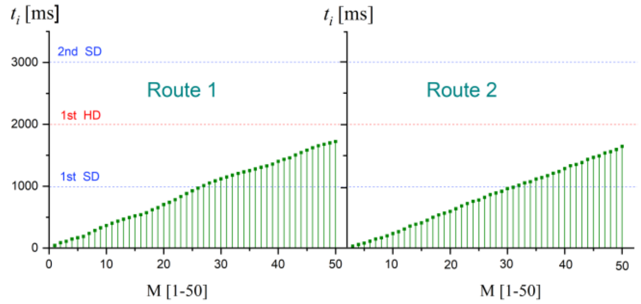

Fig. 8. Dependence of QoS parameters on subsequent data transmissions for fourth experiment a) first route, b) second route

VI. CONCLUSIONS

The article presents the model of Internet communication, dedicated directly to the needs of IoT systems, where real-time requirements are particularly important. The proposed solution is based on data transmission scheduling algorithms and the use of routing methods. The model takes into account information about time constraints at both the soft deadline level and the hard deadline level. Both proper data scheduling and routing mechanisms improve QoS parameters in the system under consideration, as demonstrated by the experiments presented in the paper.

The experiments, conclusions and observations that follow indicate the justification of the approach in which both packet data scheduling methods and appropriate routing methods are applied in RTIoT networks. Based on the simulations and calculations, it should also be noted that the number of routes used for packet transmission also plays an important role in improving QoS parameters for both individual data transmissions and the entire designed system.

The future work on the presented topic will focus on further improvements and extensions to the discussed model. In particular, we will address the implementation capabilities of dynamic routing protocols, as well as other known scheduling methods. The result will be a complete RTIoT system design and implementation environment, ensuring the development of systems with a high level of QoS.

***Abstract*—Code refactoring is supported by many Integrated Development Environments. This paper is focused on the automated code refactoring of C# programs. We have analyzed more than sixty refactorings available in three popular IDEs. We cataloged different restrictions, defects, and other quality concerns associated with the implementation of the refactorings, taking into account both modification of the production code and of the corresponding test cases. An extension to automate selected refactoring improvements has been developed for the ReSharper platform and experimentally verified.**

***Index Terms*—code refactoring, unit testing, code quality, code and test maintenance, C#.**

I. Introduction

REFACTORING techniques have been proposed to improve code quality [1][2]. Their effective application can be assisted with automated tools incorporated into Integrated Development Environments (IDEs). We have examined automated refactoring that can be used in programs written in the C# programming language. We have reviewed three environments commonly used for C# program development, namely: Microsoft Visual Studio, JetBrains Rider, and Visual Studio Code. The following research questions were addressed:

1. Can we rely on automated refactoring, i.e. is the final code always correct?
2. Are the unit tests corresponding to the refactored area adjusted together with the refactoring completed?
3. Can we, in an automated way and transparently to a developer, fix malfunctions detected in refactoring or add any improvements?

To perform the study, a benchmark program was developed covering code variants consistent with these environments. We have found that some refactorings can be correctly applied only under certain restrictions, while others can produce invalid code. Moreover, the test cases related to the refactored area could be improved.

The main contributions of the paper are the following:

- A review of over 60 automated refactorings of C# programs supported by three popular environments.
- Identification and classification of different restrictions, extensions, defects, and quality concerns associated with the refactoring implementation.
- As a proof of concept, development of Refix, a prototype that fixes defects of selected refactorings of the ReSharper tool-(used in JetBrains Rider 2022 and also as a plugin applied to the Microsoft Visual Studio [3]).

The paper is structured as follows: In the next Section we discuss the related studies. In Section 3, we give an overview of the refactoring consequences for code and tests in three popular environments. A developed tool (Refix) is briefly presented in Section 4. In Section 5, we conclude the paper.

II. Related Work

There exist many tools that help in automated refactoring in software development and maintenance. Though, their usage still causes difficulties for developers, as reported in [4].

Deficiencies in the refactoring tools were mainly studied for Java and C programs. Testing of refactoring engines [5] found 1.4% of refactoring tasks failing for Java and 7.5% for C. In [6], the problems of name binding and accessibility rules in refactoring are discussed. Some problems could be similar, but there are no studies of C#.

Another problem of refactoring implementation is its impact on the test cases [7]. Many experiments related to the test maintenance of refactored programs were performed in Java [8], [9], [10]. In [8], it was shown that tests often require additional handling when the production code is refactored. To handle this, a prototype developed in Eclipse was discussed in [9]. In [10], refactoring of Java programs with JUnit tests was examined. Various flaws in updating tests were identified. RefactorPlugin was developed to correct selected defects in tests and create additional tests in accordance with the refactoring performed.

Refactoring in C# programs was studied as one of the aspects to explore similarities and differences between test and production classes [11]. It was found that while production classes underwent more changes, the maintenance of tests caused major problems. In the thesis [12], an extension to Visual Studio was developed, but the author focused on a new kind of refactoring, not on fixing the existing ones. To the best of our knowledge, improvements in the C# code and tests after refactoring were not considered.

The impact of using the ReSharper tool on the results of test runs, builds, and version control commands was examined in [13]. Experiments on Enriched Event Stream Dataset led to a higher rate of failure builds and higher percentage of commits. ReSharper was also studied in some research and was claimed to be popular among developers [14].

III. Review of Refactoring

In the refactoring review, we have checked whether an automated refactoring provides a valid transformation of the code and whether the corresponding unit tests are correctly modified. We focused on three different IDEs that support refactoring of C# programs:

1) Refactoring embedded in Microsoft Visual Studio 2022, i.e. MVS without additional extensions.

2) JetBrains Rider 2022, and the same refactoring engine used in the ReSharper plugin applied to MVS [3][15].

3) Visual Studio Code with an addition to support the C# language (ms-dotnettools.csharp).

A. Benchmark for Refactoring Review

Analysis of the effects of refactoring was assisted by a benchmark program [16]. We have developed it to cover a set of refactoring examples and the corresponding unit tests. The production code was developed in three versions related to IDEs mentioned above.

The benchmark also encompasses three variants of a set of unit tests corresponding to the popular unit test frameworks that support C#: MSTest, NUnit, and xUnit.net.

B. Comparison of the Refactoring Capabilities

We have reviewed the way of implementation of all refactorings that were supported in the mentioned environments. As a result, we made recommendations on many refactorings. They were classified into the following four categories:

1. **Extension (E):** the refactoring implementation is extended in comparison to its basic meaning [1].
2. **Restriction (R)**: the implementation of the refactoring is restricted compared to its basic meaning.
3. **Defect (D)**: a fault was detected in the refactoring implementation that should be fixed, as it causes the project not to compile. This situation is often associated with a “conflict”, i.e. a warning reported by an IDE after an attempt of a refactoring.
4. **Quality concern (Q)**: a shortcoming occurs that does not cause a compilation error or another improvement to the code and tests could be suggested.

In Tables I and II, we summarize all refactorings implemented in three environments. The last three columns correspond to Microsoft Visual Studio - MVS, JetBrains Rider (also ReSharper) – R/R, and Visual Studio Code – VSC, accordingly. The sign ‘-’ denotes that the refactoring is not supported in the environment. If the refactoring was implemented, the character ‘+’ shows that no recommendations were related to it. Otherwise, a combination of letters (E, R, D or Q) signifies the recommendation categories associated with the refactoring. The assigned recommendations are discussed in the subsequent subsections.

C. Review of Refactoring in Visual Studio

Here, we deal with the refactorings embedded directly in MVS 2022. Those supported by the Resharper extension, often applied to MVS, are discussed in the next subsection.

Restrictions (R):

- In #43 and #44. The move method and move field refactoring is limited to static members.

Defects (D):

- In #2. In synchronization of a namespace and a folder name, the `using` directive in tests could be not updated. The situation was rare and this defect can be treated as a minor one.
- In #14. In the conversion between a property and `get` method, the refactoring does not consider references to the transformed property present in the object initialization. In this case, a warning is shown.
- In #43 and #44. It refers to moving a field or a method. A static class can be indicated as an `internal` one. Therefore, its members are not accessible in the test project. One of the popular conventions is the application of an attribute to make these internal types accessible and structural testing possible. Hence, the improvement of this defect is of low priority.

Quality improvements (Q):

- In #39 and #40. When a method or a field is pulled up to the base class, other descendant classes could be checked in terms of these member occurrences.
- In #39, #40, and #54. While a method or a field is pulled up, or when a superclass is extracted, we could consider using the base class where possible. The refactoring can be followed by another refactoring #38.

D. Review of Refactoring in ReSharper

Among the solutions discussed, the ReSharper engine, used in JetBrains Rider and as an extension in MVS, provides the largest number (64) of automated refactorings. Below, we list the recommendations passed on to these refactorings.

Extensions (E):

- In #31. The change of signature refactoring can be applied not only to a method but also properties, indexers and constructors. Moreover, two alternative forms of the transformation are available: *change signature* and *transform parameters*.

Restrictions (R):

- In #8. The refactoring to make a member static can be completed only if the method takes an instance as a parameter.

TABLE II.
COMPARISON OF AUTOMATED REFACTORING FOR C# PROGRAMS

No	Refactoring	Environment		
		MVS	R/R	VSC
1	Safe delete	-	Q	-
2	Sync namespace and folder name	D	+	+
3	Sync a type and filename	+	+	+
4	Convert an abstract class to interface/vice versa	-	+	-

48	Remove dead code	+	+	-
49	Remove unused references	+	-	-
50	Extract method	+	Q	+
51	Inline method	+	Q	-
52	Extract class	+	R	-
53	Inline class	+	R	-
54	Extract superclass	Q	+	DQ
55	Extract interface	+	+	+
56	Extract members to partial class	-	+	-
57	Introduce field	-	+	-
58	Wrap, indent and align	+	+	+
59	Sort `using` declarations	+	+	-
60	Introduce local variable	+	+	+
61	Move declaration near reference	+	+	+
62	Rename	+	+	+
63	Change member or internal type visibility to public/ internal/ protected/ private protected/ private	-	D	-
64	Change type visibility to public/ internal	-	+	-
65	Change to virtual/ non-virtual	-	D	-
66	Change to abstract/ non-abstract	-	D	-
67	Make method override/Add `new` keyword	-	+	-

- In #43. The refactoring of move method is restricted, because the target class has to be a parameter of the moved method. It does not pertain to static methods.
- In #52. The extract class refactoring includes only a variant in which the reference to the new class remains in the old one. The test cases remain unchanged, although they could have been modified by changing the subject of the tests to the new class.
- In #53 In the inline class refactoring, the absorbed class is required to include reference to the target class.

In the following cases, a refactoring could provoke erroneous behavior.

Defects (D):

- In #14. When converting between a property and `get` method, references to the transformed property that are present in the object initialization are invalid. To signal this problem, the refactoring tool creates a warning.
- In #31. In the refactoring of transform parameters, the transformation of a method with an `out` parameter to an expression is incorrect. In the method body, an assignment of the already missing parameter exists, and therefore the program cannot compile.
- In #41 and #42. After the push down refactoring, the tests of the modified base class do not compile any more. They should also be refactored and moved to the appropriate descendant class to which a method or a field was pushed down. The analogous problem is in the pull up refactoring.
- In #63. In the refactoring that changes a member or internal type visibility, the corresponding tests are not modified accordingly. In dependence of the qualifier used, `private` in particular, the final project could not compile.
- In #65 and #66. After the addition or deletion of the `virtual` or `abstract` modifiers, the corresponding tests are not updated. They either need to be deleted or adjusted by changing their subject.

Other improvements in refactoring (Q) could be suggested:

- In #1. In the refactoring of safe delete, several lines with references to a deleted element are also removed. Therefore, it could be beneficial to remove empty or pointless corresponding tests.
- In #30. Refactoring the type copy could also require modification of the corresponding tests. They could either be duplicated or enhanced by applying parametrized tests according to the refactored type.
- In #31. Depending on the details of the change signature refactoring, we could update the tests. For example, if a list of parameters was shortened, some variables could be deleted from a test case; if a parameter was added, a variable with a default value could be introduced in a test case, etc.
- In #37. If a Boolean value is inverted, an Assert could be changed to do tests more legible, e.g., substitute `Assert.True(!value)` with `Assert.False (value)`. However, the exact behavior could be different in dependence on the test library used.
- In #39 and #40. This refers to tests after a method or a field pull up. For example, the corresponding tests could be moved to the base class if they have no dependencies on the original class and if the base class is not an abstract one.
- In #50. After an extract method refactoring, a new method appears. The creation of new test cases, e.g., automated test generation, could be considered.
- In #51. After applying an inline method, the tests of the method remain and their code is merged with the tested method. Consequently, a code duplication encounter. The useless tests could be deleted.

E. Review of Refactoring in Visual Studio Code

The number of refactorings supported by Visual Studio Code (VSC) was the smallest among the three environments. As refactoring variants, two restrictions and one extension were identified.

Extension (E):

- In #32. When parameters are of the `string` type, additional checks could be applied using the `IsNullOrEmpty` method.

Restrictions (R):

- In #16. In conversion between an auto and full property, only one direction of the conversion is supported. An auto property can be converted to a full property, but the vice versa transformation is not possible.
- In #24. Conversion from the `if` instruction to the `switch` instruction or expression is restricted. It can only be applied in cases where relations in consecutive `if` statements refer to the same variable.

The following defects (D) were recognized:

- In #6. In conversion from an anonymous type to a tuple, if an object table that has a transformed anonymous type is created using the shortened inscription `new[]` then a compilation error occurs. This could be avoided by using the full description in the form `new object[]` or by casting to the object type for one of the initialization elements.
- In #14. When converting between a property and a `get` method, references to a refactored property that are used in an object initialization are not updated.
- In #54. The extract superclass refactoring does not take into account dependencies on other fields or methods. If in an extracted method, a reference to a member of the original class exists, a compilation error can arise.

Two quality improvements (Q) were recommended:

- In #17. When a field is encapsulated, visibility of the resultant field is always set to `private` and of a property set to `public`. The transformation does not take into account the initial modifiers.
- In #54. After extracting a superclass, a new base type is used instead of its descendant, where possible.

F. Summary of the Review

In general, the level of refactoring correctness in the environments is similar. Calculating the ratio of the number of refactorings classified as a defect (D) to the number of all refactorings supported by the IDE we obtained 9% for the pure MVS, 11% for JetBrains Rider (and the same for ReSharper), and finally 12% for VSC.

We observed that some defects are specific to selected environments, while others are common to different IDEs. For example, the same problem of converting a property and a `get()` method in #14, occurs in all three tools. Furthermore, similar quality issues refer to pull up refactoring (#39, #40) in the environments in which they are implemented.

The recommendations relate to the modification of the production code but also to the corresponding unit tests. Considering the defects identified in Rider/ReSharper, 5 out of 7 defects refer to test cases. Moreover, all 8 quality issues considered in this environment suggest improvements in the tests.

In summary, the first and second research questions addressed in the Introduction, have negative answers. We cannot always rely on automated refactoring, and tests associated with the refactored area are often inadequately handled.

IV. Automated Fixing of Refactoring Defects (Refix)

Based on the analysis provided, we propose an approach to extend automated refactoring. The tool should correct selected defects and improve the quality of code and tests.

We have selected the ReSharper tool to be enhanced. This platform supports a large number of refactorings, can be used in at least two popular environments, and can be extended with plugins. As a proof of concept, an extension Refix was designed and implemented [16].

The Refix extension integrates with the ReSharper platform and can react when a refactoring is executed. If required, an additional "fixing" activity is undertaken. Currently, it supports improvements of defects related to refactorings #14, #31, #41, and #42, as described in Sect.III.D.

Refix has been tested on JetBrains Rider 2022.1.2 and MVS 2022 Community Edition with ReSharper 2022.1.2.

The benchmark developed to assess refactoring in different environments was also used in the evaluation of the Refix tool (Sect.III.A). It was run with Refix in both environments mentioned above. Unit tests from all three test libraries were used in experiments. Refactoring with Refix was completed correctly, according to expectations.

Furthermore, the evaluation of Refix was based on three real programs derived from the GitHub platform [16]. The experiments were carried out using JetBrains Rider. Unit tests of the projects were run with the xUnit.net framework.

The detailed description of the prototype, and its experimental evaluation are beyond the scope of the paper.

V.Conclusion

After analyzing automated refactorings of C# supported in three popular IDEs, we have made a set of recommendations. Several malfunctions were recognized that influenced the resulting code and tests. In particular, some refactorings deliver code that does not compile. The environments significantly differ in the number of supported transformations, but their general realization quality is at a similar level. Moreover, we have recognized the same or similar problems that referred to the same refactorings in different environments.

Three frameworks for unit tests (MSTest, NUnit, and xUnit.net) were applied in all considered environments. We have not noticed any differences in using the frameworks, as far as the problems of refactored programs are concerned.

A prototype tool has been developed to automate code repair after refactoring [16]. The Refix plugin can be used in JetBrains Rider or MVS with the ReSharper extension. The tool was evaluated using the benchmark and some real programs from GitHub. Due to the prototype developed and its preliminary evaluation, we could positively answer the third research question. In the future, the tool could be extended to cover the remaining defects and other quality concerns.

Abstract— **During the COVID-19 pandemic, South African organisations were forced to provide suitable working conditions for its employees. The increased reliance on technology while working from home resulted in technostress. This paper considers how technostress experiences have evolved under the newly adopted hybrid working model. It investigates the underlying causes of technostress experiences and how employees are currently coping with technostress under the hybrid model. Semi-structured interviews were conducted and supplemented with secondary data provided by respondents who are currently working under a hybrid model and who use ICTs for work purposes. The findings reveal several hybrid working specific causes of technostress, including instances of stressful workstation setups, office disruptions and power outage issues as a result of loadshedding (rolling power blackouts). Stresses related to loadshedding appear to be a specific South African issue. To deal with technostress, employees adopted reactive and proactive coping behaviours driven by problem-focused and emotion-focused coping strategies respectively.**

Index Terms—**technostress, hybrid workplaces, South African organisations.**

I. Introduction

Technostress escalated once the COVID-19 pandemic forced organisations to impose response plans to resume work as smoothly as possible [3]. Many resorted to work-from-home (WFH) styles where employees had to adapt their current work dynamic with the incorporation of ICTs. This caused an obligated reliance on technology by the employees and the organisations [4]. An increased use of ICTs leads to higher workload demands on employees [5]. This induces the inability to manage these demands therefore stifling the capability to process further information often leading to burnout and technostress [5]. In other words, technostress occurs when there are changes in working conditions that stem from the adoption and use of ICTs. This forces employees to adapt and adjust almost instantaneously [5].

In hybrid working environments, employees are required to find a working dynamic that compliments varying reliance on ICTs between the alternating working locations i.e., at home and at the office. This unanticipated shift in working modes could either cause more technostress amongst employees or alleviate some of the technostress experienced during pure remote working. Due to the adoption of a hybrid working model being relatively new for most organisations, there remains a gap in literature pertaining to the experiences of technostress within this new working environment.

The purpose of this study is to explain the shift of employee technostress experiences along with the underlying causes and coping mechanisms. With this research purpose in mind, the research aims to address the following research questions:

Primary Research Question:

- How has the experiences of employee technostress changed when hybrid workplaces were implemented in South Africa?

Secondary Questions:

- Why are South African employees experiencing technostress in these hybrid workplaces?
- How are South African employees currently coping with such instances of technostress?

II. Literature Review (Abbreviated)

The literature review focussses only on the causes or determinants of technostress due to space limitations. It looks at the standard technostressors: system performance issues, technology demands and lack of digital literacy.

The Big Five Technostressors

Technostress literature has established the five standard technostressors: **techno-overload, techno-invasion, techno-complexity, techno-insecurity, and techno-uncertainty. Techno-overload** is triggered when ICT users are required to work for longer and at a faster pace when using ICTs [8]. This also deals with the handling of excess features and information when using ICTs for work [2]. **Techno-invasion** requires the employee to be constantly connected and available to respond timeously even outside work hours, leading to an invasion of their personal environment [2]. **Techno-complexity** refers to feelings of incompetency amongst employee when using the ICTs [9]. This is because of the inherent quality of Information Technology (IT) and ICTs [10]. Due to these feelings of appearing inadequate with IT skills, ICT users invest in spending more time and effort to fully understand the particulars of the technology [8]. **Techno-insecurity** refers to ICT users fearing the loss of their jobs in terms of having some sort of technology eventually take over their role or that their fellow colleagues possess a better understanding of the usage of the ICT. Finally, **techno-uncertainty** refers to the constant ICT upgrades that unsettle ICT users forcing them to continually learn and familiarise themselves with the new technology [8].

System Performance Issues

Technostressors can also extend to system performance issues such as problems with security, usability, and system breakdown [8]. **Security issues** originate from insecure system infrastructure that allow threats which compromise the information involved in that system. Technostress emerges when users are forced to comply with security policies implemented by the organisation which require them to remember passwords and multiple usernames [8]. **Usability** issues stem from poorly designed systems such as bad interfaces, challenges in intuitively navigating around the application/system and in general lack of effectiveness, efficiency and learnability [1]. This causes the users of these system to experience higher cognitive overloads. Finally, **system breakdown** refers to the malfunctioning of ICTs such as error messages [8].

ICT Use in the Workplace

The "technology demands" predictor signifies the costs employees incur as a result of the effort needed for ICT use. These costs are of psychological and physiological natures [11]. These types of demands involve role ambiguity, ergonomic stress, monotonous ICT activities and general work overload [11]. Role ambiguity occurs when ICT tasks are ill defined [11] which is further claimed to restrain the user's abilities and development [12]. Demands can also originate from a societal sense whereby employees experience social isolation, role conflict and emotional overload when trying to form human relationships around the usage of ICTs [11]. Technostress has a positive relationship with how often ICTs are used for work purposes. Technostress can also be instantiated by the usage of multiple ICTs at once. This is derived from higher demands or greater pressure on workers to learn and embrace multiple ICTs [5].

III. Propositions

Table I below indicates the research propositions adapted from literature that drove the data collection process:

TABLE I.
RESEARCH PROPOSITIONS

Research Area	Relationship/Themes	Reference
ICT use in the workplace	Technostress can be induced by having a high dependency on an evolving ICT/Information System in the workplace.	[8]
	If a user possesses high skill levels of digital literacy/skills, he/she will find it relatively easier to learn and adapt to new technologies.	[13]
Techno-stressors	Techno-complexity, techno-overload, techno-invasion, techno-insecurity and techno-uncertainty lead to technostress.	[2]
	Unreliability of ICTs cause technostress.	[8]
Coping behaviours	Reduce ICT-related stress: Distancing; venting.	[14]
	Establish ICT use demarcations: Time-related use, Separation of use, autonomy.	[14]

IV. Research methodology

An interpretive philosophy was adopted for this research. Interpretive research assumes that human experiences shape the social realities and invites subjective interpretations of the respondents in the social context, in this case the virtual and physical workplaces in organisations [15]. As this study adopted an interpretivist paradigm, the most suitable strategy to be adopted was a qualitative one. Qualitative research intends to derive meaning-based forms of data analysis. It enforces the notion of contextual understanding through providing in-depth descriptions of insights that cannot be shown through quantitative measures [16]. This research was conducted over eight months in 2022.

Data was collected through semi-structured interviews [16]. The target audience for this study were employees within organisations that were making use of a hybrid working model and respondents could be conveniently accessed. Twelve respondents were interviewed with ten respondents obtained from the insurance company and two respondents from a university. Table II shows respondent's job role, IT skill level and their estimate technostress level. *Data saturation was achieved after about 9 interviews.*

TABLE II.
DESCRIPTIVE SUMMARY OF RESPONDENTS

Role	Skill level	Techno stress level
Client Relationship Manager,	Medium	Medium
Finance Team Leader	Medium	Medium
Section 14 Technical Team Leader	Medium	Low
Business Specialist, MIS	High	Low-Medium
Client Relationship Manager	Medium	Dependent
Corporate Client Services Team Leader	Medium	Medium
Servicing Team Leader	High	Low- Medium
Client Relationship Manager,	Medium	Medium
Social Media Complaints	Medium	Medium-Intense
Complaints Handler	Medium	Medium-Intense
ICTs: Senior Business Analyst	High	Low-Medium
HR Analytics	High	Medium

The analysis took on the form of categorizing themes and patterns that derived at a set of concepts (codes), constructs (categories) and relationships [15]. NVivo was used to perform the thematic analysis. Ethical clearance for the study was obtained from the ethics committee of the university.

V. Research Findings and Analysis

The themes from the data analysis are discussed below.

A. Hybrid Working Specific Causes of Technostress

a) Non-assigned desk setup ("hot desks") creates unnecessary technostress

On the days designated to go work at the office, three respondents indicated device configuration issues between the provided monitors and their own laptops. These experiences were also discovered in China [7]. Five respondents complained about insufficient technical support at the office should they encounter tech-related difficulties. Two respondents alluded to occurrences of missing equipment at the office which meant search for appropriate equipment to set up their workstation, delaying the start of their working day. These stresses were more prominent at the start of the hybrid model.

b) Office distractions related to ICT use causes stress

Eight respondents expressed that being in office meant having to endure office-based interruptions where otherwise they wouldn't have experienced while working from home. Three out of the eight claimed that there are challenges with having partial teams present at the office on designated days. Those in-office would have to dial in the rest of the team who are working from home. This meant holding virtual meetings via MS Teams which would create echoes in the office, often distracting other teams and employees who are also in that day. This was claimed to add to stress as it would disturb concentration levels and productivity.

c) Power issues creating stress

Seven respondents from the interviews and three instances from the secondary data referred to the disturbances that loadshedding (rolling blackouts) has had on their workstation setup at home and in office resulting in downtime. While most confirmed that their organisation provided adequate support for power outages at home such as an UPS, some referred to the stress of worrying whether there would be enough stored power to last the loadshedding slots, especially under the higher levels of loadshedding. *"My blood pressure almost went up one day because I was panicking. I thought, where am I gonna work?" - OM05*

B. The Change in Traditional Technostressors under Hybrid Working

a) Techno-uncertainty with the adoption of a new ICT/technology when remote working was introduced

Six respondents experienced initial stress familiarising themselves with new systems implemented by their organisation. OM02 experienced communication inconsistencies when liaising with her IT department about the introduction of a new system. She expressed how stressful it was to interpret the technical jargon which created misunderstandings in the requirements for the new system.

Five respondents alluded to the minimal/insufficient technical support and training for new system rollouts. This created stress in a sense that employees were now forced to learn the new systems by themselves. This resulted in them having to factor in time to learn the new systems which meant neglecting work duties for a time period, hence creating more stress. *"There's no training on it. It's like we just learning on the job, like on top of each other, on multiple applications besides all our existing applications."- OM10*

b) Techno-overload creating technostress while WFH

Nine respondents indicated feelings of hyperconnectivity while working from home on the designated days which made it easier to be interrupted thorough application notifications and alerts. This also stems from organisational expectations on employees to be able to respond quickly and often outside of work hours. Three respondents mentioned how using multiple applications at the same time can become overwhelming and stressful especially since sometimes the systems don't easily speak to each other. This is consistent with the belief that using multiple ICTs can instantiate technostress [5].

c) Techno-insecurity creating technostress

Experiences of techno-insecurity weren't that significant amongst the sample, with only two respondents referring to feeling insecure about their IT skills. OM10 mentioned the impact of the imbalance of IT skills within the team that creates stress. This was to do with new employees in the team possessing IT skills that they have gained from experience in other teams/departments which instantiated feelings of insecurity within the old employees who didn't possess such experience. This also made them feel as if it was burdensome when bothering these new employees for IT-related help.

d) Techno-invasion distorts work/life balance when WFH

This theme relates to the distortion of work life balance as a result of ICT use for work. Six instances within the secondary data referred to challenges with work life balance under the hybrid working model. In line with [6], nine respondents from the interviews recalled feelings of techno-invasion where they often found themselves logging in after work hours, on weekends and late in the evenings. This was mainly due to having a convenient setup at home which enabled them with the ability to connect or simply the use of laptops which made it easy to resume working when coming back from the office. This meant putting in additional work hours without even realising it. One respondent mentioned the negative impact techno-invasion had on her personal relationships at home. *"Technology has invaded our private space and the lines between your work day and your domestic day have become blurred. That has led to stress in my life."- UCT01*

e) Techno-complexity causing technostress

Ten respondents indicated that some of the systems are quite complex to understand at first, sometimes even after the system/application has been used for a while. Four of these respondents referred to instances of system upgrade inconsistencies. Some expressed that the new systems that were introduced were often counterintuitive. *"These programs have to be complex. And as much as they're trying to be user intuitive, they don't often succeed there because they're trying to be different from their competitors."- OM04*

C. Coping Mechanisms Reduce Technostress

a) Proactive Coping Behaviour

Separating personal and work life by using different devices for the different ICT related tasks limits the exposure to work-related ICT tasks outside of work settings. Other forms of ICT use demarcation found in the responses were related to structuring ICT use according to time periods. UCT01 mentioned blocking out a period of time to sort out an IT-related issue or to limit usage of technology by blocking out time in his calendar to avoid using technology. Four respondents alluded to sticking to a routine therefore proactively coping with the technostress. This was described as attempts to come in early to the office to factor in time to deal with a stressful incident should it arise. OM10 stated that: *"You tend to go early so you can get that desk cause other person's gonna take it."* This also linked with trying to find a suitable, adequately equipped desk with the correct devices and cables.

Six respondents mentioned preferring to work longer hours in hopes of reducing future instances of stress, therefore displaying proactive coping behaviours. This shows that by leveraging what once were technostressors (techno-overload and techno-invasion), stress can actually be reduced.

b) Reactive Coping Behaviour

Three responses pertained to reactive coping behaviours such as walking away from the stressful situation, regrouping, and closing all applications. This demonstrates the distancing coping mechanism where employees can temporarily separate themselves from the IT-related task and focus on something else [14]. Five respondents expressed that they would usually resort to venting tactics, a reactive coping behaviour, should they encounter a stressful incident related to using an ICT/ICTs. This was believed to help employees not feel isolated and to see if others are going through similar situations.

VI. Discussion of Findings

The descriptive findings uncovered relationships between different characteristics of employees and their corresponding technostress levels.

A. Findings around the Standard Technostressors

While respondents experienced the five standard technostressors, it was clear that they had more issues with them during purely remote working than under the hybrid model.

a) Techno-uncertainty as a technostressor

There was reference to techno-uncertainty triggers that occurred when new systems were introduced when remote working was initially adopted where the reliance on ICTs spiked. This caused stress related to the initial familiarisation of the new system and the minimal technical support to accompany the new system rollout. This meant employees had to dedicate additional time to learn the new system, potentially outside of work hours therefore increasing stress levels.

b) Techno-overload as a technostressor

Respondents mentioned experiencing techno-overload with regards to technology-related interruptions while working from home which triggered stress levels. Some also referred to feeling overwhelmed with the use of multiple applications that they deal with daily. This feeling of being overwhelmed could extend to experiences at the office as respondents confirmed that they used the same number of devices and applications at the office as they did at home.

c) Techno-insecurity as a technostressor

This particular factor was not very suggestive as a trigger of technostress. Only two respondents expressed feeling stressed that fellow employees may cope better with technological demands than themselves.

d) Techno-invasion as a technostressor

The data showed instances of techno-invasion in the form of extending work hours into an employee's personal time therefore distorting boundaries between work and personal spheres when working from home specifically. This was seen to also diminish work life balance. Some respondents expressed instances of lack of separation of work-related ICTs on different devices which generated stress.

Techno-complexity as a technostressor

The data suggested employee challenges with system complexity that instantiated feelings of stress. This pointed to IT skills levels struggling to match with systems' expectations which mainly stemmed from the perceived system complexity that existed, especially in new versions of systems. This can be seen to be a result of the counter intuitiveness expressed by some of the respondents which made the systems seem unfamiliar therefore triggering feelings of stress. Either employees need to be upskilled through training programmes to have their skills match with system expectations or systems need to be more simply designed.

B. Findings around the Hybrid-specific Technostressors

The data suggested that there are also distinctive causes of technostress.

a) Using hot desks creates unnecessary technostress

Since some respondents (which was found to exclude most managers) had to secure a desk each time they came into the office on their designated days, the desks often varied in equipment availability. As a result, they had to ensure coming into the office early enough to secure an appropriate desk or to hide some equipment in cupboards to ensure they would be sorted the next time when coming into the office. This was mainly due to the instances of missing equipment such as monitors, adapters, keyboards, cables etc. which meant that the equipment floated around from desk to desk. This implies that should organisations opt to keep hybrid working models, adequate resources in terms of equipment and amenities should be provided for employees on their days in-office so as to mirror their home working stations. In addition, some respondents mentioned how stressful it was to configure and synchronise various devices when coming into the office. There was reference to compatibility issues which can be seen as a direct cause of the lack of equipment availability mentioned already.

b) Office distractions related to ICT use causes stress

The comparison between working at home and at the office surfaced consistencies across some respondents regarding the disruptive atmosphere of the office. In addition to the usual office disruptions that existed before the COVID-19 lockdown, some respondents found having partial teams present at the office raised some unusual disruptions. This broke their concentration and added to their stress levels.

c) Power issues impacting access to ICTs creates stress

Loadshedding and electricity/power issues presented challenges for employees to conduct their work using ICTs that demanded sufficient power. While the organisations provided infrastructure support, often the loadshedding schedules were unpredictable and left employees in crisis situations. This meant employees experienced anxiety and stress as they were now unable to complete any work and had to make drastic arrangements to resume work. This is a macro issue specific to South Africa that can't be solved by the organisation itself but it remains crucial to implement as much support as possible to counter the unpredictable instances of loadshedding.

C. Findings around Coping Mechanisms

a) Proactive coping behaviours

The main coping behaviour was of a proactive nature utilising a problem-focused coping strategy. Most respondents resorted to proactive tactics like demarcating ICT use according to time and separation of use. Others expressed enforcing a routine to maintain a structure that could mitigate the impacts of a stressful encounter should it occur. Most respondents confirmed that working longer hours actually helped them reduce further anticipated stress. This meant logging onto systems to perform work activities on the weekend in order to reduce work backlog and hence further stress.

b) Reactive Coping Behaviours

The data showed how the standard reactive coping behaviours remain prominent when dealing with stress. This referred to emotion-focused coping strategies such as distancing oneself from the stressful situation and venting to others in hopes of reducing feelings of isolation and anxiety.

VII. Conclusion

The purpose of this research was to understand how employee technostress experiences have changed since hybrid models were adopted in South African organisations. The research wanted to find the underlying causes of these new experiences and how employees are currently coping with these new instances of technostress.

The findings suggest that the **standard** technostressors weren't as prevalent in the hybrid working model. These seemed to be more prevalent at the start of implementing the purely WFH approach and decreased somewhat under hybrid. South African employees appear to have adapted under hybrid, pointing to new emerging experiences. **Hybrid-working-specific** causes of technostress include stressful workstation setups upon return to the office on designated days which involved configuration, compatibility, and synchronisation issues along with the lack of equipment on hand. Office distractions caused unwarranted stress for employees in-office. This specifically pertained to virtual meeting noise and related echoes. Lastly, power shortages as a result of loadshedding became a hinderance and contributed to feelings of stress. *The stresses related to loadshedding and power outages appear to be a distinctive South African issue.*

To deal with technostress, employees adopted reactive and proactive coping behaviours driven by problem-focused and emotion-focused coping strategies respectively. **Reactive** behaviours involved distancing from the stressful situation and venting to others. **Proactive** behaviours involved demarcating ICT use through structured time use and separation of use. This included implementing a structured routine and working longer hours to reduce future stressful encounters.

This research had **limitations** with regard to the sample size and representation. A bigger sample size will allow better representativeness. Since the research was a cross-sectional study, technostress experiences under the hybrid model could only be recorded within the early stages of its inception; if the research was conducted over a longer period of time, a more holistic understanding could have been extracted.

Future research could compare the three modes of working (purely remote, hybrid and purely on-site) over a longer period of time to uncover more accurate understandings of the differences in the experiences of technostress. Another recommendation is to expand on the sample size.

***Abstract*—The aim of this article is to investigate the fine-tuning potential of natural language inference (NLI) data to improve information retrieval and ranking. We demonstrate this for both English and Polish languages, using data from one of the largest Polish e-commerce sites and selected open-domain datasets. We employ both monolingual and multilingual sentence encoders fine-tuned by a supervised method utilizing contrastive loss and NLI data. Our results point to the fact that NLI fine-tuning increases the performance of the models in both tasks and both languages, with the potential to improve mono- and multilingual models. Finally, we investigate uniformity and alignment of the embeddings to explain the effect of NLI-based fine-tuning for an out-of-domain use-case.**

I. Introduction

QUERY and sentence embedding vectors are used in information retrieval to match the searched query to results, for example in ranking of the results returned by lexical search engines [1] or in vector-based similarity search [2].

The standard approach to training text encoders is to use large-scale corpora such as Wikipedia or CommonCrawl and the Masked Language Modeling (MLM) objective. A setup like this was used to train HerBERT [3], the state-of-the-art monolingual BERT for the Polish language, which utilized Polish-specific datasets and the Sentence Structural Objective in addition to MLM. CommonCrawl, Wikipedia, and MLM were also used to train XLM-RoBERTa [4], a transformer supporting 100 languages.

In past years there have been numerous applications of natural language inference (NLI) data in training large language models such as sentence encoders. One example supporting the Polish language is the multilingual Universal Sentence Encoder (USE) [5]. For the 16 covered languages, training data included question-answer pairs, translation pairs, and the SNLI [6] corpus, translated using Google Translate into target languages. The model was trained in a dual encoder setup and comes in two variants: a lightweight convolutional neural network and a transformer.

Recently, NLI data were applied in a combination with contrastive loss in a method called SimCSE [7]. It demonstrated superior performance on STS (Semantic Textual Similarity) tasks. Contrastive fine-tuning was also reported to improve ranking quality when applied to multilingual encoders [8].

Unfortunately, large NLI datasets suitable for model training are usually not available in languages other than English. For this reason, in this work we test the feasibility of using machine translated NLI data and demonstrate this approach for Polish. We will use both monolingual (Polish and English) and multilingual models and evaluate them on data in both languages.

In this paper, we focus on two information retrieval tasks: the retrieval task, which aims to find a set of documents that match the query, and the ranking task, which sorts the results by relevance to the query. To demonstrate the proposed approach, our experiments will be performed on out-of-domain models, by which we mean generic, pre-trained neural language models that have not been tuned to real-world search data such as user clicks. We explore the impact of using translated NLI data for contrastive fine-tuning. We consider how does the fine-tuning affect information retrieval and ranking tasks. Furthermore, we investigate whether the uniformity and alignment of embeddings are linked to out-of-domain information retrieval performance.

The paper is organized as follows: in Section II we introduce datasets and experimental setup, Section III discloses results and Section IV concludes the paper by drawing conclusions.

II. Experiments

A. Datasets

We examined the performance of the models on three types of benchmarks.

The first one is not directly related to information retrieval. This is a generic approach to evaluate pre-trained large neural language models. The first part is based on a GLUE-like collection for testing the selected model on a number of downstream benchmarks. We use it in Polish, where such a benchmark is the KLEJ framework [9]. In our paper we report averaged model performance on KLEJ datasets. The second part consists of semantic textual similarity (STS) tasks:

- translated SICK-R [10] available from the Polish version of SentEval[1],
- CDS-R [11], a Polish dataset based on SICK-R,
- translated STSB[2].

These datasets contain pairs of sentences human labelled based on the relatedness.

The second benchmark is ranking using a random sample consisting of 86K search listings from one of the largest e-commerce platforms in Poland. The listings consist of a search phrase and the first page of results (on average 50 offers) from the lexical search engine along with information about the clicked items. We sorted the listings according to the cosine similarity between the embedding of the search phrase and the embedding of each offer title. We assessed the performance of the models by calculating click-based NDCG and averaging the results.

The third benchmark consists of two retrieval tasks. Here we applied Polish monolingual and multilingual models used in previous benchmarks, but also English monolingual models to extend our research to other languages. To evaluate Polish models in the retrieval task, we used an internal dataset from one of the largest e-commerce Polish platforms, which consists of search results. It is a sample of 30K user queries and 1M product titles, containing at least one clicked product for each of the user queries. English language models were tested on two datasets. The first one is WANDS [12], a similar dataset from the e-commerce domain. Its test subset contains 379 queries and 43K candidate products with human-labelled query-product pairs. The main purpose is evaluation of semantic search in e-commerce. To broaden our evaluation, we further tested English models on the second English dataset, outside of e-commerce, namely SciFact [13]. It is included in BEIR [14], an information retrieval benchmark. SciFact's test subset contains 300 scientific claims (queries) verified against a corpus of 5K abstracts.

B. NLI translation

We evaluated the translations using COMET (Crosslingual Optimized Metric for Evaluation of Translation) [15] scores, an automated method of assessing translation quality. COMET is a new neural framework for evaluating multilingual machine translation models. COMET is designed to predict human judgments of machine translation quality. We used the older model, namely wmt20-comet-qe-da[3] to compare the translation results. The newer COMET release has a better correlation with human evaluation and a less skewed distribution of scores, but the calculated values were more difficult to interpret and establish a threshold value that indicates good vs bad translation quality.

The mBart[4] model reached score a of 0.49 compared to 0.40 of m2m100[5], which is why we decided to translate the data using mBart. We also experimented with choosing the best of two translations for each sentence, which we comment on later in Section III-D.

C. Training details

We selected several models for fine-tuning with the supervised SimCSE framework[6]. In the case of Polish, we applied SimCSE to the Polish monolingual model HerBERT [3], which achieved top scores in the Polish KLEJ benchmark. In the case of English, we selected the English-only monolingual base variant of BERT (BERT-base-uncased) [16]. Finally, we applied SimCSE to the multilingual model XLM-RoBERTa [4], which also is the best multilingual model on the KLEJ leaderboard. We fine-tuned HerBERT and XLM-RoBERTa models using the SNLI dataset translated to Polish[7], and the English SNLI and MNLI data in the case of English BERT and XLM-RoBERTa (in the case of English fine-tuning).

D. SimCSE: Contrastive loss using NLI

SimCSE [7] is a contrastive learning method aimed at generating sentence embeddings. First, it utilizes an unsupervised approach, which takes an input sentence and predicts itself in contrastive objective, with dropout used as noise. Authors find that dropout acts as minimal data augmentation, and removing it leads to a representation collapse. Then, they propose a supervised approach, which incorporates annotated pairs from natural language inference (NLI) datasets into the contrastive learning framework by using "entailment" pairs as positives and "contradiction" pairs as hard negatives. The contrastive loss is formulated for paired examples $D = \left\{\left(x_i, x_i^{+}\right)\right\}_{i=1}^{m}$, where x_i and x_i^{+} are semantically related. Assuming that h_i and h_i^{+} are representations of x_i and x_i^{+}, the training objective is:

$$\ell_{contrastive} = -\log \frac{\mathrm{e}^{\operatorname{sim}\left(\mathbf{h}_i, \mathbf{h}_i^{+}\right)/\tau}}{\sum_{j=1}^{N} \mathrm{e}^{\operatorname{sim}\left(\mathbf{h}_i, \mathbf{h}_j^{+}\right)/\tau}}$$

where τ is a temperature hyperparameter and sim(h_i, h_i^{+}) is the cosine similarity.

Following the SimCSE [7] we used their supervised training framework to fine-tune selected models on SNLI dataset translated into Polish. This supervised task takes advantage of human-labelled pairs of sentences. As in the original work, we treated entailment pairs as positives and contradiction pairs as a hard negatives.

[6] https://github.com/princeton-nlp/SimCSE

[7] We also tested a combination with MNLI, but this resulted in worse performance in information retrieval tasks.

E. Uniformity and alignment

Wang et al. [17] identify two key properties of embeddings, *uniformity* and *alignment*, and propose to use them to measure embedding quality. Later work [18] in the recommender domain also suggests that better uniformity and alignment increases NDCG. Alignment is meant to measure whether similar samples have similar embeddings and is given by

$$\ell_{align} \triangleq \mathbb{E}_{(x,y)\sim p_{pos}} \| f(x) - f(y) \|_2^{\alpha}, \quad \alpha > 0,$$

where f is a function mapping an entity to its embedding and p_{pos} is a distribution of positive pairs. Uniformity measures whether maximal information is preserved between the input and embedding space, which leads to spreading out of the representations, and is given by

$$\ell_{uniform} \triangleq \log \mathbb{E}_{x,y\sim p_{data}} \left[e^{-t\|f(x)-f(y)\|_2^2} \right], \quad t > 0,$$

where p_{data} is the input distribution.

III. Results

A. Results of SimCSE with translated NLI

As we can see in Table I, the role of SimCSE is ambiguous: it greatly improves the STS performance, but in the case of the best Polish monolingual model Herbert, it degrades its performance on the KLEJ benchmark.

The results regarding STS and general benchmarks such as KLEJ agree with the observations of SimCSE authors in [7]. They are somewhat selective: the focus is on evaluating SimCSE on semantic textual similarity (STS), and indeed in this benchmark their method performs in a competitive manner. However, the performance on many other typical downstream tasks, such as for example GLUE benchmark's sentiment analysis, is not competitive and is mentioned only in the appendix of the SimCSE paper. Authors conclude that sentence-level objective of SimCSE may not directly benefit such transfer tasks.

B. Results of information retrieval benchmark

Table II presents the results of the English benchmark. To get the best possible performance from used models we use both mean-pooling (average representation of tokens in sequence) and the CLS token representations. This doesn't discriminate against models which are not fine-tuned for utilisation of the CLS token (e.g. BERT). Tables III and IV show results of the Polish language tasks. Generally, SimCSE fine-tuning improves both NDCG and recall. For both languages the best results in terms of retrieval, as reflected in Recall@100 scores, were obtained by monolingual BERTs with SimCSE fine-tuning. Except for the case of the English WANDS benchmark, USE was second in terms of performance, ahead of XLM-RoBERTa fine-tuned by SimCSE. In the ranking task HerBERT, SimCSE-HerBERT, and USE shared first place when using the mean of the last hidden layer to represent the utterance. In the CLS+pooler representation, SimCSE-HerBERT was the best one.

C. Uniformity and alignment

We calculated uniformity and alignment using the search phrase and title with a click, utilizing a batch size of 1024 over 300K of pairs, with the default $\alpha = 2$ and $t = 2$. Contrastive fine-tuning improved the performance of both HerBERT and XLM-RoBERTa. However, only uniformity improved as the alignment metric increased (see Figure 1).

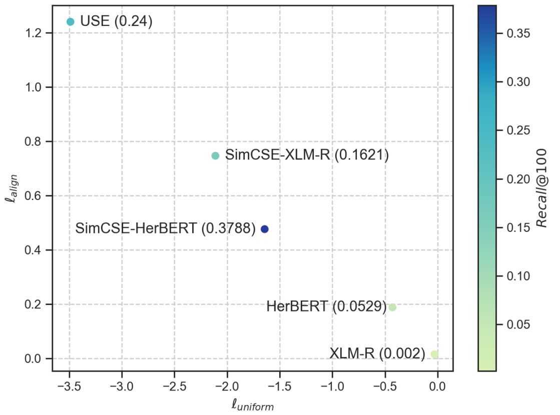

Fig. 1. Recall@100 on the plot of ℓ_{align} versus $\ell_{uniform}$ on vector-search dataset. For both axes lower is better. Colors and numbers in parentheses indicate Recall@100.

D. Influence of translation quality

In order to examine the influence of poorly translated sentences we conducted experiments where we filtered translated sentences based on the COMET score. Using both translation from mBart and m2m100 models, we selected the highest COMET score translation to pick one example from each of the translated datasets. The average COMET score on SNLI rose by 7 percentage points after filtering. After inspecting the cleaned datasets many examples with scores close to zero were still found. Removing examples with scores lower than 0.05 resulted in reducing the dataset size by 1/3. Fine-tuning the model on the cleaned dataset resulted in worse performance than baseline.

IV. Discussion

Using the translated SNLI dataset had a comparable effect to the results reported in [7]. This confirms the role of translated NLI for improving the model performance, even despite possible translation errors.

[8] We used the transformer variant available at https://tfhub.dev/google/universal-sentence-encoder-multilingual-large/3

[9] KLEJ value cannot be computed for USE in a manner directly comparable to other solutions, because it supports only one input and does not support the '[SEP]' special tokens as the other transformer models do. Some of the KLEJ subsets are paired, as for example question-answer or paraphrase data.

[10] We computed statistical significance of averaged NDCGs using the paired T-test, p-value$<$ 0.05. Non-significant pairs where we could not confirm the differences were USE vs SimCSE-HerBERT and XLM-RoBERTa vs HerBERT. In other cases the differences are statistically significant.

TABLE I

USE	0.2407	-

The USE model competes with monolingual models when it comes to STS benchmarks. Contrastive loss, as applied in SimCSE, is not used in the USE model. Moreover, the USE model is multilingual, as it supports 16 languages, and it contains only 80 mln parameters in the large variant, compared to 110 mln of the HerBERT and XLM-RoBERTa base versions. The only element that is common to both the USE and HerBERT with SimCSE fine-tuning is the usage of NLI data for model training. Therefore, we conclude that it is the NLI fine-tuning that plays the key role in information retrieval and STS performance.

Another interesting observation is that the averaged KLEJ score is not related to information retrieval capability. However, better performance on the semantic textual similarity tasks (STSB-PL, SICK-R and CDS-R) is. Our results demonstrate that SimCSE fine-tuning degrades monolingual model performance on the KLEJ benchmark, therefore it should not be considered as a one-size-fits-all method for tuning language models. We believe that using NLI data for model pre-training and/or fine-tuning has a positive effect in representing text for information retrieval problems.

We observed a link between information retrieval and uniformity dimension only. We did not observe a relationship between alignment and information retrieval as is reported in [7] or in the context of recommender systems [18]. Previous work assessed alignment and uniformity using an in-domain setting, compared to our case of an out-of-domain scenario — but the impact of this setting concerning alignment remains an open research question.

All multilingual models scored higher on uniformity compared to monolingual models. We believe this is because multilinguality makes the model use more of the embedding space. Moreover, the alignment of all multilingual models was worse compared to monolingual models. This shows that alignment and uniformity do not directly translate to capabilities of sentence encoders.

V. CONCLUSIONS AND FUTURE WORK

Our results show that state-of-the-art performance in out-of-domain retrieval and ranking tasks can be achieved with a method based on contrastive loss and NLI data, such as SimCSE, applied to a pre-trained language model. We confirm the positive effect of contrastive loss using both monolingual and multilingual models, pointing to the conclusion that the key to superior performance in out-of-domain information retrieval is fine-tuning sentence encoders using NLI data.

In this paper we did not train the model on clicks. This could be done using contrastive loss. In the future we plan to optimize sentence encoders on click data using alignment and uniformity in the loss function, as in [18].

Abstract—**Production organization plays a key role in the success of any enterprise. Optimizing workforce planning can improve the overall organization of production. The main goal is to minimize the assignment cost of the workers who will perform the planned work. The problem is known to be NP-hard, therefore we will apply methods from the field of artificial intelligence. For this reason, most of the existing methods hardly find feasible solutions. We propose Ant Colony Optimization Algorithm with hybridization, combination with local search procedures. We compare and analyze their performance.**

Index Terms—**Workforce Planning, Ant Colony Optimization, Metaheuristics, Hybrid Method, Local Search**

I. Introduction

PROPER management of human resources plays an important role in the organization of production. It is common problem for all industrial sectors. It is NP-hard optimization problem, which includes a lot of level of complexity. Workforce planning is the process of determining the skills and human resources needed to perform a given task. The problem consists of two parts: selection and assignment. First the employers are selected from the set of available workers. After they are assigned to jobs, which they will perform. The aim is minimization of assignment cost, while staying within the framework of work requirements. Human resource management includes workforce planning. Exact methods as well as traditional numerical methods are unable to solve this problem for instances with realistic size. These types of methods can be applied only on special simplified variants of the problem.

It exist various metaheuristic algorithms applied on workforce planning problem. They include genetic algorithm [1], memetic algorithm [11], scatter search [1] etc.

Ant Colony Optimization (ACO) algorithm is proven to be very effective solving various complex optimization problems [5], [10]. In our previous work [6], [7] we propose ACO algorithm for workforce planning. We have considered the variant of the workforce planning problem proposed in [1].

Current paper is the continuation of [7] and [8]. Other variant of hybridization is proposed. They are compared and discussed. The aim is to improve algorithm efficiency .

The rest of the paper is organized as follows. The mathematical description of the problem is presented in Section 2. ACO algorithm for workforce planing problem is presented in Section 3. Computational results, comparisons of different hybridization and discussion are done in Section 4 . A conclusion and directions for future work are proposed in Section 5.

II. Workforce Planning Problem

In this section we will give definition and description of the variant of Workforce Planing Problem (WPP) we solve. We intend the variant of the problem considered by Alba [1] and Glover [9].

There is a fixed period of time and a set of jobs $J = \{1, \dots, m\}$. All jobs need to be finished during this period. For every job j is known that it requires d_j hours to be completed. There are workers, which are candidates for assignment to perform the jobs, the set $I = \{1, \dots, n\}$. In terms of work quality and efficiency, each worker must work on each of their assigned jobs for a minimum of h_{min} hours. We know the availability of every worker, worker i is available for s_i hours. Workers may have different qualifications and may not be qualified for all the tasks to be performed. The set A_i contains the jobs, for which worker i is qualified. There is a limit t to the maximum number of workers that can be assigned during this period. This means that at most t workers can be selected from a set I of workers, and this must be done in such a way that they are able to perform and complete the planned work. The worker i is assigned to perform job j at c_{ij}. The purpose is to find feasible solution, that minimize assignment price, which is the objective function of this problem.

The following is the description of the mathematical model of the workforce planing problem:

$$x_{ij} = \begin{cases} 1 & \text{if the worker } i \text{ is assigned to job } j \\ 0 & \text{otherwise} \end{cases}$$

$$y_i = \begin{cases} 1 & \text{if worker } i \text{ is selected} \\ 0 & \text{otherwise} \end{cases}$$

$$z_{ij} = \text{number of hours that worker } i$$

$$\text{is assigned to perform job } j$$

Q_j = set of workers qualified to perform job j

$$\text{Minimize} \sum_{i \in I} \sum_{j \in A_i} c_{ij}.x_{ij} \tag{1}$$

Subject to

$$\sum_{j \in A_i} z_{ij} \le s_i.y_i \qquad i \in I \tag{2}$$

$$\sum_{i \in Q_j} z_{ij} \ge d_j \qquad j \in J \tag{3}$$

$$\sum_{j \in A_i} x_{ij} \le j_{max}.y_j \qquad i \in I \tag{4}$$

$$h_{min}.x_{ij} \le z_{ij} \le s_i.x_{ij} \qquad i \in I, j \in A_i \tag{5}$$

$$\sum_{i \in I} y_i \le t \tag{6}$$

$$\begin{array}{ll} x_{ij} \in \{0,1\} & i \in I, j \in A_i \\ y_i \in \{0,1\} & i \in I \\ z_{ij} \ge 0 & i \in I, j \in A_i \end{array}$$

Every manufacturer strives to reduce the cost of production. This can be achieved with good organization and optimization of production process. One of the biggest costs is the cost of hiring workers. Therefore, workforce planning and optimization is a fundamental issue for every enterprise. The goal of the problem of workforce planning is the minimization of the total assignment cost, respecting the constraints. Inequality 2 represents the limitation of the number of hours the selected worker can be assigned. Inequality 3 show the completion time for hall jobs. The limitation of the number of jobs, that every worker can perform is done by the inequality 4. If a worker works too short on a job, his work will be inefficient and often of poor quality. Therefore, a minimum amount of time is required for each worker to work on each of their assigned jobs. This requirement is represented by inequality 5. There is always some reason to limit the number of workers working at the same time. This may be the available space; the amount of tools; number of machines or something else. The limitation of the number of the assigned workers is represented by inequality 6.

This mathematical model of the workforce planning problem can be used with a variety of objective functions, depending on what our goal is and what we want to optimize. Regarding the goal, there are various variants of the problem. The focus of this paper is minimization of total assignment cost. Let's $\tilde{c}_{ij}$ is the cost the worker i to performs the job j for one hour. The cost of assigning workers to complete all assigned jobs is represented by function 7. Minimizing this function is the objective function used in this paper.

$$f(x) = \text{Min} \sum_{i \in I} \sum_{j \in A_i} \tilde{c}_{ij}.x_{ij} \tag{7}$$

Some of the workers may have preferences for some of the activities for which they are qualified. In this case, the objective function would be the maximum satisfaction of their desires. Another option is for the task to have two objective functions. Simultaneous minimization of the total cost of appointment and maximum satisfaction of preferences.

Workforce planning problems fall into two broad groups: structured and unstructured. The problem is structured when the time to complete a job is proportional to the minimal time the worker need to work on separate job, or parameter d_j is proportional to the parameter h_{min}. When d_j is not proportional to the parameter h_{min} the problem is unstructured. The algorithms find more frequently feasible solutions for structured problems, then for unstructured.

III. Hybrid Ant Colony Optimization Algorithm

One of the most successful methods for solving combinatorial optimization problems is Ant Colony Optimization (ACO). It is a metaheuristics, following the real ants behavior when looking for a food. Normally ants use chemical substance, called pheromone, to mark their path ant to can return back.

A. Main ACO Algorithm

NP-hard problems and in particular combinatorial optimization problems require exponential number of calculations and memory use. So large problems can not be solved for reasonable time by exact algorithms or traditional numerical methods [3].

First realization of the idea to use ant behavior is applied by Marco Dorigo [2] for solving Traveling Salesman Problem. Later some modifications and improvements are proposed, mainly in pheromone updating rules [3] and the method was applied on big variety of combinatorial optimization problems. The ACO methodology is based on the ants behavior simulation. One of the main things in the algorithm is the representation of the problem by graph, called graph of the problem. This allows solutions to be represented as paths in the graph. The problem boils down to finding a shortest path in a graph subject to given constraints.

The transition probability $P_{i,j}$ leads the ants how to choose the next node j to be added to the partial solution, when the last node selected is i. It is a product of the heuristic information $\eta_{i,j}$ and the pheromone trail quantity $\tau_{i,j}$ corresponding to the move from node i to the node j, where $i, j = 1, \dots, n$. The transition probability formula is as follows:

$$P_{i,j} = \frac{\tau_{i,j}^a \eta_{i,j}^b}{\sum\limits_{k \in Unused} \tau_{i,k}^a \eta_{i,k}^b}, \tag{8}$$

where $Unused$ is the set of unused nodes of the problem graph, a and b are the influence of the pheromone and the heuristics information, respectively.

Equality 8 shows that the attractiveness of a node increases, when the heuristic information and/or the quantity of the pheromone related to it increases, because the probability the node to be selected increases and it becomes more advantageous.

The level of the initial pheromone is the same for all graph elements and is set to a small positive constant value τ_0, $0 < \tau_0 < 1$. The algorithm is iterative and the goal is on the next iteration the ant to try to construct new better solutions, taking in to account the information from previous iterations. At the end of every iteration the ants update the pheromone values of graph elements according the quality of the achieved solution during the iteration. Different ACO algorithms utilize different procedures for updating pheromone values [3]. A node, from the problem graph, becomes more desirable if it accumulates more pheromone, but the accumulation of too much pheromone can lead to stagnation and repetition of the same solutions without their improvement.

The main update rule for the pheromone trail level is:

$$\tau_{i,j} \leftarrow \rho\tau_{i,j} + \Delta\tau_{i,j}, \tag{9}$$

where ρ is the evaporation parameter. It decreases the value of the old pheromone, because the old information is not so current. On the other hand, we do not lose it, but only reduce its influence. Thus we mimics evaporation in a nature and try to prevent early stagnation and help the ants to avoid local minima. $\Delta\tau_{i,j}$ is a new added pheromone, and it is proportional to the quality of the newly constructed solution. The quality of the newly constructed solutions is measured by the values of the objective function, corresponding to these solutions.

B. Workforce Planing Problem ACO Algorithm

In this section we describe ACO algorithm for workforce planning without local search procedure from our previous paper [6]. Proper graph representation of the problem play important role in ACO algorithm application. The problem is described by 3 dimensional graph. Essential is which elements of the problem are represented by the nodes and what is the meaning of the arcs. In our problem the node (i, j, z) represents the worker i assigned to the job j for time z. The maximal value of z is dependent of the completion time of job j. Completion time is different for different jobs, so the graph of the problem is asymmetric.

As we mentioned in the subsection above, an ant starts solution construction from a random node of the graph of the problem. Thus at the beginning of every iteration we generate three random numbers for every ant. The first random number belongs to the interval $[0, \dots, n]$ and shows to the worker who is chosen to be assigned. The second random number belong to the interval $[0, \dots, m]$. It is related with the job, the worker is assigned to do. In case the worker is not qualified to do this job, a new job is chosen in a random way. The third random number belong to the interval $[h_{min}, \min\{d_j, s_i\}]$ and is related with number of hours worker i is assigned to performs job j.

By traditional ACO algorithm next nodes are included applying transition probability rule. These steps are repeated till all ants construct their solutions. The termination condition of the solution construction process is the impossibility of adding new nodes without violating any of the constraints of the problem.

We propose the following heuristic information to be applied, where worker i, performs job j for time l, formula 10:

$$\eta_{ijl} = \begin{cases} l/c_{ij} & l = z_{ij} \\ 0 & otherwise \end{cases} \tag{10}$$

This heuristic information incentives the assignment of the cheaper workers for as long as possible, thereby reducing the overall cost of assigning the workers. Following the rules of ACO algorithm the next included node in the partial solution is the node with highest probability. If there happen to be several nodes with a probability equal to the maximum, then one of them is chosen at random as the next node in the partial solution. Each time a new node is included, it is checked whether the constraints of the problem are not violated, only then the new node is accepted.

If any of the constraints is not satisfied, then the value of the transition probability function corresponding to this node is set to be 0. If for all possible nodes the value of the probability function is 0 the solution construction stops, since it is impossible to include new node in the current partial solution. When the achieved solution is feasible, the value of the objective function is calculated as a sum of assignment cost of all assigned workers. The value of the objective function can not be negative. Therefore we set the value of the objective function to be -1 for infeasible solutions.

We deposit additional pheromone only on the elements of feasible solutions and it reflects the quality of the problem solution, which is measured by the value of the objective function. Workforce planning problem is a minimization problem, so the new added pheromone is proportional to the reciprocal value of the objective function:

$$\Delta\tau_{i,j} = \frac{\rho - 1}{f(x)} \tag{11}$$

So the elements of the graph of the problem, belonging to better solutions with less value of the objective function will accumulate more pheromone than others and will be more wanted in the next iteration. The global best so far solution is updated at the end of every iteration. We compare the iteration best solution with the current global best one and if the iteration best solution is better, with less value of the objective function, we accept it as a new global best solution. In our application as end condition we apply number of iterations. When the algorithm reaches the pre-fixed number of iterations, it stops further calculations.

IV. Local Search Procedures

A common practice is to combine a metaheuristic algorithm with some other algorithm. This can be another metaheuristic algorithm, a numerical method, an exact method, or a local search procedure. These are the so called hybrid approaches.

The purpose of combining algorithms can be in several directions. The combination can be aimed at avoiding local optima or falling into a region of infeasible solutions. In this case, a combination with a local search procedure is usually used. Another goal may be to prevent early stagnation of the algorithm and find better solutions. The combination of methods, especially if it is applied to each iteration, leads to an increase in the time to run the iteration. Combining methods can lead to finding good solutions at an earlier stage, with fewer iterations, and in turn reduce the time to solve the problem.

In this paper we propose several variants of local search procedures, which are specifically tailored to the workforce planning problem. Our aim is decrease the number of infeasible solutions and thus to increase the diversification.

Local search procedures generate one or more solutions to the problem based on a current solution. These solutions are called neighborhood solutions. If the neighboring solutions thus generated are feasible, then we compare the best among the feasible neighboring solutions with the current solution. If the neighboring solution is better than the current one, then we replace the current solution of the problem with the neighboring one.

As noted, the local search procedure increases the execution time of a single iteration. If it is not efficient enough, it could also increase the execution time of the algorithm, the time to find good solutions. We apply the local search procedure only on the infeasible solutions. Our goal is to increase the number of feasible solutions and thus increase the choice. This, in turn, could lead to finding good solutions at an early stage of algorithm execution, which would reduce the time to solve the problem.

The main thing in the local search procedures that we offer is the removal of some of the appointed workers and the appointment of new ones in their place. After removing part of the workers, we get a partial solution, which is supplemented by assigning new workers by the use of ACO algorithm. The algorithm is stochastic, thus with a high probability, the new solution will be different from the previous one. From our previous research [7], we have found that it is best to remove half of the assigned workers.

We have compared three variants of the local search procedure:

- The workers to be removed are randomly selected. The procedure is applied once, regardless of whether the new solution is feasible or not [7];
- The workers to be removed are randomly selected. The procedure is repeated until a valid solution is constructed [8];
- The most expensive workers are removed. The procedure is applied once, regardless of whether the new solution is feasible or not.

The workforce planning problem is very complex with tight constraints. Because of this, it happens that there are iterations in which no ant succeeds in finding a feasible solution. We observe that after applying any of the listed procedures for local search, the number of infeasible solutions in subsequent iterations is greatly reduced. So the local search procedure is mainly applied to the first iterations. In subsequent iterations, it is less and less necessary to apply it. Due to the application of the local search procedure only on the infeasible solutions and reducing the need to apply it on subsequent iterations, it does not significantly increase the execution time of the algorithm.

V. Computational Results and Discussion

In this section are shown and compared the test results of application of proposed hybridization. The proposed local search procedures, combined with the ACO algorithm are tested on 10 structured and 10 unstructured problems. In our previous work [7] we research on the impact of the number of the removed workers from the solution. We tested with removing a quarter of the assigned workers, removing half of the assigned workers and removing all of the assigned workers (full restart). We found that the best results are achieved when removing half of the assigned workers. So in this work, when we apply any of the proposed local search procedures , we remove half of the assigned workers and complete the solution applying ACO algorithm.

The software, which realizes the algorithm is written in C programming language and is run on Pentium desktop computer at 2.8 GHz with 4 GB of memory. The proposed hybridizations are tested on artificially generated problem instances from [1].

The set of test problems consist of 10 Structured problems, enumerated from S1 to S10 and 10 Unstructured problems, enumerated respectively from U1 to U10. A problem is structured, when parameter d_j is proportional to the parameter h_{min} and it is unstructured when d_j is not proportional to the parameter minimal working time h_{min}. In our previous work [6] is shown that our ACO algorithm without hybridization outperforms Genetic algorithm and Scatter search from [1]. The stopping criteria is achieving the best found solution for the same test instance from [7], [8]. We apply same parameter settings for all variants of hybridization of ACO algorithm and they are fixed after several experiments.

The process of searching and constructing solutions in solving the workforce planning problem is very complex because of the strict constraints. The aim of the application of local search procedure is as many infeasible solutions of the problem, from the current iteration, become feasible, as well as to reduce the number of infeasible solutions found by the traditional ACO algorithm in the next iterations. This increases the chance that the underlying algorithm will find better solutions, as well as reduces the number of iterations needed to find those solutions. The proposed local search procedures do not spend much computational time because they are applied only over the infeasible solutions. Moreover, there is a sharp reduction in the number of iterations required to find these solutions.

We perform 30 independent runs with every of the test problems, because the algorithm is stochastic and to guarantee the robustness of the average results. We apply ANOVA

TABLE I: Calculation time in seconds

test instance	random remove	many times remove	maximal remove
S1	4.01 s	**3.75 s**	**3.92 s**
S2	19.97 s	**4.48 s**	**4.52 s**
S3	32.96 s	17.57 s	**7.75 s**
S4	37.22 s	46.64 s	**14.50 s**
S5	3.78 s	3.79 s	**2.40 s**
S6	5.12 s	**4.26** s	7.07 s
S7	31.23 s	36.18 s	**10.50 s**

U10	**5.64 s**	6.224 s	9.95 s

test for statistical analysis to guarantee the significance of the difference between the average results. We compare the calculation time to find the best solution for every of the 20 tests.

Table I shows the needed calculation time to find best solution. The first column is the name of the test. The second column shows the needed time to find best solution, when we remove from infeasible solutions randomly chosen half of the workers, no matter if the new solution is feasible. The third column shows the needed time to find best solution, when we apply random remove of the half of the workers till the solution become feasible. The fourth column shows the needed time to find best solution when we remove from infeasible solution half for the workers, which are most expensive, no matter if the new solution is feasible. With the bold is shortest time to find best solution. Comparing structured problems, we observe that the hybrid ACO algorithm with local search procedure removing half for the workers, which are most expensive, needs less time to achieve best solution, eight of the ten cases. Regarding unstructured problems result is different. Hybrid ACO algorithm with local search procedure removing half fo the workers in a random way and applied one time, achieves best solution for a least time four times, when the local search procedure is applied many times till achieving feasible solution the least time is five times and when the local search procedure removes the most expensive workers, algorithm achieves the least time only two times. We observe big difference in hybrid algorithms performance when they are applied on structured and on unstructured problems. We can confirm that for structured problems is better to apply hybrid ACO algorithm with local search removing most expensive workers and the local search procedure can be applied only ones, no matter if the new solution is feasible. For unstructured problems it seems better to apply many times local search procedure till the solution becomes feasible. The difference comes from the fact that in unstructured problems it is more difficult to reach feasible solutions.

VI. Conclusion

In this paper we apply hybrid ACO algorithms to solve workforce planning problem. The traditional ACO algorithm is combined with several local search procedures. The local search procedures remove half of the assigned workers. Two of the procedures chose the removed workers in a random way and the third removes the most expensive workers and try to assign more cheapest. All local search procedures are applied only on infeasible solutions. The proposed hybrid algorithms are tested on 10 structured and 10 unstructured test instances. We observe that for structured instances, best performance has the local search procedure, which removes most expensive workers.

***Abstract*—XR environments are successfully used in various domains, such as medicine, education, training, and industry. Such environments contain domain knowledge expressed through content and users' behavior. However, current approaches to XR creation lack possibility of exploration of the knowledge included in the environments and expressed by the users' behavior. In this paper, we propose a method of knowledge exploration in XR environments, enabling the analysis of past and potential behavior of users and objects, with queries and automated reasoning. This solution aims to enhance knowledge dissemination using XR.**

I. Introduction

XR SYSTEMS' rising popularity stems from their potential across domains and their ability to offer immersive experiences. However, existing systems often overlook event and interaction analysis within virtual environments, leading to a loss of valuable information. To enhance user experience, there's a crucial need to focus on exploring and analyzing XR system data for hidden insights.

Actions and interactions within XR environments can be explored through semantic queries and automated reasoning, particularly beneficial in employee training systems. This exploration offers valuable insights into users' behavior across different timeframes.

The knowledge gained from exploration is vital for monitoring, analyzing, and controlling XR environments, as well as understanding users' skills, experiences, interests, and preferences. Domain-specific terminology helps specialists, the primary users of XR environments, take full advantage of behavior exploration.

This paper introduces a new method for exploring XR environments, encompassing both forward and backward exploration through semantic queries on the XR environment's knowledge-based representation. The proposed methods were applied to represent the behavior of the virtual environment in an industrial XR training system developed for Amica S.A, Poland's leading house appliances manufacturer, to train employees on specialized industrial devices.

The paper's structure is as follows: Section II presents an overview of the current state of exploring virtual environments. Then, Section III explains the methods used to describe virtual content. Section IV elaborates on exploration methods with examples and an overview of exploration for the XR training system. Finally, Section V concludes the paper and suggests potential areas for future research.

II. Related work

Numerous approaches model 3D content behavior using ontologies and semantic web standards. One notable approach, as discussed in Pellens et al. [1], [2], [3], introduces temporal operators for expressing both primitive and complex behaviors. They also offer a graphical tool to model complex behavior using diagrams, encoding it within X3D scenes [4].

In another approach, De Troyer et al. [5] combine primitive actions like move, turn, and rotate to represent complex behavior in a user-friendly manner. This approach enables end users to specify complex behavior without extensive knowledge of 3D graphics and animation.

Krieg-Brückner et al. [6] introduce a tool using semantic concepts, services, and hybrid automata to describe 3D content behavior. The tool consists of a client component based on a 3D content presentation tool (e.g., XML3D browser) and a server component with various services for content selection and configuration. Additionally, an extra module manages intelligent avatars and their perception of the scene.

Chmiel et al. [7] proposed XSD-based semantic metadata schemes for 3D object interactivity, specifying events, conditions, and actions. CL ontologies [8], [9] represent multi-user virtual environments and avatars, defining geometry, space, animation, and behavior of 3D content. They include semantic counterparts to widely used formats like VRML and X3D. Environmental objects are described by attributes like translation, rotation, and scale, while avatars have names, statuses, user interfaces (UIs), and behavior defined through code bases

In recent research, there has been a notable focus on humans and their interactions within virtual reality, particularly in creating ontologies for experimental purposes. One such recent work is the Virtual Human-Building Interaction Experimentation Ontology (VHBIEO) proposed by Chokwitthaya et al. [10]. The primary objective of this solution is to establish a standardized approach for conducting experiments related to human-building interactions within virtual reality environments. In a similar vein, Heitmayer et al. [11] have introduced another ontology focusing on the human-centred analysis and design of virtual reality conferencing. The main goals of this ontology include enhancing user experience, facilitating research on VR conferencing (particularly in the realms of psychology and behavior), and enabling the sharing of research findings among the scientific community.

III. Representation of XR Environment

In order for the XR environment to be appropriate for exploration, it needs a proper representation of interaction and 3D content. This can be created using knowledge representation technologies such as the semantic web (the Resource Description Framework—RDF [12], the RDF Schema—RDFS [13], the Web Ontology Language—OWL [14] and the SPARQL query language [15]) and ontologies.

For the presented methods of exploration, we prepared behavioral semantic models for the representation of activities, called Activity Ontology, as well as the representation of the workflow.

A. Representation of Activities and Features

Activities and features act as domain-specific states that connect the behavior model and the implementations of XR components. Within the Activity Ontology, the Semantic Web approach defines the representation of these activities and properties. This ontology comprises a TBox and an RBox that contain axioms outlining how users' and objects' features and activities are implemented within XR components and environments. The activity ontology is well suited for both procedural and object-oriented XR implementations.

Fig. 1 shows how class in the XR system is mapped to ontology to activity ontology.

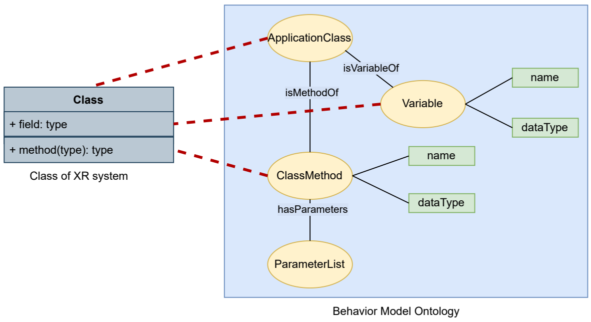

Fig. 1. Mapping XR system class to Activity Ontology

Since both procedural and object-oriented XR implementations rely on functions as the fundamental building blocks of workflow, the activity ontology supports structuring both types of implementations.

The ontology specifies the following classes and attributes associated with code elements:

1) ApplicationClass — is the class of all application classes specified in the code of XR components.
2) Variable — is the class of all variables.
3) ParameterList — is the class of all lists of method parameters.
4) ClassMethod — is the class of all methods specified in the code of XR components

The example of a knowledge base generated using activity ontology is presented in listing 1. The example shows described class *Battery*, which has variable *Charge* and method *ConnectRectifier*.

Listing 1. A fragment of knowledge base describing element of XR system

```
ao:Battery rdf:type owl:NamedIndividual ,
                    ao:ApplicationClass .

ao:ConnectRectifier rdf:type owl:NamedIndividual ,
                    ao:ClassMethod ;
           ao:isMethodOf ao:Battery ;
           ao:datatype "bool"^^rdfs:Datatype ;
           ao:name "connectRectifier"^^xsd:string .

ao:Charge rdf:type owl:NamedIndividual ,
                      ao:Variable ;
             ao:isVariableOf ao:Battery ;
             ao:datatype "integer"^^rdfs:Datatype ;
             ao:name "charge"^^xsd:string .
```

B. Workflow Representation

The workflow representation adapts the behavior model to describe states, events, and time related to the execution of class methods. Hence, it enables the specification of XR components' behavior upon their underlying imperative implementation.

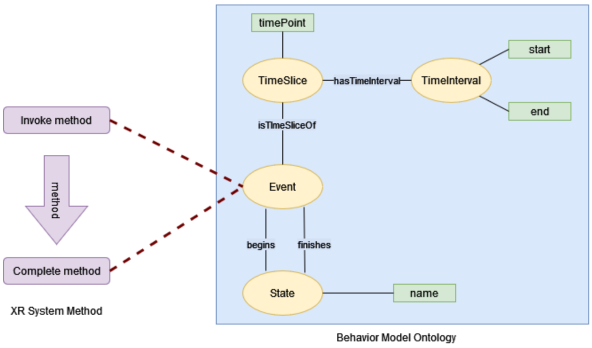

Fig. 2. Mapping the XR system method to fluent ontology

The example of the mapping method of the XR system to behavior model ontology is presented in Fig. 2. An event mapping states that the beginning of an activity is a method invocation or that a method completion is the finish of an activity. Hence, event mappings enclose states of method executions using domain events. Using such mapping, the system can generate a knowledge base, which can be treated as behavioral logs, therefore, can be explored by proper queries. An example of such a knowledge base is presented in Listing 2. The example describes two events that happened while using the system. The first event was ”The visual inspection of the battery”. That event began *BatteryState1* and finished *BatteryState2*. This event had assigned *TimeSlice*, which gives us information about when and how long the event lasted.

Listing 2. A fragment of knowledge base describing event

```
fo:Event1 rdf:type owl:NamedIndividual ,
                   fo:Event ;
          fo:begins fo:BatteryState1 ;
          fo:finishes fo:BatteryState2 ;
          fo:name "Visual␣inspection␣of␣battery"^^xsd:
               string .

fo:TimeSlice1 rdf:type owl:NamedIndividual ,
                       fo:TimeSlice ;
              fo:hasTimeInterval fo:TimeInterval1 ;
              fo:isTimeSliceOf fo:Event2 .
```

```
fo:TimeInterval1 rdf:type owl:NamedIndividual ,
                          fo:TimeInterval ;
                 fo:end "2023-05-20T10:03:12"^^xsd:dateTime
                     ;
                 fo:start "2023-05-20T10:04:22"^^xsd:
                     dateTime .
```

IV. Exploration

In this section, we propose different types of knowledge exploration and visualization within explorable XR environments, utilizing the models proposed in the previous section. We classify these exploration types based on the target periods, distinguishing between simulation with forward and backward exploration.

Simulation and forward exploration facilitate the process of reasoning and querying potential events and states in the XR environment. These events and states may remain undetermined, contingent upon the occurrence or absence of other events and states within the environment. Engaging in simulation and forward exploration necessitates a composed XR environment, which does not necessarily need to be compiled and run. Consequently, simulation and forward exploration can be initiated promptly after composing the environment.

Backward exploration enables the process of reasoning, querying, and visualizing past and present events and states that have been logged in behavior records. To engage in backward exploration, the XR environment must be executed, and behavior logs need to be generated.

Queries play a crucial role in acquiring knowledge about explorable XR environments. Nevertheless, despite their possible support in query languages such as SPARQL, our focus does not revolve around query result presentation operations like result limitation, sorting, or data aggregation. Instead, our primary emphasis lies in utilizing queries to gain deep insights into the properties and behaviors of the XR environment, facilitating exploration and understanding.

By applying these techniques for knowledge exploration and visualization, we elevate our comprehension of the dynamic nature of XR environments and empower users to interact effectively, reason, and query within these environments. These approaches serve as invaluable tools for researchers and developers, enabling them to delve into the potential of explorable XR environments and propel innovation in this field.

We used new exploration methods to query the behavior of users and 3D objects inside a virtual environment for the industrial worker training XR system, which allows trainees to learn how to act safely in an industrial setting. The training scenario implemented in the system focuses on safe work with a forklift. It was developed using resources from Amica S.A., a major producer of household equipment in Poland.

A. Simulation with forward exploration

Forward exploration facilitates reasoning and queries about the potential behaviors of users and objects within explorable XR environments. It encompasses various states and events associated with features and activities, encompassing autonomous actions and interactions among users, objects, and their interplay. Crucially, forward exploration is intimately intertwined with the simulation of environmental behavior, which aims to fulfil conditions necessary for events and states. As a result, simulation precedes forward exploration, encompassing both aspects within simulation queries. Importantly, since simulation and forward exploration revolve around potential events and states, they necessitate a workflow specification but do not mandate that the XR environment be actively running.

Simulation queries to an environment specification enable forward exploration of the environment without running it. Therefore, they must specify the conditions for which the exploration is accomplished. The illustrative simulation queries presented in this section assume that the delay between an event and another following event is equal to 0.001, and no exceptions are thrown during the execution of methods:

$Delay$ =0.001 $\bigwedge exception(executed(Method, ExecutionID), null)$.

To allow forward exploration, the following elements of the XR system were mapped to semantic representation using Activity Ontology:

Classes:

1) Trainee (class representing trainee),
2) Forklift (class representing forklift),
3) Battery (class representing battery),
4) Rectifier (class representing rectifier).

Methods:

1) startForkliftInspection (method of Trainee class),
2) finishForkliftInspection (method of Trainee class),
3) chargeBattery(method of Rectifier class),
4) insertBattery(method of Forklift class),
5) showChargingState(method of Rectifier class),
6) plugIn(method of Rectifier class)

Additional predicates were also used, allowing for the representation of temporal entities:

time(event,tp) — predicate that is true for a given event and a time point if and only if the event occurs at the time point.

holds(event,ti) — predicate that is true for a given event and a time interval if and only if the fluent is true within the time interval

Using such prepared knowledge representation, we are able to create the following queries:

1. How long will it take to check the visual state of a forklift?

$time(startForkliftInspection(Trainee, Forklift)), TP_{start}) \bigwedge time(finishForkLiftInspection, TP_{end}) \bigwedge Lenght = TP_{end} - TP_{start}$

It determines the time points of starting and finishing a forklift inspection and calculates the inspection length. (The Fig. 3 presents how a user inspects the forklift in XR system.) The query result is the following:

$TP_{start} = 10,\ TP_{end} = 22,\ Lenght = 12$

2. What will happen after a trainee finishes charging the battery?

$holds(chargeBattery(Trainee, Battery), TI_1) \bigwedge holds(Action, TI_2) \bigwedge after(T_1, T_2)$

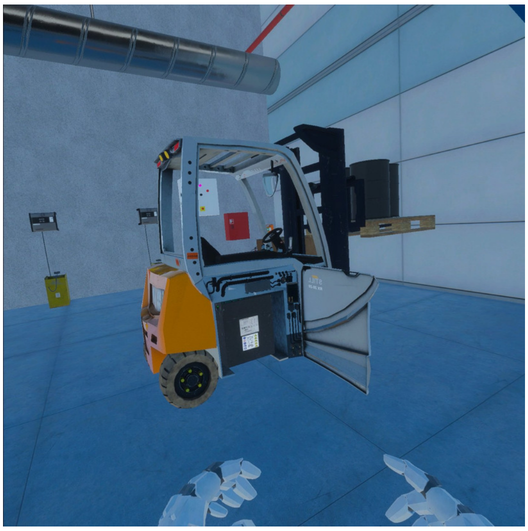

Fig. 3. A user inspects the forklift

It searches for the charging battery event and its time interval and time interval and action that happened later by using the after predicate, which compares time intervals. The query result is the following:

$Action = insertBattery(Trainee, Battery))$

3. What are the possible states (color of light) of rectifier after plugging in the battery?

$holds(showChargingState(lightColor), T_1) \bigwedge holds(plugIn(Battery), TI2) \bigwedge after(T_1, T_2)$

It searches for the event describing showing the charging state of the rectifier that happened after plugging in the battery. The possible answers are:

$lightColor = red,\ lightColor = yellow,\ lightColor = green$

B. Backward exploration

Backward exploration allows for the analysis and querying of activities that took place during the operation of an explorable XR environment.

Unlike forward exploration, which relies on simulating the environment's behavior, backward exploration uses logged activities. This eliminates the need for environmental behavior simulation. Furthermore, the inclusion of temporal statements with visual descriptors in behavior logs enables the visualization of past activities.

Queries specifically designed for backward exploration are referred to as exploration queries. The output of an exploration query is defined similarly to a simulation query. The behavior logs are structured based on RDF, enabling the utilization of the SPARQL language for conducting backward exploration. The example of behavior logs in the form of knowledge-base was presented in Listing 2.

a) Query 1: Which events had happened before the forklift was turned on?

```
SELECT  ?eventName
WHERE { ?event rdf:type fo:Event  .
        ?timeSlice fo:isTimeSliceOf ?event .
        ?event fo:name ?eventName .
        { ?timeSlice fo:timePoint ?time . }
        UNION{
        ?timeSlice fo:hasTimeInterval ?timeInterval .
        ?timeInterval fo:start ?time . }
        ?PushButtonEvent fo:name "Turning on the forklift
             "^^<http://www.w3.org/2001/XMLSchema#string> .
        ?PushButtonTimeSlice fo:isTimeSliceOf ?
             PushButtonEvent .
        ?PushButtonTimeSlice fo:timePoint ?pushButtonTime .
FILTER (  ?time < ?pushButtonTime)}
ORDER BY ?time
```

The first query provides information about what happened in the scene before the trainee pushed the press button, which activated the forklift. The query searches for events and their assigned time slices that happened before the event with the name "Turning on the forklift". The action of turning on the forklift presents Fig. 4.

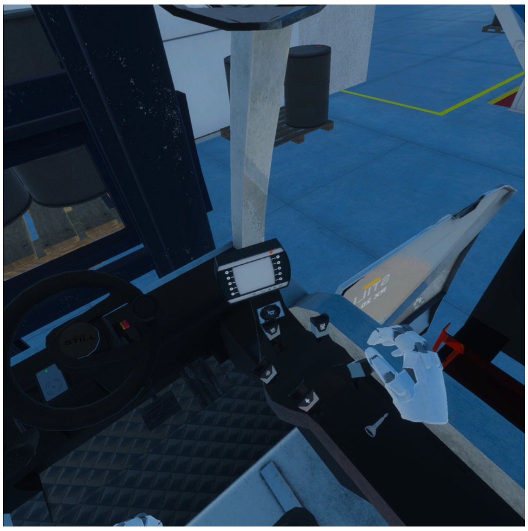

Fig. 4. A user turns on the forklift

b) Query 2: How long the battery was inspected?

```
SELECT ?start ?end
WHERE { ?event fo:name "visually controlling the battery
     "^^<http://www.w3.org/2001/XMLSchema#string> .
        ?timeSlice fo:isTimeSliceOf ?event .
        ?timeSlice fo:hasTimeInterval ?timeInterval .
        ?timeInterval fo:start ?start .
        ?timeInterval fo:end ?end .}
```

The second query gives information about the duration of the visual inspection of the battery. The query searches for the time slice of the event named "visually controlling the battery", then using the time interval object, access the information when the event started and ended. Fig. 5 presents, how user inspects the battery in virtual scene.

c) Query 3: When and What states did the battery transition into?

```
SELECT ?begins  ?stateName ?stateID
WHERE{ ?state rdf:type fo:InstantState .
        ?object fo:hasState ?state .
        ?object fo:name "battery"^^xsd:string .
        ?state fo:name ?stateName .
        ?state fo:id ?stateID .
        ?event fo:begins ?state .
```

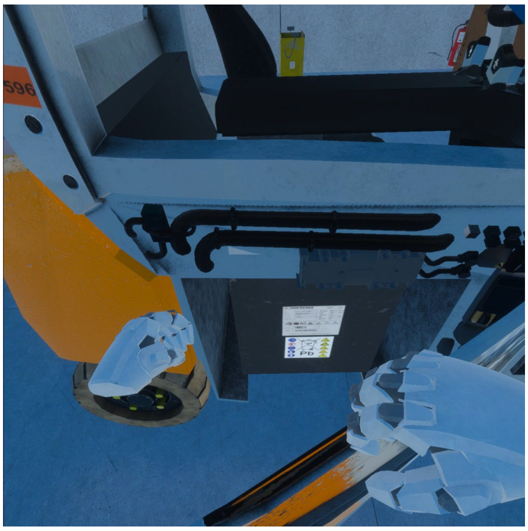

Fig. 5. The user inspects the battery

```
    ?timeSlice fo:isTimeSliceOf ?event .
    ?event fo:name ?eventName .
    { ?timeSlice fo:timePoint ?begins . }
    UNION {
    ?timeSlice fo:hasTimeInterval ?timeInterval.
    ?timeInterval fo:start ?begins . } }
ORDER BY ?begins
```

The last query provides information about what happened sequentially with the battery. The query searches for events that changed the states of the scene object named "battery". Then using proper time slices, the query determines the time by which the states are ordered. The results consist of the name and id of the states and the time when they have begun.

V. Conclusions and Future Work

The use of exploration of behavior and 3D content in XR systems can have multiple applications, like learning about users, their experience, preferences, and interests and measuring their skills. This can be beneficial, for example, in virtual training, where we want to maximize the training results.

In this paper, we have proposed methods for forward and backward exploration based on semantic queries. The presented approach uses the knowledge-based representation of the XR environment, which is represented by described ontologies. Moreover, we provided examples of explorations based on the developed XR system for employee training in an industrial environment.

The possible future research directions could focus on developing available inexperienced user plug-ins for simplifying and automating the process of creating semantic queries and visualization of the results.

***Abstract*—The use of online video content plays a vital role in marketing strategies and is a significant component of internet usage. The challenge lies in evaluating the impact of video content on user engagement and finding ways to enhance its performance without employing techniques that overwhelm users or prompt ad avoidance behavior. This study investigates the correlation between video dynamics metrics and eye-tracking patterns to determine if user engagement, as indicated by fixations, is influenced by these metrics. The findings demonstrate that dynamic metrics can accurately predict eye-tracking patterns for brief videos and can be applied to measure both inter and intra-scene dynamics in multiscene videos.**

I. Introduction

ONLINE video content is a popular medium that comprises a significant share of internet usage, with its consumption expected to rise to 82% of all internet traffic by 2022, up from 75% in 2017, according to Cisco's 2018 report [6]. Video content is widely used for marketing purposes, in the form of in-stream ads or integrated with editorial content on social platforms, games, or portals[17]. Content creators often use techniques that increase user engagement through emotional content, visual effects, and high dynamics, but these techniques can also increase cognitive load and distract users from their main goals within websites[14]. This decreased user experience may lead to users skipping advertising content, particularly when it fails to catch their attention at first glance. Hence, content producers face the challenge of creating video ads that are less likely to be skipped by consumers, which can be achieved by lowering intrusiveness and the dynamics of the video content. This paper investigates how the dynamics of video, as represented by dedicated metrics, relate to eye-tracking patterns, and whether the dynamics of video can predict user engagement, as represented by fixations. The secondary goal is to examine the impact of intra-scene differences on user attention within multi-scene videos. The primary aim is to explore methods of building videos with low dynamics and low cognitive load while maintaining enough differences between them to sustain user attention.

II. Literature review

Although there is already some research on television advertising, there is still an opportunity to delve deeper into the area of online video ads, as this format is more captivating and hence more widely used than static display or text ads [19]. Advertisers and advertising area providers need to know when video ads start to become too distracting, which can result in the use of ad blockers. This situation underscores the need to search for factors that affect video ad performance [20], especially those that can be used to attract users' attention and keep them engaged [5] [11]. High cognitive load may result from different ad characteristics, such as high video dynamics or the use of intense colors or sounds that are perceived as disturbing[15]. The following research focuses on measuring video ad dynamics as a factor affecting performance. An algorithm that automatically extracts several features, including video-level visual variance, scene-to-scene visual variance, and average scene cut frequency, was developed and published in [13] and further elaborated in [19] [2]. As the algorithm is publicly available, it was used in the following study.

One concept that plays a significant role in this notion is the level of involvement shown by consumers. Numerous writers have consistently reported that viewers who are more engaged in video content are less likely to skip it [10][21]. Other studies in this field have highlighted the correlation between ad avoidance and cognitive factors that are closely linked to engagement. For instance, in [1] [4], it was discovered that avoiding ad content may be connected to high and low arousal levels elicited by the content. A comparable finding was outlined in [18], which revealed that unstimulating, uninteresting content increases the desire to skip ads[9]. The primary factor influencing consumers' tendency to avoid ads is the engagement level of the ad content. Additionally, the length of the video ad is another critical factor that affects ad avoidance [18]. Numerous studies have discussed the relationship between ad length and the rate of ad avoidance, identifying a correlation between increased skipping behaviour and longer content [18] [12]. Other research has suggested that longer ads result in more disruption for goal-oriented search [9][3]. Recent studies have revealed that consumers' acceptance of longer videos has decreased, and nowadays, most people only accept very short video ads, such as fifteen or six seconds in length [18]. As a result, the current trend is to produce short video marketing content that better targets consumers' attention spans[7][8]. This trend is advantageous for ad providers because they can increase the rate of presenting content to consumers without increasing the total costs of a campaign. However, some studies have shown that longer ads may be more effective in enhancing brand recognition [12]. Ads that are shortened to fifteen seconds can achieve similar results in terms of awareness and brand recall as thirty-second spots[16].

In this current study, various factors were examined to evaluate the performance of videos. We aimed to investigate how the video's dynamics and differences between scenes can affect eye-tracking patterns and how user engagement relates to video dynamics, both at the level of single videos and intra-scene differences.

Conceptual framework

The conceptual drawing Figure 1 shows the stage 1 in which you can see the prepared video base divided into the length of the films and their dynamics. After preparation of the base, the test was carried out in laboratory conditions, with the intention of obtaining an increased number of fixations along with increasing dynamics.

Stage 2 presents the users' gaze pattern thanks to the eyetracker examination of interstage dynamics. You can see here an increase in dynamics in relation to the increasing number of fixations for short scenes versus long scenes, where such a relationship does not exist.

III. Algorithm description

To study video dynamics we implemented algorithm parented in Xi Li, Mengze Shi and Xin (Shane) Wang [13] and we extended it towards measuring inter and intra-scene dynamics. The input of the algorithm apart from file is the list of numbers being the numbers of consecutive frames that constitute the beginning of each new scene. Technically, a scene is a group shots which are successively taken together at a single location. A shot is a basic narrative element of the video which is composed of a number of frames that are presented from a continuous viewpoint. Automatically dividing a video into its shots is called the shot boundary detection problem in which the basic idea is identifying consecutive frames that form a transition from one shot to another. Currently, there are more or less effective solutions to this problem that can be used to obtain the above-mentioned list.

Additionally, one of the two possible parameters should be specified at the input of the algorithm. One of them takes numerical values ranging from [1, 100], and this value determines what percentage of all frames from each scene should be included in the calculation. For example, if the scene has 200 frames and the parameter value is 20, then 0.2 * 200 = 40 frames, possibly equally spaced from each other, will be extracted from the scene. The second parameter takes values greater than 0 and is an alternative to the previously described parameter. Its value determines the length of the time interval, which is the frequency with which the frame for the analysis will be extracted from the scene. If the scene is 10 seconds long and the parameter is set to 0.5 seconds, then 10 / 0.5 = 20 frames will be set in the scene.

In the first step, the algorithm loads the movie and run through its frames. Each frame is stored in the algorithm's memory as a three-dimensional matrix with dimensions equal to the resolution of the video. Each of the three layers of this three-dimensional matrix contains values that define one of the components of the RBG space for each pixel in the frame. Knowing the numbers of the first frames of all detected scenes, algorithm extracts the appropriate number of frames from each scene with a given interval or percentage, creating a new list for each scene containing the frames extracted for it.

The very measurement of dynamics of a video message is based on the measure provided by Xi Li, Mengze Shi and Xin (Shane) Wang [13]. In their work, the authors present the measure they named "visual variation" which is a normalized measure of the changes in visual information in a video. Determining the visual variation for two frames is carried out in the following few steps.

First, the frames are reduced from RGB to grayscale by averaging the color components of each pixel. The next step is to normalize the values from the range [0, 255] to the range [0, 1]. Authors of the measure mention that normalization serves the purpose of compensation for possible expousure difference. Further, the distance between the individual pixels of the two frames is calculated, where the distance is defined as the Manhattan norm

$$d(x'_i, y'_i) = |x'_i - y'_i| \tag{1}$$

After calculating the matrix with dimensions equal to the resolution of the compared frames, where each position in the matrix is the distance between individual pixels at the same position, the algorithm proceeds to the last step. Here our implementation of the measure differs from the one proposed by its authors. In the original implementation of this measure, in this step of the algorithm, all the determined absolute distances between each pair of pixels should be summed up. In our version, we chose to calculate the mean over the absolute distance of every pair of pixels. This change was aimed at obtaining the visual variation result in the range [0, 1]. This averaged value represents the size of visual variation between two frames.

In the next step determination of the internal dynamics of scenes takes place. This step consists in determining for each list containing extracted frames from individual scenes the average visual variation occurring between consecutive frames

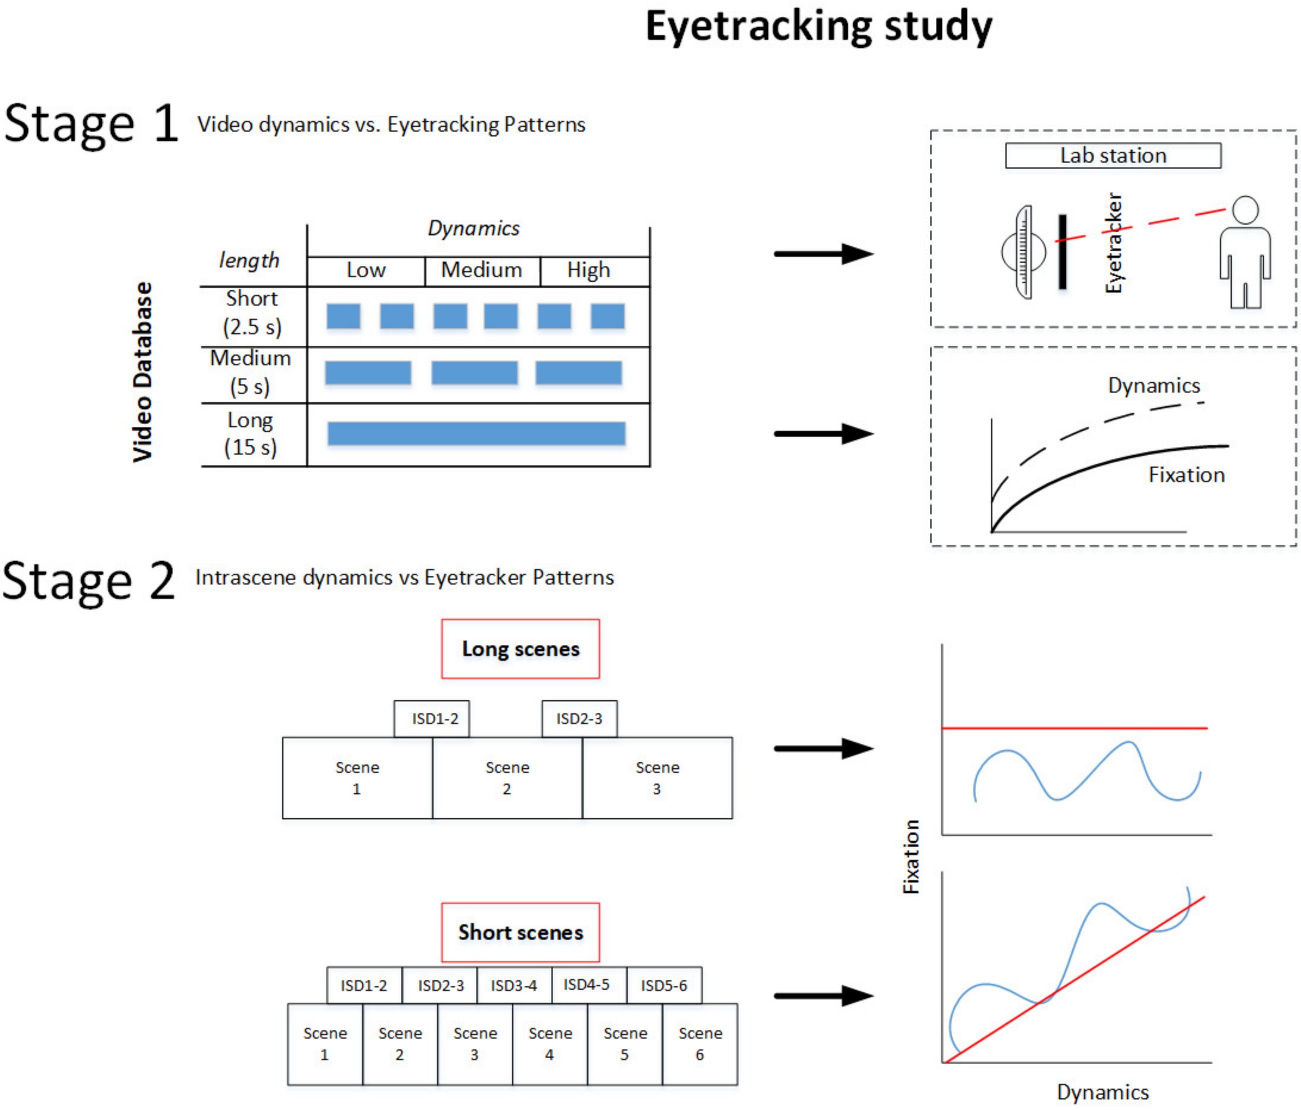

Fig. 1. Conceptual framework for study

in the list. For example, if only 3 frames have been extracted from the scene, then we calculate the value of visual variation between frames no. 1 and no. 2, and between frames no. 2 and no. 3. Then both values are averaged. The process could be written as follows

$$\mathrm{VVL} = \frac{1}{n}\sum_{i=1}^{n} d(F_i, F_{i+1}) \tag{2}$$

The equation of Visual Variation Level (VVL) where $\boldsymbol{n}$ is the number of frames, $\boldsymbol{F_i}$ is the frame number in the list and $\boldsymbol{d}$ is a function that returns the visual variation between two frames.

A. Determining the external dynamics between the scenes

External dynamics is the working name for the visual variation determined between successive scenes. The calculation of this measure takes place when the algorithm extracts appropriate frames from individual scenes into new lists. The algorithm knows the order of the lists, which corresponds to the order in which the scenes appear in the entire video transmission. Thanks to this, it can determine the visual variation between individual scenes in the same way as it was presented for a series of frames extracted from one scene.

The first step in determining external dynamics is to average the colors of all frames within each list. The averaged values should be rounded off as the values of the three-dimensional matrix should be integers in the range [0, 255]. This process can be represented by the following formula:

$$Af = [\frac{1}{n}\sum_{i=1}^{n} F_i] \tag{3}$$

Where $\boldsymbol{F_i}$ - a frame in the form of a three-dimensional matrix, $\boldsymbol{n}$ - the number of frames in a leaf, $\boldsymbol{Af}$ - the resulting averaged three-dimensional matrix.

The above step is performed for each list corresponding to a single scene. This way the algorithm comes to a point where it has an averaged three-dimensional matrix / frame for each scene. Now these averaged frames / matrices can be treated as ordinary frames for which the visual variation within one scene was calculated in the previous section. Here, however, it is done each time only between two averaged frames corresponding to two consecutive scenes (for example, the algorithm calculates the visual variation between the averaged frame from the first scene - s1 - and from the second scene - s2, then between s2 and s3, then s3 a s4… sn-1 a sn). Here, as before, each of the averaged frames is previously reduced to grayscale, normalized and the distances between individual pixels at corresponding positions are calculated, and finally the average is determined from these distances.

The algorithm returns the determined internal dynamics for each scene and external dynamics between successive scenes, as well as additional information about the total number of frames in the examined video, the length of the recording, the number of frames per second, the number of scenes, and the values of the set parameters.

Experiment and results

The experiment involved 30 people involved. The research group consists of 14 women and 16 men aged 20 to 40 years. The experiment used a 27-inch Dell monitor and the Tobii Pro X3 eyetracker with a sampling frequency of 120 Hz. A special stand with a tripod was prepared for the experiment, which made it possible to keep the head of each participant in a stationary position. The participant sat in front of the monitor at a distance of about 54 cm. Calibration was performed before each test.

The whole experiment was as follows: each person performed the task of clicking on points in accordance with the concept of Fitts' law. This task was a kind of a break between the screening of individual films prepared by us. These films were divided into 1, 3 or 6 scenes. Each of the films lasted 15 seconds. The important thing is the variety of internal and external dynamics of films. The internal dynamics have been divided into three levels: low, mid and high. The dynamics measures were determined thanks to the above-described algorithm. So the films were prepared in such a way that, depending on the number of scenes, each of them had the same dynamics.

The films have been divided into 21 combinations, as shown in the Table I The films of 3 and 6 scenes had dynamics measures individually for each of them. The division with respect to the internal dynamics was made additionally to the external dynamics between the scenes, hence so many combinations. Here we see diversity in terms of individual films and scenes. At first glance, the measures and the average number of fixations increase in line with the increase in the dynamics measure for individual scenes in specific movies. Movies and scenes with relatively the highest internal and external dynamics have the best average number of fixations. Here it should be mentioned that external dynamics can only be made for movies that have been divided into a plural number of scenes, ie more than one. Therefore, movies with one default scene were not taken into account in determining the external dynamics measures. As you can see in the Table I, the measure columns for external dynamics are defined for transitions between specific scenes. This allowed to define the dynamics just between them. Figure 2 (A) shows the influence of one intergroup factor, which is the number of fixations per scene, on the dependent variable which is the appropriate measure of dynamics. We can notice a clear upward trend in the number of fixations in relation to the increase in the internal dynamics of films. The number of fixations increases, respectively, from the average to the value of 4.4 for the low dynamics, 4.5 for the mid dynamics, up to the level of 5.0. Figure 2 (B) It shows the total dynamics of scenes for

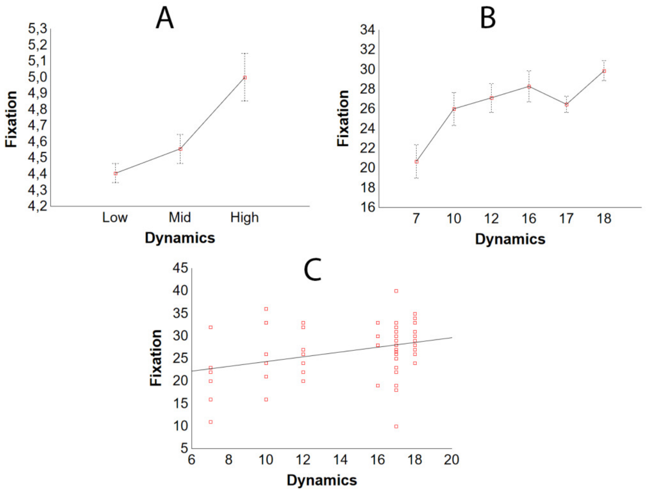

Fig. 2. Fig. A shows a curve prepared with the use of ANOVA statistics showing the trend of the increase in dynamics against the number of fixations for individual scenes. Fig. B shows the total dynamics of scenes showing the increase in dynamics in relation to the number of fixations for entire movies with 6 scenes. Fig. C shows a scatterplot for movie scenes with 6 scenes.

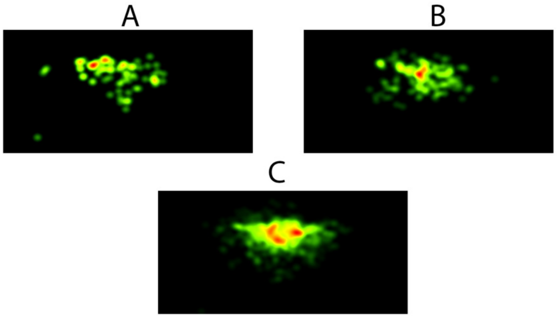

Fig. 3. Heatmaps with visible differences between the various dynamics of the film. Heatmaps A, B, C show three dynamics of movies, respectively: low, mid and high.

individual films. Here we see an increase in the number of fixations in line with the increase in dynamics in the movies. The trend is clearly increasing, i.e. the number of fixations increases proportionally to the total dynamics. We can see here the ranges for the weakest dynamics on the 7th level of the total number of almost 21 fixations, up to the range of 26 to 30 for the rest of the dynamics. Figure 2 (C) scatter regression plot shows the data in particular dynamics. The presented trend is clearly increasing. Figure 3 shows heatmaps with different dynamics variants. Heatmap A shows the dynamics of Low, the heatmap B shows the dynamics of mid, and the heatmap C the dynamics of high. You can see dense clusters for the high dynamics compared to the other two dynamics.

In this case, the analysis was based on the analysis of internal dynamics for individual films with high, medium and low dynamics. Also in this case, we see the differences between the individual films in each group of internal dynamics broken down by external dynamics.

Using Anova analysis, we see the significance for each dynamics in relation to the number of fixations for individual videos. The significance at the level of $p = 0.017$ indicates a significant dependence of the dynamics measures in relation to each film with the appropriate amount of fixations.

In order to standardize the measures, a division into three groups of dynamics was made using the cluster analysis, which made it possible to reliably and efficiently organize and standardize the groups of individual measures.

Mann - Whitney U statistical analysis, we can see that the intergroup comparison shows a statistical significance below $p < 0.05$ in a few cases. Performing an intergroup comparison here for 6 scene films only showed the significance of w between each group of dynamics. You can see strong differences between the low, mid and high dynamics.

Anova's analysis showed that the summary analysis of scenes for each type of movie shows a significance of $p < 0.05$, which is $p = 0.044$. This shows the strong influence of the amount of fixation on a given scene in the movie.

IV. CONCLUSIONS

Effective video content requires the integration of various elements that increase user engagement, such as emotional appeal, dynamic visuals, and attention-catching techniques. However, the extensive use of video content for marketing purposes has led to avoidance behaviors, such as video ad skipping or blocking. The acceptable length of videos for users has reduced to just a few seconds. Therefore, it is crucial to develop methods that allow the creation of effective content without sacrificing user experience. In our proposed approach, we demonstrated how metrics of video dynamics are correlated with eye-tracking patterns and can be used to create video content using scenes with different dynamics. By using a modified algorithm that determines the dynamics of individual films and scenes, we correlated these dynamics with the number of fixations while watching them. Our experiment's results showed that dynamic metrics as a predictor of eye-tracking patterns are effective for short videos and can be used for multi-scene films to measure dynamics between and within scenes. The statistics clearly showed an increase in the number of fixations in relation to the increase in dynamics, indicating a directly proportional relationship.

Moving forward, to address the complex challenge of combining these factors in a hybrid approach, in future we propose a framework that integrates both qualitative scene analysis and quantitative visual intensity measurements.

The hybrid approach will first involve a comprehensive scene analysis, where various elements such as objects, shapes, colors, and spatial relationships will be identified and categorized. This qualitative understanding of the scene will provide valuable context for the subsequent analysis. Nonetheless, we believe that this hybrid approach has the potential to enhance our understanding of visual perception and contribute to various fields, such as computer vision, human-computer interaction, and visual design. Through continued research and refinement, the proposed framework could open new avenues for investigating human visual perception and its applications.

Based on these findings, we recommend that advertisers create video content from short films to maximize user absorption. In the future, research will focus on identifying not only the characteristics of scenes based on color differences but also the characteristics of objects within scenes. This will allow for the evaluation of differences based on scene elements, not just visual intensities.

Performance assessment of OpenMP constructs and benchmarks using modern compilers and multi-core CPUs

Bartłomiej Gawrych and Paweł Czarnul
Faculty of Electronics, Telecommunications and Informatics, Gdansk University of Technology
Narutowicza 11/12, 80-233 Poland, email: pczarnul@eti.pg.edu.pl

***Abstract*—Considering ongoing developments of both modern CPUs, especially in the context of increasing numbers of cores, cache memory and architectures as well as compilers there is a constant need for benchmarking representative and frequently run workloads. The key metric is speed-up as the computational power of modern CPUs stems mainly from using multiple cores. In this paper, we show and discuss results from running codes such as: batch normalization, convolution, linear function, matrix multiplication, prime number test and wave equation; using compilers such as: GNU gcc, LLVM clang, icx, icc; run on four different 1 or 2-socket systems: 1 x Intel Core i7-5960X, 1 x Intel Core i9-9940X, 2 x Intel Xeon Platinum 8280L, 2 x Intel Xeon Gold 6130. Results can be regarded as suggestions concerning scaling on particular CPUs including recommended thread number configurations.**

I. Introduction

PARALLEL computing has become increasingly popular due to the widespread availability of multi- and many-core CPUs and accelerators such as GPUs, not only in cluster nodes, servers and workstations but also desktops and even mobile devices. In line with the hardware developments, many APIs are used for general purpose programming in such environments, including: OpenMP and OpenCL for shared memory systems with offloading to accelerators, OpenACC for directive based accelerator programming, CUDA for NVIDIA GPUs, Message Passing Interface (MPI) for internode communication among processes of a parallel application. OpenMP is very important due to its relatively easy to learn directive + library based multithreaded model allowing easy parallelization of sequential codes and support for offloading computations to accelerators such as GPUs [1].

The contribution of this paper over the state-of-the-art described in Section II, is assessment of OpenMP's implementation performance for a combination of: a variety of specific constructs and benchmarks, each of which benchmarked on various 1 and 2 socket systems with modern multi-core Intel CPUs and each tested using 4 compilers: GNU gcc, LLVM clang, icx, icc, run for various data sizes. Benchmarks include: batch normalization used in deep learning, convolution frequently used in signal processing, linear addition function benchmark, matrix multiplication, prime number test as well as wave equation simulation.

II. Related work

In [2] a set of microbenchmarks derived from EPCC and based on SKaMPI was run and analyzed on IBM SP3 and SunFire systems. Those included OpenMP's lock/unlock, critical section, barrier, single, parallel and parallel for directives. Times were measured for the two systems between 1 and 8 processors showing generally much better values for the Sun system especially showing sharp increases of times across the ranges for IBM SP3 vs Sun for barrier, for reduction, parallel and for single for >2 processors, critical for >4 and lock/unlock for >5 processors. In [3] performance of a Loongson-3A SMP quad-core system was assessed for EPCC microbenchmarks and NPB, using: gcc, OMPi with pthreads or psthreads. Testing parallel, for, parallel for, barrier and single for 1-4 threads, OMPi+pthreads tested best; for critical, unlock/lock, ordered and atomic gcc resulted in much larger overhead for 2-4 threads than the other very comparable solutions. For loop scheduling: static OMPi+pthreads and gcc were best while for dynamic and guided OMPi+pthread shall be preferred. The analyzed platform was also compared to Intel i5 with normalized (versus CPU clock) ratios for NPB (4 threads) between 1.3 (EP) and 5.1 (CG).

Authors of paper [4] benchmarked a 72-way Sun Fire 15K multiprocessor system with several EPCC microbenchmarks including measurements of overheads of OpenMP's frequently used construct implementations. OpenMP directives benchmarked included parallel, for, parallel for, barrier, single, critical, lock/unlock, atomic, along with scheduling modes such as static, dynamic and guided (1-128 chunk size). C and Fortran implementations were tested using 6, 12, 24, 48, 64 and 70 threads. Generally, overheads increase expectedly with the number of threads, in selected cases considerably starting with a given number of threads e.g. 48+ threads for critical, lock/unlock and atomic for the C implementation. Additionally, overhead of approximately 20% was measured for separate parallel+for in C and equivalent parallel+do in Fortran compared to combined versions. For NAS parallel benchmarks various maximum speed-ups were obtained: approximately 50 for BT and SP, 70 for LU, over 95 (superlinear) for CG, over 50 for MG and over 20 for FT.

In paper [5] the author investigated various OpenMP implementations of one of the most popular parallel programming paradigms – master-slave. Six versions were implemented, based on: OpenMP locks, the tasking construct, for loop dynamically partitioned, the latter two without and with overlapping merging results and data generation. Two concrete applications were implemented: one with irregular adaptive quadrature numerical integration and the second implementing finding a region of interest within an irregular image. gcc version 9.3.0 was used on two systems with: the first one with Intel i7-7700 3.60 GHz Kaby Lake CPU and 8 logical processors, the second one with two Intel Xeon E5-2620 v4 2.10 GHz Broadwell CPUs and 32 logical processors. All in all, for integration the best results were obtained for tasking and dynamic for with or without overlapping (for systems 2 and 1) while for image recognition for system 1 dynamic for and using locks while for system 2 dynamic for (both versions) and tasking with overlapping.

Scalability and overheads during execution of parallel code is studied in more detail in [6] where authors distinguished 4 overhead categories such as: need for synchronization among threads, imbalance, limited parallelism i.e. not (fully) parallelized code and thread management. For benchmarking the authors used OpenMP's version of NAS Parallel Benchmarks (class C) characterizing presence of particular OpenMP constructs in particular benchmarks – present mostly LOOP, PARALLEL and PARALLEL_LOOP in all tested as well (except PARALLEL in FT) as master in BT, LU, MG and SP; ATOMIC in BT, EP, LU and SP; BARRIER in IS and LU; CRITICAL in SP; SINGLE in LU. Codes were benchmarked using between 2 and 32 threads on an 32 CPU Itanium-2 based SGI Altix machine. All in all, imbalance appeared to be the largest overhead generally, as much as 20% for SP; synchronization turned out to be significant for IS (largest) and visible for LU. Thread management was noticed in IS, MG and CG although not large.

In paper [7] authors implemented and benchmarked 3 versions of OpenMP codes for an iterative Jacobi solver for 2D structured grids, representative of geometric SPMD codes such as for e.g. CFD applications. The code versions included: standard shared memory OpenMP host code with `parallel` and `do` directives, standard code augmented with `target` and `target data` directives and code with `target`, `target data`, `teams`, `distribute` directives. Codes were run on 2 systems: one with 2 Intel Xeon E5-2670 CPUs + 4 Intel 5110P Phis, the other with AMD Interlagos CPU + NVIDIA K20X GPU. For the first system (Intel compiler), offloading has been shown to be effective, even if offloading to self case, almost as good as the standard OpenMP code. For the second system (Cray compiler), only standard code on CPU and offload to GPU performed well.

In work [8] authors benchmarked OpenMP as a programming API through its language constructs on the IBM Cyclops64 system with 160 processing cores within a single chip. Specifically, EPCC microbenchmarks were used with their 3 elements testing: synchronization, scheduling as well as array directives and clauses. Overheads in terms of cycles versus numbers of threads within the 1-128 range were tested. Specifically, the overhead of `FOR` turned out to be only minimally higher than that of `BARRIER` and of `PARALLEL FOR` minimally larger than that of `PARALLEL`. The overhead of `SINGLE` is comparatively large. `DYNAMIC(1)` resulted in very large overhead, especially compared to `DYNAMIC` for chunk sizes 64-128 and `STATIC` for equivalent chunk sizes. Additionally, overheads of `PRIVATE` and `FIRSTPRIVATE` used in conjunction with `PARALLEL` add very small, minimally larger for the latter.

III. Methodology and benchmarks

Within the paper, we aim at comparative analysis of several orthogonal aspects in terms of OpenMP applications, including: many various benchmarks that differ in compute and memory intensity, as well as OpenMP directives used; tests for various input data sizes; several popular compilers: GNU gcc, LLVM clang, icx, icc; several CPUs representing various architectures and generations.

To evaluate performance, several programs were written using various OpenMP directives and their combinations. Problems benchmarked are as follows:

- **Batch-Normalization** – popular function used in deep learning, especially in computer vision problems [9].
- **Convolution** – method commonly used in signal processing, but also very popular in computer vision problems. This benchmark tests the parallelization of five nested loops and how collapse directive and its parameters are impacting performance.
- **Linear function** – performing multiplication and addition to each element of the array ($y = a * x + b$), testing if OpenMP's SIMD directive affects the execution time of the program.
- **Matrix multiplication** – we used implementation with O(n^3) complexity and parallelization with OpenMP's `schedule(static)` and `collapse` directives.
- **Prime number test** – implementation, which divides number by all numbers from 2 to $\sqrt{n}$, has been chosen in order to compare schedule clauses that are static, guided, and dynamic.
- **Wave equation** – benchmark testing the performance impact of using the `parallel` directive both within and outside of the time step loop (making the `parallel` directive called only once).

The experiments were carried out to test the performance of specific OpenMP implementations with an increasing number of threads for varying issue sizes, as well as the effect of various work-sharing directives. Multiple iterations of benchmarks were performed using sizes that were selected based on subjective criteria in order to conduct operations on various sizes, from small to large. The number of rounds was adjusted so the fastest execution of full benchmark measurement took longer than 1 second. Apart from measuring average time of a single run, our testing framework also calculated standard deviation which can be found on GitHub [10], along with full compilation configuration and compiler flags used for each platform.

IV. Experiments

A. Testbed environments

Table I details tested systems with configurations imposed by the production environments.

	CPU	S/C/T	Operating System	RAM
a)	Xeon Gold 6130	2/16/32	Ubuntu 18.04.3 LTS	256 GB
b)	Xeon Platinum 8280L	2/28/56	CentOS Linux 7 (Core)	192 GB
c)	Core i7-5960X	1/8/16	Ubuntu 18.04.5 LTS	16 GB
d)	Core i9-9940X	1/14/28	Ubuntu 20.04.2 LTS	128 GB

TABLE I
Configuration used to benchmark OpenMP implementations (S - Sockets, C - Cores, T - Threads)

Table II presents compilers and OpenMP versions which were used to evaluate the performance. Our intention was to compile with the latest stable OpenMP release available for each compiler at the time.

Compiler	Compiler Version	Name of OpenMP lib	OpenMP version in CMake
GNU GCC	10.2.0	libgomp.so	4.5
LLVM Clang	11.1.0	libomp.so	5.0
ICX	12.0.0	libiomp5.so	4.5
ICC	20.2.2.20210228	libiomp5.so	5.0

TABLE II
Benchmarked OpenMP implementations

B. Tests

Within the following tests, we present speed-ups versus the number of threads executing a particular benchmark, in selected cases for several variants and settings.

1) Batch-Norm: With the small problem size for Batch-Norm, the best performance improvement was achieved on processor (b) - peak performance was observed using only 32 threads and it was 25 times faster than sequential run. Using only 32 threads also gives the best result on processor (a), for the rest, using all available threads constituted an optimal solution.

With increased size the best performance for all examined CPUs was achieved using all available threads (Figure 1). The rapid performance loss that occurs when employing one more thread than half of those available is an interesting phenomenon – at this point, hyper-threading begins to function. Despite this problem, performance increases linearly when using more and more threads. This does not apply to the result of the GCC compiler on machine (b) where performance started to decline progressively once more than 32 threads were used.

2) Convolution: Results from Figure 2 demonstrate how crucial it is to employ the collapse clause when appropriate. If CPUs have enough threads to consume the first loop entirely, the rest of available threads will be idle. Using the `collapse` clause generates many more tasks which can be distributed among different threads, which results in better scalability than without this clause – characteristic speed-up when using divisible number of threads in relation to the iteration count of first loop no longer exists. Overall, deciding whether it is always better to use 2-level or 3-level collapsing cannot be done, as it depends on the used compiler and the machine – e.g. for the Clang compiler on machine (a), best improvement is for collapse(2), but on machine (b) for collapse(3).

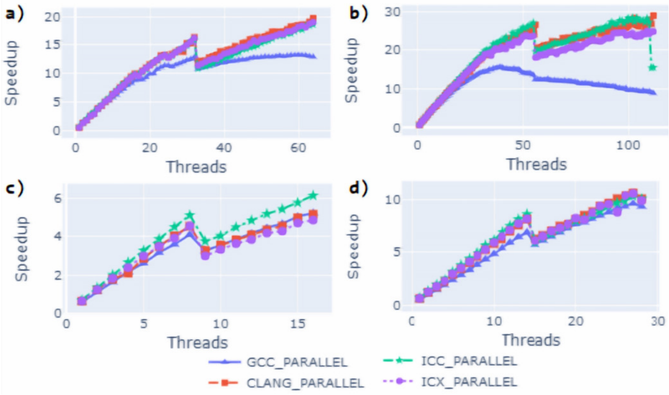

Fig. 1. Results of Batch-Norm with size N=32, C=2048, H=7, W=7

The results performed for N=256, H=112, W=112, kernel=3x3 indicate that when the first level loop has a large enough number of iterations to distribute tasks for each thread it is worthwhile to consider not using the `collapse` clause at all. It can be observed on machine (c) with GCC compiler and machine (d) ICC compiler.

3) Matrix Multiplication: For matrix-vector multiplication, in the case of desktop processors – (c) and (d), the results are satisfying and linear improvement can be observed for all compilers. Using the `collapse` clause has neither beneficial nor negative effect there. However, in server type CPUs differences show up. On machine (a) using the `collapse` clause causes performance degradation for every compiler. On machine (b) linear speed-up was disrupted by occurred anomalies after using more than 28 threads, which indicates the use of the second NUMA node.

For small square matrix-matrix multiplication desktop CPUs scale well and only a characteristic performance drop becomes apparent when hyper-threading comes into play. For configuration (a) and (b) compilers ICC and ICX allow good scaling and positive effect of using the `collapse` clause can be observed. For other configurations, scaling is much more irregular - especially for Clang on machine (b).

Increasing the size by an order of magnitude in each dimension causes all configurations but (b) to suffer from using hyper-threading as performance drops dramatically. Additionally, differences between using or not-using collapse construction are not visible for this size. The best scaling can be observed for configuration (b), but again, with anomalies visible in Figure 3 - when using HT threads.

4) Linear function: Tests performed for size=10000 showed very limited speed-ups. When the size is two orders of magnitude larger, the results are significantly better. In this example, letting the OpenMP implementation to determine chunk size automatically produces far better results than using

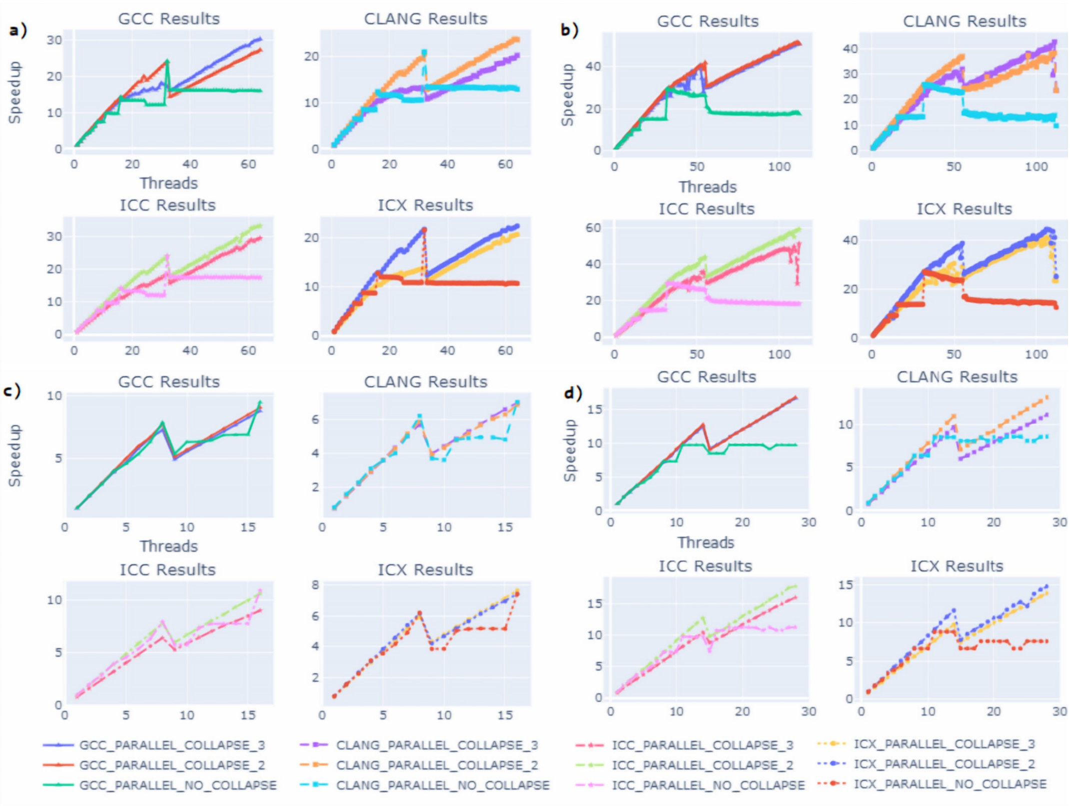

Fig. 2. Results of Convolution with size N=32, H=224, W=224, kernel=7x7

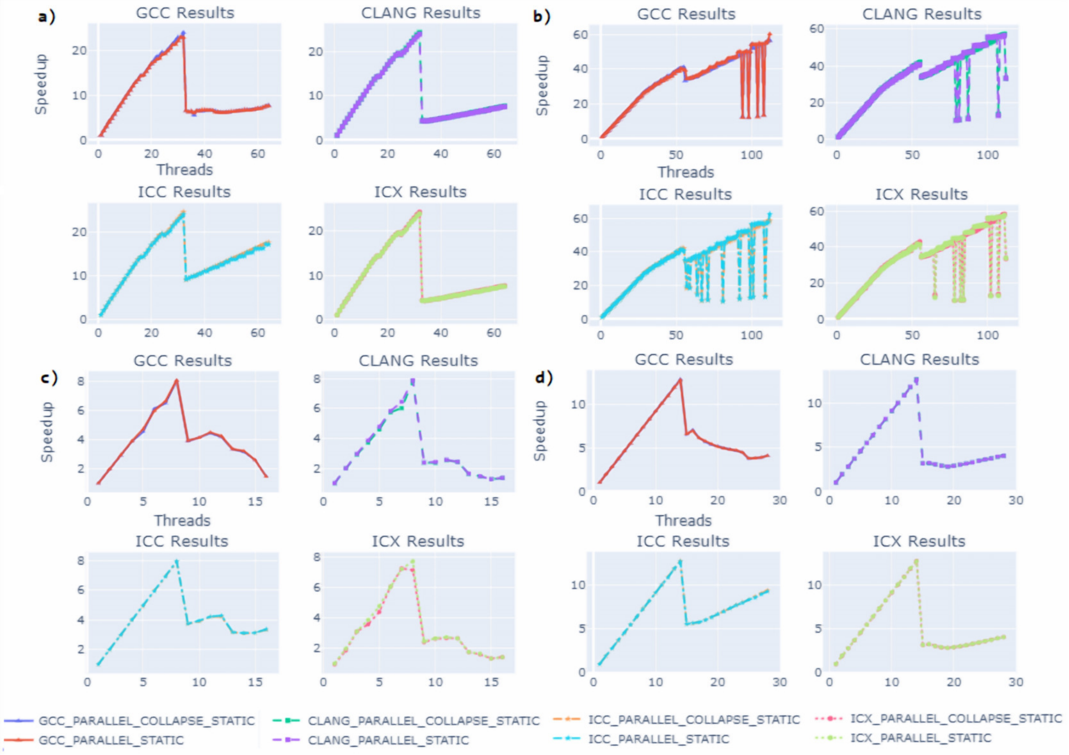

Fig. 3. Results of Matrix Multiplication with size N=1000, M=1000, K=1000

the `static` clause with a manually set chunk size. When it comes to the SIMD construction, in almost all cases it does not matter, but using this clause is beneficial when using ICC, but only on machine (d).

5) PrimeTest: Testing whether a given number is prime or not with a plain algorithm produces unbalanced amounts of work for particular threads. Results for size=10000 show that using the `guided` scheduling clause is the most stable one for every compiler. Poor performance for dynamic scheduling is visible for GCC and ICC for configurations (a), (b) and (d), but not for configuration (c), where it gives the best improvement. Another interesting observation is that a characteristic performance drop when CPU starts using hyper-threading vanished with the usage of guided scheduling.

For larger vectors of numbers to test, charts in Figure 4 are reasonably smooth and regular. Differences between using the `dynamic` and `guided` clauses are not visible and in the end, almost every configuration achieves the same level of parallelization when using all threads (except for dynamic scheduling using GCC and ICC compilers). Performance drop for static scheduling and hyper-threading still appears.

6) Wave Equation: The final benchmark determines whether it is better to place the `parallel` directive within or outside of a time-step loop, as the second iteration depends on first iteration's results. Results shown in Figure 5 are ambiguous. In most cases placing the `parallel` directive together with work-sharing for-loop gives better results. One exception to this appears on machine (b) when compiling with Clang – the chart is very irregular, but it is clear that placing parallel outside of the time-step loop produces better results.

For the larger sizes of the problem (N=5000, M=5000, T=100 tested) the differences are smaller and for desktop CPUs are almost not visible. Similar conclusions can be drawn for the server CPU from configurations where charts are overlapping each other. Only for configuration (a) some differences occurs – slightly better performance is observed when parallel clause is inside time-step loop, but scaling is then more irregular.

V. Summary and Future Work

Results show that no single best compiler nor OpenMP implementation can be chosen. In many cases compilers showed similar speed-up patterns on charts, however they differed in speed-up values. Different results and rankings were collected for various problems and various sizes of problems – consequently best configurations need to be considered on a case by base basis. In line with expectations, better scaling was achieved for bigger data sizes of problem – that suggests that data size must be large enough to get satisfying speed-ups. Often for small data sizes better performance can be achieved by using relatively few cores. It is especially visible when comparing desktop CPUs (a small number of cores) with server CPUs (a large number of cores) – in some cases exceeding a certain number of used cores caused degradation of performance. Consequently, it is recommended to benchmark own program with different OpenMP implementations in a production environment to get the best results in terms of performance before final deployment.

For future work, it would be valuable to benchmark the workloads also under power caps and determine performance-energy trade-offs [11] including optimization goals EDP, EDS as well as percentage wise performance loss for energy gains. Additionally, other benchmarks would also be of interest, such as: parallel similarity measure computations for large vectors [12] or image processing [13].

***Abstract*—We discuss an algorithm for generating all permutations of numbers between 1 and N. The algorithm is short and efficient, yet its behavior is not obvious from the code, mostly owing to the recursion. The discussion touches upon a few interesting methodological issues and brings in an educational case study in recursion.**

***Index Terms*—algorithms, recursion, permutations, algorithm analysis**

I. Introduction

NOVEL programs for generating permutations are not in big demand today, as the issue is deemed to have been “settled” by the opus of D. E. Knuth [1]. The algorithm we are about to present has been known to us since 1980, although it has never been published, except for a brief mention in [2]. It comes with a story which is best told in a narrative less formal than demanded by a research paper because announcing upfront the algorithm’s purpose removes from the yarn the essential element of suspense.

When the algorithm was first introduced to an audience of students in an introductory programming course, it caused a bit of confusion. During an exam, the students were asked to guess what the program was doing, explain its flow control, and describe the output produced, i.e., tell the ordering of the resulting sequence of permutations. The era of portable communication/computing gadgets (so nightmarish from the viewpoint of a contemporary examiner) was still far ahead, so the students were left to their own “devices.” To the one of us who devised the exam and the question the problem seemed non-trivial but well within the grasp of a university student in computer science who had acquired the understanding of recursion in programming. But it was in fact a disaster. When two local and accomplished faculty experts in algorithm design and analysis were subsequently shown the question, their reflex, after a brief deliberation, was to run to the computer terminal and see what happens. That incident left us with a feeling that has persisted to this day, that some important questions deserve a thought.

We introduce the algorithm as a case study in algorithm design. First, the nature of recursion employed in it is nontrivial and educational, as it involves both categories of data (global, local) in a manner that makes them both relevant to the workings of the algorithm. The recursion is essential to the program’s dynamics, e.g., in contrast to artificial examples where it can be trivially eliminated (like in calculating the Fibonacci function). While other recursive (and also optimal) algorithms for generating permutations are known [3], they (as most of their non-recursive relatives) assume element swapping as the basic operation. This way, the problem immediately receives an algebraic flavor and becomes that of transforming a given permutation into another permutation in such a way that all permutations are eventually mentioned in the transformation sequence. This is not necessarily the most natural expression of the problem from the viewpoint of a programmer. Our algorithm, in contrast, simply *generates* all permutations by making sure that all the elements are eventually *permuted*, i.e., each of them appears in all the possible slots, while giving all the other elements every possible chance to do the same.

Second, the basic variant of the algorithm, while being relatively easy to explain and instructional from the viewpoint of its correctness proof, is suboptimal from the viewpoint of performance. With some creativity, the algorithm can be improved such that its complexity matches the best (possible) solutions to the problem. The improved version appears more complicated (if introduced alone, it would have been considerably more difficult to analyze); however, owing to its descent from the basic variant, its analysis (both in term of correctness and performance) can be naturally carried over from the easier case. Then, we show how the algorithm can be transformed into a function that, instead of generating all the permutations in response to its zero-level call, can be invoked multiple times to yield consecutive permutations on individual demand. Overall, we believe it amounts to a case for beauty in programming, as per the views expressed in [4].

II. The basic algorithm

The algorithm has the form of a recursive procedure listed in Figure 1. It operates on three global variables:

```
var N, k : integer; A : array [1..N] of integer;
```

The array will contain consecutive permutations generated by the algorithm, and its effective size is N. We want to express the algorithm in a simple, generally understood programming language such that the code is (almost) immediately runnable. It makes sense to use a Pascal lookalike because it is convenient to have the array indexed from 1.

```
 1  procedure F ( );
 2      var i : integer;
 3  begin
 4      if k > N then
 5          ready ( )
 6      else
 7          for i := 1 to N do
 8              if A [i] = 0 then
 9                  A [i] := k; k := k + 1;
10                  F ( );
11                  k := k – 1; A [i] := 0;
12              end if
13          end for
14      end if
15  end;
```

Fig. 1. The basic variant

Before $F()$ is invoked for the first time (externally), N is set to the requisite parameter (and henceforth appears as a constant), the array A is initialized to zeros (for the indices from 1 to N), and k is set to 1.

Each call to *ready()* in $F()$ marks the moment when A contains a new permutation which can be printed out or otherwise used. Thus, the algorithm (in its boilerplate variant listed in Figure 1) *generates* all permutations, e.g., as opposed to returning them one by one on subsequent invocations [5]. Function *ready()* should be viewed as the consumer of the output produced by the algorithm. It is convenient to start the presentation with a variant where the consumer is intertwined with the procedure. Later we shall show how the two can be disentangled.

Before looking into the algorithm's behavior, let us reflect on the author's inspiration. An exam was being devised, most of the questions had been written down, and the one remaining topic to be addressed was recursion. The problem had to be stated as briefly as possible, and it had to touch upon all the essential aspects of data from the viewpoint of a recursive algorithm. Thus, we needed at least one local variable and at least one global variable (both of them relevant), and (of course) a non-trivial recursive invocation. In this respect, the two global variables k and A (N can be treated as a constant), and the local variable i nicely fit the bill. Consequently, one advantage of our algorithm is that it provides an educational case study in recursive programming, even if its practical significance is not transparent.

III. Correctness

Formal correctness proofs of our algorithm have been the topic of several studies in Algorithmic Logic [6]. Here, for the sake of brevity, we shall confine ourselves to informal arguments. Our goal is to convince the reader that the algorithm terminates and in fact generates all permutations of the numbers from 1 to N, with each permutation appearing exactly once.

The following snippet illustrates the way to invoke $F()$ as to account for the required initialization:

```
...
readln (N);
for k := N downto 1 do A [k] := 0;
...
F ( );
...
```

Note that the loop setting the array elements to zero has the side effect of initializing k to 1. Thus, when the procedure is called from the outside (as opposed to its recursive invocation within itself), A is filled with zeros and k contains 1.

The global variable k is only modified in lines 9 and 11. It is incremented just before the internal (recursive) invocation of $F()$ and brought back to the previous value when the procedure returns. As it starts from 1, before the first (outer) call to $F()$ is made, it can be viewed as the counter of the recursive levels going from 1 until $N+1$. Note that the last level ($N+1$) is special: the function uses it to present its result, which action is represented by the call to *ready()*. In lines $7-13$, the procedure executes a loop going through all elements of A. Those elements that contain nonzero values are skipped, and the same value of k is consecutively inserted into the remaining positions in the array. Then, for every possible insertion of k, the procedure is called recursively with k incremented by one. Everything is undone when the recursive invocation of $F()$ returns. Looking globally, we see that the procedure inserts 1 in all places in A (initially, when $k=1$, all of them are empty), then, for every configuration from the previous level, inserts 2 into all the remaining positions, and so on, all the way until N. This is how the problem of generating all permutations of the numbers from 1 to N is in fact defined. The procedure just literally fulfills this prescription; thus, in a sense, it can be viewed as the most natural (naive) solution to the problem.

IV. The time cost

Is our naive solution practical? To answer this question, we should gauge it against the best known algorithms for generating permutations which are known as loopless (or loop-free) ones [5], [7]. This term is somewhat unfortunate (no algorithm generating permutations can be truly loop-free) and refers to the constant average cost per permutation. In other words, the cost of generating all $N!$ permutations should be bounded by $c \times N!$ where c is some constant. Besides, a useful procedure should be able to generate *a* permutation when asked for it, i.e., one permutation at a time [1], [5], [7]–[10], as opposed to producing them all in response to a single invocation.

Let us start by calculating how many times $F()$ is called to produce all $N!$ permutations. We shall ignore the last-level call (for $k=N+1$) because its is special; its sole purpose is to present a ready permutation available in A. Denoting the number of (nontrivial) calls of the procedure by $U(N)$, we have:

$$\begin{array}{rcl} U(N) & = & N \times (1 + U(N-1)) \\ U(1) & = & 1 \end{array} \qquad (1)$$

One can easily show by induction that:

$$U(N) = N! \times \sum_{i=1}^{N} \frac{1}{i!} \qquad (2)$$

which means that:

$$U(n) < (e-1)N! \quad \text{and} \quad \lim_{N \to \infty} \frac{U(N)}{N!} = e \qquad (3)$$

V. The asymptotically optimal variant

The number of invocations of *F()* needed to solve the problem for a given N is of order $N!$ with the factor $c < e-1$. If we could prevent the *for* loop from iterating over the nonzero entries in A, which simply have to be skipped and ignored, and make it proceed directly to the next free entry on every turn, we would bring the complexity of our algorithm down to $O(N!)$. To accomplish that, in addition to the original array A, we introduce another array acting as a representation of the list of free entries in A available at the current level. The new set of global declarations becomes this:

```
var N, k : integer; A : array [1..N] of integer;
    X : array [0..N] of integer;
```

The role of A is now reduced to storing the permutation being constructed by the procedure, while X keeps track of the unoccupied slots in A. The initialization/invocation sequence is replaced with this code:

```
...
readln (N);
for k := N+1 downto 1 do X [k – 1] := 0;
...
G ( );
...
```

The new variant of the procedure shown in Figure 2 is named $G()$. We claim that it generates all permutations of values $1, \ldots, N$ in an asymptotically constant number of steps per permutation, i.e., its time complexity is bounded from above by:

$$T(N) = cN! \qquad (4)$$

To see this notice that initially the values in X describe the straightforward succession of indices in A where the head points to element 1, every subsequent element of X, for $i = 1, \ldots, N-1$ points to the next element $(i+1)$, and the last element contains a special value $(N+1)$ indicating that the list ends there. Thus, immediately after the initialization (when $k = 1$) traversing the array through the links in X will amount to going through all its elements in exactly the same order as with the straightforward loop in $F()$. When a value is inserted into A, the corresponding index in X is replaced with its successor, which has the effect of removing the index from the list for all the subsequent recursive calls. The index is restored upon return from the recursive call, equivalent to zeroing the corresponding element of A in $F()$. This implies that $G()$ carries out the same series of nonzero insertions into A as its previous version, but the total number of instructions associated with every invocation of $G()$ is now constant.

```
procedure G ( );
    var b, d : integer;
begin
    if k > N then
        ready ( )
    else begin
        b := 0;
        while X [b] <= N do begin
            d := X [b]; A [d] := k; X [b] := X [d];
            k := k + 1;
            G ( );
            k := k – 1;
            X [b] := d; b := X [b];
        end while
    end if
end
```

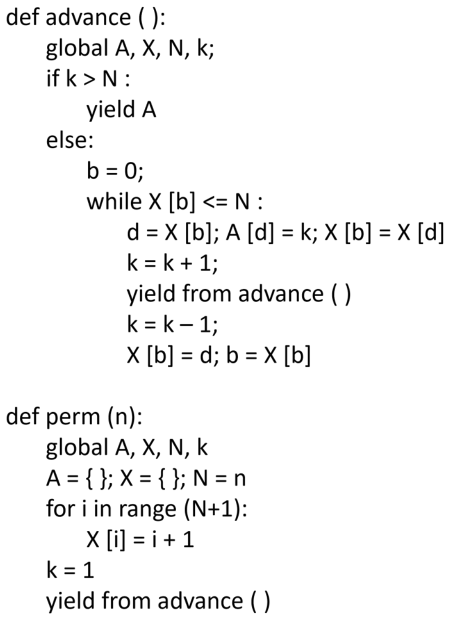
Fig. 2. The “loopless” variant

VI. One permutation at a time

The algorithm is inherently recursive which a practical programmer may see as a disadvantage. One would prefer a function that could be called from an external program each time a new permutation is needed. [5], [7]. Of course, as any recursive procedure, the algorithm can be reprogrammed in a non-recursive manner, but one can argue that the recursive form is its essential feature.

Modern programming languages and environments offer tools which make the adaptation of our algorithm to a practical usage natural and easy while retaining its essentially recursive form. These tools, under the name of coroutines, originated historically with Simula 67 [11], becoming useful features of many contemporary platforms and being available in several guises offering handy shortcuts for typical applications.

Figure 3 presents a modern-flavor coroutine-like variant of our algorithm implemented in Python. The implementation consists of a Python function *perm()*, providing the actual callable generator, and its helper function *advance()* taking care of the recursive part. The semantics of the *yield* operation [12] consist in suspending the execution of the current function and returning to its caller in such a way that on a subsequent invocation of the same function its execution will continue from the point of the last interruption. The operation *yield from* f_2 carried out by a function f_1 invokes the specified function f_2 and, when that function returns via *yield*, carries



```
def advance ( ):
    global A, X, N, k;
    if k > N :
        yield A
    else:
        b = 0;
        while X [b] <= N :
            d = X [b]; A [d] = k; X [b] = X [d]
            k = k + 1;
            yield from advance ( )
            k = k – 1;
            X [b] = d; b = X [b]

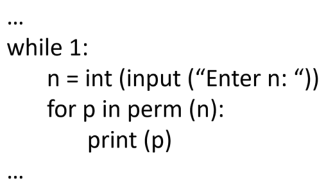
def perm (n):
    global A, X, N, k
    A = { }; X = { }; N = n
    for i in range (N+1):
        X [i] = i + 1
    k = 1
    yield from advance ( )
```

Fig. 3. A coroutine-style implementation in Python

over the effect to its original caller. Consequently, when the original caller calls f_1 again, it will continue within f_2 from the place where f_2 last yielded.

We can easily see that *advance()* is basically a straightforward rewrite of *G()* in Python, except that: 1) the function yields with the value of array A whenever *G()* would produce a complete new permutation; 2) the yield has to be carried over recursively, so the recursive call is appropriately replaced with a *yield from*.

The following code illustrates the usage of the generator:



```
...
while 1:
    n = int (input (“Enter n: ”))
    for p in perm (n):
        print (p)
...
```

In a serious project, the generator would be encapsulated into a structure isolating the namespace of its global variables.

VII. Final comments

One intriguing feature of our algorithm is the apparent difficulty to see its function at first sight and the wrong intuitions that it tends to connote for a first-time viewer, if presented without the spoiler. Our discussions, involving students as well as experts, have raised these questions:

1) Why can the designer of a few-line program (devised for educational purposes and with no malicious intentions) see things much clearer than a competent reader subsequently looking at the same piece?
2) How to best convey the “obvious” idea behind the design that, ideally, should be present there, in the very code, plain for everyone to see?
3) How to prevent misunderstandings and misrepresentations of the ideas implanted into programs by their designers? In other words, how to ensure that programs are correct?
4) How to think about programs, so the right and correct ideas can materialize and find their way into the code in a manner that will make them transparent, so they can be seen and comprehended when the code is scrutinized?

The design of procedure $F()$ began with a simple narrative: “I am going to generate all permutations of the values from 1 to N by inserting 1 into all possible places, and then, for every such insertion, inserting 2 into all places that still remain unoccupied, and so on, continuing doing so until all the values have been inserted.” This sentence seems to explain everything there is to see about the algorithm. It can also be viewed as the most straightforward plain-language specification of the problem and, at the same time, rather precisely explains the programmer’s intention. According to the paradigm of literate programming [13], it should thus be incorporated into the procedure’s code and become its integral component. Viewed in this light, $F()$ merely follows its simple specification to the letter. Considering that its efficiency is not worse than that of the most refined solutions known in the area, our algorithm should probably be viewed as the most natural solution to the problem of generating all permutations.

***Abstract*—Selecting suitable techniques for requirements elicitation in IT projects is crucial to the business analysis planning process. Typically, the determining factors are the preferences of stakeholders, primarily business analysts, previous experience, and company practices, as well as the availability of sources of information. The influence of other factors is not as evident. One of the possible ways to form recommendations for using techniques is the analysis of industrial experience. This paper is intended to analyze the application of association rules mining to define factors influencing technique selection and predict the usage of a particular elicitation technique depending on the project context and specialist background. The dataset for experiments was formed based on a survey of 328 specialists from Ukrainian IT companies. The associations found to make it possible to speed up the process of choosing elicitation techniques and improve the elicitation process efficiency.**

***Index Terms*—associations rules mining, requirements elicitation, IT project, business analysis.**

I. Introduction

REQUIREMENTS elicitation is the effort expended by the Requirements Engineer to turn implicit desires, demands, wishes, needs, and expectations — which until now were hidden in their sources — into explicit, understandable, recognizable, and verifiable requirements [1]. The outputs of elicitation serve as input for the following tasks from the core business analysis cycle: current state analysis, risk assessment, and requirement specification and modeling [2]. Elicitation activities can be divided into three tasks: preparing, conducting, and result confirming. The effectiveness of elicitation directly depends on the quality of the first – preparation. The requirement engineer/business analyst should define the available source of information, a subset of stakeholders, who should be involved in the following elicitation activities and select appropriate elicitation techniques. Professional guides and standards recommend many techniques practitioners use in IT projects. Due to time and budget constraints, specialists can't use them all and should select a set of techniques best suited to the particular project's conditions. The set of predefined elicitation techniques significantly influences the business analysis, project plan, and the associated costs and resources needed. This study was conducted to analyze the current practices of using elicitation techniques in IT projects and to find associations between project context, specialist's profile, and techniques used for requirement elicitation via Association Rule Mining. The dataset for analysis was gathered via a survey of 328 IT specialists employed by Ukrainian and international companies with branches in Ukraine via a survey [3]. The strong associations identified with Association Rule Mining made it possible to formulate recommendations on using requirements elicitation techniques in IT projects.

II. Problem Statement

The task of selecting best-suited techniques, particularly requirements elicitation techniques, is performed by a business analyst at the start of the project due to defining and estimating a list of business analysis-related activities. But that does not mean it is a one-time task, and a list of used techniques can be updated based on the efficiency monitoring results and project context changes. Considering that the requirements elicitation lays the foundation for further analysis and development activities, the optimal technique selection is an essential business analysis task. The emergence of new techniques and their development in the process of business analysis evolution, as well as the continuously changing business environment, can lead to the complication of this task. A recommendation system that considers the accumulated experience of practicing business analysts and requirements engineers can be applied to solve this problem. An important condition is the explainability of these recommendations, which will allow for checking their applicability in the unique context of each project.

III. The Best Existing Solution

There are many studies regarding solving the choosing appropriate requirement elicitation technique problem using different approaches and models.

Hatim Dafaalla et al. [4] built a model based on an artificial neuronal network (ANN). The model was learned based on the collected dataset with 1684 records about selecting the elicitation technique. By choosing the ROC AUC metric as a score of the model, the authors achieved significant accuracy of the model, which was equal to 82%. Despite good forecasting by modeling, as with any other ANN, this model has a significant weakness. ANN is a net of perceptron (miniature models of neurons). The perceptron is organized in layers, which are connected to each other. The connections might have a different architecture. Each connection of each perceptron has a weight coefficient. The learning process is a process to optimize these coefficients. Unfortunately, a single coefficient and a set of coefficients don't have meaning and can't be explained in business terms. Similarly, connections, layers, and perceptions do not have any sense separately and don't explain how ANN solved a problem. That is the way some decisions of an ANN might be seen as strange, unexplained, and untrusted [5].

Nagy Ramadan Darwish et al. [6] suggested a hybrid approach. The manuscript describes a pipeline of methods. The feature is manually selected based on literature reviews. Then multiple linear regression model was built to select critical attributes influencing technique selection. In the last stage, the ANN was built. The accuracy of the final model was declared as 81%. Despite the remarkable result, the final model has the same limitations as discussed previously. Ihor Bodnarchuk et al. [7] applied goal function for assessment and selection architecture design in the context of "light-weighted" requirements techniques.

Different machine learning approaches were applied not only to technique selection but to related areas as well. Fadhl Hujainah and others [8] suggested using a semi-automated attribute measurement criteria method for requirement prioritization and selection.

Similar method - attributes-based decision making was described by Jinyu Li [9]. Remarkably, semi-automated methods bring a possibility of bias since experts conducted the first assessment.

IV. The Proposed Solution

Associate Rule Mining (ARM) method is a machine-learning technique that combines several remarkable advantages. Firstly it doesn't require data annotation because it is an unsupervised method. Secondly, the method and output are intuitive and could be understood by domain experts and business people, which is a rare property of a machine-learning algorithm.

ARM, also known as basket analysis, was applied first in retail, but now it is widely applied in other areas. For example, Giovanna Castro and colleagues in [10] applied association rules to study the comorbidity of bipolar disorder and premenstrual dysphoric disorder. Chad Creighton [11] used association rules to discover hidden gene expression patterns. Ahmad Mirabadi and Shabnam Sharifian [12] applied the ARM to Iranian Railways data to discover patterns leading to incidents and create management manuals and guidelines. Finally, the method could detect credit card fraud [13]. The Association rules are even included in other algorithms, such as Lamma and other [14] embedded AR, as part of the SLA algorithm.

V.Conditions of the Analysis to Follow

Considered methods are applied to the particular dataset for extraction association rules. It means that if the initial dataset is biased, the found association rules will also have bias.

Moreover, as you will see in the following sections, ARM requires settled initial (apriori) hyperparameters that influence the number of found rules. According to mentioned studies above, there is no standard practice to calculate the metrics, and usually, it comes from the business perspective and domain expert knowledge. During the study, we considered various combinations of rules to find a balance between the number of rules and the reasonability in order to find the most appropriate set of rules.

During the study, we worked with two hyperparameters: support and confidence (see definitions in the next section). We began with a support level of 0.5, increasing by 0.1 while reaching 1.0. We chose 0.5, which means a rule is true for 50% of cases. We obtained an itemset with confidence levels from 0.1 to 1.0 with increments of 0.1 for each new support. Each obtained dataset was estimated among the following questions:

- How many association rules are found out?
- Does an entirely differential rule in the top 100 rules disappear compared with the previous values of hyperparameters?

We stopped the process when we obtained a set with completely differential rules at the top of the list.

VI. Details of the Proposed Solution

A. Association Rule Mining

The problem of discovering association rules was proposed by Agrawal et al. [15]. Let $I = \{i_1, i_2, \dots, i_m\}$ be a set of m items. Let T be a set of transaction $\{t_1, t_2, \dots, t_n\}$, where each t_i is set of items in which $t_i \subseteq I$. Association rules are implication rules:

$$A \Rightarrow B,$$

which is interpreted as "if A, then B". The following statements must be met: $A \subset I, B \subset I$ and $A \cap B = \emptyset$. The A term is an antecedent of the rule. The B term is a consequent of the rule.

The number of rules might be huge, so we need some mechanism for selecting strong rules from weak ones. To do that, let's postulate the following hyperparameters:

- Confidence is a measure that counts how many transactions in T that contain A also contain B. It is the probability of B being true when we already know that A is true:

$$Confidence(A \Rightarrow B) = \frac{Occurence\ of\ A\ and\ B}{Occurences\ of\ A}$$

- Support is a measure of the frequency of the transaction patterns that occur in the T:

$$Support(A \Rightarrow B) = \frac{Occurence\ of\ A\ and\ B}{Total\ transaction\ in\ T}$$

- Lift is a value that gives us information about the increase in the probability of the "then" (consequent) given the "if" (antecedent) part. If the lift equals one, we consider there are no dependencies, but if the lift is more than one, we can consider a dependency. Additionally, the lift can demonstrate the "power" of dependency: the larger the lift, the stronger the rule.

$$Lift(A \Rightarrow B) = \frac{Support(A \Rightarrow B)}{Support(A) * Support(B)}$$

Now we can define the minimal support and confidence values to select strong rules. The rules which have confidence more than the selected minimal value are called strong rules.

B. Apriori Algorithm

The Apriori, proposed by Agrawal et al. in [15], is an algorithm for discovering association rules. The algorithm is based on searching frequent itemsets. It assumes that if rule X has a confidence level of C and $X \subset Y$, so rule Y has a confidence level not less than X. In this way, we can dramatically reduce calculations by excluding many weak rules from consideration based on the frequency of every single *i* in *I*.

VII. Analysis

A. Input data

To discover association rules, we used the survey result conducted in 2020 [16]. After data cleaning, the dataset has 324 answers, which will be treated as a transaction. To describe a project context, we asked respondents about the following:

- project size;
- project domain;
- company type (IT-outstaff, IT-outsource, IT product, non-IT);
- company size;
- class of the developed system (business software, embedded software, scientific, etc.);
- belonging to the co-located or distributed team;
- role in the project;
- years of experience;
- passing certification in the chosen role;
- using adaptive, hybrid, or predictive ways of working on the project;
- project category (developing from scratch, reengineering, product or platform customization, etc.);
- involving in different Types of BA activities.

The dataset is available at the link https://data.mendeley.com/datasets/svzv7rs279.

Together the answer's options produced 96 possible items in the itemset.

Before running the apriori algorithm, we discovered the support (frequency) of single items of elicitation techniques. We decided not to consider items (and consequently rules) with a frequency less than 50% (Table 1).

The apriori algorithm was launched across the dataset with the following hyperparameters: minimal support 0.5 and minimal confidence 0.8. After removing autogenerated rules with empty antecedents, there were left 86 association rules.

Table I.
Elicitation techniques with a frequency of more than 50%

Elicitation Technique	Support level %
Interviews	87.3
Document analysis	85.5
Interface analysis	71.3
Brainstorming	69.2
Process analysis/modeling	66.1
Prototyping	66.1
Business rules analysis	54.4

The first look at consequent showed that only two techniques have strong antecedents: Document analysis and Interviews. It means that despite the frequency of other consequents, there is not a strong enough implication between any project context aspects under interest and the consequent itself. Perhaps, the choice of rest elicitation techniques is managed by factors that lay off the considered dataset.

Remarkable that both mentioned methods are often used in pairs. Rule "Document analysis → Interviews" has one of the biggest (0.77) support levels and similar "Interviews → Document analysis". This fact makes sense: a business analyst uses different sources of information due to business analysis information elicitation. Usually, documents and people are the most valuable and accessible sources.

B. Document analysis association rules

First, some rules state implications based on other elicitation methods presented in Table 2.

Table II.
Document analysis association rules

Association Rule	Support level %
Interface analysis → Document analysis	0.65
Process analysis & modeling → Document analysis	0.6
Brainstorming → Document analysis	0.6
Prototyping → Document analysis	0.58

Also, a small subset of rules combines different elicitation methods and another aspect of the project context. For example (here and further, the number in parentheses is a support level): (Business software, Interviews) → Document analysis (0.69), (Interviews, BA Role) → Document analysis (0.69), (Business software, Interviews, BA Role) → Document analysis (0.62), (Interface analysis, Role: BA) → Document analysis (0.58), (Interface analysis, Interviews) → Document analysis (0.58). But these rules have support levels smaller than in rules without other components.

Consider other strongest association rules in this group. Remarkable that BA's role in the project implicates using Document analysis: BA Role → Document analysis (0.76). And the rule includes the class of the system under interest: Business software → Document analysis also has a high (0.74) support level. The situation with mixed rules for role and class system is the same as for mixed rules of elicitation techniques: they have more minor support levels and confidence than the short version. For example, Business software, Role: BA → Document analysis (0.67), Role: BA, Requirements analysis and design definition 0.58

Behind the discovered rules, one more group influences the choice of elicitation techniques. The rule with the strongest support level is (Requirements analysis and design definition, Elicitation & Collaboration) → Document analysis (0.57)

C. Interviews association rules

The Interview's association rules are presented in table 3.

TABLE III.
INTERVIEW ASSOCIATION RULES

Association Rule	**Support level %**
Business software → Interviews	0.77
BA Role → Interviews	0.76
Elicitation & Collaboration → Interviews	0.63
Interface analysis → Interviews	0.63
Brainstorming → Interviews	0.62
Process analysis & modeling → Interviews	0.60
Team distributed → Interviews	0.55

As well as for the previous group, there are many more complex rules with three and more antecedents. However, the support level of these rules is less than the listed above, while their confidence level stays the same. Several examples illustrate the thesis: (Business software, BA Role, Document analysis) → Interviews (0.62), (Requirements analysis and design definition, Elicitation & Collaboration) → Interviews (0.57), (BA Role, Requirements analysis and design definition) → Interviews (0.57), (Business software, Requirements analysis and design definition, Elicitation & Collaboration) → Interviews (0.51), (Business software, Document analysis, Process analysis & modeling) → Interviews (0.5)

That could mean that a significant and essential implication in choosing the elicitation technique is laid out in less complex rules. Remarkable that here we can observe rules that postulate implications based on another elicitation technique, such as Interface analysis and Brainstorming.

VIII. CONCLUSION

We analyzed datasets obtained from the survey. The dataset includes 324 transactions containing items from itemset with 96 items. The apriori algorithm was used for discovering association rules. The algorithm's hyperparameters were defined as minimal support equals 0.5 and minimal confidence equals 0.8. We considered only rules with left bigger than 1. The algorithm discovered 86 associated rules.

The most frequently used elicitation techniques are Interviews, Document analysis, Brainstorming, Process analysis and modeling, Prototyping, and Business rules analysis.

The main discovering facts and rules are:

- Among all frequent rules, only two techniques - Document analysis and Interviews- form strong association rules with project context.
- Interviews and Document analysis are used together pretty often.
- Class of developing system (business software) and BA role and BA activity make using Document Analysis elicitation technique.
- Class of developing system (business software) and BA role, distributed team, Process analysis & modeling, and BA activity such as Elicitation and Collaboration and make using Interview technique.
- Some elicitation techniques (Brainstorming, Interface analysis, Process analysis & modeling) implicate using Interview technique.
- The combination class of developing system, role in the project, team distribution, and activity with other aspects of project context have more minor support levels than less complex rules having only one antecedent and could be considered a sub-option.

The following recommendations can be proposed based on found association rules:

- If a person who performs requirements elicitation uses only Document Analysis or only Interview, they might consider Interview or Document Analysis accordingly.
- If a business analyst uses Interface analysis, Process analysis & modeling, Brainstorming, or Prototyping, they might consider Document Analysis as an additional technique;
- If the system under development is business software, then Document analysis and Interview are reasonably chosen;
- If Interface analysis, Process analysis & modeling, or Brainstorming are used, Interview should be considered as an additional technique;
- Interview is a suitable technique in case of a distributed team.

***Abstract*—Digitalization is changing many areas of society and has an impact on recruiting processes. Many companies are facing the challenge of making their application processes more attractive for potential candidates. The use of gamification is becoming a new trend, which is aimed particularly at Generation Y and Z, who have grown up in the age of digitalization. The potentials and challenges of gamification are wide-ranging for applicants and companies. The framework of a qualitative empirical study according to Mayring is used to investigate this research topic. A literature review provides current findings of former research studies. The research design is based on interviews with HR experts. The potentials are reflected in a higher employer attractiveness, applicant quality and more efficiently designed processes. At the same time the implementation of gamification involves some challenges, including additional requirements, like digitalization and data protection, deterrent effects and finding the fitting target group.**

***Index Terms*—Gamification, Recruiting, Digitalization, Human Resources, Qualitative Study**

I. Introduction

NEW technologies and the progress of digitalization are important impacts on further development of companies. Due to the Covid-19 crisis an increasing focus on digital processes has been required [1]. Besides the opportunities of Big Data and Artificial Intelligence (AI), companies are facing the challenge of finding qualified employees and trying to avoid follow-up costs of wrong recruiting decisions. To attract attention, companies can invest in traditional campaigns or explore innovative concepts [2]. Gamification offers a possibility for attracting and retaining new employees, as well as increasing their motivation in recruiting processes [3]. It deals with understanding and assessing human behavior. The goal of gamification in recruiting is to bring real processes into a playful context for better selection of suitable candidates [4]. Because companies are already using gamification, research needs to address the potentials and challenges. Based on dynamic developments in research and business, gamification could be established as a significant opportunity for attracting professionals [5]. With the increasing digitalization, the use of gamification will play an important role for companies. Especially for younger generations, this represents an interesting challenge to prove their skills against other applicants. For this reason, this research study examines the potentials and challenges of using gamification in recruiting for applicants and companies.

II. Research Design

The empirical investigation is based on a qualitative research design. Because the topic is very current and there is limited literature available on the potentials and challenges for applicants and the company itself, an inductive method according to Mayring was selected [14]. Based on the aim of investigating the research question a detailed literature review was conducted first. Afterwards, eleven semi-structured expert interviews were executed for the data collection. The data were subsequently transcribed and coded by using the software MAXQDA. As a result, hypotheses were created, and a hypothesis model was derived. The results are interpreted with the findings from the literature review and finally lead to answer the research question.

III. Literature review

The recruiting process is about identifying and classifying the potential of human resource for the personnel supply and the effective use of this knowledge. Recruiting is a continuous process. In total there are five phases: planning human resources, determining the strategy, evaluation of recruitment sources, implementing recruitment methods and strategies as well as feedback and control. The aim is to identify and hire the most suitable candidate for the advertised position. A well-planned and well-structured recruitment process is important for a company to attract high quality candidates [1].

The term "Gamification" was first used by various players at the end of 2010 [6]. The term is still very controversial and many game designers and user experience designers use other terms, such as "Gameful design" or "Gamefulness" [4]. Today, games have become a growing trend in society. Due to the huge market size that is constantly increasing, non-gaming fields are also trying to take advantage of it. Gamification is therefore not only a good concept to motivate users, but it also brings the health, business, and education sectors closer to the attractive gaming world. Among other things, this can help increase the attractiveness of the company to applicants and make the application process more attractive for potential candidates [7]. Since gamification is a new subject, there is currently no valid definition. However, it can be said that gamification is an interplay of psychology and user experience design [2]. By using specific game mechanisms, it attempts to increase the engagement and enjoyment of participants in each environment. The mechanisms used are directly linked to the provision of a reward. For example, when players complete a task in a specified time, they receive a reward depending on the difficulty level. Gamification is a suitable strategy for influencing and motivating applicants [8]. Due to the close connection between gamification and recruiting, the term “Recrutainment” has been formed. It defines the merging of methods of cognitive assessment, aptitude assessment and gamification elements, which are subsequently embedded in the recruiting process of a company. The goal is to attract more younger applicants and at the same time achieve better candidate results [7].

Gamification is particularly attractive and suitable for the target group Generation Y and Z. Generation Z includes everyone born after 1995 and is also referred to as "digital natives" because they have completely grown up with digitalization [9]. Even in their early years, this generation played on their parents' laptops and smartphones. Of course, dealing with digital communication and media technologies matters for "digital natives" and is an integral part of their everyday lives. In contrast, the previous Generation Y only encountered the new technologies in childhood or adolescence but was able to acquire media skills through the development of social networks, such as Facebook. Both generations differ significantly in their communication behavior, as Generation Z's communication takes place online to an even greater extent than is the case with Generation Y [10]. However, since both generations enjoy using new technologies, gamification is a particularly good recruiting strategy for this target group. As a result, many potential applicants can be attracted to join the company [11].

By implementing gamification as a recruiting tool, the company can test certain skills and abilities, such as creativity, time management or innovative thinking, before a hiring decision is made. This way, unsuitable applicants can be quickly identified and sorted out at the initial stage, speeding up the recruiting process [11]. Before integrating gamification into their own recruiting process, it is advisable for companies to check whether enriching their own application with game-like elements will motivate candidates to further their interest in applying [2]. Gamification in recruiting is based on elements such as high scores, awards, point lists or different game levels. With gamification, the basic needs are addressed, such as receiving a reward, the desire for success, striving to be superior, or to project a certain self-image and increase one's notoriety. Gamified (online-) assessments represent one possibility for personnel selection. In a gamified assessment, applicants are exposed to a game-like environment or a virtual world. For example, the virtual world can resemble a real work environment and employees can be represented by avatars. This is used to elicit job-relevant behavior in situations that may take place in the real work environment. Gamified assessments or serious games do not necessarily have to present a realistic and work-related scenario. Gamification can be integrated into the recruiting process in two ways, either as a one-to-one assessment of applicants or as an extension to existing situational tests by adding game elements. Integrating game elements into the selection process can reduce deception, thereby improving the quality of candidate information and predicting job performance. At the same time, transparency, fun and interaction are promoted. The games can be programmed in two ways. Team based games provide the candidates with the opportunity to interact and compete with other candidates while individual based games can be used for individual evaluation, completing the task alone [10]. Due to the competition in the game, applicants are eager and strive to obtain the maximum score/reward to be achieved in the game so that they quickly advance to the next level. The use of gamification allows companies to attract and engage a variety of applicants in addition to the other types of recruitment. From an HR perspective, evaluating the skills and qualifications of a large pool of applicants following the game is a way to select only the best, who have successfully demonstrated their suitability and value to the company [6]. However, the game elements can also be incorporated into psychometric tests, for example, to test situational judgement to better evaluate candidates' soft skills [3].

When it comes to gamification, there are two different groups among experts: proponents and opponents. Proponents believe that this new tool can help improving the user experience and at the same time offer added value for the practicing company. Gamification seems particularly suitable for internal training, but also as a tool to increase employee motivation. Game thinking can help companies to engage employees more strongly [12]. The potential work performance of an applicant in the intended position can be predicted well by a gamified personnel selection. Game elements and virtual games make it difficult for applicants to pretend or embellish their behavior in the recruiting process. This increases the authenticity of the test participants and contributes to a more reliable prediction of potential job performance. In contrast to other recruiting methods, such as traditional personality tests, gamification allows more targeted statements to be made about the personality and behavior of candidates. This is because traditional personality tests have a high probability of candidates changing their behavior by giving appropriate answers to the recruiters' questions, which are not accurate [8]. Opponents argue that gamification is a currently prevalent trend among many companies. They argue that making a game out of everything is pointless. While people do many things voluntarily and out of a sense of drive, companies use gamification for the purpose of trying to control behavior that was originally intrinsically motivated with extrinsic rewards. In the end, this only achieves the opposite. The extrinsic incentives ensure that intrinsic motivation is undermined, and ultimately activities are only performed because of the prospect of a reward and not out of genuine interest in the company itself. The tricky thing here is that a reward system, like gamification, initially promises to increase engagement. In short term, this is true. Long term, employees will only do a certain activity because of the reward. Therefore, gamification opponents criticize that proponents propagate a "loyalty-for-little-effort" philosophy, which communicates that it would be easy to control the behavior of users at will [12]. Additionally, as shown in the study by J. Koivisto and J. Hamari, the usability of gamification consistently declines with age [13].

IV. Data collection

The data collection includes eleven semi-structured interviews which were conducted between January 2022 and February 2022. All interview partners are from Germany, so the interviews were also done in German language. The experts are representing companies, working with gamification in their recruiting process, HR experts and HR consultants, offering gamification solutions for recruiting processes. It was ensured that participants from different areas were interviewed to get a broader understanding of the situation and to minimize individual bias.

Table 1 provides an overview of all participants. Eleven interviews were conducted, because the minimum number of interviews required for qualitative useful results is at least ten. The qualitative interviews have been selected as research method because they provide the advantage of being able to spontaneously go into more depth on certain topics and questions. This is not possible in a survey. The knowledge gained from the literature review was used to formulate questions regarding the research question. During the formulation of the questions, it was considered that the experts would be able to answer as open and free as possible to obtain a maximum of relevant information. Therefore, the questionnaire contains open, closed and hybrid questions.

The questionnaire was divided into five categories. In the first part, the experts answer the section of "demographic questions" such as gender, age, academic background, and company questions. The second section deals with “the status of digitalization” in the company and then specifically queries for recruiting. The third section contains questions about the “recruiting process”. The focus was on personnel selection and digitalization in the recruiting process. In the section "changes in the recruiting process due to corona pandemic", challenges during the pandemic were addressed. The last section was "gamification in the recruiting process". The practical state of experience regarding gamification in human resources is surveyed here. The experts were interviewed via the platform Zoom and all interviews were digitally recorded. The duration of the interviews was between 40 and 75 minutes.

V. Data analysis

The authors focused on the content of the interviews and not on linguistic aspects. Any dialect was transferred into written language and any personal data were made anonymous. To evaluate the interviews a structured content analysis was used. This enables a more objective view of the data. Following the rules of a qualitative structural content analysis the analysis is reproducible and the intersubjectivity is verifiable. When building categories inductively, certain criteria were defined in advance to structure the coding process. With the coding method of Mayring the gathered data were analyzed, and certain categories were identified [14]. This allows to filter out correlations and commonalities between the different raw interview data and to derive various categories. In the first step, the interviews were compared and examined for relationships and contradictions. In the process of constant comparison sentence by sentence, the authors were searching for patterns to build initial categories. Later, these categories were analyzed in more detail. Throughout the first phase of coding 525 codes were generated to structure

Table I.
Interviewee overview

No.	Academic Background	Professional Field	Industry	Age	Gender
1	Diploma Business Admin.	CEO	Consumer Goods	52	Male
2	Intl. Business	Head of Recruiting	Industrial Solutions	36	Male
3	Diploma Business Admin.	CEO	HR Consulting	52	Male
4	Diploma Business Admin.	Director HR, EU & USA	Automotive Supplier	36	Male
5	Master Management	Head of Group HR	Construction Industry	37	Female
6	Diploma Business Admin.	HR Employer Branding	IT-Services	55	Female
7	Diploma Business Admin.	CEO Managing Director	HR Consulting	49	Male
8	Diploma Psychology	Director Recruiting	Consulting Digitalization	51	Female
9	Diploma Business Admin. and Economics	CEO	HR Consulting	40	Male
10	Master Intl. Management	HR Employer Branding	IT Consulting	36	Female
11	Diploma Psychology	Head of Recruiting	Transport and Logistics	47	Female

the collected data. Each aspect mentioned by the interviewees was taken into account. After coding each given statement, the second step of coding was executed. In the ongoing process of comparatively analyzing data, all the categories were constantly revised and backchecked. Characteristics in one dimension have been deleted if they were too differentiated or added if the level of differentiation should have been increased. In the end, eleven main categories incorporated 26 subcategories. During the inductive category formation, certain criteria were established to structure the coding process. This allows to filter out correlations and commonalities between the different interviews and to derive various categories.

VI. Results

In this section the results of the expert interviews about Gamification of the recruitment process are described. The conceptual model is illustrated by the findings from the expert interviews, followed by the derived hypotheses. All eleven categories which were generated through the content analysis are presented in Figure 1. Each of these categories presents either a potential or a challenge of gamification in recruiting.

Potentials of gamification

Process Efficiency. At the beginning, the implementation of gamification in recruiting is associated with additional effort. Filling the same positions lead to standardization, which minimizes the high expense. In this context, recruiting costs are saved because managers' or specialists' working time is not required for this purpose. Follow-up costs of a wrong hiring can be minimized by gamified approaches. Additionally, the feature of preselection accelerates the process as well. Some experts stated that a faster decision-making contributes to this. According to the interviews, gamification serves the purpose of an application funnel. Mostly, it saves companies from screening many application documents as well as conducting unnecessary interviews. Therefore, the company can prioritize more effectively which candidates are invited for a personal interview.

H1: Gamification positively influences process efficiency in recruiting.

Trustworthy Process. Gamification provides an objective basis for the evaluation. Nearly every expert stated that fairness is included in the consideration of applicants by lowering recruiting bias. The fact that each applicant knows that they must overcome a hurdle increases fairness and transparency. If gamified tests are valid and follow a standardized process, gamification can increase objectivity, due to a higher volume of collected data, which are considered during the evaluation.

H2: Gamification positively influences a trustworthy process in recruiting.

Employer Attractiveness. Most experts stated that gamification enhances the company image. Currently, it offers an opportunity to stand out from the competition through innovation. The gamified tasks create a candidate experience, which has a positive effect on potential applicants. Another influencing factor is the target group-oriented approach through gamified assessments. Consequently, gamification acts as a marketing instrument that increases the number of incoming applicants by making it easier to address them.

H3: Gamification positively influences employer attractiveness in recruiting.

Additional Insights. One potential of gamification is the proof of certain qualifications. The statements made clear reference that skills and hidden talents are acquired independently of oral expression. Regarding the action behavior, concentration and attention span can be tested, which allows conclusions about the psychological security of

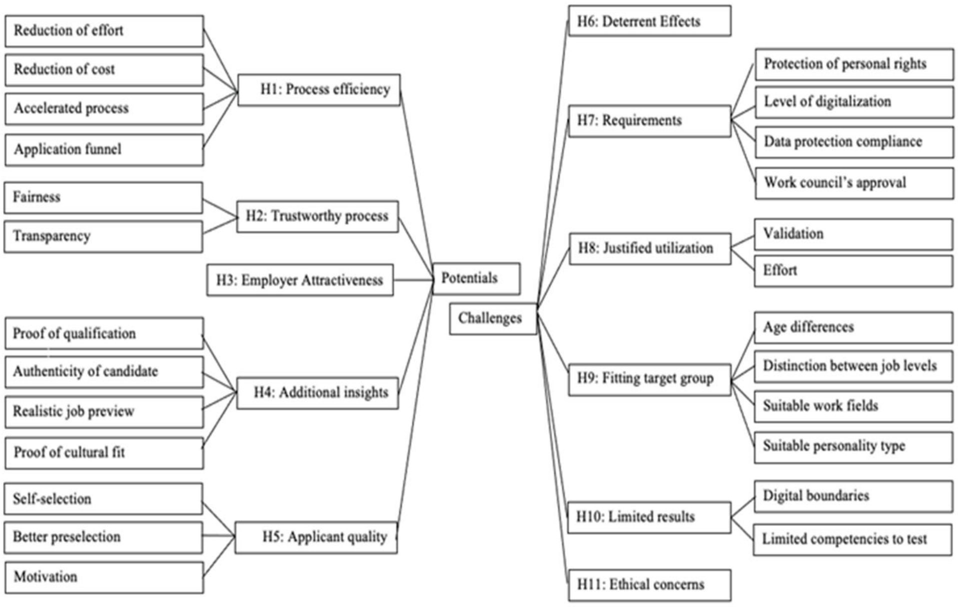

Fig 2. Conceptual Model

the applicant. Gamification creates immersive situations that engage the capacities of the brain. The applicant has no time to think but has to act spontaneously. Overall, the behavior of the applicant is more significant. The interviewees agreed, that gamification provides the packaging for a realistic job preview. Gamification promotes accuracy of expectations by experiencing and testing a workday. The applicant is assured of the job requirements, the workplace, and the company's products. Most experts claim that gamification significantly minimizes the risk of termination after hiring.
H4: Gamification provides additional insights in recruiting.

Applicant Quality. The use of gamification in self-assessment is most effective. The risk of making a wrong decision is reduced for the company and the applicant. The transparency of required skills encourages self-selection. Therefore, most interviewees favored gamification in career orientation to show the applicant which job is suitable. Findings show that gamification is especially suitable at the beginning of the recruiting process. Experts agree that gamification can select qualifications in advance. In the interviews it was mentioned that gamification increases motivation through various factors. When used as a marketing tool, it increases motivation to apply. Furthermore, motivation is raised through active engagement in the game. Most experts agreed that motivation is also achieved through a target group-oriented approach.
H5: Gamification positively influences applicant quality.

Challenges of gamification

Deterrent Effects. A common issue was the possible deterrent effect of gamification on applicants. It was frequently cited that gamification represents an additional hurdle for applicants and that their willingness to make an additional effort could be limited. Given the ongoing shortage of skilled specialists the loss of suitable candidates could be an excessive risk for some companies. Moreover, reservations regarding the scientific respectability of gamification or fear of failing could present further deterrent effects for some candidates.
H6: Deterrent effects hamper the use of gamification in recruiting.

Requirements. Almost all interviewees agree that data protection regulations result in a high level of requirements for gamification in recruiting. This includes clear communication towards the candidates as well as communication with colleagues from intertwined departments. In addition, a certain level of digitization may be required for the implementation of gamification in recruiting. This is imperative for integrating the collected data in systems and efficiently manage high numbers of participants. Additionally, gamification needs to uphold personal rights, which includes a clear communication to candidates. Most interviewees suspected that getting approval of the work council represents a challenge. Therefore, the work council should be involved early in the decision-making process. For this reason, the introduction of gamification in smaller companies without work councils might be easier and more open towards innovation.
H7: High requirements hamper the use of gamification in recruiting.

Justified Utilization. All interviewees agree that the use of gamification needs to be justified by a valid utilization. Foremost in this regard is the scientific validation of the gamified test as well as validating the method through connecting the gamified test to future work elements. Additionally, the use of gamification needs to truthfully reflect the organizational structure and overall modernness to paint a valid picture. Moreover, all interviewees agreed that gamification takes a lot of effort and involves high costs. To justify this effort, many interviewees suspect that gamification is only worth-while, when a certain number of candidates take part in the process. Therefore, to justify gamification in recruiting the use needs to be valid and the effort put in needs to be reasonable for organizations.
H8: Justification of utilization hampers the use of gamification in recruiting.

Fitting Target Group. Due to a higher gaming affinity and being more comfortable in a digital setting gamification might be more fitting for a younger generation of candidates, that grew up in a digital age. Questioning the fit of gamification for all job levels, most interviewees see more potential in using gamification for recruiting junior positions. Only few interviewees state that it is not depending on the job level. Lower levels often include more candidates and might be more suitable for gamification from an economic view. In this context, distinctions between the levels need to be considered. Furthermore, gamification might work best in job fields that involve a high level of numerical or technological understanding, like IT. In addition to that, there could be a certain personality type that gamification works better for, involving traits like a preference for gaming, motivation through gamified element, performance, or power orientation. Companies might be challenged by finding such a target group.
H9: Target group fitting hampers the use of gamification in recruiting.

Limited Results. It is feared that with losing one dimension in a digital setting, you only get limited results from digital gamification. Additional insights could be restricted by a loss of facial expressions, gesticulations, senses, or chemistry. Candidates might also get limited insights into the workplace. Less information and technological issues might lead to a bad decision-making on both sides. Therefore, more innovation might be needed. Theoretically gamification can be used to test methodical, professional, or social competencies. Most interviewees agree that not all these competencies can be adequately tested with gamified elements. Especially challenging might be testing social skills in a gamified setting.
H10: Limited results hamper the use of gamification in recruiting.

Ethical Concerns. In the interviews, ethical questions for gamification, like ageism or ableism, were discussed. Values and attitudes of the gamification developer as well as selected courses of action within gamified elements, could result in underlying developer bias. In addition, algorithms that make decisions autonomously could be classified as unethical. Therefore, a challenge of gamification in recruiting is ensuring ethical utilization.

H11: Ethical concerns hamper the use of gamification in recruiting.

VII. Conclusion and limitations

Implementing gamification in recruiting processes provide potentials and challenges for companies. For a successful implementation it is necessary to fulfill a multitude of legal, organizational, and systematic requirements. Furthermore, it is essential to ensure a certain level of digitalization. The implementation takes a lot of effort, in addition to time involving high costs. To justify the effort, it must be secured that gamified tests are scientifically valid and designed for a specific target group. Regarding the economic view, gamification is appropriate for selecting candidates from a large number of applicants. When developing gamified tests for recruiting processes, it must be ensured that underlying developer bias is excluded. In general gamification might be most suitable for younger applicants, who have a higher gaming affinity. This conclusion was also made by the study of J. Koivistro and J. Hamari [13]. Through gamification both sides involved in the recruiting process can benefit of the added information given about the applicant and the vacant position. This leads to a better fit and a higher quality of suitable candidates and simultaneously reduces fluctuation. In addition, this promotes the opportunity for better self-selection by candidates. If gamification has already been implemented in recruiting, even time savings can be generated, due to automated processes, accelerated decision making and a better preselection. Gamification can increase objectivity, if gamified tests are valid and follow a standardized process, due to a higher volume of data collected during the evaluation. Gamification in recruiting processes can be used as a tool to increase the motivation of applicants, through active engagement and a gamified way to convey content alongside the recruiting process. A model of the potentials and challenges of gamification in recruiting was developed, based on empirical data from German-speaking experts using the content analysis according to Mayring. These generated data show some important influencing factors like process efficiency, data protection, target groups, expenditure of cost and time, as well as the quality of applicants. Experts in HR and gamification mentioned all these factors repeatedly. Therefore, they can be considered as a good basis for the model. To extend the current scientific view of potentials and challenges of gamification in recruiting, current researchers can use these results additionally. There are also some practical implications that should be considered. Companies can benefit from this research by evaluating their level of digitization and their personal fit for gamification in their own recruiting processes. Besides the view of gamification potentials, this research demonstrates equally challenging aspects of gamification, which can have a negative impact on the recruiting processes of companies. Due to the fact, that this qualitative research only focuses on a small sample of experts, there are some limitations, which must be considered. This sample includes different perspectives from experts in different industries and was created to provide reliable information. To prove this qualitative method, a model validation with a quantitative approach is necessary. The influencing factors, which have been identified in this research could be an appropriate starting point for this purpose. Evaluating this model in more countries and focusing on varying aspects would be a great opportunity for future research. Further, a differentiated investigation of single German-speaking states would be interesting as well as a comparison to other counties in the EU or internationally.

***Abstract*—In terms of weed control, existing precision spraying solutions seek to reduce the unwanted impact of spraying by separate field scanning from mostly birds' eye view. In our study, we propose a hybrid approach in which the mechanical hoeing and the spraying is done simultaneously accomplished by weed recognition from a lower position where the plants' leaves do not cover weeds. We demonstrate the line and the weed recognition methods on a dataset collected from corn fields and compare different convolutional neural networks. We also investigate the feasibility on two widely known embedded platforms.**

I. Introduction

WHILE the population of Europe and world is still increasing the possible incorporation of new lands to agriculture is very limited. Weed is a major factor to limit crop yields, beside their physical clearing, spraying is a main general solution to this problem. However, the EU Green Deal agreement [1] aims 50% reduction of applied chemicals, thus conventional spraying techniques should be revised. In traditional, large field applications whole areas are being sprayed resulting in wasted chemicals on healthy and intact plants and on bare soil. The utilization of machine vision techniques for the detection of weed has been a target for decades, a good overview of different approaches can be found in [2]. Computer vision techniques have to face lots of problems if applied on the field. The leaves of weeds and crops often overlap each other at late growth stages, especially if images are taken from above, making them indistinguishable. Additionally, the plant's leaves may be obscured or damaged by unwanted material including dead leaves or clay, making identification difficult. Maize is the most produced grain in the world, with more than 1.2 billion tons produced in 2021. In Europe, the area affected by corn cultivation was approximately 20 million hectares [3]. Thus, the development of solutions for corn alone can have a significant impact on environmental protection, and the various techniques can be adapted to other crops as well. The main contributions of our article are: We are proposing a hybrid approach combining hoeing and spraying. Cameras, fixed to the cultivator, are to capture the areas between the stems of corn (or between lines); convolutional neural networks (CNNs) recognize weeds and spraying is concentrated only on those areas near stems. Hoeing is made between the lines simultaneously, there is no need for multiple scanning of the fields. Fig. 1 illustrates the region of interest (ROI) areas for possible spraying. We introduce a new free annotated dataset of images of corn lines. Binary labels indicate the presence of weeds. We investigate the use of a popular scalable DNN (EfficientNet [18]) and less complex CNNs for weed recognition. The feasibility on micro-controllers is also part of our study. To narrow down the target area for spraying the physical setup is calibrated with image homography.

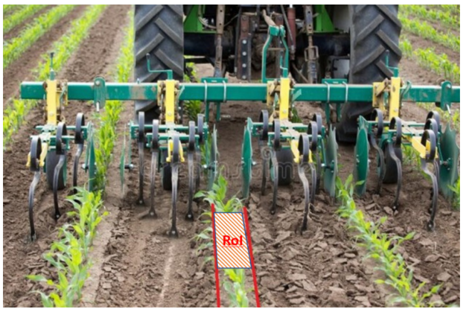

Fig. 1: Corn fields being hoed and only the ROI areas to be sprayed where weed is detected.

II. Literature Overview

Traditional approaches typically consist of four main steps: pre-processing, segmentation, feature extraction, and classification. Pre-processing tries to "standardize" global image properties, while segmentation is to separate vegetation from background. Since weed and crops have similar properties it is difficult to find the proper features and their representation to achieve the best possible classification. Four feature categories can be identified in papers, such as spectral features (mean and standard deviation of RGB, HSV, and chlorophyll vegetation index values), textural features, morphological features, and spatial contexts.

For textural features common techniques can be utilized, for example in [4] single-level Haar discrete wavelet decomposition was used to obtain four sub-images (approximate image,

We acknowledge the financial support of the Hungarian Scientific Research Fund grant OTKA K-135729. We are grateful to the NVIDIA corporation for supporting our research with GPUs obtained by the NVIDIA Hardware Grant Program.

vertical details, horizontal details, and diagonal details), and then gray level co-occurrence matrices were extracted from these sub-images for weed detection. In [5] Gabor filters were applied but also the co-occurrence matrix features were finally calculated. The shape of leaves can be very characteristic for recognition and dozens of such traditional descriptors have already been utilized for weed recognition: eccentricity, circularity, convexity, elongatedness, invariant moments, just to mention a few. The above mentioned approaches did not consider the spatial context, while the sowing pattern of crops is typically very specific: they are sowed or planted in almost straight lines thus the spatial contexts or position information could help to improve the recognition process. It is natural to think of the variants of the Hough transformation, linear regression, the vanishing point, or the frequency analysis of the lines or repetitive patterns. More sophisticated approaches (such as [6] which uses dynamic programming and energy optimization) can also handle curved lines. However, applying strict assumptions about crop positions can result in false detections. In [7] the upper limit of detection accuracy was investigated when using information about sowing geometry and positions. The uncertainty in real crop positions and the disturbing effect of weeds can have a significant effect on detection accuracy, thus complex solutions are required.

Beside RGB cameras, special sensors such as depth cameras can also be used for weed recognition. For example in [8], beside color, position, and texture features also depth features, obtained by a special RGB-D camera, were also utilized to recognize weeds in wheat fields. The AdaBoost algorithm was employed for the integrated learning of multiple classifiers. Experimental results showed accuracy between 81 and 88%, depending on the growth phase of wheat (the different experiments used 50-600 images).

Considering the theoretical and practical problems of the above specified four main steps, there is no surprise for the breakthrough of deep learning methods. As an early attempt to overcome the weak generalization ability of manually designed features [9] used K-means clustering to construct a feature dictionary, fed to a single-layer network, to create an identification model. The approach in [10] can be considered as a hybrid solution where both hand crafted features (requiring segmentation) and DNN features, generated by a pre-trained GoogLeNet [11] network, were used with four kinds of clustering methods. Interestingly, the technique was used to cluster four kinds of weeds but the number of test images were much below a thousand. In [12] an embedded system on a UAV was introduced utilizing the YOLOV3-tiny network to detect the pixel coordinates of weeds in images. The mean Average Precision (mAP) was 72.5% at 2FPS on a mobile device. The average positioning error was 10.31 cm. Tests were carried out on a total of 2000 images, taken at 2 m high, of winter wheat with 5 types of weeds. The most relevant paper from our point of view is [13] where a classification approach of Zea mays L. (corn), narrow-leaf weeds, and broadleaf weeds from multi-plant images are presented. Compared to previously discussed articles, a large image dataset was generated: 13,000 recordings were made in natural field conditions, at different locations and at different stages of plant growth. The ROIs were detected using connected component analysis, whereas the classification was based on VGG [14] and Xception [15] CNNs (and alternatively by SVMs). The best method for weed classification, at early stages of growth and in natural corn field environments, was the CNN-based approach, as indicated by the 97% accuracy obtained.

For the reader interested in hand-designed feature methods we propose to read the review of Wang et al. in [2] while for more recent DNN approaches go for [16].

III. A Maize Image Dataset

Contrary to hand-designed approaches machine learning methods, especially DNNs, don't require much pre-processing but large datasets with enough generality are a must. While some articles were trying to recognize the different types of weeds (e.g. [10]) or tried to increase the variety of viewpoints (f.e. [13]) we have different purposes: Since between the lines of corn hoeing is made, weeds are to be detected (and sprayed if found) only between maize stems. Weed types are out of interest and three types of images are to be classified: only weed, only maize, and weed and maize. The cameras can be placed on the cultivators approximately 25 cm high and 25 cm laterally from the corn row, with the optical axis of 45 degrees to the ground plane.

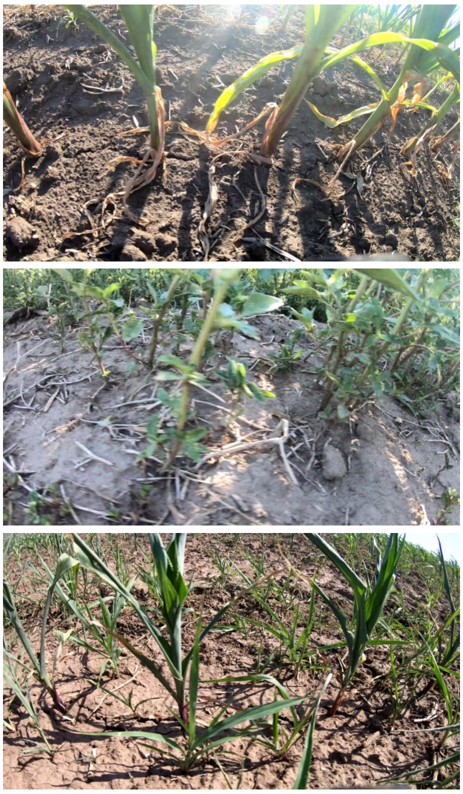

Fig. 2: Example images of the "Corn and Weed" dataset. Top: clear maize. Middle: only weeds. Bottom: maize and weeds.

Images of our publicly available dataset (downloadable at https://keplab.mik.uni-pannon.hu/images/caw/) were made in a second-sown corn field. Sowing time was late May - early June 2022. The average row spacing was usually 70 cm, while the distance between the stems was on average 25 cm. The height of the plants varied between 20-50 cm depending on the nutrient and water supply of the area. The shots were made with a GoPro 7 camera at 2704 × 1520 resolution and at an average speed of 4 km/h, with different corn line orientations. The dataset contains 816 images with only weed, 1231 images with only corn, and 1796 images with corn and weed. Original images are downscaled to 640 × 480, example photos are in Fig. 2.

IV. Detection of Corn Lines and Safety Margin Area

For the most accurate localization of the ROI we make the following steps: First we segmented corn stems. For the instance segmentation of corn stems we used Mask-R CNN [17] pre-trained on the COCO dataset. For transfer learning with two classes (background and corn stem) 50 images (with circa 200 corn plants) were manually annotated. We used stem bottom endings as the lowest points of Mask-R CNN masks to fit lines with linear regression. ROI was set with planar homography (see Subsection IV-A).

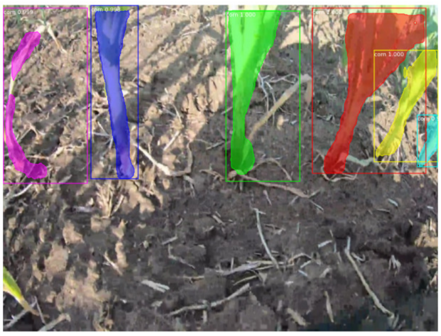

Fig. 3: Segmented maize stems with Mask R-CNN.

A. Planar Homography for ROI Designation

To find the border lines of the ROI the size of the safety margin should be considered. In our layout 10 cms were given on both sides of corn lines. To determine the border lines in the image space we computed the homography matrix with the help of ArUco markers. By applying plain homography we assumed the smoothness of the ground (the relative pose of the camera plane and soil at the stem endings is constant). Naturally, this is not always true but considering the spread of the spray we accepted the resulting inaccuracy. The result is illustrated in Fig. 4.

Starting from our initial dataset now we arrived to a smaller set: there are only two labels (weed free and with weed) and to avoid a very unbalanced configuration the number of weed free images were limited. Tab. I gives the number of images per category in our experiments.

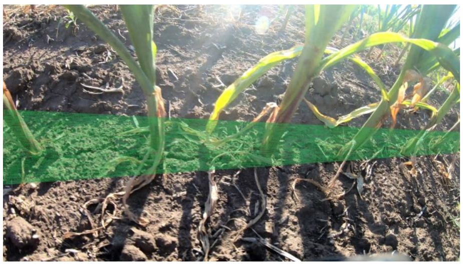

Fig. 4: ROI defined by stem endings and homography of safety margins.

TABLE I: The ROI based dataset used in experiments.

	Weed free	With weed	Total	Percentage
Training images	851	808	1659	72%
Validation images	230	209	439	19%
Test images	59	160	219	9%
Total	1140	1177	2317	100%

V. Comparison of Different Weed Recognition Models

Assuming approximately 15 km/h average speed of the cultivator, circa 70° viewing angle, and 10% overlapping of images at least 4 FPS processing speed should be reached. There are two main purposes of the following experiments: First, to investigate the effect of masking: what happens if the whole area (i.e. the context) is considered during the classification at the ROI. Second, to find the limit to minimize the complexity of the applied CNNs so to increase the processing speed without a painful degradation of accuracy. In 2019, Google Brain published the open source EfficientNet [18] network family for image classification. The members of the family are the differently scaled versions (from B0 to B7) of the base model, B7 being the largest variant achieving state-of-the-art Top-1 accuracy on ImageNet in 2019. It was created with a compound scaling method to scale the depth (number of layers), the width (number of kernels in a layer), and resolution (size of input image) of an existing model and a baseline network with fine-tuned layers, in a balanced manner, to consider the computation limits. We used the ImageNet pre-trained B0 version without the top classification parts after adding two dense hidden layers with 512 and 128 neurons and two output neurons.

Tab. III compares results showing almost perfect classification accuracy on both masked and whole area images. Thus our next step was to create CNNs with decreasing number of parameters to reach the smallest size without a significant drop in accuracy. We started with a network (named CNN 2) specified in Fig. 5 and then decreased the number of convolutional blocks and dense layers as given in Tab. II. Each convolutional block had 16 filters of size 5 × 5, all images are downscaled to 224 × 224. As given in Tab. III the experiments showed that the information from the context could help the classification accuracy (or there is a strong correlation in the presence of weeds between the lines and between the neighboring stems in the ROI area). While we can see a decreasing trend in accuracy from CNN 2 to CNN 5, the reduction of number of parameters is not significant (see Tab. II). Thus we made further variants of CNNs: reduced the number of neurons in dense layers and reduced the number of convolutions. In this process we generated 7 models, namely CNN 3.2, 3.3, 3.4, 3.5, 5.2.1, 5.2.2, and 5.3. The number of parameters and accuracy of these networks are visible in Tab. IV, Fig. 6, and Fig. 7. It is clear to see that there is a significant drop in accuracy for CNN 3.5, and halving the number of neurons in the dense layers of CNN 5.2.1 was not a good idea. Many of these simplified networks produces rather good results, the question is their computational power needed.

VI. Performance on Embedded Systems

All in the previous experiments we used cloud services with massive GPU support which is not very typical in field applications often far from high-bandwidth networks. Luckily there are different embedded system platforms for application developers which could be operated in cultivators.

A. Experiments on the Jetson AGX Xavier Development Platform

The NVIDIA Jetson AGX Xavier Series is an industrial platform for massively parallel computations reaching up to 32 TOPS. We run our tests on a 512 cores Volta architecture with 64 Tensor cores. As given in Tab. V, all models could run at high speed.

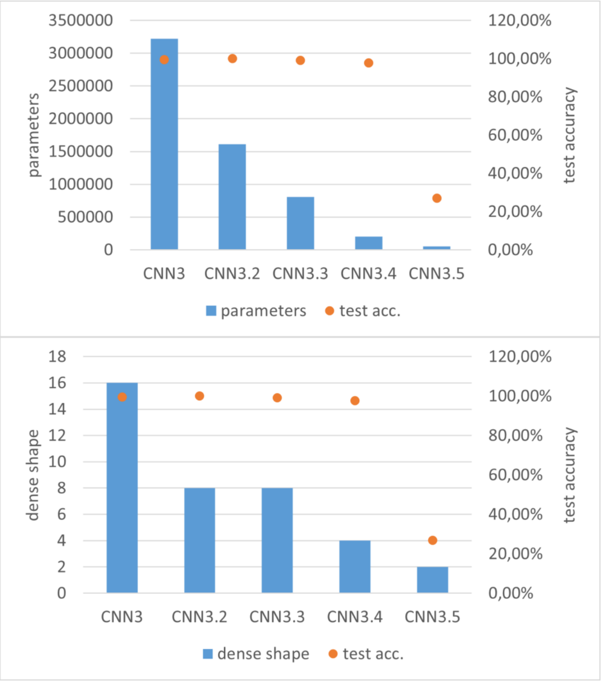

Fig. 6: Top: Accuracy and number of parameters of the CNN models created from model CNN 3. Bottom: Accuracy and shape of the same models.

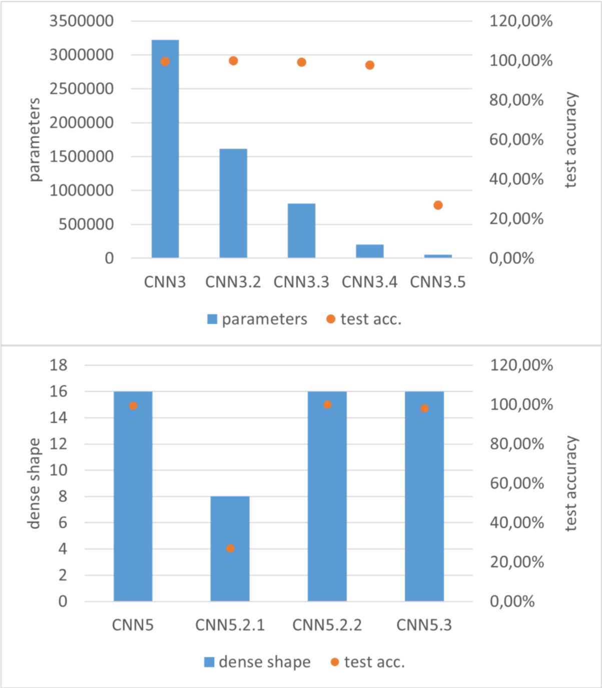

Fig. 7: Top: Accuracy and number of parameters of models created from model CNN 5. Bottom: Accuracy and shape of the same models.

TABLE V: The running performance of different CNN models on the Jetson AGX Xavier platform.

CNN Model	2	3.2	3.3	3.4	3.5	4	5	5.2	5.2.2	5.3
FPS	15.63	28.57	37.04	45.45	33.33	25.0	41.67	47.67	45.45	50

B. Experiments on the STM32 Platform

STMicroelectronics produces different boards built on ARM cores which can be possible platforms for on-field weed recognition. It is possible to test different DNN models in a cloud service of STMicroelectronics at https://stm32ai-cs.st.com/home. Uploaded models can be optimized for speed, for memory usage, or for both. We have chosen the third option to test four of the previous CNN models on two platforms. According to Tab. VI acceptable FPS could be achieved with model CNN 5.3 only on the STM32H735G-DK platform.

TABLE VI: The running performance (FPS) of different CNN models on two specific STM32 boards.

CNN Model:	2	3.2	5.2	5.3
STM32H735G-DK	0.065	0.173	2.15	4.26
STM32F469I-DISCO	0.012	0.032	0.29	0.57

VII. Conclusion

We have outlined a hybrid weed control approach where hoeing is combined with spraying, ensuring that the amount of applied chemicals is very low. We found that the localization of lines can be achieved by Mask-R CNN segmentation of corns, while the recognition of weeds can be done with relatively small size CNNs. Considering the typical speed of cultivators both the NVidia AGX Xavier platform and the STM32H735G-DK board of STMicroelectronics are applicable for recognition. The detection of maize lines with Mask-R CNN on the Xavier platform is for future work as well as capturing new field images under different weather conditions and growth phases of corns. Since corn is the most produced cereal worldwide, our study shows that environmental friendly hybrid approaches can significantly contribute to reaching short term aims of agriculture.

***Abstract*—In the face of the recent surge in energy prices, intensified use of free renewable sources of energy (RSE) gains much importance. Unfortunately, the operation of RSE highly depends on weather conditions, which perturb the balance between the industrial and home energy dissipation patterns. This disparity induces price fluctuations or even destabilizes the energy supply system, yet can be alleviated by the installation of energy depots. While electrochemical depots are hardly cost-effective, they may be supplemented or replaced by small hydro plants with the ponds located above the plant recognized as energy reservoirs. However, inappropriate use of the plant is likely to cause floods or droughts down the river. In this paper, following a rigorous mathematical argument, a cost-optimal controller of a cascade of hydro plants is designed and its properties are formally proved. It is shown to flatten the price pattern, by reducing the load fluctuation of the legacy supply system, as well as provide a concrete revenue for prosumers.**

***Keywords*—hydro plants, green energy, optimal control, networked systems, time-delay systems**

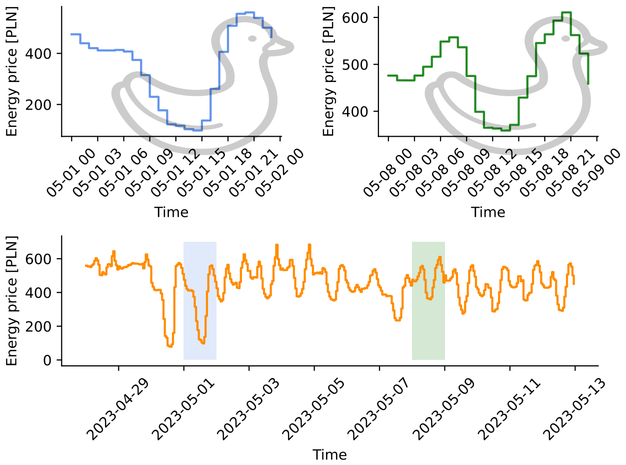

Fig. 1. Fluctuation of energy prices [PLN/MWh] on the Polish market in May 2023 [3] *following 'duck curve'.*

I. Introduction

The energy demand grows day by day, including home users, industry, transportation, building cooling, heating, etc. Unfortunately, the price of electrical energy increases even faster, thwarting domestic budgets. The use of fossil fuels is more and more penalized in Europe, thus the only way to decrease operational costs is to generate energy from renewable sources (RSE), e.g., the sun, wind, waves, geothermal sources, and water flow [1]. Unfortunately, RSEs are capricious in the sense that the amount of retrieved energy heavily depends on weather conditions, whereas the dissipation depends on human activities. These factors oppose each other which leads to substantial price fluctuations. In essence, an RSE generates inexpensive energy around noon and maximum demands (thus high prices) are in the evening when costly fuel-sourced plants need to be engaged. As a result, one obtains the energy price variation resembling the so-called 'duck curve', illustrated in Fig. 1 for a 2-week evolution of the Polish market in May 2023. On May 1st the price in the evening was over 6 times higher than at noon on that day. Meanwhile, on May 8th, this ratio was less than 2, and overall prices have been higher.

A typical business objective from the grid owner's viewpoint is to level the supply-demand disparity – to "behead the duck"" [2] – by decreasing the imbalance in the evening. The only practical way available today to achieve this goal is via energy depots. However, such systems, e.g., pumped hydroelectric storage, or chemical batteries, are expensive to install and later on to maintain. The business objective for plant owners is revenue, thus, despite the government stimulus, the energy depots are introduced infrequently. The problem can be mitigated if different kinds of power plants mutually cooperate [4]. However, it is the domain of commercial plants rather than prosumer ones.

Not all RCSs are susceptible to the influence of weather conditions. A good example is hydro plants [5]. In Poland, there are numerous former mills, currently abandoned, that can be converted into small power plants without significant expenditures from prosumers, i.e., in the same way, the photovoltaic installations have been engaged. To increase the revenue and speed up the return on investment, instead of keeping a constant flow through generators, one may suppress the flow when energy is cheap and boost it when the price is high. Then, the water in the reservoirs located above the plant dams constitutes an energy store. Currently, in Poland, less than 5% of possible installations are used for energy production [6], thus the application area of research presented here is meaningful.

Contrary to broad and deep artificial lakes built on major rivers, the prosumer ponds are relatively small and can be filled up or drained quickly, yet the water supply from upstream reservoirs is subject to delay. To capture this effect, the dynamical model constructed in the work explicitly incorporates the information about different delays among the water flows on the links connecting the reservoirs. Using the system's dynamical representation, an optimization

This work has been performed in the framework of a project "Robust control solutions for multi-channel networked flows" no. 2021/41/B/ST7/00108 financed by the National Science Centre, Poland.

problem is stated and solved analytically. The optimal control law is expressed in an easy-to-implement closed form. The proposed solution brings profits not only to prosumers by increasing their economic gain, but also to the power grid operators by reducing the load changes of standard power plants.

The remaining part of the paper is organized as follows. In Section II, a discrete-time dynamic model of water flow in a multi-hydro-plant system is constructed. It explicitly takes into account different plant characteristics, e.g., capacity, and delays on the conduits linking the reservoirs. Based on the mathematical formulation of system dynamics, an optimization problem is defined and solved. The analytical solution is detailed in Section III and its properties are illustrated in a numerical example presented in Section IV. Conclusions are drawn in Section V.

II. System Model

Usually, the modeling of hydropower plants concentrates on the optimization of the work of generators, leaving the supply system apart [7]. Here, the generator is considered a black box, and the focus is placed on the hydrological aspects of the water plant operation. A key point to consider in a water reflow system is the nonnegligible time between issuing the control action at one reservoir before it influences the water level at a downstream one. Therefore, as opposed to the earlier models of storage networks, e.g., [8], in the approach advocated here, the control principles from time-delay storage systems [9, 10], will be applied. However, the models proposed in [9, 10] assume continuous-time control adjustment, which is difficult to realize in a water control system owing to the specifics of mechanical components steering the dam weirs. The model in this work explicitly covers the effects of finite sample time and will be constructed directly in the discrete-time domain.

A. Single-plant system

Let us consider the model of a single hydro plant illustrated in Fig. 2. The water budget dynamics at the plant will be described via the recursive relation

$$s_j(k+1) = s_j(k) - f_j(k) + \sum_{i \in \text{plants upstream}} f_i(k - T_{ij}) + r_j(k), \qquad (1)$$

where

- $s_j(k)$ is the water volume (water level) of the reservoir near plant j,
- $f_j(k)$ is the amount of water used to drive power generators installed at dam j between time instants k and $k + 1$,
- $r_j(k)$ is the supply from external hydrological sources like rain (and its runoff), melting snow, uncontrolled tributaries, vaporization, etc. The values of $r_j(k)$ can be obtained from the weather forecast and hydrological models within the planning horizon of m periods. $r_j(k)$ is assumed known.

The tributaries supply the pond with water previously used by the plants upstream. The water from upstream plant i arrives at plant j with $T_{ij} > 0$ delay. The period length Δk, i.e., the time between instants k and $k + 1$, can be selected arbitrarily, but according to the pace of price changes, it is reasonable to choose 1 hour (or 15 minutes in the near future). Similarly, the planning horizon m usually covers a 24-hour window of known energy prices (the next-day market). The initial flow $f_j(k \le 0)$ and the initial water level $s_j(0)$ are assumed known. The terminal condition $s_j(m)$ can be selected arbitrarily.

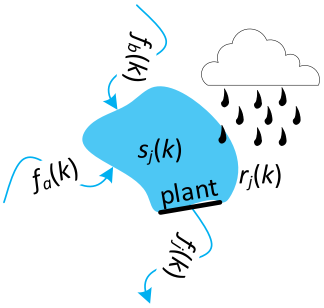

Fig. 2. Model of a single waterpower plant: $f_a(k)$, $f_b(k)$ – water inflow from reservoirs a and b to pond j with the current level $s_j(k)$; $r_j(k)$ – water supply from exogenous sources; $f_j(k)$ – outflow supplying the power generators.

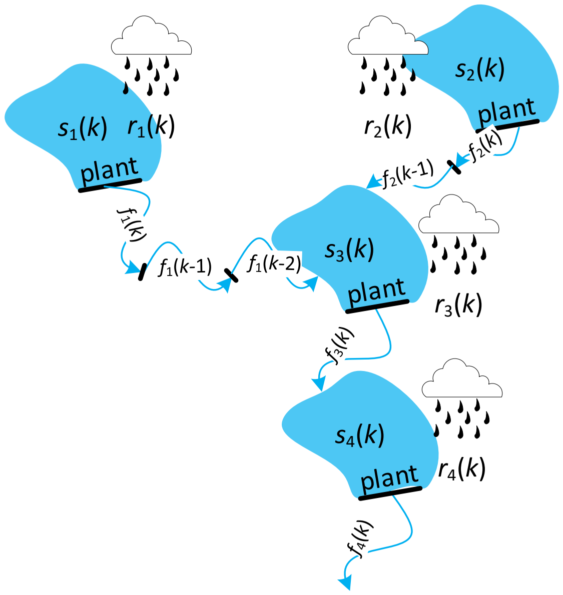

Fig. 3. Model of connected hydro plants. Different canal length inflicts different delay of water reflow between the plants.

The period income from the plant may be calculated as

$$J_j(k) = \eta_j p(k) f_j(k) \Delta k, \qquad (2)$$

where

- $p(k)$ is the energy price at instant k. Usually, it reflects the duck curve, but the actual profile may be subjected to specific local demands.
- η_j is the efficiency of power generators, including the impact of the dam height. For prosumer generators in the lowlands, the flow of 1 m^3/s corresponds to power generation of 5-7 kW.

B. Multi-plant system

In the case of n power plants under common management (an example system with four plants illustrated in Fig. 3), it is convenient to describe the model in a vector form. Let

$$\mathbf{s}(k)=\begin{bmatrix} s_1(k) \\ s_2(k) \\ \vdots \\ s_n(k) \end{bmatrix}, \mathbf{f}(k)=\begin{bmatrix} f_1(k) \\ f_2(k) \\ \vdots \\ f_n(k) \end{bmatrix}, \mathbf{r}(k)=\begin{bmatrix} r_1(k) \\ r_2(k) \\ \vdots \\ r_n(k) \end{bmatrix}, \tag{3}$$

denote the vector of reservoir water level, the water volume of inter-reservoir flows, and the water volume from exogenous sources, respectively.

The proposed state-state representation is given as

$$\begin{aligned} \mathbf{s}(k+1) &= \mathbf{s}(k)-\mathbf{f}(k)+\sum_{t=1}^{T}\boldsymbol{\Theta}_t\mathbf{f}(k-t)+\mathbf{r}(k) \\ &= \mathbf{s}(k)+\sum_{t=0}^{T}\boldsymbol{\Theta}_t\mathbf{f}(k-t)+\mathbf{r}(k). \end{aligned} \tag{4}$$

Introducing $\mathbf{x}(k)$ as a controlled part of the flow, i.e., $\mathbf{x}(k) = \mathbf{f}(k) - \mathbf{f}^{\mathrm{ref}}$, where $\mathbf{f}^{\mathrm{ref}}$ is the vector of natural flows, the system dynamics becomes

$$\mathbf{s}(k+1)=\mathbf{s}(k)+\sum_{t=0}^{T}\boldsymbol{\Theta}_t\mathbf{x}(k-t)+\mathbf{r}(k), \tag{5}$$

where T is the maximum delay, matrix $\boldsymbol{\Theta}_0 = -\mathbf{I}$, $\mathbf{I}$ being the $n\times n$ identity matrix, and matrices $\boldsymbol{\Theta}_1, \ldots, \boldsymbol{\Theta}_T$ group the information about flow delays,

$$\boldsymbol{\Theta}_t=\left[\theta_{ij}\right]_{n\times n} \tag{6}$$

with $\theta_{ij} = 1$, if the flow from reservoir j reaches reservoir i with delay t, and 0, otherwise. The entries on the main diagonal $\theta_{ii} = 0$. Contrary to [11], here, the distance between plants is nonnegligible. For the example from Fig. 3, the longest delay $T = 3$ (the flow between reservoirs 1 and 3) and

$$\boldsymbol{\Theta}_1=\begin{bmatrix} 0&0&0&0\\0&0&0&0\\0&0&0&0\\0&0&1&0 \end{bmatrix}, \boldsymbol{\Theta}_2=\begin{bmatrix} 0&0&0&0\\0&0&0&0\\0&1&0&0\\0&0&0&0 \end{bmatrix}, \boldsymbol{\Theta}_3=\begin{bmatrix} 0&0&0&0\\0&0&0&0\\1&0&0&0\\0&0&0&0 \end{bmatrix}.$$

III. Optimization problem

The optimal values of $\mathbf{x}(k)$ can be obtained from numerical procedures, like [12-16]. However, here, we present an analytical solution, based on the theory of optimal control systems. The obtained closed form is amenable to physical interpretation and can be directly and efficiently implemented in dam control systems.

A. Problem statement

With the initial water level $\mathbf{s}(0)$ and initial flow $\mathbf{x}(k \leq 0)$, the task is to reach level $\mathbf{s}(m)$ within m periods so that imposed cost criteria are fulfilled. Formally, the optimization problem may be stated as

$$\max_{\mathbf{x}(k)} J_E(p(k),\mathbf{x}(k))=\frac{1}{2}\sum_{k=0}^{m-1}p(k)\mathbf{x}'(k)\mathbf{N}\mathbf{x}(k), \tag{7}$$

where $\mathbf{N} = diag\{\eta_1, \eta_2, \ldots, \eta_n\}$ is a positive definite matrix of weighting coefficients that correspond to the efficiency of energy conversion at the plants. []' denotes transposition.

The considered problem is difficult to treat analytically owing to the delays in water reflow. For that reason, an alternative, equivalent system description will be used. Let $\mathbf{y}(t)$ denote the overall system resource level, i.e., the sum of water volume accommodated in the reservoirs and the water flowing between them subjected to control $\mathbf{x}$,

$$\mathbf{y}(k)=\mathbf{s}(k)+\sum_{j=1}^{T}\sum_{t=j}^{T}\boldsymbol{\Theta}_t\mathbf{x}(k-t). \tag{8}$$

Using a similar approach as in [17], it can be shown that the dynamics of $\mathbf{y}(t)$ follows

$$\mathbf{y}(k+1)=\mathbf{y}(k)+\boldsymbol{\Theta}\mathbf{x}(k)+\mathbf{r}(k). \tag{9}$$

B. Solution

For the performance index in problem (7), the Hamiltonian can be defined as

$$\mathbf{H}(k)=\frac{1}{2}p(k)\mathbf{x}'(k)\mathbf{N}\mathbf{x}(k)+\boldsymbol{\lambda}'(k+1)\left[\mathbf{y}(k)+\boldsymbol{\Theta}\mathbf{x}(k)+\mathbf{r}(k)\right], \tag{10}$$

where $\boldsymbol{\lambda}'(t+1)$ is a row vector of Lagrange multipliers.

The necessary conditions are as follows:

- state equation

$$\mathbf{y}(k+1)=\frac{\partial\mathbf{H}(k)}{\partial\boldsymbol{\lambda}(k+1)}=\mathbf{y}(k)+\boldsymbol{\Theta}\mathbf{x}(k)+\mathbf{r}(k), \tag{11}$$

- costate equation

$$\boldsymbol{\lambda}(k)=\frac{\partial\mathbf{H}(k)}{\partial\mathbf{y}(k)}=\boldsymbol{\lambda}(k+1), \tag{12}$$

- stationarity condition

$$\begin{aligned} 0 &= \frac{\partial\mathbf{H}(k)}{\partial\mathbf{x}(k)}=\frac{1}{2}p(k)(\mathbf{N}+\mathbf{N}')\mathbf{x}(k)+\boldsymbol{\Theta}'\boldsymbol{\lambda}(k+1) \\ &= p(k)\mathbf{N}\mathbf{x}(k)+\boldsymbol{\Theta}'\boldsymbol{\lambda}(k+1). \end{aligned} \tag{13}$$

Solving (13) for $\mathbf{x}$, yields

$$\mathbf{x}(k)=-p^{-1}(k)\mathbf{N}^{-1}\boldsymbol{\Theta}'\boldsymbol{\lambda}(k+1). \tag{14}$$

Note that since $\mathbf{N}$ is positive definite (a diagonal matrix with all positive entries), its inverse does exist.

Then, substituting (14) into (11), gives

$$\mathbf{y}(k+1)=\mathbf{y}(k)-p^{-1}(k)\boldsymbol{\Theta}\mathbf{N}^{-1}\boldsymbol{\Theta}'\boldsymbol{\lambda}(k+1)+\mathbf{r}(k). \tag{15}$$

Equation (12) is a homogeneous difference equation. Its solution with the terminal condition $\boldsymbol{\lambda}(m)$ is

$$\boldsymbol{\lambda}(k) = \boldsymbol{\lambda}(m)\,. \tag{16}$$

Substituting (16) into (15), yields

$$\mathbf{y}(k+1) = \mathbf{y}(k) - p^{-1}(k)\boldsymbol{\Theta}\mathbf{N}^{-1}\boldsymbol{\Theta}'\boldsymbol{\lambda}(m) + \mathbf{r}(k)\,. \tag{17}$$

With the initial resource level $\mathbf{y}(0)$ the solution of (17) is

$$\mathbf{y}(k) = \mathbf{y}(0) + \sum_{i=0}^{k-1}\left[\mathbf{r}(i) - p^{-1}(i)\boldsymbol{\Theta}\mathbf{N}^{-1}\boldsymbol{\Theta}'\boldsymbol{\lambda}(m)\right]. \tag{18}$$

The initial state $\mathbf{y}(0)$ and the final state $\mathbf{y}(m)$ are fixed, so their first derivatives are equal to zero. Using (18), the final resource level may be calculated as

$$\mathbf{y}(m) = \mathbf{y}(0) + \sum_{i=0}^{m-1}\left[\mathbf{r}(i) - p^{-1}(i)\boldsymbol{\Theta}\mathbf{N}^{-1}\boldsymbol{\Theta}'\boldsymbol{\lambda}(m)\right]. \tag{19}$$

Hence, the terminal value of the Lagrange multiplier vector

$$\boldsymbol{\lambda}(m) = -\left(\boldsymbol{\Theta}\mathbf{N}^{-1}\boldsymbol{\Theta}'\right)^{-1}\left[\mathbf{y}(m) - \mathbf{y}(0) - \sum_{i=0}^{m-1}\mathbf{r}(i)\right] / \sum_{i=0}^{m-1} p^{-1}(i), \tag{20}$$

and, using (16),

$$\boldsymbol{\lambda}(k) = \boldsymbol{\lambda}(m) = -\frac{\left(\boldsymbol{\Theta}\mathbf{N}^{-1}\boldsymbol{\Theta}'\right)^{-1}\left[\mathbf{y}(m) - \mathbf{y}(0) - \sum_{i=0}^{m-1}\mathbf{r}(i)\right]}{\sum_{i=0}^{m-1} p^{-1}(i)}. \tag{21}$$

Note that since $\boldsymbol{\Theta}\mathbf{N}^{-1}\boldsymbol{\Theta}'$ is symmetric and $\mathbf{N}^{-1} = diag\{\eta_1^{-1}, \eta_2^{-1}, \ldots, \eta_n^{-1}\}$ positive definite, $\boldsymbol{\Theta}\mathbf{N}^{-1}\boldsymbol{\Theta}'$ is positive definite, thus invertible.

Using (14) and (21), the optimal control

$$\begin{aligned}\mathbf{x}(k) &= -p^{-1}(k)\mathbf{N}^{-1}\boldsymbol{\Theta}'\boldsymbol{\lambda}(k+1)\\ &= \frac{p^{-1}(k)\mathbf{N}^{-1}\boldsymbol{\Theta}'\left(\boldsymbol{\Theta}\mathbf{N}^{-1}\boldsymbol{\Theta}'\right)^{-1}\left[\mathbf{y}(m) - \mathbf{y}(0) - \sum_{i=0}^{m-1}\mathbf{r}(i)\right]}{\sum_{i=0}^{m-1} p^{-1}(i)}.\end{aligned} \tag{22}$$

Since $\boldsymbol{\Theta}$ is invertible and $\mathbf{N}^{-1}$ a diagonal matrix with non-zero entries

$$\mathbf{N}^{-1}\boldsymbol{\Theta}'\left(\boldsymbol{\Theta}\mathbf{N}^{-1}\boldsymbol{\Theta}'\right)^{-1} = \mathbf{N}^{-1}\boldsymbol{\Theta}'\left(\mathbf{N}^{-1}\boldsymbol{\Theta}'\right)^{-1}\boldsymbol{\Theta}^{-1} = \boldsymbol{\Theta}^{-1}. \tag{23}$$

Therefore, (22) simplifies to

$$\mathbf{x}(k) = p^{-1}(k)\boldsymbol{\Theta}^{-1}\left[\mathbf{y}(m) - \mathbf{y}(0) - \sum_{i=0}^{m-1}\mathbf{r}(i)\right] / \sum_{i=0}^{m-1} p^{-1}(i). \tag{24}$$

It follows from (8) that

$$\mathbf{y}(m) = \mathbf{s}(m) + \sum_{j=1}^{T}\sum_{t=j}^{T}\boldsymbol{\Theta}_t\mathbf{x}(m-t), \tag{25}$$

so the control system is noncausal. However, when m » T, then $\mathbf{y}(m) \cong \mathbf{s}(m)$, which results in the following control law

$$\mathbf{x}(k) \cong \frac{p^{-1}(k)}{\sum_{i=0}^{m-1} p^{-1}(i)}\boldsymbol{\Theta}^{-1}\left[\mathbf{s}(m) - \mathbf{s}(0) - \sum_{i=0}^{m-1}\mathbf{r}(i)\right]. \tag{26}$$

C. *System properties*

Looking at how the flow control signal in (26) is established, a few observations can be made:

1) The current flow value depends on the current price, yet not on the water level. Thus, prone-to-error water level measurements are not needed for control law implementation.
2) Since $-\boldsymbol{\Theta}$ is a positive matrix and the price is also positive, the flow control signal does not change the sign in the entire planning horizon. It either reduces the water inflow in the case of heavy rainfall and a risk of flood or magnifies the flow intensity for users to gain profit.
3) The flow intensity does not depend on the temporary rainfall intensity, but on its cumulative value $\sum_{i=0}^{m-1}\mathbf{r}(i)$, only. It improves the control system robustness to weather condition fluctuations. In fact, it is resistant to temporal changes of opposite polarity.
4) With

$$\mathbf{K} = \frac{\boldsymbol{\Theta}^{-1}}{\sum_{i=0}^{m-1} p^{-1}(i)}\left[\mathbf{s}(m) - \mathbf{s}(0) - \sum_{i=0}^{m-1}\mathbf{r}(i)\right], \tag{27}$$

substituting (26) for $\mathbf{x}(k)$ in (5), one obtains

$$\mathbf{s}(k+1) = \mathbf{s}(k) + \sum_{t=0}^{T}\boldsymbol{\Theta}_t p^{-1}(k-t)\mathbf{K} + \mathbf{r}(k). \tag{28}$$

Therefore, the closed-loop system with control (26) does not lose the integrating property. For any k, one has

$$\mathbf{s}(k) = \mathbf{s}(0) + \sum_{i=0}^{m-1}\sum_{t=0}^{T}\boldsymbol{\Theta}_t p^{-1}(i-t)\mathbf{K} + \sum_{i=0}^{m-1}\mathbf{r}(i). \tag{29}$$

The water level exhibits neither oscillations nor overshoots. It is confined to the interval determined by the initial $\mathbf{s}(0)$ and final value $\mathbf{s}(m)$.

IV. Numerical example

In order to verify the analytic considerations from the previous sections, a series of tests for the topology from Fig. 3 and the price profile from May 1st Fig. 1 has been conducted. The system is supplied with the precipitation and corresponding runoff depicted in Fig. 4. The system experiences the following input: the initial pond occupancy $\mathbf{s}(0)$ = [6, 9, 15, 18] * 10^3 [m^3], and $\mathbf{s}(m)$ = [1.4, 2.1, 3.5, 4.2] * 10^4 [m^3]. The evolution of $\mathbf{x}(k)$ and $\mathbf{s}(k)$ computed according to (26) is presented in Fig. 5.

In the considered example, one observes the accumulation of energy in the ponds. Each plant in the cascade 1-3-4 and 2-3-4 throttles the flow all the more it is located down the river, which is intuitively justified. All the propitious system properties described in Section III.C are evidenced in graphs from Fig. 5.

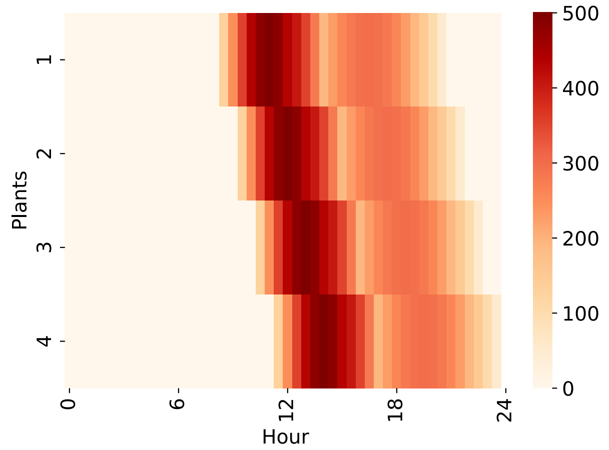

Fig. 4. Moving wave of rain and resulting runoff $\mathbf{r}(k)$ *[m^3/period].*

V. Conclusions

The paper's focus was to design an optimal control strategy to steer the system of connected hydro plants so that the power grid operators benefit from price profile flattening ("beheading the duck), and, at the same time, the plant owners gain monetary profit from their installations. In this way, the natural small rivers and reservoirs form a set of distributed, short-term energy depots deployable with low capital and operational expenditures. Additionally, the ponds, which slow down the precipitation runoff, elevate resilience to floods and droughts, whose risk grows as the climate changes.

A closed-form expression of the designed control law allows for a formal study of system properties. In particular, it has been shown that oscillations and overshoots are avoided so that the capacity constraints of reservoirs and riverbeds can be maintained. The control law is straightforward to implement and recompute for different system settings and weather conditions. No involving numerical treatment is required.

***Abstract*—This paper considers structural control by reinforcement learning. The aim is to mitigate vibrations of a shear building subjected to an earthquake-like excitation and fitted with a semi-active tuned mass damper (TMD). The control force is coupled with the structural response, making the problem intrinsically nonlinear and challenging to solve using classical methods. Structural control by reinforcement learning has not been extensively explored yet. Here, Deep-Q-Learning is used, which appriximates the Q-function with a neural network and optimizes initially random control sequences through interaction with the controlled system. For safety reasons, training must be performed using an inevitably inexact numerical model instead of the real structure. It is thus crucial to assess the robustness of the control with respect to measurement noise and model errors. It is verified to significantly outperform an optimally tuned conventional TMD, and the key outcome is the high robustness to measurement noise and model error.**

***Index Terms*—structural control, semi-active control, reinforcement learning, tuned mass damper (TMD).**

I. Introduction

In this paper, a novel control strategy for reducing structural vibrations in shear-type building structures under seismic excitation is presented and assessed. To achieve this, machine learning techniques, specifically reinforcement learning (RL), were customized, developed, and applied. Structural vibrations in engineering structures can have a negative impact on structural condition and operation, and they can negatively impact structural integrity. Various approaches have been developed to mitigate these effects, including passive, active, and semi-active control methods [1], [2]. The semi-active methods are appealing, since they do not require significant power sources and can be designed to be failure-safe. However, the control forces are coupled with the structural response, which leads to formulations that are challenging to be solved using classical methods [3], [4]. This paper focuses on semi-active control through the use of a semi-active tuned mass damper (TMD). The TMD is a classical device used to mitigate structural vibrations by adding a secondary mass that opposes the motion of the main structure [5], [6]. The semi-active TMD applied here is controllable through a switchable level of viscous damping.

The main aim of this contribution is to test the application potential of reinforcement learning (RL) in semi-active structural control, and in particular, the robustness of the trained agent to measurement noise and structural errors. This is a crucial problem for potential practical applications in civil engineering, since for safety reasons the RL agent must be trained using a numerical model instead of the physical target structure. The structure investigated here is an 11-story shear-type building equipped with a semi-active TMD. The structure is modeled using the finite element (FE) method, and the specific parameters of the models are taken from literature [7]. The TMD is controlled by switching its viscous damping coefficient in an on/off manner (bang–bang), as suggested by the Pontryagin minimum principle [8]. The structure is subjected to an earthquake-like random base excitation. A Deep Q Learning (DQN) algorithm is applied. The trained RL agent reduces the structural vibrations effectively and to a greater extent than a conventional tuned mass damper. Importantly, the contribution demonstrates and evaluates *also* the robustness of the trained agent with respect to measurement noise and model error.

II. Reinforcement Learning – the technique and system architecture

Reinforcement learning is a set of machine learning techniques that aim to teach an agent to determine the most effective actions by engaging in trial-and-error interactions with its environment. During the process the agent receives feedback in the form of rewards or punishments, which it uses to enhance its decision-making abilities over time. This research investigates the capability of reinforcement learning (RL) to enhance semi-active structural control. Unlike supervised learning that depends on optimal control sequences, which are often unknown in semi-active control, and unlike unsupervised learning, which solely relies on exploring input data, RL enables learning from interactions and seems to be well-tailored to the needs of structural control. However, despite the large successes of RL in mastering other complex tasks [9], including control-like problems [10]-[13], it is still a novel and very scarcely explored approach in structural control with only a handful of publications [14]-[16].

IEEE Catalog Number: CFP2385N-ART ©2023, PTI

In this study, the reinforcement learning (RL) agent employs a dense artificial neural network (ANN) to learn and encode the Q-function. The ANN is implemented in the Python programming language using two popular open-source libraries, TensorFlow and Keras. TensorFlow is a low-level library used for building and training machine learning models, while Keras is a high-level API that simplifies the process of building neural networks. The ANN used in this study consists of six hidden sequential dense layers, each with 40 neurons. The input layer provides the network with measurements of structural response, while the output layer consists of two neurons corresponding to the possible states of the control signal. The activation function used in the neural network is rectified linear unit (ReLU) [17].

III. Shear building and excitation

The structure analyzed in this study is a shear-type building consisting of 11 stories with a semi-active tuned mass damper (TMD) attached to the top story (Fig. 1). The TMD is a well-known classical engineering device that comprises a mass, spring, and viscous damper and is widely used to reduce vibrations in structures subjected to external excitations, such as earthquakes [5]. Such a setup results in a total of twelve degrees of freedom (DOFs) which correspond to each of the eleven stories and the TMD. The equation of motion for the building model under seismic excitation can be expressed as:

$$[M]\{\ddot{u}\} + [C]\{\dot{u}\} + [K]\{u\} = -[M]\{r\}a(t) \quad (1)$$

The vector $\{u\}$ has 12 rows and represents the absolute displacements of each DOF, while the vector $\{r\}$ also has 12 rows and represents the displacement resulting from unit horizontal ground displacement for each DOF. The ground acceleration is denoted by a(t), while the matrices [M], [C], and [K] are 12 × 12 in dimension, and represent the mass, damping, and stiffness of the structure, respectively. The material damping model is assumed, and the damping matrix $[C]$ is proportional to the stiffness matrix with the proportionality coefficient chosen to achieve 2% critical damping for the first mode of vibration of the structure without the TMD. The control directly affects the entries in $[C]$ that correspond to the damping of the TMD, see Fig. 1, by switching it between zero and a large value. The mass matrix $[M]$ is diagonal. The masses of each story and the TMD are thus listed on the diagonal of the mass matrix, assuming lumped masses at each floor level. Building specifications, including the number of stories, their masses, and stiffnesses, are based on the literature data [7]. The first undamped natural frequency is 0.89 Hz for the building with the TMD and 1.05 Hz for the building without the TMD.

In this study, an effort has been made to safeguard the RL agent from acquiring a limited response pattern conditioned on a particular collection of ground movements. This restriction is essential to avoid overfitting, a common issue in supervised learning. To address this concern, the seismic load a(t) is assumed to be the white Gaussian noise. Consequently, it is generated afresh for every training and evaluation episode, guaranteeing that the proposed control system is exposed to diverse ground motions without any bias towards specific patterns [7].

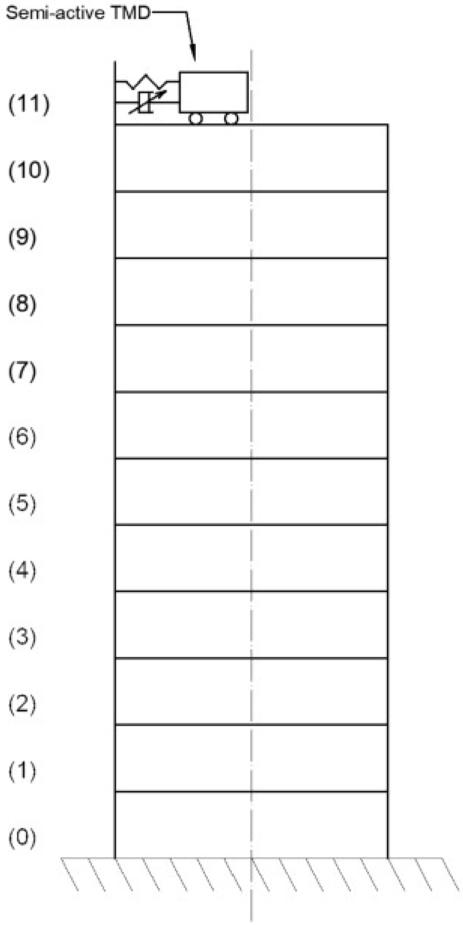

Fig. 1. The investigated 11-DOF structure with a semi-actively controlled TMD placed on the top level

IV. RL training

The state of the RL environment employed for training and control purposes is based on linearly transformed full structural state vector, and it is comprised of the relative displacements and velocities between the ground, subsequent floors, and the TMD. Such a choice is practical, as the relative interstory displacements and velocities are relatively easy to be measured in a real setting.

The training proceeds in episodes. Each episode consists of 1000 RL steps of 25 ms each, and it corresponds to about 25 periods of the fundamental structural vibration. For fidelity of structural response simulation, each RL step is internally further subdivided into 5 simulation steps, each of 5 ms.

The aim of the control is to reduce the oscillations experienced by the highest floor of the structure. For structural control purposes, the control efficiency is usually assessed using the root mean square (RMS) of the displacements in each episode. Consequently, the agent's training is based on the rewards it receives in each step of the interaction episodes, and the rewards are evaluated using the displacement level of the top floor. The maximum reward of 1 is assigned when the displacement is zero. The rewards are used to update the agent's Q-function, allowing it to improve its performance in future episodes.

The total reward signal at the end of each episode reflects the agent's performance and the distance from the equilibrium point over all time steps. Fig. 2 shows the total reward per training episode, together with its EMA50, which increases as the agent learns. The value of 1000 denotes a perfectly stationary top floor, and the chart includes the effect of a 10% exploration rate (10% of actions, on average, is selected randomly to ensure ongoing exploration of the action space).

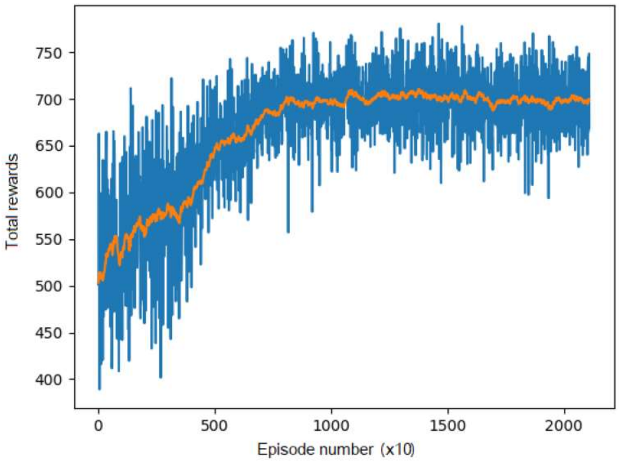

Fig 2. Total rewards per training episode (blue line) and its EMA50 (orange line)

V. Robustness to measurement noise and model error

The intended ultimate application scenario involves a real physical environment (building structure) rather than just its idealized mathematical model. There are two main factors that inevitably differentiate a physical structure from its numerical model: 1) measurement noises overlaid on signals from physical sensors, and 2) model errors that represent the modeling inaccuracies. These factors can negatively affect the control efficiency applied by an RL agent trained using an idealized environment.

The first test involves applying simulated measurement noise to the agent's observations, which is modeled as a Gaussian white noise and added to the input to the neural network (sensor measurements). The test examines increasing larger levels of noise, which is quantified in the signal RMS terms (noise standard deviation related to the RMS of the original sensor signal). The control effectiveness is assessed in terms of the ratio of the top floor displacement RMS in the controlled structure to the top floor displacement RMS in the structure equipped with an optimally tuned passive TMD. Values smaller than 1.0 denote a better effectiveness in comparison to the passive system. To account for the random character of the earthquake-like base excitation, 1000 episodes of 2000 time steps are simulated for each noise level. Fig. 3 plots the mean value of the RMS ratio (blue line) together with its 1 sigma band (yellow).

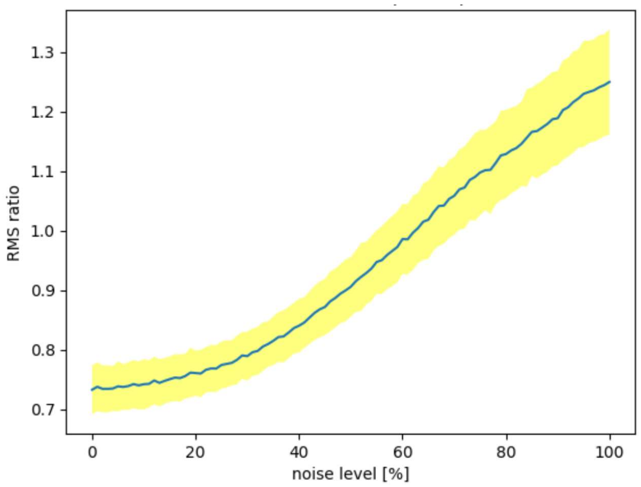

Fig 3. Control efficiency for various measurement noise levels, assessed in terms of the ratio of the top floor displacement RMS between the controlled structure and the structure equipped with an optimally tuned passive TMD: mean value (blue) and 1 sigma band (yellow)

The next evaluation assesses how the trained agent handles model errors, which are possible deviations of physical engineering structures from their ideal mathematical models. The stiffness and mass of individual floors are subject to random change. The generated error follows a normal distribution, limited at 10% of the original level to avoid near-zero or negative values. The evaluation results are presented in Fig. 4. Similarly as in Fig 3, the figure depicts the top floor displacement mean RMS ratio (blue) and its 1 sigma range (yellow), evaluated at each error level using 1000 episodes of 2000 steps each.

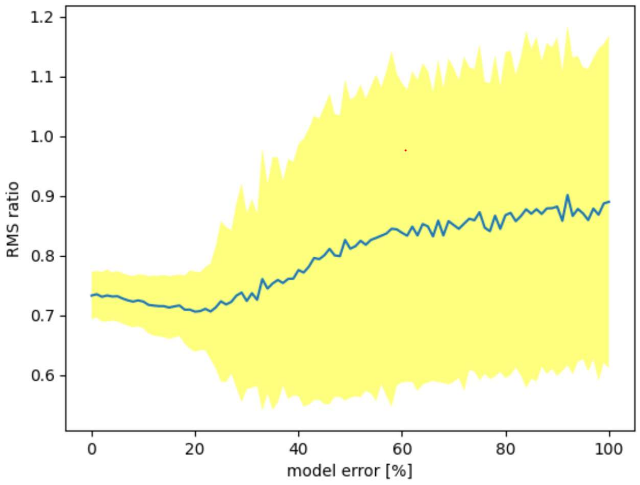

Fig 4. Control efficiency for various model error levels, assessed in terms of the ratio of the top floor displacement RMS between the controlled structure and the structure equipped with an optimally tuned passive TMD: mean value (blue) and 1 sigma band (yellow)

The control performance was not significantly affected by even large levels of measurement noise and model error, as indicated by the observed stable RMS ratio. In particular, the control was more effective than the optimal passive TMD up to measurement noise of about 60% rms. In case of model errors, the mean control effectiveness remained surprisingly good in the entire tested error range; however, the variability of the results increased considerably for model errors above the level of 20%. Such results suggest that the trained model possesses a certain degree of tolerance to disturbances in the form of measurement noise and model errors, allowing it to maintain reliable performance even in the presence of real-world environmental variations.

One possible reason for the model's low sensitivity to disturbances could be attributed to its neural network architecture. Neural networks, particularly those with deeper structures, are known for their ability to learn and extract meaningful features from noisy data. The network layers and parameters might have been optimized during training to capture relevant patterns and generalize well, enabling the model to disregard irrelevant noise components. Additionally, the random character of the base excitation could also contribute to the model resilience, as it prevents the agent from overfitting the specific characteristics of the model and signals and allows it to explore the entire control space.

Further analysis and experimentation can provide deeper insights into the model's robustness and shed light on the specific architectural and training aspects that contribute to its noise tolerance. Understanding these factors will not only enhance our understanding of the model's behavior but also guide the development of more resilient and reliable models in various scientific and engineering domains.

VI. Conclusion

This contribution studied the efficiency of an RL-based semi-active control scheme applied to a shear-type building subjected to an earthquake-like base excitation. The evaluation revealed a noteworthy characteristic of the control system, namely its remarkable insensitivity to measurement and model errors. Despite potential deviations or inaccuracies in the mathematical model used for control, the system demonstrated a high level of robustness and stability. This implies that the control algorithm could effectively compensate for discrepancies between the actual system behavior and the idealized mathematical representation, ensuring reliable performance in real-world scenarios. The observed low insensitivity to noises and errors highlights the effectiveness and practical applicability of the RL-based control methodology in the considered context.

The promising results provide initial insights into the potential of reinforcement learning for improving and ensuring the performance of semi-active damping systems, even though the use of RL in structural control, particularly in semi-active control, is not yet widespread.

***Abstract*—An approach to speaker's emotion recognition based on several acoustic feature types and 1D convolutional neural networks is described. The focus is on selecting the best speech features, improving the baseline model configuration and integrating in the solution a gender classification network. Features include a Mel-scale spectrogram and MFCC-, Chroma-, prosodic- and pitch-related features. Especially, the question whether to use 2-D maps of features or reduce them to 1-D vectors by averaging, is experimentally resolved. Well–known speech datasets RAVDESS, Tess, Crema-D and Savee are used in experiments. It appeared, that the best performing model consists of two convolutional networks for gender-aware classification and one gender classifier. The Chroma features have been found to be obsolete, and even disturbing, given other speech features. The f1 accuracy of proposed solution reached 73.2% on the RAVDESS dataset and 66.5% on all four datasets combined, improving the baseline model by 7.8% and 3%, respectively. This approach is a serious alternative to other proposed models, which reported accuracy scores of 60% - 71% on the RAVDESS dataset.**

I. Introduction

A HUMAN is able to effectively recognize the emotions of the speaker, but attempts to create automatic systems of this type (SER - speaker's emotion recognition) give quite limited results – their intensive development is still carried out [1]. SER systems can find a variety of applications: detecting the emotions of mobile phone users, call center operators and customers, car drivers and other participants of human-machine communication [2]. In some situations, this would allow computer-generated characters to be used to have natural conversations by appealing to human character. Only with this ability is it possible to achieve a fully meaningful dialogue between man and machine.

Human emotionality includes personality, character, temperament, and inspiration as the main psychological parameters that drive human emotions." It can therefore be concluded that there are different sources of communication through which a person expresses his emotions. These include, among others, facial expressions, gestures, speech and writing. On the basis of each of these methods, models can be constructed that will enable the recognition of emotions. One can expect, that a reliable emotion recognition system will require the use of various information modalities, like face videos synchronized with speech and wearable sensor recordings [3].

In the theory of basic emotions [4], it is assumed that people have a limited number of emotions (e.g. joy, anger, fear) that are biologically and psychologically basic. Each of them manifests in the majority of society in an organized, repeating pattern of related behavioral components [5]. Thanks to this, it is possible to label them. However, for this purpose, the number of possible classes must be specified. One of the theories was developed by Robert Plutchik. He distinguished eight basic emotions: joy, acceptance, fear, surprise, sadness, anger, disgust, and anticipation [6].

Despite the relatively easy task of classifying emotions into several categories, it can be problematic even for people if they are not exaggerated. It turns out that in the case when they need to determine the emotional state of an unknown person, the recognition rates are about 60% [7]. Errors in labelling can also affect the quality of automatic classification systems at a later stage.

Currently developed systems for speaker's emotion classification are based on acoustic modeling used in speaker recognition (speaker identification and verification) systems [8]. The basic classic machine learning methodologies used for this problem are UBM-GMM (Universal Background Model - Gaussian Mixture Model) and "i-vectors" [9]. An early solution based on deep neural networks is the ”x-vector” [10] network.

In section 2, related work and database issues are introduced in more details. The implemented system SER (speaker's emotion recognition) is presented in section 3. The main experiments and emotion classification results are shown in section 4. At the end, in section 5, we conclude the work.

II. Related work

A. Speech features and recognition techniques

The development of SER systems is inseparably connected with the use of machine learning techniques. It turns out that the vast majority of solutions used to recognize emotions based on speech are based on these solutions. These include [11]: neural networks (NN), convolutional neural networks (CNN), deep neural networks (DNNs), hidden Markov models (HMM), support vector machines (SVM) [12], decision trees and random forests [13].

This work was supported by ”Narodowe Centrum Badań i Rozwoju”, Warszawa, Poland, grant No. CYBERSECIDENT/455132/III/NCBR/2020. The publication was funded by Warsaw University of Technology.

In various studies, it has been shown that reducing the number of features has a positive effect on classification. It increases the generalization abilities of individual models, and the time of their training decreases. What's more, it turned out that reducing the number of features did not negatively affect the accuracy of emotion prediction, and sometimes even led to its improvement. For example, using the SVM algorithm, reducing the number of attributes from 276 to 75 resulted in an increase in the recognition rate by 5% [12]. In other studies, using the random forest method, selecting 16 traits out of 84 dropped the accuracy by 5%[13].

From the analysis of existing methods we can conclude the following motivation for our research work:

1) Acoustic features of man and women usually differ. For example, the fundamental frequency (pitch) of women voice is usually higher than man.
2) Prosodic features are useful in emotion recognition. The correlation between prosodic features and emotional states of has been already demonstrated [14]. Thus, our work will take such features into account.
3) The use of pitch classes for emotion recognition need to be evaluated. A pitch class is a set of notes with a given halftone pitch from all octaves. Chroma features associated with pitch classes are most often used to recognize emotions in musical works, but some works indicate their correlation with emotional states expressed by speech [15].
4) As the problem is similar to the classification of speaker groups, the solution can well be based on speaker identification methods, like GMM-UBM, JFA, i-vectors or x-vectors. However, we focus on lightweight neural network models using network types, like MLP and CNN.

B. Datasets

Four databases of annotated speech recordings were used for training and testing of the proposed speaker's emotion recognition (SER) system - the ”Ryerson Audio-Visual Database of Emotional Speech and Song” (RAVDESS) [16], the ”Toronto emotional speech set” (TESS) [17], the ”Crowd-sourced Emotional Multimodal Actors” dataset (Crema-D) [15], and the ”Surrey Audio-Visual Expressed Emotion” dataset (Savee) [18]. We use the RAVDESS and TESS databases in initial experiments, dealing with the selection of feature sets and the tuning of network models. An overall evaluation of the proposed solution is also given on a combination of the four datasets. The RAVDESS set is most important for us, as it contains recordings of 24 actors (12 Male and 12 Female voices) and annotates the full number of 8 emotional states: *angry, disgust, fear, happy, neutral, sad, surprise* and *calm*. The TESS database is larger, but uses only the first 6 emotion classes and contains samples of 2 female actors only. Savee holds samples of 7 emotion classes (no *calm* class) from 4 male speakers and Crema-D – samples of first 6 classes only from 91 actors (48 male and 43 female actors). In RAVDESS, every actor delivered 60 sentences with the content "Kids are talking by the door" or "Dogs are sitting by the door", giving a total of 1440 recordings with an average recording length of approximately 3.7 s.

III. System SER

A. Structure

The SER (System for Emotion Recognition) solution was designed with a general structure shown in Figure 1. There are three basic stages of processing:

1) Signal segmentation and detection of acoustic features;
2) Gender classification;
3) Two emotion classifiers - trained separately for male and female speakers.

The results of studies of models with different configurations indicate that it is useful to pre-classify the gender of the speaker and train separate models for male and female voices. Hence, the target configuration of the emotion classifier has three networks - one gender model for binary classification into Male and Female speaker and two emotion models for male and female emotion classification.

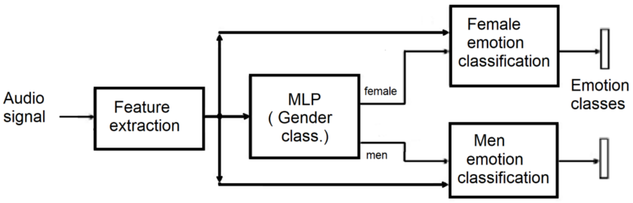

Fig. 1. Structure of the SER solution

B. Acoustic features

The feature vector in our solution can contain features of six types: zero-crossing rate (ZCR), Chroma, RMS value of the signal (root mean square), MFCC–based features, Mel-spectrogram coefficients, and prosodic features (e.g., mean and variance of the fundamental frequency). To determine the above features, the audio signal is processed by functions from the librosa library [19]. Different combinations of the above characteristics were investigated as well as individual types of features. In a final chosen solution, based on 1D convolutional layers, the features are averaged over time (over signal frames) to give a 1D input data – each recording may be represented by a vector of up to 162 features. We also experimented with solutions based on true 2D CNNs and LSTM networks – the feature averaging was omitted to provide a map of 2D features as input to the neural networks (Fig. 2).

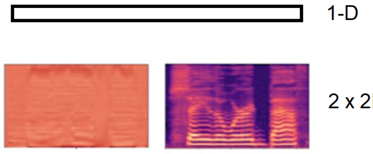

Fig. 2. Alternative input features of SER: a 1D vector of features averaged over time, two 2D maps of features

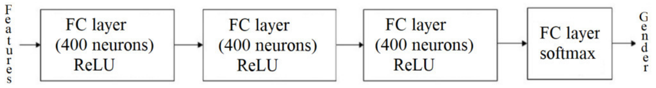
Regarding a prosody feature, we tracked the basic frequency (”pitch", F0) over time. In general, there are useful prosody features, like: waveform F0 (mean, minimum, maximum, variance), average energy of the voiced and voiceless parts, tempo of speech (inverse of the average time of voiced parts in a statement).

C. Gender model

For gender classification, we use an MLP network with 1D input (Figure 3). The model has three fully connected hidden layers containing 400 neurons each followed by a 0.1 dropout for each layer.



Features
FC layer (400 neurons) ReLU
FC layer (400 neurons) ReLU
FC layer (400 neurons) ReLU
FC layer softmax
Gender

Fig. 3. Structure of the MLP network for gender classification

D. 1D-based SER

For emotion classification, we use a baseline solution built from 1D convolutional layers [20]. There are four layers with 1x5 masks followed by ”MaxPooling1D” layers. After the flattening layer there are two Dense layers - one with ReLu activation and the other with softmax. During experiments with various feature sets and model parameters, under a gender-aware policy, the performance of this baseline model was improved by several percent. The final architecture of our emotion classifier (used both for man and female emotions) differs from the base network mainly by the final two layers and the input vector (Table I). The last convolutional layer has 96 filters (replacing 64), while the fully connected layer has 128 neurons (replacing 32). The input data consists of 150 features, as the Chroma features have been found useless for this network configuration.

TABLE I
THE MODEL ”LAYER 128-96” FOR EMOTION RECOGNITION

Layer (type)	Output (shape)	Param. number
conv1d (Conv1D)	(None, 150, 256)	1536
max_pooling1d (MaxPooling1D)	(None, 75, 256)	0
conv1d_1 (Conv1D)	(None, 75, 256)	327936
max_pooling1d_1 (MaxPooling1D)	(None, 38, 256)	0
conv1d_2 (Conv1D)	(None, 38, 128)	163968
max_pooling1d_2 (MaxPooling1D)	(None, 19, 128)	0
dropout (Dropout)	(None, 19, 128)	0
conv1d_3 (Conv1D)	(None, 19, 96)	61536
max_pooling1d_3 (MaxPooling1D)	(None, 10, 96)	0

dense (Dense)	(None, 128)	123008
dropout_1 (Dropout)	(None, 128)	0
dense_1 (Dense)	(None, 8)	1032
Total params: 679016		
Trainable params: 679016		
Non-trainable params: 0		

E. 2-D based SER

For a 2-D data input, models based on CNN networks were studied. We considered two processing streams - one for the MFCC-based feature map and one for the Mel-spectrogram. Each 2D map is processed by a CNN model with convolutional layers and 3 maxpooling layers. The outputs of both models are concatenated and processed by a fully connected layer with softmax activation.

F. Data augmentation

A well-known approach in machine learning is data augmentation [21]. For automatic increase of the number of annotated recordings, there will be synthetic secondary recordings generated from existing recordings by following operations: adding noise, stretching or compressing the signal over time, and changing the frequency of the basic tone (F0). The operation of adding noise does not change the envelope of the signal, so it also does not change the type of emotion in the recording. Other operations can change the class, so the scope of changes has been limited.

G. Evaluation metrics

The metrics used to evaluate a classification system is typically based on the following counts of model prediction: TN – True Negative, TP – True Positive, FN – False Negative, FP – False Positive. The appropriate relationships of the above results lead to evaluation metrics of the system:

- Precision – the correctness degree of the positive prediction result of a given class: $Precision = TP/(TP+FP)$ Observe that ”false positive rate”: $FPR = 1 - Precision$.
- Recall = TPR (true positive rate) – the degree of correct prediction of examples of a given class: $Recall = TP/(TP+FN) = TPR$
- F1 score – the degree of correct positive predictions: $F1 = 2 \cdot (Recall \cdot Precision)/(Recall + Precision)$
- ROC (receiver operating characteristic) – a curve, $TPR = f(FPR)$ that relates true positive rate (TPR) versus false positive rate (FPR) (where such pairs of values are obtained for the same decision thresholds).
- AUC (area under the ROC curve) – it determines the probability that the classifier will rank a random example of a positive class higher than a random example of a negative class. Ideally, its value is 1.

IV. EXPERIMENTAL RESULTS

A. Gender classification

The gender classifier (Fig. 3) was tested on the RAVDESS set (24 speakers). The accuracy on the test set was 98.7% and the AUC value was 0.9993. These results show a high quality of the proposed model.

B. Effect of recording times

The effect of time (length) of the recording onto the emotion classification was tested using the MLP model as emotion classifier (with 8 outputs) and all the 165 features (Table II). For the two datasets (RAVDESS and TESS), the classification accuracy increased with increasing recording time and saturated between 4 and 6 seconds. In further experiments, sequences with a length of 4 s were chosen for analysis.

TABLE II
DIFFERENT LENGTHS OF RECORDINGS AND THEIR INFLUENCE ONTO CLASSIFICATION ACCURACY

Length	TESS		RAVDESS	
[s]	Test accuracy	AUC field	Test accuracy	AUC field
2	0,78	0,9725	0,43	0,8274
3	0,92	0,9945	0,55	0,9029
4	0,98	0,9998	0,60	0,9117
6	0,99	1,0000	0,62	0,9418

C. Effect of input features

In early experiments with the MLP-based emotion classification on the RAVDESS dataset, we studied the effect of using single types of features. The following test accuracies (F1 score) were observed: for prosodia features 0.49, MFCC 0.39, Mel-spectrogram 0.37, Chroma 0.20, all features 0.62. Thus, when combining all the features into an input vector for the 1D emotion classifier, the effect of cancelling Chroma features was tested. It turned out, that the modified baseline network, in every configuration performs better without the Chroma features (Table III). The presented results of training and test (validation) accuracies come after 50 or 100 training epochs, with batch size 64.

TABLE III
EFFECT OF MODIFYING THE FEATURE SET AND THE BASE MODEL ON EMOTION CLASSIFICATION ACCURACY

Model	All features (162)		No Chroma (150)	
	Avg. recall	F1	Avg. recall	F1
Baseline (100 ep.)	0.64	0.654	0.67	0.681
Layer 128-64 (100 ep.)	0.69	0.696	0.71	0.716
Layer 128-96 (100 ep.)	0.69	0.700	0.72	0.719
Baseline (50 ep.)	0.66	0.661	0.66	0.664
Layer 64-128 (50 ep.)	0.66	0.678	0.67	0.684
Layer 96-64 (50 ep.)	0.66	0.655	0.67	0.682
Layer 64-64 (50 ep.)	0.67	0.672	0.68	0.690
Layer 64-96 (50 ep.)	0.67	0.669	0.68	0.685
Layer 96-96 (50 ep.)	0.67	0.676	0.68	0.693

D. Effect of layer size modification

The experimental results, collected in Table III, also show, that by increasing the number of neurons in the FC layer to 128, and the number of filters in the last convolutional layer to 96, a significant increase of the performance can be achieved. This configuration is denoted as ”Layer 128-96”.

E. Gender-aware emotion classification

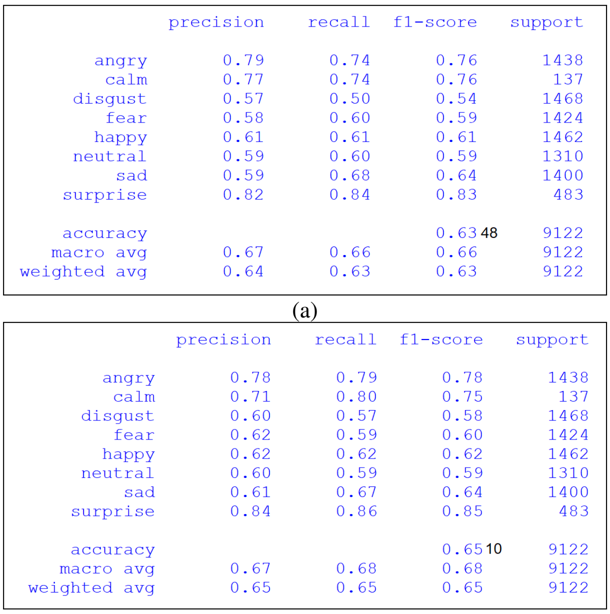
We complete the experiments on our 1D SER approach by training and testing two separate emotion classifiers – one for Males and one for Females. The results provided in Table IV are twofold. There is no significant increase of the performance of the baseline model when applied under perfect gender classification conditions. The practical observable performance is even slightly lower for the gender-aware (G-A) solution. A different effect is observed for our best modified model (Layer 128-96) used for separate gender emotion modelling – the F1 accuracy is now increased by 2.3% (in theory) and 1.3% (in practice) on the RAVDESS dataset.

TABLE IV
EFFECT OF GENDER-CONTROLLED EMOTION CLASSIFICATION

Model	All features (162)		No Chroma (150)	
	Avg. recall	F1	Avg. recall	F1
Baseline female	0.68	0.7019	0.73	0.7426
Baseline male	0.58	0.6019	0.61	0.6222
2x Baseline theoretic	0.63	0.6519	0.67	0.6824
2x Baseline real	0.622	0.645	0.664	0.675
Female Layer 128-96	0.69	0.7241	0.76	0.7796
Male Layer 128-96	0.66	0.6722	0.70	0.7037
G-A 2x Layer 128-96	0.675	0.6982	0.73	0.7417
Real G-A 2x Layer 128-96	0.667	0.689	0.722	0.732

F. Comparison on 4 datasets

Finally, the baseline solution has been compared with our best modified model (Layer 128-96, no Chroma) by training and testing both on the four available datasets: RAVDESS, TESS, Crema-D and Savee. Classification reports are given in Figure 4. Again, our modified model keeps an advantage of 2% in the F1 score.



```

Fig. 4. Classification reports of (a) the baseline model and (b) our modified baseline model, when trained and evaluated on four emotion datasets

G. The 2D SER

Two-dimensional data is in the form of a feature map, where one axis represents discrete time (indexes of subsequent frames) and the other feature indexes for one frame. We studied maps representing the mel-spectral features and cepstral features of the MFCC. Each feature map was obtained from a recording with a duration of 4 seconds. We applied CNN or CNN+LSTM models for emotion classification. The best result was achieved for a Mel-spectrogram input – an accuracy of 37%, based on RAVDESS. For the MFCC feature map, an accuracy of 34% was reached. We also uses the well-known pretrained VGG16 convolutional model. Here the best result was an accuracy of 43%, achieved on the Mel-spectrograms. The results of the classification based on the LSTM network have reached 34% only.

H. Comparison with other works

It should also be mentioned that for the RAVDESS set, the highest accuracy values achieved by different authors are 60% – 71%, but using much more complex models than ours [22], [23], [24], [25]. Some recent results, obtained on the RAVDESS dataset, are listed in Table V. Our best solutions — the single model "Layer 128-96" and the gender-aware configuration of three models – have outperformed other known solutions.

TABLE V
COMPARISON WITH OTHER WORKS EVALUATED ON THE RAVDESS DATASET

Model [ref]	Aver. Recall (%)	F1 (%)
CVT+SVM [22]	-	60.1
ResNet [23]	50.3	53.3
GResNet [23]	59.7	60.35
VGG16 [24]	71.0	-
Our "Layer 128-96"	72.0	71.86
Our "G-A 2x Layer 128-96"	72.2	73.2

V. CONCLUSIONS

In our research, we have confirmed a good performance of models processing a 1D feature vector. The approach to emotion classification based on 2D feature maps has failed. The use of a proper subset of speech features (without Chroma), a modification of the baseline network and the gender-aware approach have all contributed to a final result, that outperforms other known approaches validated on the RAVDESS dataset. The aim of our future research will be to explore more deeply prosodic features in emotion recognition.

Abstract—**Hearing is one of the most crucial senses for all humans. It allows people to hear and connect with the environment, the people they can meet and the knowledge they need to live their lives to the fullest. Hearing loss can have a detrimental impact on a person's quality of life in a variety of ways, ranging from fewer educational and job opportunities due to impaired communication to social withdrawal in severe situations. Early diagnosis and treatment can prevent most hearing loss. Pure tone audiometry, which measures air and bone conduction hearing thresholds at various frequencies, is widely used to assess hearing loss. A shortage of audiologists might delay diagnosis since they must analyze an audiogram, a graphic representation of pure tone audiometry test results, to determine hearing loss type and treatment. In the presented work, several AI-based models were used to classify audiograms into three types of hearing loss: mixed, conductive, and sensorineural. These models included Logistic Regression, Support Vector Machines, Stochastic Gradient Descent, Decision Trees, RandomForest, Feedforward Neural Network (FNN), Convolutional Neural Network (CNN), Graph Neural Network (GNN), and Recurrent Neural Network (RNN). The models were trained using 4007 audiograms classified by experienced audiologists. The RNN architecture achieved the best classification performance, with an out-of-training accuracy of 94.46%. Further research will focus on increasing the dataset and enhancing the accuracy of RNN models.**

I. Introduction

HEARING is considered an essential sensory organ since it provides us with valuable information about the external environment. In addition, it enables us to interact with the outside world, communicate with others, remain safe, and derive enjoyment from a variety of auditory experiences. Hearing complements our other senses, such as sight and sensation, to provide a complete understanding of our surroundings.

According to the World Health Organization (WHO), more than 1.5 billion persons worldwide suffer from hearing loss, of which 430 million have moderate or severe hearing loss in their better hearing ear. According to the projections of the World Health Organization, by 2050 nearly 2.5 billion people will have hearing loss and at least 700 million will require rehabilitation services. Fortunately, many instances of hearing loss can be prevented through early detection and intervention [1].

Although the majority of ear diseases are curable, accurate diagnosis is a significant barrier to effective treatment. Audiologists, who are essential for the execution and interpretation of testing, are scarce worldwide. Approximately 93% of low-income countries have fewer than one audiologist per million people [1]. Given the disparity between the supply and demand for hearing specialists, artificial intelligence (AI) has the potential to resolve this problem. AI employs algorithms that enable computers to recognize particular data analysis patterns and make conclusions. The most prevalent AI application in tonal audiometry is hearing aid personalization, in which AI systems assist both the hearing-care expert and the patient in more precisely and efficiently adjusting hearing aids to the client's preferences [2, 3, 4].

Another possible application of expert systems in audiology is interpreting results of pure-tone audiometry, which is the standard method for diagnosing hearing loss. Typically, the examination is conducted while situated in an anechoic chamber. It entails conveying increasing-intensity pure tones through headphones and determining the threshold for air and bone conduction. In general, the results of the pure-tone audiometry test are presented as an inverted graph called an audiogram, which allows for identifying hearing impairment.

When describing hearing loss, three aspects are considered: the type of hearing loss, the degree of hearing loss, and the configuration of hearing loss. Three types of hearing loss are distinguished: sensorineural, conductive, and mixed. The pattern of hearing loss across frequencies is determined by the configuration (shape) of the audiogram, whereas the severity is determined by the degree of hearing loss [5].

Classification of automated audiometry data has been investigated for a very long time. In the past ten years, there have been a number of initiatives to develop an automated classification system sufficiently accurate for clinical application. The most successful have been presented by Elbaşı and Obali [6], who compared Decision Tree, Naive Bayes, and Neural Network Multilayer Perceptron (NN) models for determining hearing loss. The research was conducted on a data set containing 200 samples divided into four categories: normal hearing, conductive hearing loss, sensorineural hearing loss, and mixed hearing loss. The accuracy of the classification algorithms was 95.5% for Decision Tree, 86.5% for Naive Bayes, and 93.5% for NN. While that work used raw audiometry test results, Crowson et al. [7] applied the ResNet models to classify rasterized results in the form of audiogram images into four categories of hearing (normal, sensorineural hearing loss, conductive hearing loss, mixed hearing loss) on a set of 1007 audiograms. Instead of completely training the classifier from scratch, the authors used transfer learning to train the classifier using widely recognized raster classification models. This method achieved a classification accuracy of 97.5%, but it is limited to image analysis.

In conclusion, the combination of machine learning and increased computational resources in innovative hardware architectures has the potential to generate faster overall test results and more exhaustive evaluations in audiology [8]. Despite the type of hearing loss, the classification accuracy of the currently proposed solutions ranges from 86 to 97%, which, while extremely high, still leaves a substantial margin of error. Moreover, while the best available audiogram classifier, presented by Crowson et al. [7], achieved 97.5% accuracy, it cannot be applied to the original data series produced by tonal audiometry due to being an image classifier. This means that before classification the datasets would need to be converted into a particular format of audiogram images (although the structure of audiograms is generally analogous, audiograms generated by different software can vary quite significantly). Additional problems would stem from the fact that some types of software generate two audiograms (one for each ear), while other software combines the information from both ears into a single audiogram, posing a great difficulty in universal analysis. Consequently, an image classifier cannot form the core of a versatile solution for classifying tonal audiometry results. Moreover, the abovementioned studies on determining the type of hearing loss were carried out with a relatively small data set, ranging from 200 test results in Elbaşı & Obali [6] to 1007 in Crowson et al. [7], which might have led to an optimistic and uncertain evaluation of model performance.

This study establishes the benchmark for machine learning and deep learning algorithms using a large set of discrete tonal audiometry data series. Throughout the course of this investigation, multiple AI models were trained and evaluated using 4007 audiogram data series analyzed and classified by professional audiologists. The purpose of this study was to investigate the performance of various AI solutions when applied to raw tonal audiometry data.

II. MATERIALS & METHODS

A. Data

The study was carried out on 4007 data series containing the results of pure tone audiometry tests performed between 2017 and 2021 by clinicians at the Otolaryngology Clinic of the University Clinical Centre in Gdansk, Poland. The data class proportion is presented in Fig. 1. Conductive hearing loss only has 674 examples, while mixed hearing loss has 1594 and sensorineural hearing loss has 1739. Each patient provided a maximum of two test results, one for the left ear and one for the right, resulting in no duplication of data from the same patient and ensuring adequate data variety.

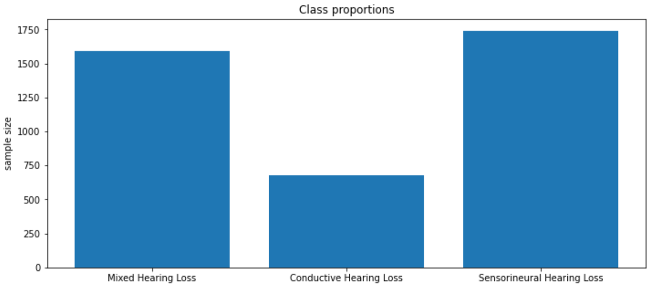

Figure 1. The three forms of hearing loss represented in the dataset, along with their respective proportions.

Tonal audiometry was used to evaluate patients' hearing according to the American Speech-Language-Hearing Association (ASHA) guidelines. All tests were conducted in soundproof chambers (ISO 8253, ISO 8253). The TDH39P headphones were utilized for air conduction testing, while the Radioear B-71 bone-conduction vibrator was used for bone conduction testing [9].

Experienced audiologists labeled the morphologies of hearing loss on the audiometry test results, dividing the set into three classes according to established methodology [5]: mixed hearing loss, conductive hearing loss and sensorineural hearing loss.

Typically, the results of pure-tone audiometry are depicted as an audiogram, which is a graphical representation of how loud sounds must be at various frequencies for them to be audible. In addition to a graphical representation, audiology software generates XML files that comprise all information regarding tonal points in the audiogram. This study processes raw audiometry data using XML files, analyzing five primary frequencies (250, 500, 1000, 2000, 4000 Hz) from both air conduction and bone conduction.

B. Methodology

The aim of the study was to test the performance of several different machine learning algorithms at the task of classifying tonal audiometry data. The goal of each method was to accurately categorize each dataset as mixed hearing loss (M), conductive hearing loss (C) or sensorineural hearing loss (S).

a) Machine learning algorithms

The initial phase of research involved testing the following machine learning classification algorithms: Gaussian Naive Bayes, K-Nearest Neighbors (KNN), Logistic Regression, Support Vector Machines (SVMs), Stochastic Gradient Descent (SGD), Decision Tree and Random Forest. The second phase of the study involved testing the following ANN architectures: Feedforward Neural Network (FNN), Convolutional Neural Network (CNN), Graph Neural Network (GNN), and Recurrent Neural Network (RNN). These techniques were previously applied to the classification problem of medical data [10, 11].

b) Data preprocessing

The input data series consisted of vertical information about tonal points of air and bone conduction, defined as volume (dB) for a given frequency (Hz), obtained from XML files. The frequency range of the dataset included 250Hz, 500Hz, 1000Hz, 2000Hz, and 4000Hz. Each frequency tested has been designated a loudness level between -10dB and 120dB. The dataset did not contain any empty values.

Since GNN requires graph input, the vector was turned into a directed graph with 10 nodes and 18 edges. Frequency and loudness values have been assigned to nodes. Figure 2 shows a graphical depiction of the graph.

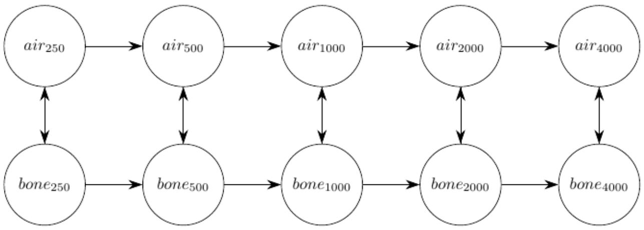

Figure 2. The GNN architecture's input graph structure.

c) Model evaluation

The performance of the tested models was evaluated using K-fold Cross-Validation, which is the process of splitting a dataset into K folds, using K-1 datasets for training and one for validation. The datasets are then rotated in consecutive tests, allowing for more accurate assessment of best, worst and average classification performance. Based on the magnitude of the dataset and the available computational resources, K was set to 5 in this study. Consequently, the ratio of train to test datasets is 80% to 20%, respectively.

III. Results and Discussion

The initial stage of research tested the classification performance of a set of machine learning algorithms. The results have been expressed in terms of accuracy, precision, recall, and F1 score. Due to the aforementioned class imbalance, macro averaging was calculated. The outcome of those tests is presented in Table I.

Receiver Operating Characteristics (ROC) curves with corresponding Area Under the Curve (AUC) parameters, displaying the discrimination performance of the tested machine learning models in terms of true positives vs false positives are presented in Fig. 3. The ROC Curve and the ROC AUC score are essential tools for evaluating binary classification models, but they can also be applied to multi-classification problems. OvR method was selected, which stands for "One versus the Rest" and is a method for evaluating multiclass models that evaluates each class in comparison to the others simultaneously. In this scenario, one class is deemed the "positive" class, while the other classes are deemed the "negative" class. This reduces the multiclass classification output to a binary classification output, allowing the use of all known binary classification metrics to assess this scenario [12].

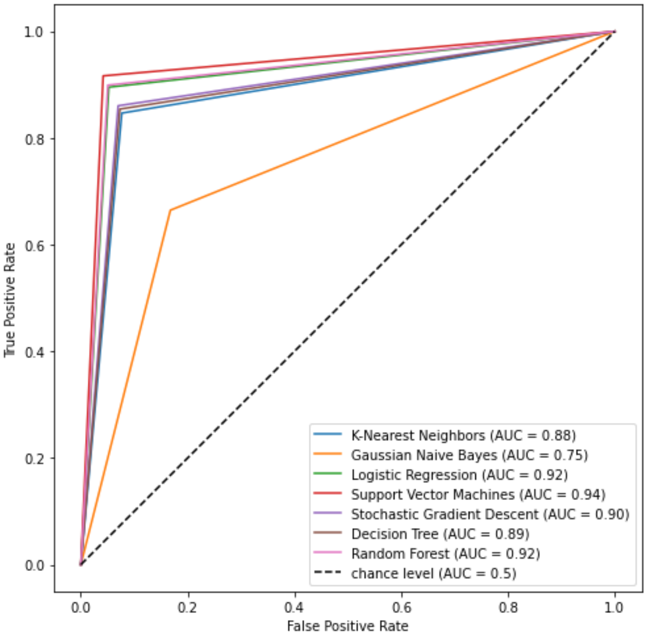

Figure 3. ROC curves with the AUC parameters for machine learning models.

As far as machine learning algorithms are concerned, the best results have been achieved by the Support Vector Machine classifier, which earned 83.38% accuracy. The algorithm also received best scores in precision, recall, F1, and AUC. The Logistic Regression and Random Forest models, which closely followed SVM, also scored above 80% accuracy.

TABLE I.
COMPARISON OF PERFORMANCE RESULTS OF MACHINE LEARNING MODELS. BEST RESULTS IN EACH CATEGORY HAVE BEEN HIGHLIGHTED IN GREEN

Algorithm	**Gaussian Naive Bayes**	**K-Nearest Neighbors**	**Logistic Regression**	**Support Vector Machines**	**Stochastic Gradient Descent**	**Decision Trees**	**Random Forest**
Accuracy	62.14% (+/- 8.43%)	74.40% (+/- 7.29%)	82.48% (+/- 7.21%)	**83.38%** **(+/- 6.21%)**	76.81% (+/- 7.78%)	79.49% (+/- 2.16%)	81.26% (+/- 4.46%)
Precision	87.68% (+/- 9.95%)	92.51% (+/- 5.92%)	94.74% (+/- 5.69%)	**94.97%** **(+/- 4.08%)**	90.96% (+/- 7.77%)	92.99% (+/- 5.68%)	94.27% (+/- 4.52%)
Recall	62.14% (+/- 8.43%)	74.40% (+/- 7.29%)	82.48% (+/- 7.21%)	**83.38%** **(+/- 6.21%)**	76.81% (+/- 7.78%)	79.49% (+/- 2.16%)	81.26% (+/- 4.46%)
F1	71.06% (+/- 5.32%)	81.12% (+/- 4.51%)	87.38% (+/- 5.62%)	**88.05%** **(+/- 3.76%)**	80.51% (+/- 9.62%)	85.16% (+/- 2.35%)	86.58% (+/- 2.70%)

Stochastic Gradient Descent and K-Nearest Neighbors achieved accuracy of 76.81% and 74.40%, respectively, which puts them well behind the three leading methods, but still a league above Gaussian Naive Bayes which scored only 62% accuracy.

It is worth noting that tree-based classifiers have shown the best accuracy stability in terms of 5-Fold validation, with approximately 2% standard deviation in Decision Tree and around 4.5% in Random Forest, whereas for all other models this parameter exceeds 6%. The problem of unbalanced data, which is definitely present in this study, is one of the elements that could have a negative impact on the scores of machine learning algorithms, which is particularly evident e.g. in the poor performance of Gaussian Naive Bayes.

The second phase of research involved deep learning architectures such as FNN, CNN, GNN, and RNN, which were examined using the same criteria as machine learning models. The results of these tests are shown in Table II. The ROC curves with AUC parameters are presented in Fig. 4.

Concerning the tested artificial neural network models, RNN performed best in terms of accuracy, precision, recall, F1 score and AUC, with 94.46% accuracy and 94.45% F1 score. This was to be expected, as the input datasets could be considered sequential data, which is a known strength of RNN [13]. These results also confirm the findings of a recent study [14], which evaluated different neural network designs in order to develop a binary classifier for normal and pathological hearing loss based on similar data, where the best results were also achieved by the RNN architecture. The second best model was CNN with roughly one percentage point less, which may be a little surprising given that CNNs are generally employed to evaluate images. This may be explained by the fact that CNNs perform best when processing data matrices, and the input datasets could be interpreted as small (5x2) matrices. FFN generally achieved third place, while GNN achieved the worst scores.

The overall performance differences between machine and deep learning models are largely in favor of artificial neural networks, with the exception of GNN, which remained at the level of machine learning techniques. The achieved results differ significantly from previous research (performed by Elbaşı and Obali [6]), which achieved 95.5 % accuracy in classifying raw audiometry data with Decision Tree. It should be noted, however, that the validity of those results may be questioned because they were obtained on only 200 samples, which is 20 times less than the dataset used in the current work. Furthermore, there is no information on the class proportion and the employed cross validation process.

TABLE II.
COMPARISON OF PERFORMANCE RESULTS OF DEEP LEARNING MODELS. BEST RESULTS IN EACH CATEGORY HAVE BEEN HIGHLIGHTED IN GREEN

Model	**FFN**	**CNN**	**GNN**	**RNN**
Accuracy	89.67% (+/-2.12%)	93.46% (+/- 0.83%)	83.15% (+/- 9.09%)	**94.46%** **(+/-0.91%)**
Precision	90.27% (+/-1.78%)	93.50% (+/- 0.83%)	86.04% (+/- 4.68%)	**94.50%** **(+/- 0.91%)**
Recall	89.67% (+/-2.12%)	93.46% (+/- 0.83%)	83.15% (+/- 9.09%)	**94.46%** **(+/- 0.91%)**
F1	89.71% (+/-2.09%)	93.46% (+/- 0.83%)	82.15% (+/- 11.02%)	**94.45%** **(+/- 0.91%)**

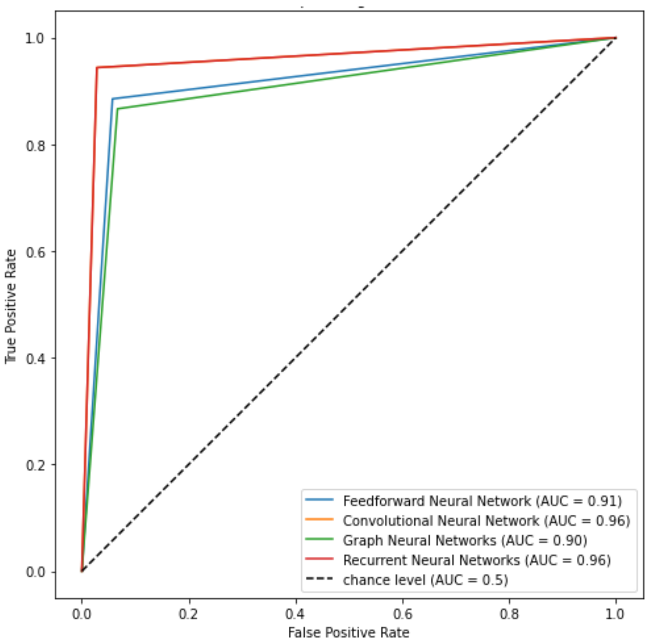

Figure 4. ROC curves with the AUC parameters for deep learning models.

In the above context, while best accuracy of 94,46%, achieved by RNN, is lower than the current state of the art in classification of audiometry test results (97.5%) held by Crowson et al. [7] for raster datasets, that score could be put in question as well. The most significant challenge with training deep learning models from scratch is that it must be done on a large dataset, or else it may miss important patterns. Reliable training of ANN classification models usually requires datasets consisting of at least 10000 samples. For raster datasets this may be alleviated somewhat by employing augmentation of much smaller datasets (which was the strategy applied by Crowson et al. [7]). Unfortunately, this method works best if the input dataset was sufficiently representative. In this case, various types of audiometry software can generate significantly different images, ranging from minor differences in plot color and measurement point indicator size to changes that can significantly impair the performance of an automated classifier, such as displaying test results from both ears on a single plot. As a result, unless an appropriately comprehensive audiogram database is constructed (which would require collection and classification of hundreds of thousands of audiograms produced by all types of audiometry software), image-trained classification models will only work with certain types of audiometry data. In comparison, a classifier which operates on raw audiometry data allows for more flexible and wider application in the clinical environment. This being said, the best classification accuracy of 94,46%, which was achieved in this test by RNN, could be considered too low for clinical application due to a prohibitively large number of false negatives. The latter would suggest that producing a reliably accurate raw audiometry data classifier will require constructing an appropriately large and representative training dataset.

IV. Conclusion

The presented work aimed to test several AI-based algorithms for classification of discrete tonal audiometry data series into three types of hearing loss: sensorineural, conductive, and mixed. In the course of this study, several different machine and deep learning models, including Gaussian Naive Bayes, K-Nearest Neighbors, Logistic Regression, Support Vector Machines, Stochastic Gradient Descent, Decision Trees, Random Forest, Feedforward Neural Network, Convolutional Neural Network, Graph Neural Network, and Recurrent Neural Network, have been trained and tested with the use of 4007 audiometry data series analyzed and classified by professional audiologists. The highest classification accuracy was achieved with Recurrent Neural Network at 94.46% (+/-0.91%). The results of the study verified the general hierarchy of classification performance established by prior research, however they also suggest that the previously reported levels of classification accuracy (achieved for vastly inferior dataset sizes) might have been overly optimistic. In the above context, further work will concentrate on expanding the dataset and improving RNN models in terms of accuracy.

Abstract—**Complex networks attract attention in various scientific fields due to their ability to model real world phenomena and potential for problem-solving. It is essential to evaluate these networks to simulate and solve various issues. Evaluating social networks is challenging due to the unequal status of nodes and their unknown impact on everall characteristics. Existing measures of centrality often need to consider the global structure of the network, which requires the involvement of experts and creates space for multi-criteria decision-making methods usage. Unfortunately, more access to established decision-making models is often needed for various reasons. In this article, we propose an innovative approach called Dynamic Stochastic IdenTifiCation Of Models (Dynamic SITCOM), which considers the preferences of characteristic objects and the characteristic values of criteria, enabling the re-identification of multi-criteria decision models. The approach evaluates nodes in Facebook's complex social network, focusing on prediction accuracy using similarity measures and Mean Absolute Error. The study shows that a stable decision model can be created and applied to evaluate nodes in complex networks.**

I. Introduction

COMPLEX networks have attracted the interest of researchers from various scientific fields, such as biology, sociology, physics, and computer science [1]. Their occurrence in a wide variety of fields makes evaluating and analyzing these networks of great importance. Evaluating complex networks is essential in many fields because it allows for simulating and solving various problems [2].

For example, assessing the importance of nodes in the context of power networks makes it possible to identify critical points whose failure could lead to network shutdown. In the case of communication networks, assessing the importance of nodes makes it possible to optimally maintain connections and prevent disruptions in the flow of information. Complex networks also have applications in preventing the spread of rumors or diseases [2]. By identifying and assessing the importance of crucial nodes, it is possible to influence the control and limit the propagation of such phenomena. In addition, complex networks are widely present in the social domain, where assessing the importance of nodes is crucial for identifying opinion leaders, influential individuals, or experts in a community.

Due to the growing popularity of social media, it has become one of the most effective marketing tools. Using visual content on platforms such as Twitter, Facebook, and Instagram can help companies build their image and increase the reach of their brand. Social media allows companies to connect directly with customers and monitor product and service feedback [3]. However, one of the main problems with social networks is viral marketing, which involves using social networks to spread information about a product or service through users who pass the information on to their friends.

In addition, companies promoting themselves on social media have begun using virtual influencers to advertise products and services. Through them, companies can reach new audiences and increase the reach of their brand. However, the use of virtual influencers is controversial among consumers, who believe it is a scam and lacks authenticity.

Therefore, evaluating social networks is particularly important to identify critical nodes that play a crucial role in the network. This, in turn, allows us to control and limit the spread of rumors or use them for marketing purposes [4]. By identifying key nodes, we can also increase the reach of positive information and make positive community changes.

Due to the statuses of nodes found in complex networks, which are unequal and different, a problem arises in evaluating them. The main methods used are methods of evaluating nodes based on measures of node centrality. The most popular centrality measures used to evaluate complex networks are degree centrality, inter-node centrality, proximity centrality, PageRank centrality [5], Katz centrality [6], and k-shell [7].

Unfortunately, although centrality criteria are widely used, they have some shortcomings and deficiencies [2]. Measures of node centrality, such as degree centrality, do not always consider the global structure of the network [8], [9]. Therefore, it is common to use the knowledge of domain experts to evaluate key nodes based on the information gathered by selected centrality metrics. Multi-criteria decision analysis methods are also used, using some aggregation of centrality metrics to determine network node ratings [10].

Therefore, this article proposes a new Dynamic SITCOM approach to re-identify the decision model based on the evaluated decision variants. The main novelty of the Dynamic

SITCOM approach is the two-stage optimization. In the case of the baseline Stochastic IdenTifiCation Of Models (SITCOM) approach, optimization is based only on the preferences of characteristic objects that reflect the decision maker's preferences [11], [12]. In contrast, the proposed approach also optimizes the characteristic values responsible for the position of characteristic objects in the decision grid. This leads to the possibility of considering more non-linear problems.

The proposed approach will be applied to the problem of evaluating Facebook nodes in a complex network. For this problem, the expert evaluates nodes with a specific model based on four criteria reflected in the form of centrality metrics. This model is unavailable, so the Dynamic SITCOM approach used is to re-identify it. The study focuses on the accuracy of this approach using similarity measures of rankings and Mean Absolute Error (MAE).

The rest of the article is organized as follows. Section II presents the state of the art of MCDA/MCDM methods related to the topic of node evaluation in complex networks and a brief introduction of Stochastic IdenTifiCation Of Models (SITCOM). Section III presents a proposal for the Dynamic SITCOM approach. Section IV presents research related to the accuracy of the Dynamic SITCOM approach in the problem of evaluating the nodes of the Facebook complex network. The V section presents conclusions and future research directions.

II. Preliminaries

A. State of the art

Multi-criteria decision analysis/Multi-criteria decision-making (MCDA/MCDM) methods assess node importance in complex networks by using centrality metrics, such as node degree, betweenness, and closeness. These methods aggregate multiple criteria to provide a comprehensive evaluation of node significance, aiding in the identification of crucial nodes for network performance. Table I presents examples of the use of MCDA/MCDM methods for complex network evaluations. Khaoula et al. proposed a novel seed-centered approach based on TOPSIS and the k-means algorithm to find communities in a social network [13]. Zhang and Ng proposed a ranking method based on entropy weights and the TOPSIS approach, named EWM-TOPSIS, to evaluate the criticality of nodes considering various node characteristics in complex public transportation networks (PTNs) [14]. Lu used the TOPSIS method to evaluate and compare the ARPA network and the standard IEEE 39 bus system [15]. Meng et al. used the WTOPSIS approach to evaluate complex networks in urban rail transit (URT) [16]. Mi et al. used the VIKOR approach to evaluate a road network with 28 intersections in Shenzhen [17]. Kharanagh et al. proposed using SAW, TOPSIS, and ELECTRE I approaches to analyze social networks in water resources management [18]. Lin et al. used the CRITIC approach to assess the importance of nodes in reconfiguring the electricity grid backbone network [19].

B. Stochastic IdenTifiCation Of Models (SITCOM)

Stochastic IdenTifiCation Of Models (SITCOM) is a new approach to re-identify a decision model based on evaluated decision variants [11], [12]. This approach's operation mechanism is based on the logic of the selected stochastic optimization algorithm and Characteristic Object METhod (COMET). The stochastic algorithm determines the preferences of the Characteristic Objects (CO), which in the case of the COMET method, represents the preferences of the decision maker. Then, when selecting appropriate values of characteristic object preferences is over, it is possible to evaluate new decision variants. A full description of the algorithm can be found in the initial papers [11], [12].

III. Dynamic SITCOM

In this article, we propose to extend the above SITCOM approach with additional optimization. Since the base SITCOM approach only uses characteristic object preference values for optimization, the model may not consider some non-linearity occurring in expert knowledge. Therefore, the present proposition is based on the characteristic objects building factor, i.e., the characteristic values of the criteria. The characteristic values are mainly responsible for the model's grid and irregularity. In addition, the starting and ending values included in the vector of characteristic values of the COMET method are responsible for the boundaries of the model. Therefore, in the proposed approach, in addition to optimizing the preference of characteristic objects, we will focus on optimizing the middle characteristic values of the model.

The proposed method is based on a two-stage optimization. The first optimization, as in the case of the original SITCOM, will be based on the search for the best possible preferences of characteristic objects. The second optimization, on the other hand, will focus on the search for the best possible middle values for the characteristic values of the considered criteria. Due to the grid change, a loop was applied to query the optimized models to change the preferences of the characteristic objects with the newly found middle values for the characteristic values and vice versa.

IV. Study case

In this paper, we will focus on investigating the accuracy of the Dynamic SITCOM approach based on the problem of evaluating nodes of complex networks. First, it will get the selected dataset presented, and the study will be conducted in the next section.

A. Dataset description

The selected dataset concerns a complex network, which consists of nodes that are Facebook profiles. This dataset is anonymized and derived from the paper [20]. It consists of 4039 nodes and 88234 edges that connect the selected nodes. The network and the degree of the given nodes can be represented by Fig. 1.

TABLE I
EXAMPLES OF THE USE OF MCDA/MCDM METHODS IN EVALUATING NODES OF COMPLEX NETWORKS.

MCDA approach	No. of nodes	No. of criteria	Problem	Year	Reference
TOPSIS	4039	4	Evaluation of nodes from Facebook's network	2023	[13]
EWM–TOPSIS	95	3	Evaluation of the MTR network in Hong Kong	2021	[14]
TOPSIS	21	7	Evaluation of the ARPA network and the standard IEEE 39-bus system	2020	[15]

VIKOR	28	3	Analysis of traffic safety at intersections	2020	[17]
SAW, TOPSIS, ELECTRE I	54, 30, 32, 26	12	Social network analysis of water resources management	2019	[18]
CRITIC	66	7	Evaluation of the Guangdong power system in China	2017	[19]

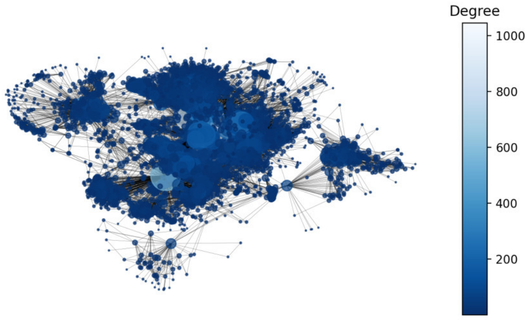

Fig. 1. Facebook's complex network of anonymized profiles [20].

Due to the problem of evaluating the nodes of the present network, four metrics were selected to serve as criteria. The selected network centrality metrics are degree centrality, closeness centrality, betweenness centrality, and eigenvector centrality.

A decision matrix incorporating criteria and preferences, including expert ratings, will guide the re-identification of the decision model. It utilizes min-max normalization for all criteria, employing stochastic optimization in the training process. Table II displays the first ten decision variants with normalized values for criteria and preferences.

B. Research on the accuracy of the approach

This research case will investigate the accuracy of the proposed Dynamic SITCOM approach. For this purpose, the selected stochastic algorithm for re-identification of the multi-criteria model is the genetic algorithm. For optimization in the genetic algorithm in determining the preferences of characteristic objects and the means of characteristic values, 50 chromosomes were selected. On the other hand, for each criterion, the characteristic values were defined as a set of 0, 0.5, 1 because the criterion values were normalized. The implementations used in this study are from the *mealpy* library (genetic algorithm: `BaseGA`) [21] and the *pymcdm library* (COMET method) [22]. The related study evaluates subsets of test collections derived from tenfold cross-validation. The entire set in this study is divided into two parts, i.e., the training part (90 percent of the original set) and the testing part (10 percent of the original set). This division made was 10 times, where the selection of Folds is generated using the sklearn library. The subsets of the train and test sets are drawn 1,000 times and have 10,15,25,50,100 decision variants. These subsets evaluated were to use the learned SITCOM model on the selected Fold training set. Their evaluation is then compared with a reference evaluation determined subjectively by the expert using the MAE measure. In addition, the output evaluation from the learned decision variant model and the expert evaluation ranked is, and their similarity examined is using the r_w and WS measures. The training set has high quality and was similar to the test set, so it was decided to present only the research on the test set.

The results of the test set presented are in Tables III, IV and V for different numbers of randomly selected alternatives: 10, 15, 25, 50, and 100. The tests repeated were 1000 times. The Tables contain information on accuracy, expressed by the r_w, WS, and MAE metrics. Analyzing the MAE metric in the present case, the minimum MAE was smallest for 10 alternatives and was 0.002259, while the largest minimum error occurred for 100 alternatives and was 0.003226. The average values of the MAE for all the numbers of alternatives considered ranged from 0.021608 to 0.021710. As for the maximum values, the largest value was reached for 10 alternatives, while the smallest value occurred for 100 alternatives. The standard deviation indicates the spread of the results around the mean value of the MAE, which was approximately 0.012 for all cases.

TABLE III
MAE VALUES FOR SELECTED 1000 DRAWS OF GIVEN NUMBERS OF ALTERNATIVES FROM THE TEST SET.

No. of alts.	Min	Mean	Max	Std
10	0.002259	0.021665	0.059992	0.012677
15	0.002419	0.021710	0.057319	0.012469
25	0.002580	0.021608	0.055091	0.012236
50	0.002832	0.021657	0.050384	0.012166
100	0.003226	0.021674	0.048271	0.012082

The results of the r_w ranking similarity metric for randomly selected alternatives from the test set shown are in the following table. The table contains the minimum, mean, and maximum values of the r_w metric and the standard deviation. The table shows that the smallest minimum values of the r_w metric achieved were for 10 random alternatives, where they amounted to 0.388430. In comparison, the most significant minimum values occurred for 100 alternatives, where they reached a value of 0.929653. The average values of the r_w metric for all the considered numbers of alternatives range from 0. 985462 to 0.992024. Virtually all maximum values obtained were equal to 1, except for 100 alternatives, where the highest value was 0.999972. The standard deviation indicates the spread of results around the average value of the r_w metric, which ranged approximately from 0.010770 to 0.037956 for the different cases.

TABLE IV
r_w VALUES FOR SELECTED 1000 DRAWS OF GIVEN NUMBERS OF ALTERNATIVES FROM THE TEST SET.

No. of alts.	Min	Mean	Max	Std
10	0.388430	0.985462	1.000000	0.037956
15	0.638393	0.987587	1.000000	0.028707
25	0.656923	0.989946	1.000000	0.019518
50	0.871222	0.991282	1.000000	0.014129
100	0.929653	0.992024	0.999972	0.010770

Examining Table V, it can be seen that the minimum values of the WS metric for the various numbers of randomly selected alternatives range from 0.418711 to 0.888070. The average values of the WS metric for all the numbers of alternatives considered ranged from 0. 978925 to 0.994398. All the obtained maximum values of the WS metric equal 1. The standard deviation shows the spread of the results around the average value of the WS metric, which ranged from 0.007709 to 0.048627 for the different cases.

TABLE V
WS VALUES FOR SELECTED 1000 DRAWS OF GIVEN NUMBERS OF ALTERNATIVES FROM THE TEST SET.

No. of alts.	Min	Mean	Max	Std
10	0.418711	0.978925	1.0	0.048627
15	0.493393	0.980259	1.0	0.041311
25	0.511516	0.983272	1.0	0.032187
50	0.571031	0.988155	1.0	0.020861
100	0.888070	0.994398	1.0	0.007709

The visualizations associated with the r_w, WS, and MAE measures for randomly selected alternatives from the test set, repeated 1,000 times, are shown in Figs. 2, 3, and 4. Analyzing the MAE measure, the most accurate model was obtained for Fold number 2, while the least accurate model obtained was for Fold number 10. The smallest number of outliers was observed for Fold number 8, while the most significant was for Fold number 9. Turning to the similarity measure of rankings r_w, the lowest similarity of rankings occurred for Fold numbers 6 and 10, while the highest similarity of rankings observed was for Fold number 7.

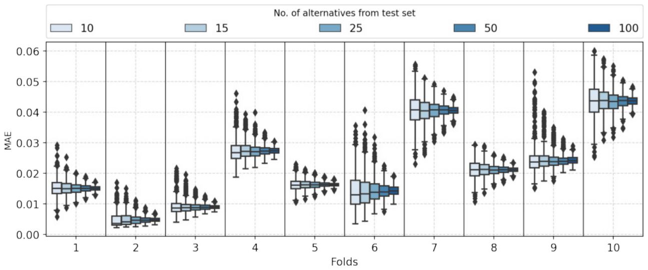

Fig. 2. Distributions of MAE values for selected 1000 draws of given numbers of alternatives from the test set for 10-fold crosvalidation.

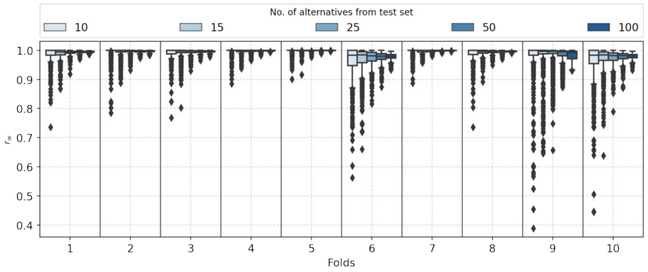

Fig. 3. Distributions of r_w values for selected 1000 draws of given numbers of alternatives from the test set for 10-fold crosvalidation.

V. CONCLUSIONS AND FUTURE RESEARCH

The study related to Dynamic SITCOM shows that it is possible to create a stable decision model for complex network nodes. Several conclusions can be taken by analyzing the presented research results related to the proposed Dynamic SITCOM approach. The first is that the larger the number of randomly selected alternatives, the smaller the value of the

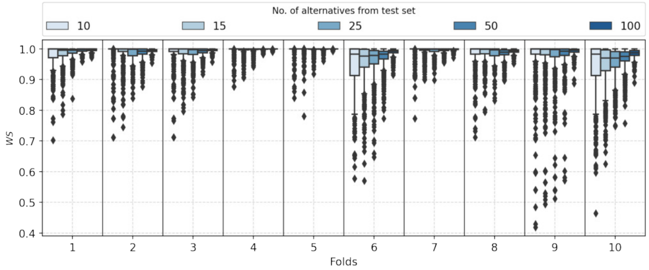

Fig. 4. Distributions of WS values for selected 1000 draws of given numbers of alternatives from the test set for 10-fold crosvalidation.

maximum MAE, suggesting that a more significant number of alternatives leads to better prediction accuracy. However, the average values of the MAE for all the numbers of alternatives considered are very close, indicating the stability of the model.

A similar trend observed is for the similarity measures of the r_w and WS rankings, where a more significant number of alternatives has larger minimum, average and maximum values. The maximum values are close to 1 for all cases, meaning the model represents reality well.

The conclusion is that a more significant number of randomly selected nodes presented as decision alternatives lead to better prediction accuracy and a more accurate reflection of the decision maker's preferences in the Dynamic SITCOM approach. At the same time, the models achieve stable results, as evidenced by the low variability of mean values and low standard deviation.

Future research directions could focus on considering more characteristic values for optimization. In addition, compromise solutions should be considered for characteristic objects with similar criterion values. It is also necessary to consider the applicability of the Dynamic SITCOM approach to other multi-criteria problems, such as selecting suppliers or creating a stable recommendation system.

***Abstract*—The rapid growth of the Internet of Things has significant security implications. In the current IoT security landscape, many institutions and entities are defining security requirements, but no industry-wide standard has been agreed upon. There are solutions in the present state-of-the-art that fulfill a subset of secure IoT device requirements, but none adheres to all of them. However, the existing technologies introduced by those solutions could be combined to create a design framework which provides security baseline features to support requirements of a secure IoT device. In this paper, a configurable and comprehensive hardware-software security framework is proposed, that, when applied in the process of designing System on Chip for IoT, will ensure its cybersecurity by providing security core baseline features. The proposed sollution is CPU-agnostic, in the sense that no assumptions are made about the CPU's support for privilege levels, memory protection schemes, or any security mechanisms.**

I. Introduction

IoT devices are becoming an increasingly important aspect of our lives and can be sensed everywhere around us.

Due to the inherent characteristics of IoT devices, data is continuously transmitted, processed, and stored in the cloud. Studies have indicated that many IoT devices that have been compromised lack adequate security measures. IoT security is not just device security, as all elements need to be considered, including the device, cloud, mobile application, network interfaces, software, use of encryption, use of authentication, and physical security. Recent research directions in IoT focus on addressing these challenges and improving the performance and security of IoT systems [1].

Much research focuses on software, network, and cloud security; however, hardware security in these devices has been overlooked. Although software-based solutions are less expensive to implement and update, they have their limitations and are also more vulnerable to attacks. Hardware-based solutions may be more expensive and time-consuming to implement, but integrating hardware security can significantly strengthen the system's defenses against attackers and in the long run, this type of solution is better positioned to protect sensitive communications and personal data from exposure.

Many renowned institutions have already come forward with their security guidelines for developers, distributors, and users. Among the first was the National Institute of Standards and Technology (NIST), that in [2] has defined an Internet of Things (IoT) device cybersecurity capability core baseline, which is a set of device capabilities generally needed to support common cybersecurity controls that protect an organization's devices as well as device data, systems, and ecosystems. This core baseline provides organizations a starting point to use in identifying the device cybersecurity capabilities for new IoT devices they will manufacture, integrate, or acquire.

In [3] the authors provide an overview of security guidelines for IoT proposed by various organizations and evaluate some of the existing technologies applied to ensure IoT security against these guidelines. In the paper, recommendations proposed by selected government organizations, international associations, and advisory groups are gathered and compiled into a set of the most common and important considerations, divided into eight categories. Then the authors chose a number of representative examples from IoT security technologies and evaluated them against these criteria. Conclusions captured in that paper show that there is no exhaustive and CPU-agnostic solution. While none of the examined solutions fulfill all recommendations on their own, the existing technologies introduced by those solutions could be combined to create a design framework that satisfies all the requirements of a secure IoT device.

In this paper the concept of an IoTrust framework has been proposed. This hardware-software solution, when applied in the process of designing System on Chip (SoC) for IoT, will ensure its cybersecurity by providing security core baseline features. The proposed framework architecture assumes the combination of the mechanisms from the area of Hardware Root of Trust (HWRoT), Trusted Execution Environment (TEE), and Trusted Computing in order to ultimately create a configurable and comprehensive solution ensuring the security of IoT nodes.

This work was funded by The Polish National Centre for Research and Development under project No. CYBERSECIDENT/456446/III/NCBR/2020.

II. State of the Art

The security of IoT devices is an area of active research due to unsatisfactory levels of safety and the immense range of applications. The constrained resource nature of many IoT devices increases the challenge of an all-in-one solution. That is why there are many solutions that solve pinpointed areas of the SoC, but the security of the entire device is still a novel topic which has yet to have an industry-wide accepted solution.

A. Key enabling technologies

Security architectures defined for traditional embedded systems are also currently used in IoT devices, solving some security issues. However, further improvements to these architectures are necessary to address new varieties of device vulnerabilities in the IoT ecosystem. Trustworthy computing is a major challenge in the field of cybersecurity.

1) Trusted Execution Environments: Solution which provides a secure environment for applications to run, regardless of the security in the rest of the system. TEEs are complex systems that consist of both hardware and software components and offer an enhanced execution environment [4]. TEE is a tamper-resistant computing environment running a separation kernel that guarantees the authenticity of program code, integrity of crucial system assets (processor registers, secured memory), and confidentiality of code and data stored in persistent memory [4]. Additionally, a TEE is useful in providing authentication and identification of the system. To the outside world, TEE is a module that guarantees isolation between secure and non-secure environments for both code and data.

2) Hardware Root of Trust: A key technical challenge for TEEs is ensuring trust, meaning that the system behaves as expected by the user. To address this challenge, there has been significant support for the use of hardware-based root-of-trust (HRoT) implementations to establish trust in secure computing. Hardware RoTs are preferred over software RoTs due to their immutability, smaller attack surfaces, and more reliable behavior. They can provide a higher degree of assurance that they can be relied upon to perform their trusted functions [5].

3) Physically Unclonable Functions: A Physically Unclonable Function (PUF) is a physical random function that typically displays a unique challenge-response behavior for each of its instances. The response to a given challenge is randomly generated based on the intrinsic physical properties of the hardware in which it is embedded. Recently, PUFs have been proposed as key components in cryptographic mechanisms and security architectures [6]. They can be used for device identification and authentication, binding software to hardware in a platform, securely storing cryptographic secrets and designing secure protocols.

B. Existing solutions

Trusted computing solutions for IoT devices are essential for ensuring the security and integrity of IoT systems. To address this challenge, a number of solutions have been proposed. Some of them are already mature and currently in use for IoT devices, and some are emerging concepts that might bring new quality to the topic.

The evaluation of representative IoT security technologies against criteria presented in [3] shows that while there are solutions with the potential to meet all these recommendations, no solution currently addresses all requirements in an out-of-the-box capacity. This leaves room for further research in this field.

Here, we briefly describe a few example solutions.

1) ARM TrustZone: A security extension provided by ARM for both application processors (Cortex-A family) and microcontrollers (Cortex-M family) [7]. It is based on a TEE concept. TrustZone divides the system into secure and non-secure environments by providing two virtual processors with hardware-based access control. Memory isolation and a special processor mode dedicated to monitoring (the secure monitor) ensure complete separation of the two execution environments in hardware.

TrustZone offers a comprehensive security solution, but it requires a good understanding of the framework, creative implementation, and support from external IPs. It is important to note that TrustZone is designed for ARM infrastructure and relies on additional hardware such as CryptoCell and applications to do so. TrustZone alone is not an off-the-shelf, ready-to-use solution.

2) Intel SGX: A set of CPU instructions that enable the creation of isolated software containers called enclaves [8]. These enclaves provide a secure environment for a program's code, data, and stack through hardware-based access policy control and memory encryption. This isolation protects the program from other processes, even those with higher privilege levels. From a hardware perspective, Intel SGX isolates Processor Reserved Memory (PRM) and protects it against all memory accesses from outside an enclave. This includes access attempts by the kernel, hypervisor, system management mode, and DMA accesses requested by peripherals.

3) Keystone: An open-source framework designed for creating TEE environments based on an unmodified RISC-V architecture [9]. It uses RISC-V Physical Memory Protection (PMP) and the programmable machine mode (M-Mode) to implement a memory protection scheme. The Trusted Security Monitor (SM) is proposed at the M-Mode level and is responsible for managing secure hardware handling and context switching between enclaves. The SM should be executed entirely from on-chip memory and satisfies typical TEE requirements such as memory isolation and code/configuration attestation. Keystone does not provide direct resource management; this responsibility falls on the secure enclave application developer. Also, several platform requirements are listed by the authors, including support for a trusted boot process, an unique authentication key dedicated to this process, and a hardware source of randomness. Keystone can be a good starting point for securing an IoT device, but it is not sufficient on its own.

4) OpenTitan: An open-source Hardware Root of Trust implementation endorsed by leading non-profit, academic, and commercial organizations [10]. As an open-source project, its sources are available online for inspection by the broader community, which should improve its security. While OpenTitan's core is still under development, and several features are missing from its early-stage top-l el, its creators' intentions are well-documented. In its complete form, OpenTitan should be a robust solution for securing various systems as a HWRoT module that supports secure boot procedures and implements miscellaneous cryptographic primitives.

5) CURE: A security architecture providing Trusted Execution Environments with different types of enclaves: subspace enclaves provide vertical isolation at all execution privilege levels, user-space enclaves provide isolated execution to unprivileged applications, and self-contained enclaves allow isolated execution environments that span multiple privilege levels. CURE's protection mechanisms are based on new hardware security primitives on the system bus, the shared cache, and the CPU. It also enables the exclusive assignment of system resources, such as peripherals, CPU cores, or cache resources, to a single enclave [11]. The authors assume the CPU supports privilege levels to separate user space from the more privileged kernel space through virtual address spaces using a MMU. Moreover, it is assumed that the system performs a secure boot on reset, with the first bootloader stored in CPU Ready-Only Memory (ROM) and verifying the firmware through a chain of trust.

III. Concept of the IoTrust framework

In this work, we present a security framework called IoTrust that addresses security issues in a customizable way. The solutions presented are CPU-agnostic, meaning no assumptions are made about the CPU's support for privilege levels, memory protection schemes, or any security mechanisms.

A. Threat model

The presented framework focuses on securing code integrity, control flow integrity, and confidentiality and integrity of secrets of an application running on an IoT device installed in the field. The secrets to be protected include encryption keys, certificates, and hashes, as well as the application's sensitive data. The IoTrust architecture's trusted computing base consists of the system's on-chip hardware components as well as a dedicated hypervisor software component. While the source of data in on-chip memory is assumed to be correct, the framework does not trust off-chip memory, the operating system, the applications, or the physical protection provided by the device manufacturer. Side-channel attacks, cloud security, and network security are beyond the scope of this work. Potential attacks include cold boot attacks, physical code injection, and compromising the hypervisor.

B. IoTrust architecture

Fig. 1 shows the architecture of a sample SoC system for an IoT device based on a standard CPU, system bus fabric, typical off-chip memory blocks and input/output devices with additional specialized components of the IoTrust framework.

The IoTrust framework is intended to be a configurable SoC framework for IoT devices that leverages TEE environment concepts. A set of developed IP Cores is proposed, which enable the implementation of a HWRoT, proxy modules that filter interfaces that are connected to off-chip components, a secure DMA that encrypts based on per-enclave cryptographic keys and, a CPU agnostic module that allows compartmentalization of software execution space. The proposed solution can be adapted for IoT implementations using both FPGA (Field Programmable Gate Array) and ASIC (Application Specific Integrated Circuit) technologies.

The software part of the framework consists of the **Security Manager Software** (SM-SW). It is responsible for managing enclaves and their lifecycle while acting as a hypervisor. It allocates processor time to enclaves and queues enclaves that are waiting for CPU execution time. Using emulated software interrupts, enclaves are provided with a secure way to interact with the rest of the system through the SM-SW API and data exchange between enclaves is enabled. The SM-SW module also includes interrupt handling of interrupts generated by the Security Manager Hardware (SM-HW) module during active enclave switching. This procedure ensures a safe and secure switch between a potentially untrusted enclave and the hypervisor code, which has full access to all system components. For this implementation, the **enclave context** is defined as the extension of the processor's context (the state of the CPU registers used by the executed program) by adding the state of API registers included in the SM-HW.

Furthermore, the SM-SW ensures proper configuration of the hardware modules of the framework at the boot time. Before starting enclaves, it writes definitions of the privileges enforced by the hardware, such as the interrupt filtering or virtual address spaces, to SM-HW registers.

To guarantee a safe enclave switching procedure and successful preemption even if the CPU runs malicious code, SM-SW programs a **handshake sequence** based on handler execution and a watchdog timeout.

The software part includes libraries that provide trusted Application Programming Interfaces (APIs), enabling the implementation of typical cybersecurity mechanisms and modules that implement functionalities outlined in the aforementioned core baseline requirements. The solution can provide a comprehensive, configurable software/hardware framework for building a trusted TEE runtime environment together with hardware specific to IoT security solutions.

The hardware part of the IoTrust framework consists of the following main parameterizable modules that are added at the SoC level.

The **Security Manager Hardware** together with the Security Manager Software enables the implementation of Trusted Computing concepts by creating enclaves where code is executed and ensuring their physical isolation (each enclave has access to dedicated hardware resources), which, with the proper use of the HWRoT module, allows for the implementation of a state-of-the-art TEE environment. It manages transactions between CPU and system bus. Additionally, in-

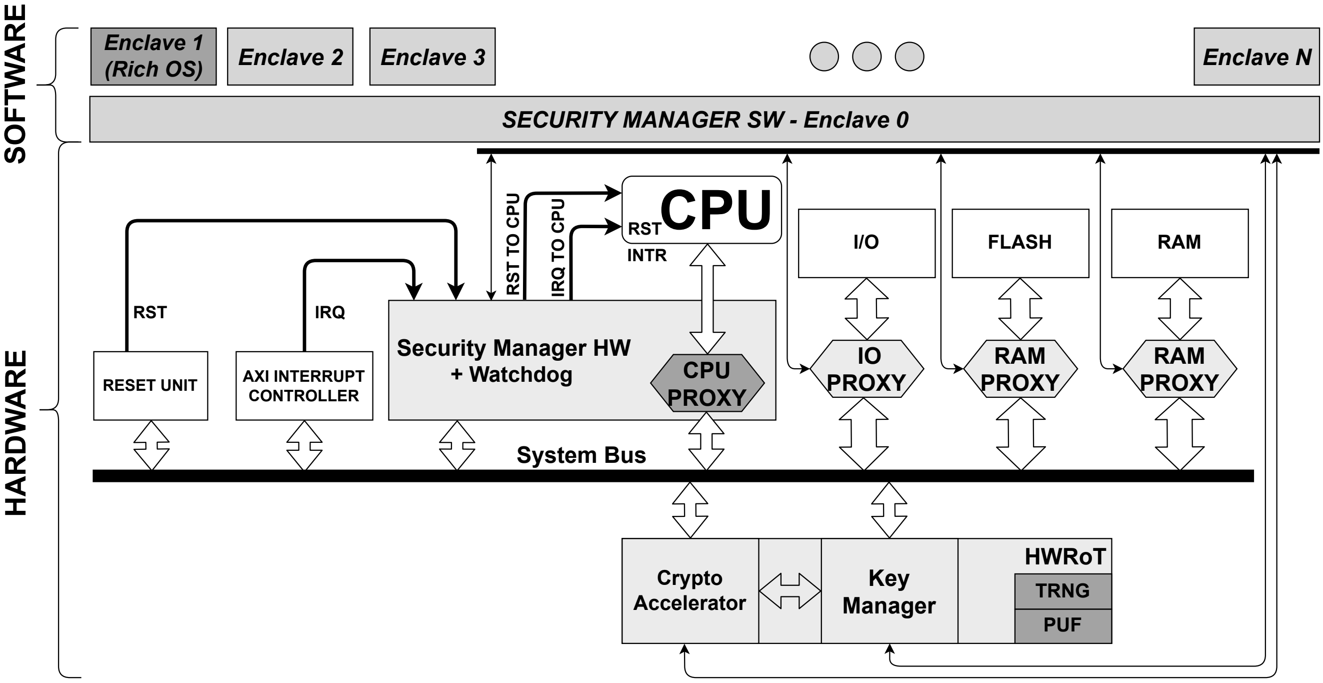

Fig. 1. Block level diagram of an example SoC integrating with the IoTrust framework

formation about the currently active enclave is passed to other IoTrust framework blocks to ensure synchronized isolation of processes from system devices and enable memory access (encryption/decryption) associated with the keys tied with the currently running enclave. Configuration changes and access violations are reported using a cybersecurity event logging module and the created logs are sealed to ensure their confidentiality and integrity when read by an authorized entity.

The **Hardware Root of Trust** (HWRoT) acts as an anchor of trust in the system and provides secure hardware implementations of necessary cryptographic algorithms. This component consists of hardware modules that provide security functions necessary to ensure trust within a platform (such as confidentiality, integrity, verification, authorization, secure storage, and updating). Its essential traits are immutability and predictability - it always behaves in the same way under known conditions. A hardware implementation enables meeting these conditions. HWRoT is treated as an inherently trusted element of the system. Thanks to the security services it offers, it can verify the correctness of subsequently launched software modules during the runtime of a Rich OS or other kernels. In this way, trust can be propagated within the platform and, the so-called Chain of Trust is formed, with HWRoT as the first element and the operating system or application running in it as the last. The secure system startup process including the creation of the Chain of Trust is called secure boot.

The **RAM Proxy** handles accesses to an external RAM with data protection. The task of the RAM Proxy module is to secure and manage accesses to external RAM. It is an essential component that mediates between the SM-HW and the memory controller during data exchange. Additionally, it works closely with the HWRoT module for data encryption and decryption.

IV. Implementation

The IoTrust framework's components have been developed using Verilog HDL and C/assembler. An example SoC based on the Xilinx Microblaze soft CPU and Vivado system platform has been designed as a proof of concept.

A Trusted Execution Environment of the IoTrust framework is a secure and isolated execution area within a computing unit that provides the authenticity of executed code, integrity of resources (such as CPU registers, memory, or input/output devices), and confidentiality of code, data, and states of non-volatile memory. In the IoTrust framework a TEE is implemented using the concept of enclaves.

An **enclave** is defined as a secure runtime environment managed by the Security Manager software and hardware, along with its metadata (a set of hardware access permissions, checksums, and digital signatures for the code) and an isolated address space where verified application instances are launched. Each enclave running on the processor operates in a separate virtual address space. Access to peripherals is limited by the Security Manager Hardware and is configurable per enclave.

A. IoTrust Hardware

1) Security Manager Hardware: The Security Manager Hardware module (Fig. 2) is directly connected to the CPU and is responsible for implementing Trusted Computing features. It is composed of:

- Enclave switch control – a module that monitors the CPU instruction bus to detect the sequence of instructions indicating enclave switch. The sequence can be programmed in the register file. The CPU Proxy is instructed to change the enclave context when the sequence is detected.
- CPU Proxy – a module responsible for hardware translation of transaction addresses from the virtual space seen by a given enclave to the physical space of the system bus. Transactions that violate access rights are rejected, and security breach logging processes are started. The module labels each AXI transaction with the number of the currently active enclave using AXI USER signals. This information is used by other IoTrust framework blocks to ensure isolation of enclaves from each other and enable memory access by encryption/decryption of its content using the keys tied with the currently running enclave.
- Interrupt Proxy – system interrupts are intercepted and subsequently forwarded to the computing unit only if they are authorized to be handled by the currently executing enclave. The Current Enclave register and the Watchdog interrupt mechanisms enable run-time security control of the system and detect anomalies. If the designated enclave fails to handle a specific interrupt within the appropriate time, the Watchdog module signals a system malfunction due to an error or a cyber attack. The event is then reported in a sealed log, and the system is reset.

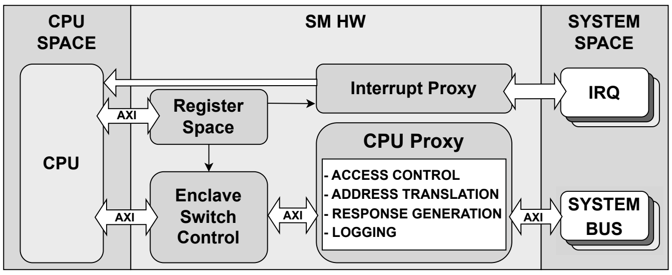

Fig. 2. Block level diagram of the SM HW module

2) Hardware Root of Trust: The Hardware Root of Trust of the IoTrust platform (Fig. 3) consists of three main components. The first one is a read-only memory for the first bootloader, which performs the initial system initialization and does the initial configuration of the HWRoT blocks during the secure boot procedure. The next component is the crypto accelerator block, which implements necessary cryptographic primitives (including lightweight algorithms suitable for hardware resource-constrained devices) and includes a DMA unit for efficient data operations. This module assists in the encryption of RAM for individual enclaves. The last component is the **secret top** block, which manages cryptographic keys and other secrets (such as physical and logical device identifiers, owner identity). It also generates secure cryptographic random sequences (to generate cryptographic keys within the HWRoT itself) and includes a Physical Unclonable Function block, which provides a unique fingerprint for each device.

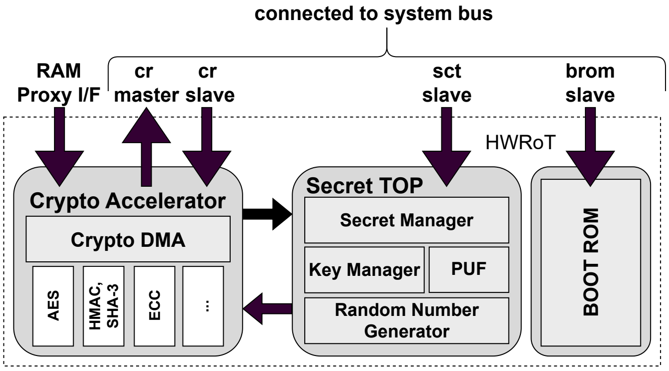

Fig. 3. Block level diagram of the HWRoT module

3) RAM Proxy: RAM Proxy is a component which connects system and the RAM. It intercepts memory accesses and is responsible for data protection. At first, appropriate data block is read from the memory and passed to HWRoT with enclave identifier (for cryptographic key selection) to be decrypted. If the requested operation is read, the decrypted data block is transmitted on the system bus. In the case of write operation, the corresponding data fragment is replaced, and the data block is then re-encrypted in HWRoT, and passed to the memory controller. Module has cache buffer that stores recently read memory blocks and increases the system's efficiency, because it allows to reduce the number of interactions with off-chip memory and the HWRoT.

4) IO Proxy: Allows hardware-based control of interface access in the SoC. For example, a local JTAG debug interface, Bluetooth, or Ethernet. It can filter transactions to and from peripherals. It contains a register that must be accessed by the SM-SW before usage due to hardware access restrictions when the peripheral is not enabled.

B. *IoTrust Software*

The SM-SW is functionally split into several modules. The Enclave Manager contains the main loop and is responsible for enclaves' management. Memory manager allocates/deallocates memory regions (*memory slices*) and is responsible for their safe clearing. It translates between virtual space and physical system bus addresses (Fig. 4). The hypervisor implements dedicated mechanisms for scheduling, safe switching of the enclaves, and data exchange between enclaves.

V. Synthesis results

Synthesis and implementation were performed using Vivado tools version 2022. The results presented are for the Trenz evaluation board TE0712 [12] equipped with a Xilinx Artix-7 XC7A200T FPGA. Table I presents the resource utilization of the entire system by assessing the number of LUTs, Slice, DSPs and block RAMs.

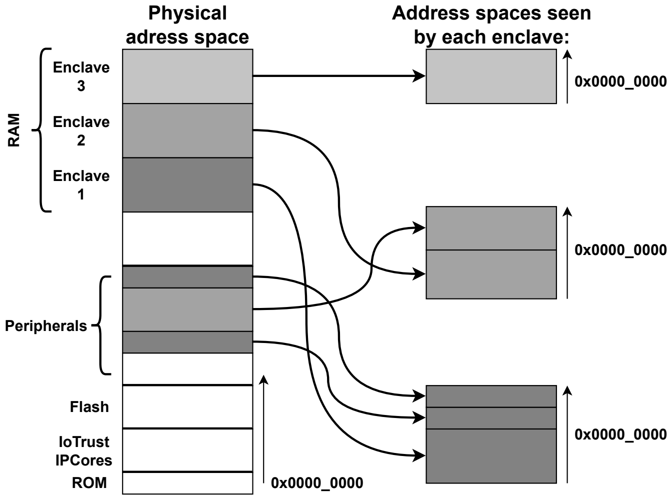

Fig. 4. Virtual address spaces of the enclaves are mapped onto the system's physical address space.

TABLE I
UTILIZATION RESULTS

	Used	**Available**	**Util [%]**
Slice LUT	59719	133800	44.63
LUT as Logic	58105	134600	43.19
LUT as Memory	2064	46200	4.47
Slice Registers	31023	269200	11.52
Slice	18363	33650	54.57
Block RAM	41	365	11.23
DSPs	4	740	0.54

The article presents the Proof of Concept of the IoTrust framework. For this reason, the target solution may be optimized for utilization, power consumption, or frequency. The results presented do not include the HWRoT module. Considering the number of logic cells used, the solution can be classified as a lightweight solution.

The power estimation analysis indicates, that the whole SoC consumes about $1.5\ W$ of power. Since the DDR memory controler consumes about $1\ W$ of power, the rest of the system components use $0.5\ W$ of power.

VI. CONCLUSIONS

The IoT ecosystem presents new security challenges beyond traditional data security. There is a need for IoT security guidelines, and many organizations worldwide have proposed recommendations to help ensure secure IoT infrastructure. While device designers and vendors have their own proprietary solutions that address some issues, they fall short in others. Evaluation of representative examples of IoT security technologies shows that while there are solutions with the potential to meet all recommendations, none currently do so in an out-of-the-box capacity.

In this paper, we proposed the concept of the hardware-software security framework that, when applied in the process of designing System on Chip for IoT device, will ensure its cybersecurity by providing security core baseline features. The proposed IoTrust framework consists of custom hardware IP Cores designed in Verilog HDL as well as C/assembler software procedures that can be included in SoC design, enabling the combination of the mechanisms from the area of Hardware Root of Trust, Trusted Execution Environment and Trusted Computing. This ultimately creates a configurable and comprehensive solution ensuring the security of IoT nodes.

The solution discussed does not make any assumptions about the CPU's support for privilege levels, memory protection schemes, or security mechanisms and is therefore CPU-agnostic.

A proof-of-concept implementation has been demonstrated where the IoTrust framework has been applied to SoC based on MicroBlaze soft-processor. As the prototype platform the Trenz evaluation board TE0712 equipped with a Xilinx Artix-7 XC7A200T FPGA has been used. Example execution scenarios have been included, that demonstrate basic functionalities of proposed solution.

***Abstract*—The Gower similarity coefficient is a popular measure for comparing objects with possibly mixed-type attributes and missing values. One of its characteristics is that it calculates the coefficient value without considering attributes with missing values. In this article, we explore the properties of the coefficient in detail, including the consequences of omitting attributes with missing values. We also introduce strict lower and upper bounds on the actual similarity value on an attribute and strict lower and upper bounds on the actual value of the Gower similarity coefficient, derive a number of their properties and propose a new coefficient as a solution to the identified problem with the Gower similarity coefficient.**

***Index Terms*—Gower similarity coefficient, mixed-type attributes, quantitative attributes, qualitative attributes, dichotomous attributes, missing values.**

Introduction

THE Gower similarity coefficient [4] is a popular measure for comparing objects with possibly mixed-type attributes (quantitative, qualitative and/or dichotomous) and missing values. One of its characteristics is that it calculates the coefficient value without considering attributes with missing values. The approach is easy and intuitive and finds many applications (see, e.g. [1], [2], [3], [5], [6], [8]). It is also considered as an easily extensible template of calculating (dis)similarities of objects with mixed-type attributes [2], [5], [7]. However, as we show in the article, Gower similarity coefficient has some deficiencies. In particular, we show that in the case of objects with missing values, the coefficient may take a similarity value impossible to obtain with any replacement of missing values with values from the domains of attributes.

Our main contribution in the article includes:

- Introduction of strict lower and upper bounds on the actual similarity value on an attribute and strict lower and upper bounds on the actual value of the Gower similarity coefficient, which are obtainable after replacing missing values with respective attribute domain values.
- Showing that in the case of a pair of objects one of which has missing value for at least one quantitative attribute, the Gower similarity coefficient may take an incorrect value, which will be less than the lower bound on the actual value of the Gower similarity coefficient.
- Derivation of a number of properties of similarity value of objects on the attribute, the Gower similarity coefficient and the introduced bounds.
- Proposing new similarity coefficient G' as a correction of the Gower similarity coefficient, which eliminates the problem found for quantitative attributes with missing values.

The layout of the article is as follows: First, we recall the definitions of attribute value similarities, their weights and the Gower similarity coefficient, as well as introduce additional basic notions that are used throughout the article. Then, we show example objects for which the Gower similarity coefficient takes an incorrect value, caused by the occurrence of a missing value of a quantitative attribute for one of them. We also illustrate the consequences of the occurrence of missing values for qualitative and dichotomous attributes. Next, we introduce strict lower and upper bounds on the actual similarity value on an attribute and on the actual value of the Gower similarity coefficient, as well as derive a number of their properties. In addition, the coefficient G', being the modification of the Gower similarity coefficient, is proposed, which, unlike the original Gower similarity coefficient, always returns similarity values that do not exceed the presented lower and upper bounds.

Basic notions related to Gower Similarity Coefficient

Gower proposed a measure of objects' similarity, which can be applied in the case of qualitative attributes, quantitative attributes, dichotomous attributes or their mixtures [4]. In the measure, only the attributes for which it is possible to determine their similarity are taken into account; the other are ignored. In particular, if for a pair of objects, an attribute value for at least one of these objects is missing, then the two objects are treated as not comparable on this attribute and the Gower similarity coefficient is calculated without taking this attribute into account.

In the remainder of the article, we assume that objects are characterized by n, where $n \geq 1$, attributes whose domains contain at least two different values. The missing value will be denoted by *. The value of attribute i of object u will be denoted by u_i.

The function $w_i(.,.)$ is used to indicate whether two objects are comparable on attribute i or not. Let u and v are objects under consideration. If u and v are comparable on attribute i, then $w_i(u,v) = 1$; otherwise $w_i(u,v) = 0$. We already mentioned that two objects u and v are incomparable on attribute i if the value of at least one of the objects is missing and so, $w_i(u,v) = 0$. However, in the case of a dichotomous attribute (indicating whether or not a feature is present), the objects may also be incomparable, even if their values are known (this happens when two objects do not have the feature represented by the dichotomous attribute).

The Gower similarity coefficient [4] for objects u and v is denoted by $G(u,v)$ and is defined as follows:

$$G(u,\, v) = \frac{\sum_{i=1}^{n} w_i(u,v) \times s_i(u,v)}{\sum_{i=1}^{n} w_i(u,v)},$$

where $s_i(u,v)$ is a coefficient determining similarity of two objects on attribute i, $i = 1..n$, taking values from the interval $[0,1] \cup \{undefined\}$. It is assumed that whenever $w_i(u,v) = 0$, then $w_i(u,v) \times s_i(u,v) = 0$. Thus, the Gower similarity coefficient is the average similarity of two objects on the attributes on which they are comparable.

In the case when the values of attribute i are not missing for both objects u and v, then $w_i(u,v)$ and coefficient $s_i(u,v)$ are determined as follows:

- If attribute i is qualitative:
  - $w_i(u,v) = 1$,
  - $s_i(u,v) = \begin{cases} 1, \text{if } u_i = v_i \\ 0, \text{if } u_i \neq v_i \end{cases}$;
- If attribute i is quantitative:
  - $w_i(u,v) = 1$,
  - $s_i(u,v) = 1 - \frac{|u_i - v_i|}{range_i}$;

  where $range_i = max_i - min_i$, where max_i is the maximal value of attribute i, while min_i is the minimal value of attribute i.
- If attribute i is dichotomous:
  - $w_i(u,v) = \begin{cases} 1, \text{ if } (u_i = +) \text{ and } (v_i = +) \\ 1, \text{ if } (u_i = +) \text{ and } (v_i = -) \\ 1, \text{ if } (u_i = -) \text{ and } (v_i = +) \\ 0, \text{ if } (u_i = -) \text{ and } (v_i = -) \end{cases}$,
  - $s_i(u,v) = \begin{cases} 1, \text{ if } (u_i = +) \text{ and } (v_i = +) \\ 0, \text{ if } (u_i = +) \text{ and } (v_i = -) \\ 0, \text{ if } (u_i = -) \text{ and } (v_i = +) \\ 0, \text{ if } (u_i = -) \text{ and } (v_i = -) \end{cases}$.

In the case when the value of attribute i is missing for at least one of the objects u or v, then $w_i(u,v)$ and the coefficient $s_i(u,v)$ is determined for any type of attribute i in the same way as follows:

- $w_i(u,v) = 0$,
- $s_i(u,v) = undefined$.

Now, we are ready to formally define *comparable* and *incomparable objects on an attribute*. *Objects u and v* are defined as *incomparable on attribute i* if:

- either the value of attribute i is missing for at least one the two objects
- or attribute i is dichotomous and the values of both objects are equal to $-$.

Otherwise, *objects u and v* are *comparable on attribute i.*

Property 1.

a) Objects u and v are incomparable on attribute i iff $w_i(u,v) = 0$.

b) Objects u and v are comparable on attribute i iff $w_i(u,v) = 1$.

c) If objects u and v are incomparable on attribute i, then $w_i(u,v) \times s_i(u,v) = 0$.

d) If objects u and v are comparable on attribute i, then $w_i(u,v) \times s_i(u,v) = s_i(u,v)$.

e) $s_i(u,v) = s_i(v,u)$ and $w_i(u,v) = w_i(v,u)$.

In the remainder of the article, we will use the following notation:

- *CMP_ATT*(u,v) denotes the set of attributes on which u and v are comparable; that is, *CMP_ATT*(u,v) = {attribute i| $w_i(u,v) = 1$}.
- *INCMP_ATT*(u,v) denotes the set of attributes on which u and v are not comparable; that is, *INCMP_ATT*(u,v) = {attribute i| $w_i(u,v) = 0$}.
- *INCMP*_ATT*(u,v) denotes the set of attributes on which either u or v or both have missing values.
- $INCMP^d\_ATT(u,v)$ denotes the set of dichotomous attributes on which both u and v have value $-$.

Property 2.

a) $G(u,v) = \frac{\sum_{i \in CMP\_ATT(u,v)} s_i(u,v)}{|CMP\_ATT(u,v)|}$.

b) $|CMP\_ATT(u,v)| + |INCMP\_ATT(u,v)| = n$.

c) $INCMP{*}\_ATT(u,v) \cap INCMP^d\_ATT(u,v) = \emptyset$.

d) $INCMP\_ATT(u,v) = INCMP{*}\_ATT(u,v) \cup INCMP^d\_ATT(u,v)$.

e) $|CMP\_ATT(u,v)| + |INCMP{*}\_ATT(u,v)| \leq n$.

Objects u and v are defined as *comparable* if they are comparable on at least one attribute; that is, if $\sum_{i=1}^{n} w_i(u,v) > 0$ (or equivalently, if $|CMP\_ATT(u,v)| > 0$).

Otherwise, *objects u and v are* defined as *incomparable*; that is, when $\sum_{i=1}^{n} w_i(u,v) = 0$ (or equivalently, if $|CMP\_ATT(u,v)| = 0$). Please note that the value of $G(u,v)$ is not defined for incomparable objects. Otherwise, if u and v are comparable, then $G(u,v) \in [0, 1]$.

NEW RESULTS

A. What's Wrong with Gower Similarity Coefficient?

Though Gower similarity coefficient is appreciated by the ease and intuitiveness of dealing with attributes on which objects are incomparable, we will show that it may take an unacceptable value if the values of attributes are missing (see Example 1).

Example 1. Table I presents Set 1 of example objects characterized by qualitative attribute 1 (*colour of hair*) and quantitative attribute 2 (*age*). Let $max_2 = 100$, $min_2 = 0$, so $range_2 = 100$.

Objects u and v are comparable and different on attribute 1 (so, $w_1(u,v) = 1$ and $s_1(u,v) = 0$) and are not comparable on attribute 2 (so, $w_2(u,v) = 0$, $s_2(u,v) =$ *undefined*). Hence, $G(u,v) = (1 \times 0 + 0 \times$ *undefined*$) / (1 + 0) = 0 / 1 = 0$.

TABLE I.
SET 1 OF EXAMPLE OBJECTS

object o	1 (*colour of hair*)	2 (*age*)	$w_2(u,o)$	$s_2(u,o)$	$G(u,o)$
u	brown	**40**	1	1–|50–50|/100=1	2/2=1
v	blond	*	**0**	***undefined***	**0/1=0**
v_1	blond	0	1	1–|40–0|/100=0.6	0.6/2=0.3
v_2	blond	10	1	1–|40–10|/100=0.7	0.7/2=0.35
v_3	blond	20	1	1–|40–20|/100=0.8	0.8/2=0.4
v_4	blond	30	1	1–|40–30|/100=0.9	0.9/2=0.45
v_5	blond	**40**	**1**	**1–|40–40|/100=1**	**1/2=0.5**
v_6	blond	50	1	1–|40–50|/100=0.9	0.9/2=0.45
v_7	blond	60	1	1–|40–60|/100=0.8	0.8/2=0.4
v_8	blond	70	1	1–|40–70|/100=0.7	0.7/2=0.35
v_9	blond	80	1	1–|40–80|/100=0.6	0.6/2=0.3
v_{10}	blond	90	1	1–|40–90|/100=0.5	0.5/2=0.25
v_{11}	blond	**100**	**1**	**1–|40–100|/100=0.4**	**0.4/2=0.2**

Now we will consider what would be the Gower similarity coefficient of objects u and v_i, where v_i represents v after replacing its missing value of attribute 2 with some value from the domain range [0, 100]. Objects $v_1, \ldots, v_{11}$ in Table I represent object v under assumption that its actual value of attribute 2 is 0, 10, …, 100, respectively. Clearly, each instance v_i of object v is comparable with u on both attributes and is different from u on attribute 1, which is qualitative (so similarity of v_i to u on attribute 1 equals 0). Hence, $G(u,v_i) = (1 \times 0 + 1 \times s_2(u, v_i)) / (1 + 1) = s_2(u,v_i) / 2$.

Clearly, $G(u,v_i)$ reaches maximum for the greatest value of $s_2(u,v_i)$. This happens for object v_5, for which $s_2(u,v_5) = 1$ and, in consequence, $G(u,v_5) = 0.5$.

$G(u,v_i)$ reaches minimum for the least value of $s_2(u,v_i)$ (that is, for the largest absolute value of the difference between *age* of u and v_i). This happens for object v_{11}, for which $s_2(u,v_{11}) = 0.4$ and so, $G(u,v_{11}) = 0.2$. Please note that this least achievable value of 0.2 of $G(u,v_i)$ is greater than $G(u,v)$, which equals 0.

As shown in Example 1, $G(u,v)$ may take a value that is not obtainable for any actual completions of missing values of quantitative attributes of objects u and v.

In the further part of the article, we introduce strict lower and upper bounds on the actual similarity value of any objects u and v on an attribute from the set $INCMP^*\_ATT(u,v)$ and on the actual value of the Gower similarity coefficient for these objects. The bounds will make it possible to check when the Gower similarity coefficient takes values unattainable for any completions of missing values.

B. Lower and Upper Bounds on Actual Similarity Value on an Attribute

Let us recall that objects u and v are not comparable on attribute i either because at least one of the objects has missing value for this attribute (i.e. $i \in INCMP^*\_ATT(u,v)$) or the attribute is dichotomous and both objects have value – for it (i.e. $i \in INCMP^d\_ATT(u,v)$). If u and v are incomparable on attribute i, then $w_i(u,v) = 0$, and so attribute i does not contribute to the value of $G(u,v)$. Nevertheless, in the case of attribute $i \in INCMP^*\_ATT(u,v)$, u and v may become comparable on attribute i if the actual values of attribute i become known for both objects. Then, $w_i(u,v)$ can become equal to 1, and so, $s_i(u, v)$ can contribute to the value of $G(u,v)$. Example 1 illustrates how replacing missing value of quantitative attribute i affects the values of $w_i(u, v)$, $s_i(u, v)$ and $G(u,v)$. This influence is also illustrated for a qualitative attribute and a dichotomous attribute in Examples 2 and 3, respectively.

Example 2. Table II presents Set 2 of example objects characterized by qualitative attribute 1 (*colour of hair*) and quantitative attribute 2 (*age*). Let $max_2 = 100$, $min_2 = 0$, so $range_2 = 100$.

Objects u and v are not comparable on attribute 1 ($w_1(u,v) = 0$ and $s_1(u,v) =$ *undefined*) and are comparable on attribute 2 ($w_2(u,v) = 1$, $s_2(u,v) = 0.9$). Hence, $G(u,v) = (0 \times$ *undefined* $+ 1 \times 0.9) / (0 + 1) = 0.9 / 1 = 0.9$.

TABLE II.
SET 2 OF EXAMPLE OBJECTS

object o	1 (*colour of hair*)	2 (*age*)	$w_1(u,o)$	$s_1(u,o)$	$G(u,o)$
u	**brown**	40	1	1	2/2=1
v	*	30	**0**	***undefined***	**0.9/1=0.9**
v_1	**brown**	30	**1**	**1**	**1.9/2=0.95**
v_2	**blond**	30	**1**	**0**	**0.9/2=0.45**

Objects v_1 and v_2 in Table II present instances of object v after replacing its missing value of attribute 1 with some value from the domain of this attribute. Clearly, unlike v, v_1 and v_2 are comparable with u on attribute 1. Since, u and v_1 have identical value of attribute 1, their similarity on this attribute is the greatest possible; namely, $s_1(u,v_1) = 1$. Since,

u and v_2 differ on attribute 1, their similarity on this attribute is the least possible; namely, $s_1(u,v_2) = 0$. Please note that $G(u,v) \in [G(u,v_2), G(u,v_1)] = [0.45, 0.95]$.

Example 3. Table III presents Set 3 of example objects characterized by qualitative attribute 1 (*colour of hair*), quantitative attribute 2 (*age*) and dichotomous attribute 3 (*has a car*). Let $max_2 = 100$, $min_2 = 0$, so $range_2 = 100$.

Objects u and v are comparable on attributes 1 and 2 ($w_1(u,v) = w_2(u,v) = 1$, $s_1(u,v) = 0$, $s_2(u,v) = 0.9$) and are not comparable on attribute 3 ($w_3(u,v) = 0$, $s_3(u,v) = undefined$). Hence, $G(u,v) = (1 \times 0 + 1 \times 0.9 + 0 \times undefined) / (1 + 1 + 0) = 0.9 / 2 = 0.45$.

TABLE III.
SET 3 OF EXAMPLE OBJECTS

object o	1 (*colour of hair*)	2 (*age*)	3 (*has a car*)	$w_3(u,o)$	$s_3(u,o)$	$G(u,o)$
u	brown	40	–	0	0	2/2=1
v	blond	30	*	**0**	***undefined***	**0.9/2=0.45**
v_1	blond	30	–	**0**	**0**	**0.9/2=0.45**
v_2	blond	30	+	**1**	**0**	**0.9/3=0.3**

Objects v_1 and v_2 in Table III present instances of object v after replacing its missing value of attribute 3 with either – or +. Since, both u and v_1 have value – of attribute 3, they are not comparable on this attribute (so, $w_3(u,v_1) = 0$) and $s_3(u,v_1) = 0$. This means that attribute 3 does not contribute to the value of $G(u,v_1)$ even though its value is known both for u and v_1. Now, since, u and v_2 have values – and +, respectively, on attribute 3, they are comparable on attribute 3 (so, $w_3(u,v_1) = 1$) and their similarity on this attribute is the least possible; namely, $s_3(u,v_1) = 0$. Please note that $G(u,v) \in [G(u,v_2), G(u,v_1)] = [0.3, 0.45]$.

In Examples 1, 2 and 3, we considered instances of example object u, with known values for all attributes, and object v, with missing value only for one given attribute i. We considered all or some instances of object v in which missing value was replaced by possible actual values including those instances of object v whose similarity on attribute i was the least and greatest, respectively. Clearly, these least and greatest values are lower and upper bounds, respectively, on similarity values of objects u and v on the examined attributes.

Let $i \in INCMP^{*}\_ATT(u, v)$. *Lower bound on the actual similarity value of u and v on attribute i* will be denoted by $\underline{s}_i(u,v)$, while *upper bound on the actual similarity value of u and v on attribute i* will be denoted by $\overline{s}_i(u,v)$. The associated *weights for the bounds* will be denoted as $\underline{w}_i(u,v)$ and $\overline{w}_i(u,v)$, respectively.

In Table IV, we provide the values of the similarity bounds $\underline{s}_i(u,v)$ and $\overline{s}_i(u,v)$ and their weights, respectively, under assumption that the value of attribute i is missing for at least one object. In fact, $\underline{s}_i(u,v) = \underline{s}_i(v,u)$, $\underline{w}_i(u,v) = \underline{w}_i(v,u)$, $\overline{s}_i(u,v) = \overline{s}_i(v,u)$ and $\overline{w}_i(u,v) = \overline{w}_i(v,u)$, thus, without loss of generality, we assume that the value of attribute i is missing for object v. The results are provided for quantitative, qualitative and dichotomous attributes. We also indicate for which possible actual values of v and eventually u, $s_i(u,v) = \underline{s}_i(u,v)$ and $s_i(u,v) =\overline{s}_i(u,v)$, respectively. Thus, we show that $\underline{s}_i(u,v)$ and $\overline{s}_i(u,v)$ are strict lower and upper bounds on the actual similarity value of objects u and v on each attribute $i \in INCMP^{*}\_ATT(u, v)$.

Please note that $\underline{w}_i(u,v)$ equals 1 for each attribute $i \in INCMP^{*}\_ATT(u, v)$. On the other hand, the lower bound $\underline{s}_i(u,v) = 0$ in all cases considered in Table IV except for quantitative attribute i whose value is missing for only one of the two compared objects. In that exceptional case, $\underline{s}_i(u,v)$ depends on the known value of the other object and can be

TABLE IV.
STRICT SIMILARITY BOUNDS $\underline{s}_i(u,v)$, $\overline{s}_i(u,v)$ AND THEIR ASSOCIATED WEIGHTS $\underline{w}_i(u,v)$ AND $\overline{w}_i(u,v)$ FOR MISSING VALUE OF OBJECT v AND KNOWN OR MISSING VALUE OF OBJECT u.

Type of attribute *i*	**Value of attribute *i* for object *u***	$\underline{w}_i(u,v)$	$\underline{s}_i(u,v)$	**When $s_i(u,v) = \underline{s}_i(u,v)$?**	$\overline{w}_i(u,v)$	$\overline{s}_i(u,v)$	**When $s_i(u,v) = \overline{s}_i(u,v)$?**
qualitative	missing	1	0	when actual value of v is different from actual value of u	1	1	when actual value of v is equal to actual value of u
	x	1	0	when actual value of v is different from x	1	1	when actual value of v is equal to x
quantitative	missing	1	0	when actual value of v is minimal and actual value of u is maximal or vice versa	1	1	when actual value of v is equal to actual value of u
	x	1	$\min\{(x - min_i), (max_i - x)\} / range_i$	when the absolute value of the difference between x and actual value of v is the largest possible; that is, is equal to $max\{(x - min_i), (max_i - x)\}$.	1	1	when actual value of v is equal to x
dichotomous	missing	1	0	when actual value of v is different from actual value of v	1	1	when actual value of v and actual value of u are equal to +
	+	1	0	when actual value of v is equal to –	1	1	when actual value of v is equal to +
	–	1	0	when actual value of v is equal to +	0	0	when actual value of v is equal to –

greater than 0 (as shown in Table IV, in this case, $\underline{s}_i(u,v) = \min\{(x - min_i), (max_i - x)\} / range_{i.})$.

Property 3. Let i be a quantitative attribute. Let the value of attribute i be missing for object v and be equal to x for object u. Then:

a) $\underline{s}_i(u,v)$ reaches maximum, which is equal to 0.5, for $x = (min_i + min_i) / 2$.

b) $\underline{s}_i(u,v)$ reaches minimum, which is equal to 0, for $x = min_i$ or $x = max_i$.

Proof: Follows from $\underline{s}_i(u,v)$ for a quantitative attribute (see Table IV).

Note also that for each attribute $i \in INCMP*\_ATT(u, v)$, upper bound $\overline{s}_i(u,v) = 1$ and $\overline{w}_i(u,v) = 1$, unless attribute i is dichotomous and its value is equal to $-$ for one object, say u, and is missing for the other object, say, v. In that exceptional case, $\overline{w}_i(u,v) = 0$ and $\overline{s}_i(u,v) = 0$ (which corresponds to the situation when the actual value of v is also equal to $-$), while $\underline{w}_i(u,v) = 1$ and $\underline{s}_i(u,v) = 0$ (which corresponds to the situation when the actual value of v equals $+$). In the former case, attribute i does not contribute to the Gower similarity coefficient, while in the latter case, attribute i contributes to it with the least possible value of 0.

C. Lower and Upper Bounds on Actual Value of Gower Similarity Coefficient

We start with defining lower and upper bounds on the actual value of the Gower similarity coefficient, which are achievable after replacing all missing values in the compared objects with some values from the domains of corresponding attributes.

Lower bound on the actual value of $G(u,v)$ is denoted by $\underline{G}(u,v)$ and is defined as follows:

$$\underline{G}(u,v) = \frac{\sum_{i \in CMP\_ATT(u,v)} s_i(u,v) + \sum_{i \in INCMP*\_ATT(u,v)} \underline{w}_i(u,v) \times \underline{s}_i(u,v)}{|CMP\_ATT(u,v)| + \sum_{i \in INCMP*\_ATT(u,v)} \underline{w}_i(u,v)}.$$

Upper bound on the actual value of $G(u,v)$ is denoted by $\overline{G}(u,v)$ and is defined as follows:

$$\overline{G}(u,v) = \frac{\sum_{i \in CMP\_ATT(u,v)} s_i(u,v) + \sum_{i \in INCMP*\_ATT(u,v)} \overline{w}_i(u,v) \times \overline{s}_i(u,v)}{|CMP\_ATT(u,v)| + \sum_{i \in INCMP*\_ATT(u,v)} \overline{w}_i(u,v)}.$$

Clearly, if $|CMP\_ATT(u,v)| + \sum_{i \in INCMP*\_ATT(u,v)} \underline{w}_i(u,v) > 0$, then $\underline{G}(u,v)$ is the strict lower bound on the actual value of $G(u,v)$, which is obtainable for some completion of missing attribute values of objects u and v, while $\overline{G}(u,v)$ is the strict upper bound on the actual value of $G(u,v)$ provided $|CMP\_ATT(u,v)| + \sum_{i \in INCMP*\_ATT(u,v)} \overline{w}_i(u,v) > 0$.

As shown in Table IV, the weight $\underline{w}_i(u,v) = 1$ for each attribute $i \in INCMP*\_ATT(u,v)$. Hence, $\underline{G}(u,v)$ can be rewritten as presented in Property 4:

Property 4.

a) $$\underline{G}(u,v) = \frac{\sum_{i \in CMP\_ATT(u,v)} s_i(u,v) + \sum_{i \in INCMP*\_ATT(u,v)} \underline{s}_i(u,v)}{|CMP\_ATT(u,v)| + |INCMP*\_ATT(u,v)|}.$$

b) $$\underline{G}(u,v) \geq \frac{\sum_{i \in CMP\_ATT(u,v)} s_i(u,v) + \sum_{i \in INCMP*\_ATT(u,v)} \underline{s}_i(u,v)}{n}$$ if $|CMP\_ATT(u,v)| + |INCMP*\_ATT(u,v)| > 0$.

Proof: Ad a) By definition of $\underline{G}(u,v)$ and the fact that $\underline{w}_i(u,v) = 1$ for each attribute $i \in INCMP*\_ATT(u,v)$ (see Table IV).
Ad b) By Property 4a and Property 2e.

Property 5. If there are no quantitative attributes in $INCMP*\_ATT(u, v)$, then

a) $$\underline{G}(u,v) = \frac{\sum_{i \in CMP_{ATT(u,v)}} s_i(u,v)}{|CMP_{ATT(u,v)}| + |INCMP*\_ATT(u,v)|}.$$

b) $\underline{G}(u,v) \geq \frac{\sum_{i \in CMP\_ATT(u,v)} s_i(u,v)}{n}$ if $|CMP\_ATT(u,v)| > 0$.

c) $\underline{G}(u,v) \leq G(u,v)$ if $|CMP\_ATT(u,v)| > 0$.

Proof: Ad a) By Property 4a and the fact that $\underline{s}_i(u,v) = 0$ for each non-quantitative attribute i in $INCMP*\_ATT(u, v)$ (see Table IV).
Ad b) By Property 5a and Property 2e.
Ad c) By Property 5a and Property 2a.

Example 4. Let us consider again objects u and v from Example 1 (see also Table I), whose attribute 2 is quantitative. Then, $G(u,v) = 0$, $\underline{s}_2(u,v) = \min\{(40 - 0), (100 - 40)\} / 100 = 0.4$ (see Table IV), $\underline{G}(u,v) = (1 \times 0 + 1 \times 0.4) / (1 + 1) = 0.2$. Thus, $\underline{s}_2(u,v) > G(u,v)$ and $\underline{G}(u,v) > G(u,v)$.

Example 4 allows us to conclude what follows:

Property 6. Let u and v be comparable objects. Let i be a quantitative attribute with missing value for object u and known value for object v. Then:

a) It is probable that $\underline{s}_i(u,v) > G(u,v)$.

b) If $\underline{s}_i(u,v) > G(u,v)$, then it is probable that $\underline{G}(u,v) > G(u,v)$.

Corollary 1. It is probable that $\underline{G}(u,v) > G(u,v)$ when there is a missing value in u or v. If $\underline{G}(u,v) > G(u,v)$, then $G(u,v)$ takes an incorrect value, which cannot be obtained for any possible actual value of attribute i of object u.

To avoid the problem stated in Corollary 1, one may use, depending on an application, the lower bound $\underline{G}(u,v)$, the upper bound $\overline{G}(u,v)$ or an appropriately modified version of $G(u,v)$ instead of $G(u,v)$ itself. Below we introduce new $G'(u,v)$ similarity coefficient defined as follows:

$$G'(u,v) = \frac{\sum_{i \in CMP\_ATT(u,v)} s_i(u,v) + \sum_{\substack{i \in INCMP*\_ATT(u,v), \\ \underline{s}_i(u,v) > G(u,v)}} \underline{s}_i(u,v)}{|CMP\_ATT(u,v)| + |\{i \in INCMP*\_ATT(u,v) \mid \underline{s}_i(u,v) > G(u,v)|}.$$

In fact, $G'(u,v)$ can be regarded as an improved version of $G(u,v)$.

Let $INCMP*\_QNT\_ATT(u,v)$ be the set of the quantitative attributes in $INCMP*\_ATT(u,v)$. Now, we will express $G'(u,v)$ in terms of attributes in $CMP\_ATT(u,v) \cup INCMP*\_QNT\_ATT(u,v)$.

Property 7. Let |*CMP_ATT*(*u*,*v*)| > 0. Then:

$$G'(u,v) = \frac{\sum_{i\in CMP\_ATT(u,v)} s_i(u,v) + \sum_{\substack{i\in INCMP*\_QNT\_ATT(u,v,\\ \underline{s}_i(u,v)>G(u,v)}} \underline{s}_i(u,v)}{|CMP\_ATT(u,v)| + \ |\{i\in INCMP*\_QNT\_ATT(u,v)|\ \underline{s}_i(u,v)>G(u,v)|}.$$

Proof: By assumption, u and v are comparable, so $G(u,v) \geq 0$. If i is a qualitative or dichotomous attribute in *INCMP*_ATT*(*u*, *v*), then $\underline{s}_i(u,v) = 0$ (see Table IV), and so, $\underline{s}_i(u,v)$ is not greater than $G(u,v)$. So, $\underline{s}_i(u,v)$ can be greater than $G(u,v)$ only if i is a quantitative attribute in *INCMP*_ATT*(*u*, *v*); i.e., if $i \in$ *INCMP*_QNT_ATT*(*u*,*v*).

Please note that $G'(u,v)$ differs from $G(u,v)$ in that the value of $G'(u,v)$ is calculated not only on the attributes on which u and v are comparable (as in the case of $G(u,v)$), but also on those quantitative attributes i on which u and v are not comparable provided $\underline{s}_i(u,v) > G(u,v)$.

Property 8. Let u and v be comparable objects. Then:

a) $G'(u,v) \geq G(u,v)$.

b) $G'(u,v) \geq \underline{G}(u,v)$.

Proof: Ad a) By definition of $G'(u,v)$ and Property 2a.
Ad b) By definition of $G'(u,v)$ and Property 4a.

Example 5. In the case of objects u and v from Example 1 (see also Table I), $G'(u,v) = \underline{G}(u,v) = 0.2 > G(u,v) = 0$.

We will consider now the properties of the upper bound on Gower similarity coefficient.

Property 9. If there are no dichotomous attributes in *INCMP*_ATT*(*u*, *v*), then:

$$\overline{G}(u,v) = \frac{\sum_{i\in CMP\_ATT(u,v)} s_i(u,v) + |INCMP*\_ATT(u,v)|}{|CMP\_ATT(u,v)| + \ |INCMP*\_ATT(u,v)|}.$$

Proof: By definition of $\overline{G}(u,v)$ and the fact that $\overline{s}_i(u,v) = 1$ and $\overline{w}_i(v,u) = 1$ for any non-dichotomous attribute i on which u and v are incomparable (see Table IV).

Finally, we check the relationship between $\overline{G}(u,v)$ and $G'(u,v)$ as well as between $\overline{G}(u,v)$ and $G(u,v)$.

Property 10. Let u and v be comparable objects. Then:

a) $\overline{G}(u,v) \geq G'(u,v)$.

b) $\overline{G}(u,v) \geq G(u,v)$.

Proof: Ad a) In the proof, we will use the property saying that $\overline{s}_i(u,v) = 1 \geq \underline{s}_i(u,v)$ and $\overline{w}_i(v,u) = 1$ for any attribute $i \in$ *INCMP*_QNT_ATT*(*u*,*v*) (*) and that for any attribute $j \in$ *INCMP*_ATT*(*u*,*v*) \ *INCMP*_QNT_ATT*(*u*,*v*) either: (i) $\overline{s}_j(u,v) = 1$ and $\overline{w}_j(u,v) = 1$ or (ii) $\overline{w}_j(u,v) = 0$ (**).

Thus, by definition,

$$G'(u,v) =$$

$$\frac{\sum_{i\in CMP\_ATT(u,v)} s_i(u,v) + \sum_{\substack{i\in INCMP*\_QNT\_ATT(u,v,\\ \underline{s}_i(u,v)>G(u,v)}} \underline{s}_i(u,v)}{|CMP\_ATT(u,v)| + \ |\{i\in INCMP*\_QNT\_ATT(u,v)|\ \underline{s}_i(u,v)>G(u,v)|}$$

/ by (*) /

$$\leq \frac{\sum_{i\in CMP\_ATT(u,v)} s_i(u,v) + \sum_{i\in INCMP*\_QNT\_ATT(u,v)} \overline{w}_i(u,v)\times\overline{s}_i(u,v)}{|CMP\_ATT(u,v)| + \sum_{i\in INCMP*\_QNT\_ATT(u,v)} \overline{w}_i(u,v)}$$

/ by (**) /

$$\leq \frac{\sum_{i\in CMP\_ATT(u,v)} s_i(u,v) + \sum_{i\in INCMP*\_ATT(u,v)} \overline{w}_i(u,v)\times\overline{s}_i(u,v)}{|CMP\_ATT(u,v)| + \sum_{i\in INCMP*\_ATT(u,v)} \overline{w}_i(u,v)}$$

$$= \overline{G}(u,v).$$

Ad b) By Property 10a and Property 8a.

SUMMARY

In the article, we introduced lower and upper bounds on the actual similarity value on an attribute and on the actual value of the Gower similarity coefficient. We showed that the Gower similarity coefficient for two objects may take an incorrect value, which would be less than the lower bound on the actual value of the Gower similarity coefficient for those objects, if one of the objects has a missing value for at least one quantitative attribute. To solve this problem, we introduced coefficient *G'*, being a modification of the Gower similarity coefficient, that is free from this deficiency. A number of properties of similarity value of objects on the attribute, the Gower similarity coefficient, the introduced lower and upper bounds and the coefficient *G'* were derived.

***Abstract*—Among the solutions for the detection of cause-and-effect relationships are methods based on knowledge, statistical solutions or methods allowing the use of deep learning. The solution presented in the article uses bidirectional artificial neural networks LSTM to detect such relationships in legal texts in Polish. The analysis was performed at the sentence level, but due to the specific legal language and the focus on Polish, two separated networks were used in the experiment. The task of the first one is to classify whether a sentence contains a conditional, while the second one is to identify the elements of this relationship. Both use word embedding sets for the Polish language corpus. The results of the experiment prove that it is possible to perform such extraction with satisfactory results, and raise questions and point to further possible ways forward.**

I. Introduction

DETECTING cause-and-effect relationships in texts, is a task that requires advanced cognitive processes and is not a trivial problem. Inference itself can often be a very difficult task for human beings, so it is not surprising that attempts are made to automatically process and extract such relationships. Such data can be of significant value to many fields of science, including the field of law. Performing inference and argumentation in a proper and automatic manner can be used for many purposes and can assist those using legal texts in their daily work.

A. Causality relationship

We can define causality as a relationship between events e_1 and e_2, such that the occurrence of event e_1 results in the occurrence of event e_2 [1]. The following division of causality is made [2]:

- Explicit causality, which occurs in a sentence in the form of overt, often with conjunctions or causal phrases, such as in the sentence: “I did not attend the event because I was not invited.”
- Implicit causality, which does not occur in overt form overt, and can often be split into several sentences, such as in the sentences: “Drive slower. It’s slippery.”

It should be noted that in some cases the sentences, causes or effects may be unequal to each other, such as “The reason for the verdict was the evidence supporting the defendant’s guilt, but also the lack of cooperation on his part”. In this example, both “evidence supporting the defendant’s guilt” and “a lack of cooperation on his part” are causes in a sentence. Cause and effect can also be nested as in the sentence: “Refusal to testify or failure to appear at trial cause the court’s disfavor and the defense counsel’s concern.”. In this case, both “refusal to testify” and “failure to appear at trial” may cause further effects. Associations may also share certain parts with each other. In the next example, the effect of the first cause is also a cause for the next effect: “The defendant’s inappropriate behavior caused agitation in the courtroom, as a result of which the court had to cancel the hearing”.

Causality can be single-sentence or multi-sentence. Single-sentence is often combined with so-called overt causal conjunctions and phrases, which we can divide into:

- causal conjunctions: “because”, “as”, “cause”,
- result phrases: “as a result”, “due to”, "because of”,
- conditional phrases: “if ... then ...”.

In the case of implicit or multi-sentence causality, it is up to the reader to use basic knowledge to analyze and infer to detect it. These are much more complicated and therefore more difficult to analyze [3].

B. Practical uses

Detecting causal relationships in texts is of immense value and can be used in predictive and analytical tasks [3]. Having such information can be helpful in many fields [4], such as

- medicine, when analyzing medical cases,
- learning about the causes of security incidents,
- learning about the effects of natural disasters, etc.

In the context of the legal field, information about such relationships can carry a lot of value, for example, in the context of adjudicating court cases (especially in countries where the law of precedent is used, such as the US) and can be an important aid to judges in formulating a verdict. Also for prosecutors, or attorneys, such information can help in taking the right strategy in the courtroom.

II. Research status

Two main types of methods can be found in articles and scientific papers to detect cause-and-effect relationships [3]:

- methods based on patterns or rules [5], [6], [7],

- methods based on machine learning techniques [8], [17], [18], which we can divide into statistical methods (e.g. using decision trees, Naive Bayes algorithm or linear regression) and deep learning methods (neural networks).

The first type manifests weakness in many areas due to the need to create very sophisticated rules or patterns, thus requiring a lot of domain knowledge. Methods based on machine learning, on the other hand, although built without human intervention, need to be programmed and trained, thus requiring a lot of hardware and time resources.

A common approach appearing in the literature, is the use of a two-step causality extraction: first the detection of candidates is done, and then the classification of relationships. In this approach, there can be so-called cascading errors [19], i.e. errors that, when present in the first step, can significantly affect the results of the next step.

A. Data preparation

In order for the model to be trained, proper data preparation is required. The authors of [13] used the technique of labeling words using the Cartesian product of entity and relation tags, and then assigned a unique tag to the word. On the other hand, in [8] a new approach was proposed, the so-called "BIO and CEEmb" labeling of words based on tags: cause (C), effect (E) and embedded causality (Emb). An additional step is to mark each word as the beginning of the cause/effect (B), the continuation of the cause/effect (I), and another word (O). This approach makes it possible to formulate causal triples. Suppose we have a sentence, "The court refused to continue the trial due to the absence of the defendant." After analyzing this example, we can formulate a causal triple, where two events are divided by the type of relationship (in this case, cause-effect): "refusal to continue the trial, cause-effect, the absence of the defendant".

However, some tagging schemes, such as the one proposed in [17], cannot identify overlapping relationships. To solve this in [8], the authors use the "Tag2Triplet" algorithm, which allows the extraction of nested relationships in which individuals can be part of multiple ones. For example, the sentence "As a result of the incident, the plaintiff was unable to testify, leading to incorrect conclusions." contains an effect, i.e. the lack of testimony, which is also the cause of another effect, i.e. "incorrect conclusions."

B. Detecting and extraction

Following the determination process, the dominant approach is using recurrent LSTM neural networks in varieties with connection to conditional random fields [8] or in the Bi-LSTM type [4]. Some works in [21] or [22] have focused on detecting causality per se without dividing it into full relations (they detect sentences in which such a relation exists without dividing them into cause and effect), and some, e.g. in [4] or [23] focus on identifying linguistic expressions useful in describing causality (such as conjunctions and causal phrases).

In [8], [24], authors also point out that the use of word embedding layers makes a significant contribution to improving the performance and overall results of causality extraction. To improve the detection of relationships that remain far apart, various techniques are being introduced, such as the so-called self-suggestion mechanism [25], which, unlike the classical LSTM approach, can lead to a connection between arbitrarily distant words [26], and thus detect relationships between words in a more sophisticated way. This is because the meaning of a word is defined in the context of its entire surroundings, and not just (as in simple recurrent networks) based on what is immediately before or after it. The main problem in causality extraction is the embedding of such relationships in the text. On the other hand, extracting prepositions or effects without traditional conjunctions ("because", "since", "if", etc.) is an extremely difficult task [8].

III. Experiment

Causality can often be buried very deeply in a text, and even a person himself may have trouble pointing it out. Extracting such relationships from legal texts significantly narrows the corpus of words that can be used. In addition, the collection can be narrowed even further when focusing on a specific type of legal texts, such as the texts of court judgments. Among current studies, such experiments, i.e. causality analyses for legal texts, are lacking, especially when talking about Polish.

In the experiment, we focused on the extraction of explicit causality at the sentence level. This task is divided into two parts — the first goal is to indicate whether a sentence contains a causal relationship, while the second is to label and extract parts of such relationships. Not only semantic analysis becomes important here, but also the construction of the sentence itself. The biggest problem in this type of experiment is undoubtedly the lack of a suitable learning set in Polish. Therefore, it became necessary to manually prepare such a set before starting further analysis. In order to perform it, recurrent neural networks with LSTM-type cells were used, along with layers of word embeddings.

A. Data preparation

To conduct the experiment, it was necessary to prepare a dataset. For this purpose, legal texts were used, specifically court judgments from several open sources [9], [10], [11], [12]. The total number of judgment texts was 150. Using the author's script (adopting the beautifulsoup library in Python [13]), court judgments were downloaded from the above-mentioned sources in HTML format, and then converted to text and divided into sentences (using the NLTK library [14]). Each document has been marked accordingly (as indicated below). Two datasets were manually prepared for the experiment: the first set in order to perform binary classification on it — each sentence was assigned a positive or negative label, depending on the presence or absence of a cause-and-effect relationship in it. The second set was prepared based on sequence labeling, where each word in a sentence was assigned a label indicating its type in a sentence with causality. Both collections were prepared manually, requiring human intervention. We marked

Example 3.1 (Examples of elements of the first set):

Natomiast przedawnieniu podlega samo ustalenie odszkodowania, gdyż wg woli ustawodawcy następuje ono w formie decyzji administracyjnej.;1

Niezbędne jest dodatkowo wykazanie konieczności wyjaśnienia zakresu sprawy.;0

TABLE I
THE NUMBER OF CLASSES IN THE FIRST SET

	Number of elements	Percentage
Class 0 (no relation)	22060	92.01%
Class 1 (with a relationship)	1914	7.99%
Total	23974	100%

the data manually on our own, then we verified it (for this purpose we used Doccano software [15]).

1) First dataset: In the first set, each sentence was labeled, i.e. assigned a corresponding class, according to the presence of a causal relationship (class 1, positive) or its absence (class 0, negative), as shown in the Example 3.1. It is worth noting that this set is not a balanced set — the negative clause significantly dominates (Table I), which has implications for further text analysis.

2) Second dataset: Each sentence that contained a cause-effect relationship was additionally labeled, i.e. each word was given a membership in one of the groups: cause (class 0), effect (class 1), causal phrase (class 2), other (class 3). A collection of such sentences, divided into words, has been marked accordingly (Example 3.2). Each element was labeled in such a way that it could contain multiple consecutive words within it (Table II). The tagging method is a modified version of the method presented in the [20].

Example 3.2 (Example element of the second set):

w ocenie sądu okręgowego nagrody z zakładowego funduszu nagród wypłacone wnioskodawcy niepodlegają uwzględnieniu przy ustalaniu podstawy wymiaru renty gdyż nie były zaliczane do wynagrodzeń osobowych 11111111111111111111112000000 cause-effect-sentence

TABLE II

Class 3 (other)	139	2.58%
Total	5390	100%

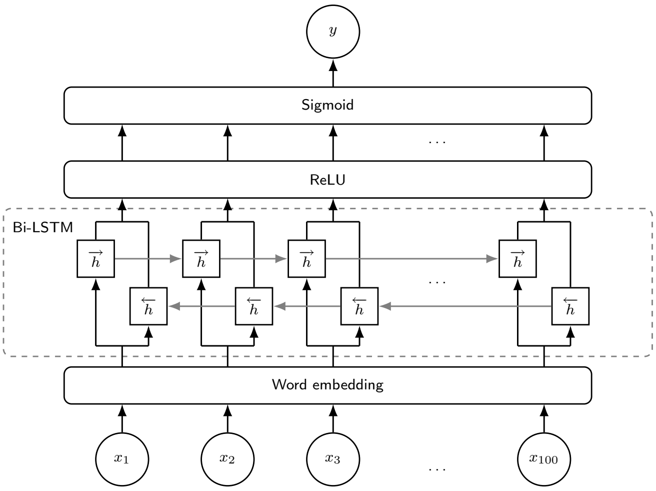

Fig. 1. The architecture of the network responsible for marking a sentence as having causality or not

B. RNNs structures

The program for detecting explicit cause-effect relationships was built on the basis of two separated neural networks. For this purpose, the Tensorflow library and the Keras interface were used [16]. The first network is responsible for binary classification of whether a cause-effect relationship is present in a sentence. The second network is tasked with performing cause-and-effect extraction, i.e. labeling a sentence with a cause-and-effect relation, assigning each word a token of the appropriate class. In both cases, validation of the correctness of the trained models is carried out at the end of the subroutines.

1) First network: The input data is properly prepared before entering the network, by dividing it into tokens, removing punctuation and whitespace characters. The set is divided in a 7:3 ratio into a learning set and a validation set. The next step is to transform the sentences into a dense feature vector using a set of word embeddings for the Polish language [27], [28], i.e. a 100-dimensional corpus containing all parts of speech, created using the CBOW architecture. Based on the subset counts, the weights of each class are calculated (due to the unbalanced dataset). The data then becomes the input for a recurrent neural network in the Bi-LSTM variant, in which the first layer is the word embedding layer (loaded earlier). The detailed architecture of the network is shown on Fig. 1.

The model was created using standard binary cross entropy as a loss function and the adam optimization algorithm. After training, the model is tested with a validation set and evaluated (precision, recall, F1 and accuracy values are calculated, as well as the ROC curve and the value under the AUC curve). The training process took place in 8 epochs, during which all the above metrics were measured.

2) Second network: The task of the second neural network is to extract cause-and-effect relationships from a sentence evaluated positively as containing causality. Each word must be assigned one of four classes: cause, effect, connective phrase or another word. The input sentences, as in the case

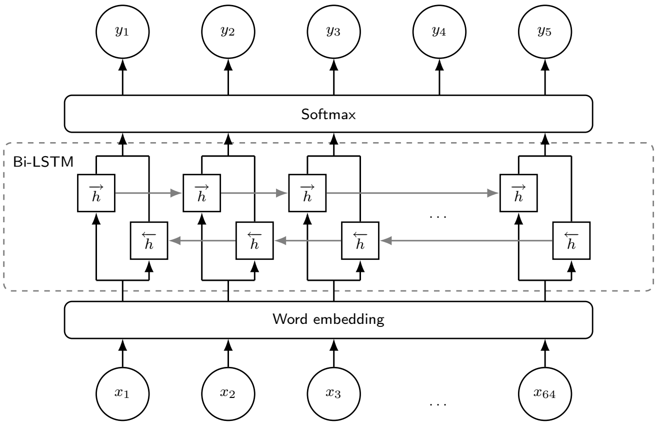

Fig. 2. The architecture of the network responsible for extracting the cause and effect parts

TABLE III
THE RESULTS OF THE FIRST NEURAL NETWORK

	Precision	**Recall**	**F1**
Class 0	0.81	0.89	0.85
Class 1	0.99	0.98	0.99
Macro	0.90	0.94	0.92
Weighted	0.98	0.98	0.98

of the first neural network, undergo preprocessing (identical to that described above), and then go as input to the neural network in the Bi-LSTM variant (Fig. 2). Due to the small size of the collection, cross-validation was used in the validation process, i.e. the collection was divided into ten parts and trained nine of them at a time, and tested the last one. After the training process, the results of the network are validated using the metrics of precision, accuracy, recall, and F1 index, both for each class and the entire collection. The training process took place over 10 epochs, during which all of the above metrics were measured.

IV. Results

The following tables present the values of the metrics for each set and each program. Table III shows the validation results of the first neural network tasked with binary classification. The accuracy for the entire set was 97.68%.

The value of AUC = 0.9822, which shows that the classifier can correctly distinguish class elements. The high precision is maintained throughout the learning period of the model due to issues related to the unbalanced dataset, described below. Details of the values of the metrics at training time (at a specific epoch) are shown in Fig. 3-7. Noteworthy, this curve gives an incomplete picture of the classifier, due to the unbalanced dataset. The more important information is the values for the class with causality sewn in, the results of which no longer look so good (as can be seen in the confusion matrix of validation set in Table IV).

As the results indicate, the classification of such relationships is not a simple task, but to some extent it is feasible.

TABLE IV

This is greatly influenced by words that are parts of causal phrases, but it should be noted that there is never such certainty. For example, when a sentence contains the word “albowiem”, which often occurs in legal language, this may or may not indicate conditionality. The word “bowiem” in most cases separates the cause and effect parts, but there are also exceptions to this.

Table V shows the results for the second neural network, which was tasked with extracting the parts belonging to causal relationships. The results here are much worse. What stands out here is the better result of the causal phrase class, due to the frequent occurrence of the same phrases and words. The results here are probably also influenced by the small collection. In contrast, class with other words (class 3) performs in a clearly negative way, given the problem of indicating it in a sentence, because there are no special rules formulated in the experiment for the occurrence of such a class.

TABLE V
THE RESULTS OF THE SECOND NEURAL NETWORK

	Precision	Recall	F1
Class 0	0.58	0.58	0.58
Class 1	0.50	0.51	0.51
Class 2	0.72	0.89	0.80
Class 3	0.18	0.06	0.09
Macro	0.60	0.61	0.60
Weighted	0.83	0.83	0.83

It should also be noted that legal texts (especially court judgments) often have sentences that are very rote in their construction, i.e. contain many subordinate sentences, which also affects such analysis. The network also did not cope when a word or phrase indicating causality was located at the beginning of a sentence. In such a case, the word “ponieważ” does not separate the causal part from the effect, so the network’s results were subject to high error.

V. Conclusions

The biggest problem with the argument extraction experiment became the lack of a suitable training set. There is no such set for the Polish language in the sources, which made it necessary to create such a set manually. This was a tedious activity, but at the same time required adequate attention. Closing the corpus of words to the texts of court rulings, significantly simplified the analysis and marking of sentences, due to the orderly structure of the text, often containing similar causal phrases. Judgment texts, like other legal texts, are often written in correct language, but stylistic, punctuation and even spelling errors can be found among them (unlike, for example, the texts of statutes). The structure of a court decision itself looks very similar, regardless of the court or its type (division into a operative part, justification or cited provisions).

In the case of the first set (the input for the first neural network tasked with binary classification), sentences that have a causal relationship in them make up a small percentage of the set. Hence, it is necessary to set up the neural network in such a way as to notify it of the greater importance of certain elements of the set. The reason for using such a set is to reflect the real ratio of sentences that contain a causal relationship to those that do not. The use of a word embedding layer with a trained set of vectors for the Polish language also has a broad impact on better results.

In some cases, the word occurs with cause (without effect), indicating that causation is missing at the sentence level. Thus, it cannot be assumed that syntactic analysis alone would carry significant information about the semantics of the sentence, but it would be largely sufficient. Reviewing the results, we can note the following regularities. For example, a sentence containing a causal connective phrase has a high degree of certainty about the occurrence of a cause in it. On the other hand, a sentence that does not have such a phrase with the highest probability is assigned to a class with no such relationship.

VI. Future works

To develop the topic of causal relationship extraction in the future, it would therefore be important to create a suitably large and diverse test dataset. Semantic analysis at the level of the whole document, and not just at the sentence level, would also be an important element. This would allow detection of arguments that are implicit relationships (sewn into the text), often found in different parts of the document. As research in the field of detecting such relationships shows, this task is not easy. When analyzing texts in Polish, we often also have to pay attention to other elements absent in other languages, which makes such texts significantly more difficult to analyze semantically for causality. The resulting data from this experiment can successfully serve for further research and be the basis for other tasks in the area of machine learning in the field of law.

***Abstract*—In this paper the problem of parameter estimation of Gaussian mixture models using the expectation-maximization (EM) algorithm is considered. Four variants of the EM algorithm parallelized using the OpenMP standard are proposed. The main difference between the variants is the degree of usage of vendor-optimized linear algebra libraries. The computational experiments were performed using 25 large datasets on a system with two 12-core Intel Xeon processors. The results of experiments indicate that the EM variant using level 3 (matrix-matrix) operations and L3 cache blocking is the fastest one. It is 1.75–2.75 times faster than the naive version using level 2 (matrix-vector) operations. Its parallel efficiency relative to the sequential version is always greater than 83%.**

I. Introduction

FINITE mixture models [1] are a very versatile tool used for modeling complex probability distributions. Gaussian mixture models (GMMs) which assume multivariate normal density of a component, are arguably the most popular mixture models. GMMs have been successfully applied to many problems in engineering, finance, biology and data mining.

The maximum likelihood estimation (MLE), which seeks a maximum of the log-likelihood function, is a method of choice for GMM parameter estimation. The expectation-maximization (EM) algorithm [2] is the most common approach for MLE of GMM parameters. The algorithm is simple and easy to implement. Its important drawback is high computational complexity. The complexity of a single iteration is $O(NKd^2)$, where N is the number of data items, K is the number of mixture components, and d is the dimension of a feature space. These high computational requirements limit the usability of the EM, especially when d is large.

The problem of high computational requirements can be tackled a by parallel realization of the EM for GMMs (e.g., [3]). The importance of parallel formulations of the EM stems from ubiquity of relatively cheap multi-core processors. However, these processors have complex structures with multiple SIMD execution units and two- or three-level hierarchy of cache memory. This complexity makes an efficient implementation of the EM a tedious task. The difficulties in an efficient implementation can be alleviated by using a vendor-optimized matrix algebra libraries, for instance based on the BLAS standard [4].

This paper proposes four such parallel formulations, two of which use level 2 BLAS calls, and the remaining two leverage more efficient level 3 BLAS operations. The proposed algorithms are parallelized using the OpenMP standard, implemented in C++, and employ the Eigen template library[1] which seamlessly invokes the BLAS calls. We also investigate the use of blocking [5] for L3 cache. The computational experiments indicate that this optimization significantly improves the performance of the EM variant based on level 3 BLAS calls.

II. GMM parameter estimation

A finite mixture model with K components has the probability density function given by:

$$f(\mathbf{x}|\boldsymbol{\Theta}) = \sum_{m=1}^{K} \alpha_m \phi(\mathbf{x}; \boldsymbol{\theta}_m), \tag{1}$$

where $\phi(\mathbf{x}; \boldsymbol{\theta}_m)$ is the probability density function of the m-th component parameterized on $\boldsymbol{\theta}_m$, and $\alpha_1, \ldots, \alpha_K$ are the mixing proportions which must satisfy the following two conditions: $\alpha_1 + \cdots + \alpha_K = 1$ and $\alpha_m \geq 0$ for $m = 1, \ldots, K$. $\boldsymbol{\Theta} = \{\alpha_1, \ldots, \alpha_k, \boldsymbol{\theta}_1, \ldots, \boldsymbol{\theta}_K\}$ is the complete set of parameters defining the mixture.

In Gaussian mixture models each component has the following (multivariate normal) probability density function:

$$\phi(\mathbf{x}; \boldsymbol{\theta}_m) = \mathcal{N}(\mathbf{x}; \boldsymbol{\mu}_m, \boldsymbol{\Sigma}_m) = \\ \frac{1}{(2\pi)^{d/2} \det(\boldsymbol{\Sigma}_{\mathbf{m}})^{1/2}} e^{\left[-0.5(\mathbf{x}-\boldsymbol{\mu}_m)\boldsymbol{\Sigma}^{-1}(\mathbf{x}-\boldsymbol{\mu}_m)^T\right]}, \tag{2}$$

with the set of parameters $\boldsymbol{\theta}_m = [\boldsymbol{\mu}_m, \boldsymbol{\Sigma}_m]$, where d is the dimension of the feature space, $\boldsymbol{\mu}_m \in \mathbb{R}^d$ is the mean

This work was supported by the grant WZ/WI-IIT/4/2023 from Białystok University of Technology. Computations were carried out using the computers of Centre of Informatics Tricity Academic Supercomputer & Network, in Gdansk, Poland.

[1] http://eigen.tuxfamily.org

and $\mathbf{\Sigma_m}$ is the $d \times d$ covariance matrix. Thus, for a GMM the complete set of mixture parameters is given by $\mathbf{\Theta} = \{\alpha_1, \ldots, \alpha_K, \boldsymbol{\mu}_1, \ldots, \boldsymbol{\mu}_K, \mathbf{\Sigma}_1, \ldots, \mathbf{\Sigma}_K\}$.

Given a set of N independent and identically distributed feature vectors $X = \{\mathbf{x}_1, \ldots, \mathbf{x}_N\}$, where $\mathbf{x}_i \in \mathbb{R}^d$, the log-likelihood function, corresponding to a K-component mixture is given by:

$$\log f(X|\mathbf{\Theta}) = \sum_{i=1}^{N} \log \sum_{m=1}^{K} \alpha_m \mathcal{N}(\mathbf{x}; \boldsymbol{\mu}_m, \mathbf{\Sigma}_m). \tag{3}$$

The maximum likelihood estimate of parameters is obtained as: $\mathbf{\Theta}^* = \underset{\mathbf{\Theta}}{\operatorname{argmax}} \log f(X|\mathbf{\Theta})$.

The EM algorithm [2], [6] is an iterative procedure which, given an initial estimate of parameters $\mathbf{\Theta}^{(0)}$, produces a sequence of estimates with increasing log-likelihood (3). j-th iteration of the algorithm consists of two steps called expectation step (E-step) and maximization step (M-step).

In the E-step [7], using the parameters $\Theta = \{\alpha_1, \ldots, \alpha_K, \boldsymbol{\mu}_1, \ldots, \boldsymbol{\mu}_K, \mathbf{\Sigma}_1, \ldots, \mathbf{\Sigma}_K\}$ from the previous iteration, for each feature vector $\mathbf{x}_i$, $i = 1, \ldots, N$ and for each mixture component m, $m = 1, \ldots, K$ the posterior probability that $\mathbf{x}_i$ was generated from m-th component is calculated as:

$$P(m|\mathbf{x}_i) = \frac{\alpha_m \mathcal{N}(\mathbf{x}_i; \boldsymbol{\mu}_m, \mathbf{\Sigma}_m)}{\sum\limits_{k=1}^{K} \alpha_k \mathcal{N}(\mathbf{x}_i; \boldsymbol{\mu}_k, \mathbf{\Sigma}_k)}. \tag{4}$$

The M-step [7], using the posterior probabilities $P(m|\mathbf{x}_i)$, computes new estimate of parameters $\mathbf{\Theta}$ as $(m = 1, \ldots, K)$:

$$\alpha_m = \frac{1}{N} \sum_{i=1}^{N} P(m|\mathbf{x}_i), \tag{5}$$

$$\boldsymbol{\mu}_m = \frac{\sum\limits_{i=1}^{N} P(m|\mathbf{x}_i)\mathbf{x}_i}{\sum\limits_{i=1}^{N} P(m|\mathbf{x}_i)}, \tag{6}$$

$$\mathbf{\Sigma}_m = \frac{\sum\limits_{i=1}^{N} P(m|\mathbf{x}_i)(\mathbf{x}_i - \boldsymbol{\mu}_m)^T(\mathbf{x}_i - \boldsymbol{\mu}_m)}{\sum\limits_{i=1}^{N} P(m|\mathbf{x}_i)}. \tag{7}$$

The E-step and M-step are applied alternately until a convergence criterion is met.

III. Four formulations of the EM using matrix algebra libraries

All formulations of the EM algorithm for GMMs discussed in this section store the training set in a matrix (two-dimensional array in the C++ language) $\mathbf{X} = [x_{i,j}]_{1 \le i \le N, 1 \le j \le d}$, where i-th row, denoted by $x_{i,*}$ stores the feature vector $\mathbf{x}_i$. Similarly, the posterior probabilities are stored in a matrix $\mathbf{P} = [p_{i,j}]_{1 \le i \le N, 1 \le j \le K}$, where $p_{i,j} = P(m|\mathbf{x}_i)$.

Algorithm 1 shows a high-level overview of the EM. The equations (3) and (4) indicate that in order to perform both the convergence check and the E-step we need to compute Gaussian probability density function values multiplied by the corresponding mixing proportions. An obvious optimization is to compute densities weighted by mixing proportions once, store them in a matrix $\mathbf{W} = [w_{i,j}]_{1 \le i \le N, 1 \le j \le K}$, where $w_{i,j} = \alpha_j * \mathcal{N}(x_{i,*}; \boldsymbol{\mu}_j, \mathbf{\Sigma}_j)$ and use them in subsequent E-Step and computation of log-likelihood.

The four variants of the EM discussed in the paper follow this pattern. After the computation of weighted densities $\mathbf{W}$ (line 3 of Algorithm 1), the log-likelihood using (3) is computed (line 4). If the algorithm is not terminated in line 6, then the posterior probability matrix $\mathbf{P}$ using weighted densities $\mathbf{W}$ is obtained by equation (4) (line 8). The computation of the log-likelihood L and the matrix $\mathbf{P}$ based on $\mathbf{W}$ are very straightforward. We have implemented them using Eigen C++ library, which generates an efficient vectorized code. The iterations of the EM algorithm are performed until either the algorithm converges or the maximal number of iterations M is reached.

Algorithm 1 The pseudocode of the EM algorithm

```
Require: $\mathbf{X}$, $\mathbf{\Theta}^0$, $M$, $\varepsilon$
 1: $\mathbf{\Theta} \leftarrow \mathbf{\Theta}^0$
 2: for $i \leftarrow 1$ to $M$ do
 3:   $\mathbf{W} \leftarrow$ WeightedDensities($\mathbf{X}$, $\mathbf{\Theta}$)
 4:   $L' \leftarrow L$, $L \leftarrow$ Loglikelihood($\mathbf{W}$)
 5:   if $i > 1$ and ConvergenceCheck($L, L'$) then
 6:     Terminate the algorithm
 7:   end if
 8:   $\mathbf{P} \leftarrow$ EStep($\mathbf{W}$)
 9:   $\mathbf{\Theta} \leftarrow$ MStep($\mathbf{X}, \mathbf{P}$)
10: end for
11: return $\mathbf{\Theta}$
```

The four variants of the EM algorithm differ in implementation of `WeightedDensities` and `MStep` functions.

A. Variant I: EM-L2

This variant uses BLAS Level 2 (matrix-vector) calls in implementation of `WeightedDensities` and `MStep`, hence its name EM-L2. The pseudocode of `WeightedDensities` function is shown in Algorithm 2. The function starts (lines 1–3) with the computation of invariants which do not depend on the feature vector. The inverse and determinant of covariance matrices are calculated (line 2) using the Cholesky decomposition [8]. Next, the loop (lines 4–10) iterating over all rows of $\mathbf{X}$ and $\mathbf{W}$ is executed. In this loop, for each mixture component j a squared Mahalanobis distance between the i-th row $x_{i,*}$ and mean vector $\boldsymbol{\mu}_j$ is calculated in lines 6–7. The computations in line 7 are done using `cblas_dsymv` and `cblas_dot` calls [4]. Next (line 8) weighted normal density is calculated.

Algorithm 3 shows the pseudocode of `MStep` function. The function calculates sums in equations (5)–(7) in two passes over rows of matrices $\mathbf{X}$ and $\mathbf{P}$. In the first pass (lines 4–8),

Algorithm 2 `WeightedDensities` function in EM-L2

```
Require: $\mathbf{X}$, $\mathbf{\Theta}$
 1: for $j \leftarrow 1$ to $K$ do
 2:   $\mathbf{S}_j \leftarrow \mathbf{\Sigma_j}^{-1}$, $b_j \leftarrow 1/\left((2\pi)^{d/2}\det(\mathbf{\Sigma_j})^{1/2}\right)$
 3: end for
 4: for $i \leftarrow 1$ to $N$ do
 5:   for $j \leftarrow 1$ to $K$ do
 6:     $\mathbf{y} \leftarrow x_{i,*} - \boldsymbol{\mu}_j$
 7:     $w_{i,j} \leftarrow -0.5\mathbf{y}S\mathbf{y}^T$
 8:     $w_{i,j} \leftarrow \alpha_j b_j \exp(w_{i,j})$
 9:   end for
10: end for
11: return $\mathbf{W} = [w_{i,j}]$
```

Algorithm 3 `MStep` function in EM-L2

```
Require: $\mathbf{X}$, $\mathbf{P}$
 1: for $j \leftarrow 1$ to $K$ do
 2:   $\mathbf{\Sigma}_j \leftarrow \mathbf{0}$, $\boldsymbol{\mu}_j \leftarrow \mathbf{0}$, $s_j \leftarrow 0$
 3: end for
 4: for $i \leftarrow 1$ to $N$ do
 5:   for $j \leftarrow 1$ to $K$ do
 6:     $s_j \leftarrow s_j + p_{i,j}$, $\boldsymbol{\mu}_j \leftarrow \boldsymbol{\mu}_j + p_{i,j}x_{i,*}$
 7:   end for
 8: end for
 9: for $j \leftarrow 1$ to $K$ do
10:   $\boldsymbol{\mu}_j \leftarrow \boldsymbol{\mu}_j/s_j$, $\alpha_j \leftarrow s_j/N$
11: end for
12: for $i \leftarrow 1$ to $N$ do
13:   for $j \leftarrow 1$ to $K$ do
14:     $\mathbf{y} \leftarrow x_{i,*} - \boldsymbol{\mu}_j$
15:     $\mathbf{\Sigma_j} \leftarrow \mathbf{\Sigma_j} + p_{i,j}\mathbf{y}^t\mathbf{y}$
16:   end for
17: end for,
18: for $j \leftarrow 1$ to $K$ do
19:   $\mathbf{\Sigma_j} \leftarrow \mathbf{\Sigma_j}/s_j$
20: end for
21: return $\mathbf{\Theta} = \{\alpha_1, \ldots, \alpha_K, \boldsymbol{\mu}_1, \ldots, \boldsymbol{\mu}_K, \mathbf{\Sigma}_1, \ldots, \mathbf{\Sigma}_K\}$
```

for each component j, the sum of posterior probabilities s_j and the sums in the numerators of (6) are accumulated. Next, the final values of mixing proportions α_j and mean vectors $\boldsymbol{\mu}_j$ are obtained (lines 9–11). In the second pass (lines 12–17), using the mean vectors computed in the first pass, for each component j, the sum in the numerator of (7) is obtained. The computation in line 15 is performed using `cblas_dsyr` call [4], which calculates rank-1 update of a symmetric matrix. Finally, in lines 18–20, the covariance matrices are obtained from accumulated numerators of (7).

B. Variant II: EM-L2-reordered

Our initial experiments with EM-L2 indicated the abysmal performance, where both dimension of the feature space d and the number of mixture components K are high. However, a simple interchange of loops in lines 12–17 of Algorithm 3, which places the loop iterating over the mixture components first was able to significantly improve the performance. We call this variant EM-L2-reordered. It used the same formulation of `WeightedDensities` function as EM-L2.

C. Variant III: EM-L3-blocking

This variant uses Level 3 BLAS operations [4], which usually have have $O(n^2)$ memory complexity and much larger $O(n^3)$ computational complexity, which allows for higher reuse of data and higher level of optimization [5]. Additionally it uses employs blocking (called also loop tiling [5]) to further optimize the most time-critical operations of `WeightedDensities` and `MStep` functions. We apply this technique to process the data in smaller blocks that are more likely to fit in the last level of cache memory. The `WeightedDensities` and `MStep` functions are shown in Algorithms 4 and 5, respectively. These functions require additional parameter, which is the number of blocks. This parameter is denoted by β in `WeightedDensities` function and by γ in the `MStep` function.

In the `WeightedDensities` function the computation of squared Mahalanobis distance is performed for blocks of rows of the data matrix $\mathbf{X}$. To simplify description, we assume that the number of feature vectors N is divisible without remainder by the number of blocks β. In such case the size of each block equals $B = N/\beta$. The outermost loop (line 5) iterates over blocks. It starts by the computation of the indices of the first (i_s) and the last (i_e) row in current l-th blocks. These must satisfy the condition $i_e - i_s + 1 = N/\beta$. The inner loop (lines 7–13) is performed for submatrix of $\mathbf{X}$ consisting of rows $i_s, i_{s+1}, \ldots, i_e$, which we denote as $\mathbf{X}_{i_s:i_e,*}$. All the matrices involved in the inner loop nest including the submatrices of $\mathbf{X}$ and $\mathbf{W}$ have B rows. Since the computations in lines 8–12 are repeated K times, this approach allows for much greater reuse of data in the cache memories.

The code in lines 7-13 computes the squared Mahalanobis distances and stores them in a block of the matrix $\mathbf{W}$. Using the Cholesky decomposition of Σ_j^{-1} the squared distance between a feature vector in i-th row of X and j-th mixture component can be written as:

$$(x_{i,*}-\boldsymbol{\mu}_j)\mathbf{\Sigma}_j^{-1}(x_{i,*}-\boldsymbol{\mu}_j)^T = (x_{i,*}-\boldsymbol{\mu}_j)\mathbf{L}_j\mathbf{L}_j^T(x_{i,*}-\boldsymbol{\mu}_j)^T = \left[(x_{i,*}-\boldsymbol{\mu}_j)\mathbf{L}_j\right]\left[(x_{i,*}-\boldsymbol{\mu}_j)\mathbf{L}_j\right]^T. \quad (8)$$

Lines 8–12 implement this computation efficiently using two temporary matrices. The $B \times d$ temporary matrix $\mathbf{Y}$ is obtained by subtracting $\boldsymbol{\mu}_j$ from each row of the block of $\mathbf{X}$. The temporary $B \times d$ matrix $\mathbf{Z}$, where i-th row is given by $z_{i,*} = (x_{i,*} - \boldsymbol{\mu}_j)\mathbf{L}_j$ is computed in line 7 using `cblas_dtrmm` (Level 3) BLAS call [4], which multiplies a general matrix by a triangular matrix.

The pseudocode of `MStep` function is shown in Algorithm 5. The less time-consuming ($O(NKd)$ computational complexity) computation of mean vectors $\boldsymbol{\mu}_j$ and posterior sums s_j (lines 4–11) is performed similarly to EM-L2 version shown

Algorithm 4 `WeightedDensities` function in EM-L3-blocking

```
Require: $\mathbf{X}$, $\mathbf{\Theta}$, $\beta$
 1: for $j \leftarrow 1$ to $K$ do
 2:     $\mathbf{S}_j \leftarrow \mathbf{\Sigma_j}^{-1}$, $\mathbf{L}_j \leftarrow \texttt{chol}(\mathbf{S}_j)$
 3:     $b_j \leftarrow 1/\left((2\pi)^{d/2}\det(\mathbf{\Sigma_m})^{1/2}\right)$
 4: end for
 5: for $l \leftarrow 1$ to $\beta$ do
 6:     $i_s, i_e \leftarrow \texttt{BlockIndices}(N, \beta, l)$
 7:     for $j \leftarrow 1$ to $K$ do
 8:         $\mathbf{Y} \leftarrow \mathbf{X}_{i_s:i_e,*} - \boldsymbol{\mu}_j$
 9:         $\mathbf{Z} \leftarrow \mathbf{Y}\mathbf{L}_j$
10:         for $i \leftarrow i_s$ to $i_e$ do
11:             $w_{i,j} \leftarrow \sum_{k=1}^{d} z^2_{i-i_s+1,k}$
12:             $w_{i,j} \leftarrow b_j\alpha_j * \exp(-0.5 * w_{i,j})$
13:         end for
14:     end for
15: end for
16: return $\mathbf{W} = [w_{i,j}]$
```

Algorithm 5 `MStep` function in EM-L3-blocking

```
Require: $\mathbf{X}$, $\mathbf{P}$, $\gamma$
 1: for $j \leftarrow 1$ to $K$ do
 2:     $\mathbf{\Sigma}_j \leftarrow \mathbf{0}$, $\boldsymbol{\mu}_j \leftarrow \mathbf{0}$, $s_j \leftarrow 0$
 3: end for
 4: for $j \leftarrow 1$ to $K$ do
 5:     for $i \leftarrow 1$ to $N$ do
 6:         $s_j \leftarrow s_j + p_{i,j}$, $\boldsymbol{\mu}_j \leftarrow \boldsymbol{\mu}_j + p_{i,j}x_{i,*}$
 7:     end for
 8: end for
 9: for $j \leftarrow 1$ to $K$ do
10:     $\boldsymbol{\mu}_j \leftarrow \boldsymbol{\mu}_j/s_j$, $\alpha_j \leftarrow s_j/N$
11: end for
12: for $l \leftarrow 1$ to $\gamma$ do
13:     $i_s, i_e \leftarrow \texttt{BlockIndices}(N, \gamma, l)$
14:     for $j \leftarrow 1$ to $K$ do
15:         for $i \leftarrow i_s$ to $i_e$ do
16:             $y_{i-i_s+1,*} = (x_{i,*} - \boldsymbol{\mu}_j) * \sqrt{p_{i,j}}$
17:         end for
18:         $\mathbf{\Sigma}_j \leftarrow \mathbf{\Sigma}_j + \mathbf{Y}\mathbf{Y}^T$
19:     end for
20: end for
21: for $j \leftarrow 1$ to $K$ do
22:     $\mathbf{\Sigma_j} \leftarrow \mathbf{\Sigma_j}/s_j$
23: end for
24: return $\mathbf{\Theta} = \{\alpha_1, \ldots, \alpha_K, \boldsymbol{\mu}_1, \ldots, \boldsymbol{\mu}_K, \mathbf{\Sigma}_1, \ldots, \mathbf{\Sigma}_K\}$
```

in Algorithm 3. The only change is the reordering of loops starting in lines 4–5.

However, sums in numerators of (7) are obtained (lines 12–17) in a completely different way. Similarly to Algorithm 4, the data are processed in γ blocks, with size of block equal $C = N/\gamma$. After a calculation of temporary $C \times d$ matrix $\mathbf{Y}$ in lines 12–15, the numerator of (7) is updated by a single `cblas_dsyrk` level 3 BLAS call [4].

The `WeightedDensities` and `MStep` functions of the EM-L3-blocking variant were designed to delegate the most time-consuming code fragments with $O(Nd^2)$ complexity to Level 3 BLAS calls. `MStep` requires additional $O(N)$ square root calculations (line 14 of Algorithm 5) per single covariance matrix.

The method for choosing numbers of blocks β and γ remains to be described. Denote by L the total capacity of last level cache in bytes. In our implementation, to conserve memory, we store $\mathbf{X}$ using single precision floating point numbers. $\mathbf{Y}$, $\mathbf{Z}$, $\mathbf{W}$, $\mathbf{P}$ are stored using double precision numbers. Taking into consideration that a single precision number needs 4 bytes of storage and a double precision 8 bytes, the loop in lines 7–13 of Algorithm 4 needs $4dB$ bytes for storage of $\mathbf{X}_{i_s:i_e,*}$, $8dB$ bytes for $\mathbf{Y}$ and $\mathbf{Z}$ and $8KB$ bytes for the submatrix of $\mathbf{W}$. Assuming, that the total working set in the loop should be equal to L bytes, we have:

$$\beta = \frac{(20 * d + 8K)N}{L}. \tag{9}$$

After performing a similar analysis of the loop in lines 14–19 of Algorithm 5 we get:

$$\gamma = \frac{(12 * d + 8K)N}{L}. \tag{10}$$

D. Variant IV: EM-L3

This variant is a simplification of EM-L3-blocking, which does not perform loop tiling, i.e., sets the number of blocks $\beta = 1$ and $\gamma = 1$. We implemented this variant in order to assess the influence of blocking on the performance of the variant III.

IV. Parallelization for shared-memory systems

All the EM variants described in the previous section can be parallelized using data decomposition approach. We have designed parallel formulation of the algorithms and implemented them using the OpenMP standard [9] for shared-memory architectures.

An OpenMP application can be viewed as a group of cooperating threads. At the begin, only a master thread executes. When this thread encounters the `#pragma omp parallel` directive, the execution of the following block of code is performed by a team of threads. When a team of threads encounters the `#pragma omp for` directive, a succeeding `for` loop is parallelized by the team of threads. In this case each thread executes a subset of the loop iterations. In our approach we use static loop scheduling, where each of t threads is assigned approximately n/t iterations, when n is the total number of loop iterations.

In the parallelization of the `WeightedDensities` and `EStep` functions we use the fact that the rows of output matrices ($\mathbf{W}$ and $\mathbf{\Theta}$, respectively) can be computed using the corresponding rows of the input matrices ($\mathbf{X}$ and $\mathbf{W}$, respectively) without the knowledge about the remaining rows. We employ the data decomposition of the matrices $\mathbf{X}$, $\mathbf{W}$, $\mathbf{P}$ in which each thread is responsible for a block of consecutive rows. In case of EM-L3-blocking, where data are processed in blocks we divide further each of β or γ blocks into t sub-blocks.

Similar decomposition scheme is applied to the parallelization of `Loglikelihood` function, where each thread computes the local sum (3) using its assigned block of rows. Next, the local sums computed by the team of threads are added up giving the final log-likelihood. This is an example of the reduction operation which, for a single variable, can be easily carried-out using the OpenMP `reduction` clause.

The above decomposition scheme can be easily applied to `WeightedDensities` in Algorithm 2, by placing a `#pragma omp parallel for` directive before loops starting in lines 1, 5, and 12. For the `WeightedDensities` function shown in Algorithm 4 we use `#pragma omp for` before lines 1 and 10, and manually divide the rows of matrices $\mathbf{Y}$ and $\mathbf{Z}$ (lines 8–9) into t threads of the OpenMP team.

The parallelization of `MStep` functions is also based on data decomposition. Additionally, we have to tackle the problem of computing the s_j and the sums in numerators of (5), (6) and (7). We use a similar approach to that in the `Loglikelihood` function. Each OpenMP thread calculates local sums which are added up using the reduction operation. Since OpenMP 4.5 does not provide reduction operation for user-defined datatypes we have used the binary tree reduction algorithm [10].

V. Experimental results

All the results reported in this section were obtained using single compute nodes of the Tryton cluster installed in Centre of Informatics Tricity Academic Supercomputer and Network in Gdansk, Poland. A single node of the cluster is equipped with two 12-core Intel Xeon E5-2670 v3 (2.3 GHz) CPUs and 128 GiB of DDR4 RAM. The programs were compiled using the Intel C/C++ compiler (icpc) version 2021.7.1 and linked with the Intel MKL library version 2022.2.1, which provided the BLAS calls. We run the sequential version of EM-L3-blocking on a single core, assuming in (9) and (10) the last level cache size $L = 30 * 2^{20}$ bytes, according to manufacturer specification of the processor. We run parallel versions of all four algorithms using all 24 cores and assuming the last level cache size of multiplied by two: $L = 60 * 2^{20}$ bytes, because two processors were used in the calculations.

The experiments were performed on synthetic datasets obtained by the MixSim simulator proposed in [11]. The experiments were executed as follows. First we chose $d \in \{20, 40, 60, 80, 100\}$ and $K \in \{20, 40, 60, 80, 100\}$. For each of 25 combinations of K and d we generated a single dataset using the MixSim simulator. The number of feature vectors N was chosen to set the total size of the dataset as close of 512MiB ($512 * 2^{20}$ bytes) as possible. Thus, all the datasets were much larger as the total size of last level cache memory in a compute node. For each dataset we generated a single initial solution of the EM algorithm. This solution was used to initialize all the variants of the EM algorithm. Because all the variants started from the same solution, they converged after the same number of iterations. We obtained the average iteration time by dividing the total execution time measured using a system high-precision real time clock by the number of iterations. The shorter average EM iteration time indicated the higher performance of the algorithm.

The results indicated that EM-L3-blocking is the fastest of all parallel algorithms in all the experiments. Due to space limitations we have to omit the presentation of average iteration times in a table. These times ranged from 1.13 second (EM-L3-blocking, $d = 20$, $K = 20$) to 150 seconds (EM-L2, $d = 100$, $K = 100$). Using these measurements we have calculated the algorithmic speedup and parallel efficiency of the EM-L3-blocking. Figure 1 shows the algorithmic speedup of the EM-L3-blocking variant over the EM-L3. For a given dataset. an algorithmic speedup S of EM-L3-blocking over another variant A is defined as: $S = t_{\mathrm{A}}/t_{\mathrm{EM-L3-blocking}}$, where t_{A} and $t_{\mathrm{EM-L3-blocking}}$ denote average iteration times of EM variant A and EM-L3-blocking, respectively. The figure indicates that EM-L3-blocking is faster than EM-L3 for all datasets and its advantage is increased with decreased feature space dimension d.

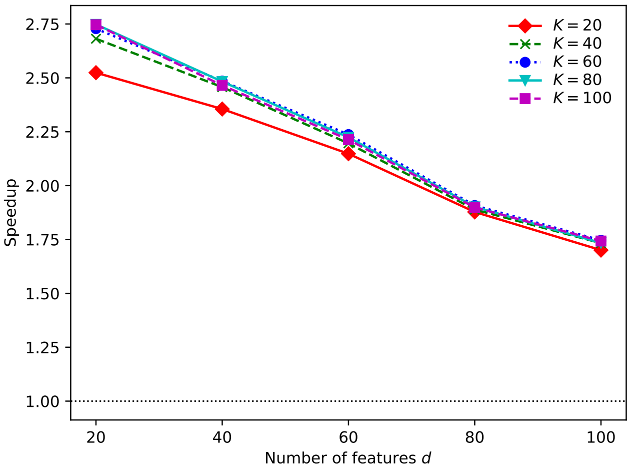

Fig. 1. Algorithmic speedup of the EM-L3-blocking variant over EM-L3 variant. The dotted horizontal line indicates equal speed of both algorithms.

Figure 2 shows the algorithmic speedup of the EM-L3-blocking over the faster of two variants (EM-L2 and EM-L2-reordered) using level 2 BLAS operations. The plots indicate that EM-L3-blocking is always faster and its advantage is increased with the increase of the dimension d.

We end the presentation of the results by showing the parallel efficiency of EM-L3-blocking with respect to its sequential version. A parallel efficiency (in percent) is defined as the ratio of measured parallel speedup to the ideal linear

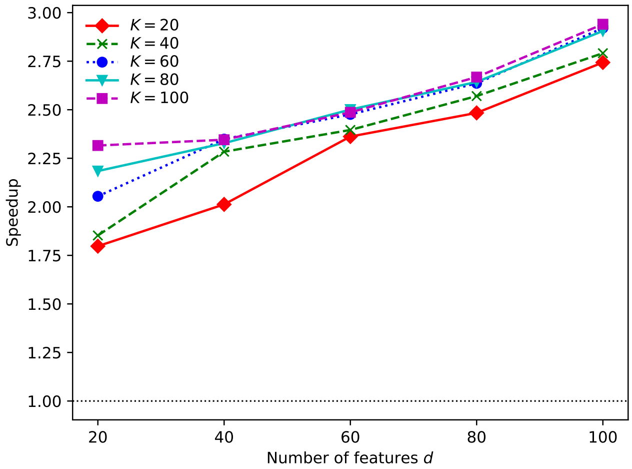

Fig. 2. Algorithmic speedup of the EM-L3-blocking variant over the fastest variant using L2 BLAS operations. The dotted horizontal line indicates equal speed of both algorithms.

speedup (equal to the number of the cores in a compute node). In turn, the parallel speedup is given by the ratio of the iteration time of the sequential version to iteration time of the parallel version of the algorithm. The plots indicate that the EM-L3-blocking variant scales very well with the efficiency higher then 83% in all the cases and higher than 90% where $K \geq 40$ and $d \geq 40$.

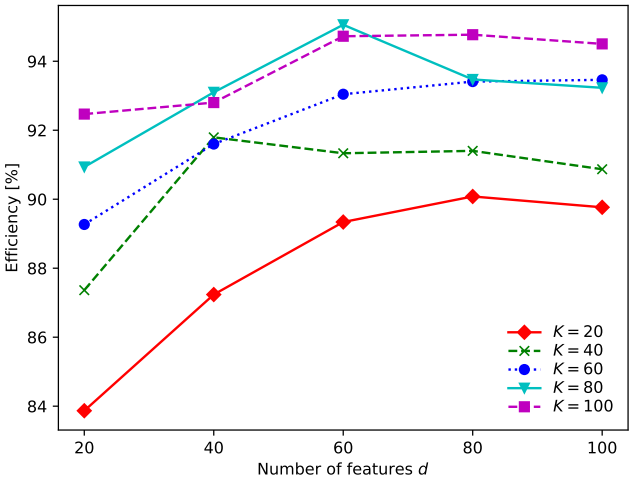

Fig. 3. Parallel efficiency of the EM-L3-blocking variant of the EM algorithm.

VI. Conclusions and future work

In the paper we described four variants of the EM algorithm. Two of them use level 2 BLAS operations while the remaining two are based on level 3 BLAS operations which can be implemented more efficiently on the contemporary hardware. We proposed a parallelization scheme for all the variants using OpenMP threads. The results of the study indicate that a combination of level 3 BLAS operations with the blocking for last level cache achieves the shortest runtime for all tested datasets. The resulting algorithm scales very well on a 24-core system.

An obvious extension our work would be a hybrid parallelization using many nodes of the cluster. In this method a parallel application could consists of processes communicating using a message-passing (e.g., MPI [12]) framework. One MPI process would be executed in each compute node of the cluster. Each process would execute in several OpenMP threads, with the number of threads equal to the number of cores in a compute node. A reduction operation in the `MStep` function would be performed hierarchically, first on the process level, then on the MPI application level. We have successfully applied this approach to multi-node parallelization of the well-known K-means algorithm [13].

***Abstract*—It was shown that block-circulant preconditioners, applied to a conjugate gradient method, used to solve structured sparse linear systems, arising from 2D or 3D elliptic problems, have very good numerical properties and a potential for good parallel efficiency. In this contribution, hybrid parallelization based on MPI and OpenMP standards is experimentally investigated. Specifically, the aim of this work is to analyze parallel performance of the implemented algorithms on a supercomputer consisting of Intel Xeon processors and Intel Xeon Phi coprocessors. While obtained results confirm the positive outlook of the proposed approach, important open issues are also identified.**

I. Introduction

IN THIS contribution, we are concerned with the numerical solution of linear boundary value problems of an elliptic type. After discretization, such problems are reduced to finding the solution of a linear systems in the form $A\mathbf{x} = \mathbf{b}$. In what follows, symmetric and positive definite problems are considered. Moreover, it is assumed that A is a large matrix. Obviously, the term “large” is relative, as what was large in the past, is no longer large. Therefore, it is assumed that the size of the linear system (matrix) is defined as large, in the context of capabilities of currently existing computers.

In practice, large problems of this class are often solved by iterative methods, such as the conjugate gradient (CG) method. At each step of such methods, a single product of A with a given vector $\mathbf{v}$ is needed. Therefore, to minimize number of arithmetic operations, the sparsity of the matrix A should be explored. On the other hand, exploration of sparsity may be in conflict with parallelization (for large number of processors and cores) of the iterative process.

Typically, the rate of convergence of CG methods depends on the condition number $\kappa(A)$ of the coefficient matrix A. Specifically, the smaller $\kappa(A)$ is, the faster the convergence. Unfortunately, for elliptic problems of second order, usually, $\kappa(A) = \mathcal{O}(n^2)$, where n is the number of mesh points in each coordinate direction. Hence, conditioning of the matrix grows rapidly (gets worse) with n. To accelerate the convergence of the iterative process, a preconditioner M is applied within the CG algorithm. The theory of the Preconditioned CG (PCG) methods says that M is a good preconditioner if it significantly reduces the condition number $\kappa(M^{-1}A)$ and, at the same time, if it allows one to efficiently compute the product $M^{-1}\mathbf{v}$, for a given vector $\mathbf{v}$. The third important aspect should be considered, namely, the need for efficient implementation of the PCG algorithm on modern parallel computer systems, see e.g. [1], [2]. Here, again, the question can be raised, what does it mean “modern” as the practical meaning of this term evolves. Establishing how the problem should be approached on a computer current to the time of conducted research is one of the issues that inspired this work.

II. The 3D elliptic problem

Let us now consider the following 3D elliptic problem:

$$-\frac{\partial}{\partial x_1}\left(k_1\frac{\partial u}{\partial x_1}\right)-\frac{\partial}{\partial x_2}\left(k_2\frac{\partial u}{\partial x_2}\right)-\frac{\partial}{\partial x_3}\left(k_3\frac{\partial u}{\partial x_3}\right)= f(x_1,x_2,x_3), \qquad \forall(x_1,x_2,x_3)\in\Omega, \tag{1}$$

$$0<\sigma_{\min}\le k_1(x_1,x_2,x_3), \quad k_2(x_1,x_2,x_3), \quad k_3(x_1,x_2,x_3)\le\sigma_{\max},$$

$$u(x_1,x_2,x_3)=0, \qquad \forall(x_1,x_2,x_3)\in\Gamma=\partial\Omega,$$

to be solved on the unit cube $[0,1]^3$. Let the domain be discretized by a uniform grid with n grid points in each coordinate direction.

A. Finite Difference Method

Let us consider the usual seven-point centered difference approximation for problem (1). This discretization leads to a system of linear algebraic equations

$$A\mathbf{x}=\mathbf{b}$$

where the vector of unknowns $\mathbf{x}$ has size n^3. If the grid points are ordered along the x_3 and x_2 directions first, the resulting matrix A admits a standard block-tridiagonal structure. Here, the diagonal blocks are block-tridiagonal matrices, while the off-diagonal blocks are diagonal matrices. Overall, the matrix A can be written in the following form

$$A = tridiag(A_{i,i-1}, A_{i,i}, A_{i,i+1}) \qquad i = 1, 2, \ldots, n,$$

where $A_{i,i}$ are block-tridiagonal matrices which corresponds to one x_1-plane. For details see [3], [4], [5], [6].

III. Circulant Block-Factorization Preconditioning

Let us recall that a circulant matrix C has the form $(C_{k,j}) = \left(c_{(j-k) \bmod m}\right)$, where m is the size of C. Moreover, for any given coefficients $(c_0, c_1, \ldots, c_{m-1})$, let us denote by $C = (c_0, c_1, \ldots, c_{m-1})$ the circulant matrix

$$\begin{bmatrix} c_0 & c_1 & c_2 & \cdots & c_{m-1} \\ c_{m-1} & c_0 & c_1 & \cdots & c_{m-2} \\ \vdots & \vdots & \vdots & & \vdots \\ c_1 & c_2 & \cdots & c_{m-1} & c_0 \end{bmatrix}.$$

Any circulant matrix can be factorized as

$$C = F \Lambda F^*,$$

where Λ is a diagonal matrix containing the eigenvalues of C, F is the Fourier matrix

$$F = \frac{1}{\sqrt{m}} \left\{ e^{2\pi \frac{jk}{m} \mathbf{i}} \right\}_{0 \le j,k \le m-1}$$

and $F^* = \overline{F}^T$ denotes adjoint matrix of F. Here, $\mathbf{i}$ stands for the imaginary unit.

Let us now denote the general form of the CBF preconditioning matrix M, for the matrix A, by

$$M_{CBF} = tridiag(C_{i,i-1}, C_{i,i}, C_{i,i+1}) \qquad i = 1, 2, \ldots n$$

Here, $C_{i,j} = Block - Circulant(A_{i,j})$ is block-circulant approximation of the corresponding block $A_{i,j}$ [3], [4]. Note that the approach to defining block-circulant approximations can be interpreted as simultaneous averaging of the matrix coefficients, and changing the Dirichlet boundary conditions to the periodic ones.

Each PCG iteration consists of one solution of the linear system with the preconditioner. The CBF preconditioner can be written in the form

$$M_{CBF} = (I \otimes F \otimes F)(\Lambda \otimes I \otimes I)(I \otimes F^* \otimes F^*)$$

and the solution of the linear system with M_{CBF} requires one forward 2D Discrete Fourier Transform (DFT), solution of the tridiagonal linear systems, and one backward 2D DFT.

The details of the sequential and parallel realizations, of the CBF preconditioner, have been described in [5], [6], which should be consulted for the remaining details.

IV. Numerical Tests – Experimental Setup

Conducted experiments have been selected to illustrate the convergence rate, as well as the parallel performance of the developed algorithms for the 3D elliptic problems. Specifically, test problems, with variable coefficients in the form

$$\begin{aligned} \frac{\partial}{\partial x_1}\left[\left(1 + \frac{\epsilon}{2}\sin\left(2\pi\left(x_1 + x_3\right)\right)\right)\frac{\partial u}{\partial x_1}\right] &\quad + \qquad (2) \\ \frac{\partial}{\partial x_2}\left[\left(1 + \frac{\epsilon}{2}\sin\left(2\pi\left(x_1 + x_2\right)\right)\right)\frac{\partial u}{\partial x_2}\right] &\quad + \\ \frac{\partial}{\partial x_3}\left[\left(1 + \epsilon e^{x_1 + x_2 + x_3}\right)\frac{\partial u}{\partial x_3}\right] &\quad = \quad f\left(x_1, x_2, x_3\right) \end{aligned}$$

where $\epsilon \in [0, 1]$ is a parameter have been considered. It is well known that the circulant preconditioners are competitive with the incomplete LU factorization for moderately varying coefficients. This reflects the averaging of the coefficients, used in the block-circulant approximations.

The right hand side f, is chosen in such a way that the problem (2) has solution

$$u\left(x_1, x_2, x_3\right) = \sin 2\pi x_1 \sin 2\pi x_2 \sin 2\pi x_3.$$

All computations are done in double precision. The standard iteration stopping criterion is $||\mathbf{r}^{N_{it}}||_{M^{-1}} / ||\mathbf{r}^0||_{M^{-1}} < 10^{-6}$, where $\mathbf{r}^j$ stands for the residual at the jth iteration step of the preconditioned conjugate gradient method. The code has been implemented in C. For the implementation of the preconditioning, Fast Fourier Transform (FFT) was used, and functions fftw_init_threads, fftw_plan_with_nthreads, fftw_plan_many_dft, and fftw_execute from the FFTW (the Fastest Fourier Transform in the West) library were used. A hybrid parallel code, based on joint application of MPI and OpenMP-based parallelizations has been developed [7], [8], [9], [10], [11].

In this contribution, the parallel code has been tested on cluster computer system Avitohol, at the Advanced Computing and Data Centre of the Institute of Information and Communication Technologies of the Bulgarian Academy of Sciences. The Avitohol consists of HP Cluster Platform SL250S GEN8. It has 150 servers, and two 8-core Intel Xeon E5-2650 v2 8C processors and two Intel Xeon Phi 7120P coprocessors per node. Each processor runs at 2.6 GHz. Processors within each node share 64 GB of memory. Each Intel Xeon Phi has 61 cores, runs at 1.238 GHz, and has 16 GB of memory. Nodes are interconnected with a high-speed InfiniBand FDR network (see, also http://www.hpc.acad.bg/).

For the experiments, Intel C compiler has been used and the code was compiled using the following options: "-O3 -qopenmp -L$(MKLROOT)/lib/intel64 -lmkl_intel_lp64 -lmkl_intel_thread -lmkl_core -lpthread -lmkl_rt -lm" for the processors, and "-O3 -qopenmp -mmic -L$(MKLROOT)/lib/mic -lmkl_intel_lp64 -lmkl_intel_thread -lmkl_core -lpthread -lmkl_rt -lm" for the coprocessors. Intel MPI was used to execute the code on the Avitohol computer system.

V. EXPERIMENTAL RESULTS AND ANALYSIS

The first series of experiments established the "baseline" performance. In Tables I and II results obtained using processors of a single node of Avitohol are presented. Table I shows the used memory, the number of iterations, the maximal error of the obtained solution, and the total execution time. The results have been obtained using only shared memory parallelism: i.e. there was one MPI process and up to 32 OpenMP threads.

The first observation concerns memory use. For n increasing from 120 to 720, memory consumption grows from 707 Mb to 52542 Mb. This means that the limit of size of the problem that can be solved on a single node has been reached. This was checked experimentally, and increasing n to 840 resulted in an "out of memory" error.

Second, let us note that for $n = 120$ there is no performance gain with the number of used threads. Clearly, problem is too small. However, for $n = 720$ speedup of order of 5 has been reached for 16 threads. This was also the "best result". Moving to 32 threads resulted in speedup decreasing to approximately 3. Interestingly, almost no performance improvement was observed when moving form 1 to 2 threads.

Approaching the performance from the"completely opposite" perspective, Table II shows the execution time when using only distributed memory parallelism; i.e. one OpenMP thread and up to 32 MPI processes. It should be noted that in the current (prototype) implementation, the algorithm works correctly only if the number of mesh points in each coordinate direction (n) is divisible by the number of processes. In the Table, the best execution time, for each size of the problem, is marked in bold.

It is easy to note that, for $n = 120, 240, \ldots 720$ the algorithm works much faster when using only MPI parallelism and utilizing multiple threads (in comparison to using OpenMP based multi-threading). For the largest case ($n = 720$), the solver that is using MPI and 30 threads is more than 2 times faster than using OpenMP and 16 threads (the fastest result from Table I). Overall, for the smallest problem ($n = 120$) the fastest execution is obtained when using 15 MPI processes. For bigger problems, on the other hand, the best results have been reached when using 30 processes.

TABLE II
EXECUTION TIME (IN SECONDS) FOR THE EXECUTION OF THE PARALLEL ALGORITHM ON ONE NODE USING ONE OPENMP THREAD.

n	processes			
	15	16	30	32
120	**1.68**		2.07	
240	26.02	24.50	**19.66**	
360	167.61		**83.46**	
480	532.95	589.49	**286.14**	306.16
600	1200.36		**709.44**	
720	2535.59	2385.89	**1834.67**	

The second series of experiments concerned use of individual processors. Specifically, Table III shows the execution time when using only processors from multiple nodes (from 2 to 8). Here, results for 1 OpenMP thread, as well as 16 and 32 threads are reported. Note that, results for $n = 960$ are also reported. This was possible due to the fact that the problem was "split" into at least two nodes and, therefore, it "fit in" (did not generate out of memory errors). Again, the best execution time, for each problem size, is marked in bold.

The algorithm runs the fastest when using 16 threads in just few cases, i.e. for $n = 120$ on 3 and 8 nodes, for $n = 240$ on 5 nodes, and for $n = 960$ on 2 nodes. In the remaining cases, the execution using one thread is the fastest. Considering the largest case ($n = 960$), for a single OpenMP thread, speedup of order 6 can be observed when moving from 2 to 8 nodes. Moreover, when comparing results with those reported in Table II, for $n = 720$, the best result on 8 nodes is more than 6 times faster.

In the next series of experiments, the performance of the co-processors has been evaluated [12]. Specifically, Tables IV and V present times collected on the Avitohol using only Intel Xeon Phi co-processors (processors have not been used for solving the computational problem). Here, Table IV shows the execution time on one co-processor for $n = 120, 240, 360$. Again, the best execution time is marked in bold.

Here, the positive effect of combining OpenMP and MPI based parallelism can be observed. For the largest problem that fit in the memory of the co-processor ($n = 320$), use of 4 OpenMP threads improved the performance by more than 4 times. This could be interpreted as a case of super-linear speedup. However, delving into this point is out of scope of this contribution.

Next, Table V presents execution times obtained when solving the problem on co-processors (only), but using up to 8 nodes. Note that, since the code is a prototype, case of 7 nodes had to be excluded. Here, again, it was possible, for

larger number of nodes, to solve the problem for $n = 960$. In the Table, the best execution time is marked in bold.

It can be seen that the algorithm runs faster using 2 threads for $n = 120$ and 4 threads for $n = 240, 360$. In this context, it should be recalled that the memory of one co-processor is only 16 GB. This memory limit is the reason that the code could have been run only for small size problems. In particular, for problems with $n = 480$ at least 2 co-processors were needed, while for $n = 960$ the code could have been executed starting from 12 co-processors.

In the final series of experiments, processors and co-processors have been jointly used. Specifically, Table VI shows the best execution times collected on the Avitohol using Intel Xeon processors working together with the Intel Xeon Phi co-processors. Here, the code was executed using: on processors — p_c MPI processes and every process runs q_c OpenMP threads; on co-processors — p_m MPI processes and every process runs q_m OpenMP threads. In each case, the optimal combination of the number of MPI processes and the number of threads has been used. These combinations have been established experimentally. The memory limitation resulted in not being able to run experiments, for $n = 960$, for less than 3 nodes. For the reasons explained above, there are no results for 7 nodes.

As can be seen, due to the, above stated, memory limitations on co-processors, the largest problem size $n = 960$ required at least 3 nodes to be solved. Considering problem of size $n = 720$, use of 8 nodes turned out to be ineffective, as solution time increased, as compared to the use of 6 nodes. For 6 nodes an almost perfect speedup (larger than 5), has been obtained. Interestingly, for all problem sizes, use of 8 nodes resulted in performance that was inferior to 6 nodes. We do not have an explanation of this fact, other than possibility that in this case operations not related to the solution of the problem had to run “somewhere” and their execution interfered with execution of the solver. For the largest problem, when comparing the performance obtained on 3 and on 6 nodes, a speedup of almost 6 was recorded. This shows that if ample resources are provided, the proposed approach behaves as expected and parallelizes well, when applying hybrid approach to algorithm parallelization.

To better visualize the relationship between execution times, they have been visualized also in Figure 1. Here, the execution time of the hybrid code, on up to 8 nodes for

960	64	1	56	34	5230.96	96	1	96	30	3630.39	16	16	16	244	3725.99

$n = 240, 480, 960$, for CPU-only, co-processor only and when both CPU and co-processor were used. For each of these cases, results are represented using the same color and marking.

It can be seen that use of multiple nodes allows one to solve large problems. Nevertheless, the speedup, resulting from adding nodes is not overwhelming.

VI. CONCLUDING REMARKS

The aim of this contribution was to experimentally explore relationship between (1) 3D elliptic solver, based on preconditioned conjugate gradient, (2) its hybrid parallelization consisting of applying shared memory OpenMP threads and distributed memory MPI approach, and (3) complex supercomputer architecture, based on nodes, processors and co-processors. It has been established that memory availability is one of the key issues that strongly influences parallel performance. In this context it is difficult to apply standard performance measures, such as speedup, since largest problems require large number of nodes to be executed. However, even if a code can be executed on different number of nodes, adding more nodes may not result in performance gains. There is a "sweet spot" where the problem is executed the fastest and adding more resources does not help. This also means that potential for standard speedup is somewhat limited.

All these observations can be linked to complex interplay between hybrid parallelization and hybrid computer architecture. This may be also a warning sign that potential gains from hybrid approaches may be outweighed by losses caused by complexity of interactions between various "components".

***Abstract*—While straightforward machine translation got significant improvements in the last 10 years with the arrival of encoder-decoder neural networks and transformers architecture, controllable machine translation still remains a difficult task, which requires lots of research. Existing methods like tagging provide very limited control over model results or they require to support multiple models at once, like domain fine-tuning approach.**

In this paper, we propose a method to control translation results style by transferring features from a set of texts with target structure and wording. Our solution consists of new modifications for the encoder-decoder networks, where we can add feature descriptors to each token embedding to decode input text into the translation with the proposed domain. In conducted experiments with English-Ukrainian translation and a set of 4 domains our proposed model gives more options to influence the result than some existing approaches to solve the controllability model.

***Index Terms*— Machine Translation, Controllability, NLG, Style Transfer.**

I. Introduction

LAST 10 years became very prolific for machine translation solutions as they finally achieved quality, which can be compared to a human processed results in many cases. The first significant step was the usage of recurrent encoder-decoder models, however, they were significantly overperformed by new attention-based transformer networks [1], which compare each part of the input sequence to multiple parts of input simultaneously. Their architecture allowed to reduce training time and made parallelization of the process easier compared to RNNs as they always need the n-1 state to compute the nth one. Pretrained models like mBART[2] gave the ability to capture low-resource languages much better than ever before.

However, these models usually do not give any methods to influence their results. We can get multiple options out of them or interpret their decisions by using SHAP [3] and similar frameworks, but we can't easily change the way these decisions are made. The easiest way to modify model behavior would be to finetune it using a small specialized corpus, but we need to support a whole model zoo for each separate domain or style to implement this approach, which can become expensive and difficult to manage.

The cheapest method to change at least some words in translation would be by applying usage dictionaries and finding another possible translation for a certain word or phrase, which could correspond better. This method will not allow us to modify translation according to a certain external context, we would just search for another option among popular ones.

Another approach proposes adding tags with style or other necessary features to influence the model. It should work well with both recurrent and bidirectional encoders as such tags are usually added at the beginning of the text, so their embeddings can further influence every step of translation generation [4]. This solution is not flexible enough as we can't encode all necessary features into a set of special markers and we do not know how the model will act if we change their order. Also, even a slight change in this marking would require us to completely retrain the model, which would be time-consuming and expensive.

Some new papers propose concatenating vectors with certain features like length, sentiment, officialness, or politeness to text embedding. However, we need to mark each translation with necessary feature values before training and any change in this marking or addition of a new feature would require a full-on retraining of such a model.

Modern generative models like GPT3 [5] and its next versions can conduct translation once they are given some examples even if they were not originally trained specifically for any other language than English. They still can generate some transliterations instead of translations or confuse related languages. Such models can be controlled via prompts, so we can try to add some statements like "make it more serious" to change the features of the translation. So in order to control such a model we need to pass some examples of the desired behavior and know the desired result to some extent.

In this research, we present an architecture based on transformer encoder-decoder models, which should conduct style transfer of a certain domain during translation by concatenating token embeddings with a text descriptor vector before decoding embeddings into the target translation. We provide explanations for this approach, comparisons with other available methods by both token and embedding metrics, and example translations generated by the proposed model.

II. *Datasets*

As our main aim was to increase machine translation models controllability by using transfer learning techniques we needed to gather some domain-specific and datasets, which contain texts of a certain style and structure. Styles should be distinct to enrich the model with knowledge in as many different types of texts as possible. We prepared 4 small specialized datasets with English-Ukrainian pairs with the following styles:

- general texts, which contain photo descriptions from the Multi30k dataset [6], which was translated by our team, and the results were presented in our previous paper;
- official texts, which consist of laws translations gathered from the Verkhovna Rada of Ukraine website [7];
- scientific texts use abstracts from Ukrainian papers gathered from Google Scholar service;
- programming documentation sentences, which were gathered from the official Vue framework website.

More information on these datasets is available in our previous papers. They describe mining, transformations, and cleaning for those specialized corpora.

We targeted sentence granularity for all text pairs, however, pairs in some domains contain one compound Ukrainian sentence and some simple English corresponding ones. Such behavior was spotted mostly in the scientific domain (abstracts from Ukrainian papers). We left them as they were written without splitting them. Other pairs with multiple sentences, which could be split into multiple ones, were transformed into 2 or more pairs of sentences.

Another large set of texts we used was gathered from multiple OPUS corpora [8]. They contain book reviews, subtitles, TED talk transcriptions, etc. They contain lots of messy data, which can even harm the model performance. As an example, there are a lot of texts with incorrect translations or translations, which can be understood only in a full original text context. Some texts contain some scrapping leftovers like tags or links. Many entries propose translations not in Ukrainian but in other similar languages, but it can be useful to learn some similar grammar or words, especially when the target language is a low-resource one. Another group of task is NER in low-resource languages [9].

There are around 60 million text pairs for the English-Ukrainian language set in OPUS, but we used only 2,247,528 texts. Cases like links or tags were cleaned using Python libraries, but we still needed to clean some incorrect translations. We could not check even this small chunk of OPUS manually, so we needed to automatize meaning comparisons of original and translated texts. Siamese XLM-R [10] for the semantic search was used to accomplish this as it supports both English and Ukrainian. We encoded each text into a vector with 512 elements and calculated the cosine similarity to its Ukrainian counterpart. The model was initialized from the **distiluse-base-multilingual-cased-v2** [11] checkpoint from the huggingface hub. This checkpoint was trained by using the Knowledge Distillation method. After checking multiple pairs and their cosine similarities we decided to use 0.4 as a threshold value. Pairs, which have lower similarity scores, are considered to be incorrect.

Some examples which have a value lower than 0.4 were examined. Most of them were really bad translations or missed some crucial part of the original text to understand why they should be translated this way. However, one corpus had lots of phraseologies, which were scored as errors by the XLM-R model as it tried to understand them in their literal sense. As an example, the phrase "murder will out" was translated as "правда вспливе". This is a correct translation, but the score is less than 0.4 as the model does not understand figurative sense. Such cases were not deleted from datasets and were used during model training as such cases can be really useful and hard to learn correctly.

The removal of texts with only links, tags, or empty lines and the removal of incorrect pairs reduced the dataset from 2,247,529 texts to 1,642,849 ones. Table 1 shows the number of pairs in each corpus and assigns a certain domain to each one except OPUS sets.

It is worth noting that OPUS corpora were used only in one step of the conducted experiment. Other specialized sets were used at each step of the experiment. Also, we split 25% of gathered specialized corpora into a test subset, which contains 9,625 text pairs with all 4 mentioned domains.

III. *Proposed Solution*

We propose a further development of the previously mentioned technique with the concatenation of the vector of target features to the input text tokens embeddings. As it was described before this method used vectors with a fixed set of features like length, sentiment, etc. We propose to use semantic descriptors of text, which can be combined with de-

TABLE I.
DATASETS OVERVIEW

Dataset name	Domain	Number of text pairs
Subset of OPUS corpora	-	1 642 849
Laws translations from Verkhovna Rada of Ukraine website	Official	4 000
Scientific articles abstracts from Google Scholar	Scientific	2 000
Vue framework documentation	Documen tation	2 500
Photo descriptions from Multi30k	General	30 000
Total	**-**	**1 681 349**

scriptors of domains to conduct style transfer from a certain domain to the input text translation.

Architecture would use a pretrained encoder and decoder and all the changes would happen after the creation of token embeddings and before their decoding into the target language translation. This way we can use an already established model as a foundation for our new solution instead of training the MT model from scratch, which would require millions of text pairs, lots of computational resources, and time.

Semantic descriptors of texts can be obtained from an external pretrained model trained for semantic search task. It would return a vector descriptor of the input text, which would allow us to place it into a certain embedding space and compare input to other texts the model has previously seen. Similarity to other texts can point the model towards the usage of certain words and styles as it can find suitable examples of target translations in this embedding space. It means that the descriptor does not carry any information about the style or features of translation output, but it shows the model text pairs which can be used as examples of necessary behavior as their descriptors are similar to the input descriptor. Fig. 1 shows 2D projections of semantic descriptors obtained from the semantic search model (in this case it was siamese BERT).

X and Y here are values generated by TSNE to reduce vectors from 384 elements to just 2, which we can easily visualize as a scatterplot. Texts from all 4 domains form multiple clusters and even subclusters based on their meaning, usage of words, sentiment, and tone. That is exactly what we need as further we can point the model toward one of these subclusters to gather translation features out of it and pass them to the decoder.

We need not only the input text descriptor to control the translation process but also domain descriptors. We will consider the average vector descriptor of all texts in a certain domain as a descriptor of this domain. In the next formula, we show the calculation of each element of the domain descriptor.

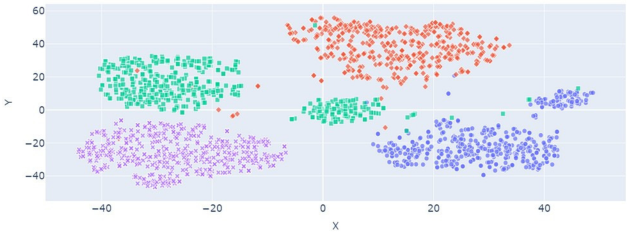

Fig 1. 2D projections of text semantic embeddings

$$V_{mean\,domain_j} = \frac{\sum_{i=0}^{N} V_{i,j}}{N} \quad (1)$$

So in this approach, we need to combine original text descriptor and this domain descriptor. We propose to do it by conducting a linear combination of the original text descriptor and vector of difference between text and domain. It is shown in the following formula, where is a transformation power coefficient, $V_{original}$ is an embedding vector of original input text, $V_{mean\,domain}$ is a mean embedding vector of texts in certain domain and descriptor is the final vector, which provides context on the way the text should be translated:

$$difference = V_{original} - V_{mean\,domain} \quad (2)$$

$$descriptor = V_{original} - \alpha * difference \quad (3)$$

Our hypothesis is that usage of semantic search embeddings should provide more control over the way the encoder-decoder model translates a text by showing it the desired domain and putting the text among ones with similar features. The transformation power $coefficient\,\alpha$ should indicate the power of changes, which we want to make and how much should descriptor be shifted into a certain embedding subspace.

However, the concatenation of the vector to each row of the token embeddings matrix will change its form. Let's say that matrix of token embeddings has the form NxM, where N is the number of tokens and M is the dimensionality of the embedding. Let's mark the size of the semantic descriptor as K. After concatenation our token embedding matrix will have the form Nx(M+K). Such a matrix would be impossible to pass into the original decoder as it still expects just an NxM matrix. We either need to create our own decoder and train it from scratch or create a dimension reduction layer, which would reduce the new concatenated matrix to its original size, so we can use a pretrained decoder. However, even the second option still requires some tuning as we add a new raw layer, which will make values in the matrix different from the initial ones. We would lose the connection between the encoder and decoder, so it has to be restored by tuning a new dimension reduction layer, so it would make new em-

Reduced matrix with size NxM
Pretrained machine translation model decoder

Fig 2. Diagram of proposed machine translation model

beddings closer to the original ones and incorporate new knowledge obtained from the semantic search model.

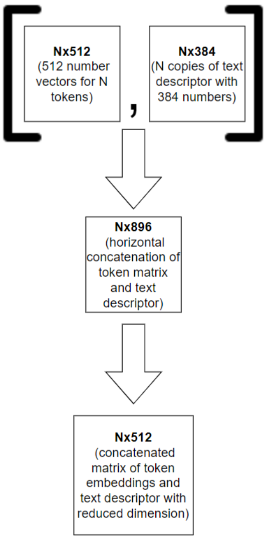
Fig. 2 shows the architecture of a proposed machine translation model with style transfer abilities.

Currently we implemented dimension reduction as a linear layer with the number of output features equal to M. We used SiLU activation with batch normalization after the linear unit. We see the usage of Variable Selection Networks as another good option for this task, which we want to explore in our further research. This layer proved its effectiveness for classification tasks and time series feature selection, so we would like to see if it preserves such quality in the case of embedding dimensionality reduction to pass only the most significant values to the decoder for each token.

We want to use transformed semantic search embeddings of texts (combined with a certain domain embedding) concatenated to each token embedding as an additional mapping to give the decoder a hint of the necessary translation style, words domain, and tone, which we want to get. These vectors will not carry the style features themselves and they will not be hardcoded in there with a certain allowed range like in other similar approaches. They should be generated by an external model and linearly combined with a domain descriptor vector to shift features into the necessary cluster and make the overall vector closer to the texts with the desired style in the feature space. Semantic embeddings should only point toward texts with a translation style similar to the one we would like to achieve.

This way we can use any pretrained encoder-decoder machine translation model as a foundation for this architecture. Then we need to choose an external model to obtain sentence embeddings for texts and add a concatenation step for each row of the token embedding matrix to add values from sentence embedding at the end of each row. The final modification step would be to add a dimensionality reduction layer, which would restore the original dimension of token matrix rows, so we can use the original pretrained decoder. This process is shown in Fig.3 with an example where we have 512 feature embeddings for tokens and 384 number sentence embeddings.

The modified model will still need some fit as a new layer will not be trained at all, which would cause wrong translations due to the decoder getting previously unseen values. The only change for the train and validation datasets would be the need to calculate sentence embeddings.



Nx512
(512 number vectors for N tokens)
,
Nx384
(N copies of text descriptor with 384 numbers)
Nx896
(horizontal concatenation of token matrix and text descriptor)
Nx512
(concatenated matrix of token embeddings and text descriptor with reduced dimension)

Fig 3. Semantic search embeddings injection process

The perfect case for this architecture would be to transfer style from a single provided example, but we should check this hypothesis. The primary use case would still be to combine text and domain descriptors to modify translation generation.

IV. *Metrics*

We use both token and embedding metrics in this research to measure the performance of obtained solutions. BLEU [12] was chosen as a default machine translation token metric and METEOR [13] was chosen as it works better with morphologically rich target languages due to the usage of stemming and synonyms dictionaries during scoring.

As for the embedding metrics we decided to use BERT Score [14] as it proposes a method to measure text generation quality by measuring semantic similarities of token embeddings obtained from the BERT model. So this way we would be able to compare texts by both their structure using token metrics and meanings by embeddings.

Generated examples of controllable translation [15] should be scored as well, however, we do not have references for all possible modifications of final translations, so mentioned token and embedding metrics will not have any chance to measure the quality of results as they need benchmarks in the target language. We will use a siamese XLM-R trained for multilingual semantic search to measure cosine similarity of original English text to each new generated Ukrainian translation. We will use a siamese XLM-R trained for multilingual semantic search to measure cosine similarity of original English text to each new generated Ukrainian translation. Model will be initialized from clip-ViT-B-32-

multilingual-v1 [11] checkpoint, because it was trained to replicate image domain embeddings, which should be useful for model, so it can gather knowledge not only from text information but also from pictures.

V. *Model Zoo*

Our main model for experiments will be MarianMT [16] pretrained for English-Ukrainian translation by Helsinki University on OPUS corpora. We used implementation from huggingface transformers library, which uses the BART interface. The model has 6 layers bidirectional encoder, like in BERT models, and 6 layers autoregressive decoder, like in GPT models. In this research we use this model with the following modifications to achieve controllability:

1. MarianMT fine-tuned with a small specialized corpus to capture its style, structure, and common words. We create a separate version of the model for each domain;

2. MarianMT tuned with all gathered specialized corpora to check how cross-domain knowledge can help the model learn the language better and if it still would be able to distinguish styles;

3. MarianMT with the addition of a special token-marker of necessary style at the beginning of the input text without fine-tuning (for example: "[official] Ukraine is a sovereign and independent, democratic, social, law-based state");

4. MarianMT with the addition of a special token-marker of necessary style at the beginning of the input text tuned on full specialized corpora to use all the advantages of bidirectional encoding and autoregressive decoding to better distinguish provided domains;

5. MarianMT modified with our proposed solution (concatenation of text-descriptor on each token embedding and dimensionality reduction for the obtained matrix to pass it into the original decoder). As it was mentioned before we would need to train the dimensionality reduction layer to restore the connection between the original encoder and decoder, so that is where we are going to use cleaned OPUS corpora. We will train this model using both our specialized datasets and OPUS data.

So we train variants 1, 2, and 4 only on 4 small specialized datasets. Version 3 will not be fine-tuned at all and version 5 gets trained with both OPUS and our datasets, as it needs to teach a new layer from scratch and learn how to use text descriptors for domain adaptation. We train each model with a fixed budget of 36 hours on Nvidia T4 GPU and then compare them by whole test dataset results and on separate domains in it to measure the controllability of obtained solutions.

Text descriptors will be gathered from siamese BERT for semantic search initialized from all-MiniLM-L6-v2 [17] checkpoint trained by the sentence-transformers team. It returns vectors with 384 elements, while MarianMT encodes each token in a vector with 512 elements. So after the concatenation of the token and text descriptor, we will have vectors with 896 elements. It means that the dimensionality reduction layer should reduce the size from 896 back to 512 elements, so we can pass the results to the original, pretrained decoder.

VI. *Experiments. Comparing models on full test dataset*

First of all we will train separate models for each domain and one, which would receive all gathered, specialized corpora. All these models should be scored on the full version of the test dataset. Table 2 shows the results of the training.

The best score on full test dataset was achieved with the model, which got all specialized corpora, which is expected as this model saw every style features. The second place is occupied by the model, which was trained with official texts (laws translation), which can be explained by the difficulty of this specific domain. Sentences there contain a lot of specific, uncommon words and phrases or even common words with new senses. The structure is strict and differs significantly from other styles.

We expected higher results from the scientific domain as it can also provide some unique knowledge to a model, which would not be possible to retrieve from other groups of texts. However, it gets lower scores in all 3 metrics than the official domain model. As we mentioned earlier this domain contains some difficult cases, where English text consists of multiple simple sentences and its Ukrainian counterpart has just one big compound sentence. It can confuse the model and also makes it difficult to calculate token metrics correctly.

Table II.
Separate models for each domain

№	Model variant	BLEU	METE OR	BERT F1 Score
1	Original OPUS MT MarianMT	11.20	0.2807	0.8115
2	MarianMT tuned with general texts	12.70	0.3034	0.8380
3	MarianMT tuned with official texts	25.34	0.3861	0.8630
4	MarianMT tuned with scientific texts	18.80	0.3347	0.8448
5	**MarianMT tuned with all special corpora**	**34.16**	**0.4754**	**0.8983**

Original OPUS MT MarianMT and version tuned with general texts have the lowest and quite similar scores. Photo descriptions from Multi30k did not give any new insights as they mostly consist of simple sentences with just a subject, an action, and sometimes a brief description of the environment. It does not differ from the original OPUS corpora, which contain lots of general domain texts too.

The next step is to check how a special token marker would affect the model performance. Table 3 shows scores for the model, which gets such markers without any fine-tuning, and for the fine-tuned version, where each text is marked with a style tag.

Special token without any fine-tuning does not give any significant boost to the original model scores and even makes the BERT Score worse. However, a tuned version of MarianMT, which learned how to use such tokens, overperforms even the previous best result obtained with MarianMT tuned with all specialized corpora without any tags. As we said before this special tag can influence every other token embedding and the decoder behavior due to their bidirectional and autoregressive natures respectively. The model distinguishes styles better and still learns information from all of them simultaneously.

The final step would be to teach our proposed model. We were able to teach it for 5 epochs with our set budget. Fig. 4 shows the metrics plot for each epoch and compares them to the previous best solution (MarianMT tuned with all specialized corpora with style tags).

We scaled BLEU to the 0-1 range in this plot to place all plots in the same subspace. The model completely loses the ability to translate after modification of the addition of concatenation with semantic descriptor and dimensionality reduction layer. The new embedding matrix has the same shape as the original one, but the values are not matched with what the decoder was getting earlier. Token metrics show it really well as they become almost equal to 0. However, BERT Score still gives average scores, which can be a huge misdirect if we do not calculate token metrics simultaneously. The model just generates random Ukrainian texts without any connection to the original English one. For example, our input is “Laws have been around for over 4000 years”. Generated translation without any fine-tuning was “Це означає, що ми маємо право вирішувати, що робити, а що ні.”. The model completely lost the ability to translate and embedding metrics were not able to capture it properly. The results of this experiment proved that BERT Score can not be used as a single metric to measure translation quality as it should be accompanied by some classic token approaches. It can be explained by the usage of multilingual BERT as an encoding model, as we compared it to other models for the Ukrainian language in previous papers. It completely loses to ones like XLM-R, so the default implementation of the BERT Score does not work well as a benchmark for Ukrainian language text generation tasks.

Table III.
Special token-marker models

№	Model variant	BLEU	METEOR	BERT F1 Score
1	Original OPUS MT MarianMT	11.20	0.2807	0.8115
2	MarianMT tuned with all special corpora	34.16	0.4754	0.8983
3	MarianMT with special token without tuning	11.72	0.3086	0.8085
4	**MarianMT with special token tuned**	**37.08**	**0.4923**	**0.9019**

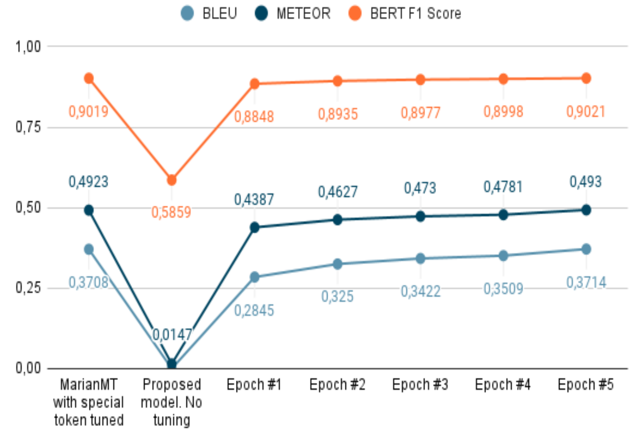


Fig 4. Training plot of proposed model

5 epochs of training with both OPUS corpora and our specialized sets were enough to restore the connection between the encoder and decoder of MarianMT and incorporate new knowledge obtained from semantic embedding space. Our model was able to overcome the previous best results scored with MarianMT tuned on all specialized corpora with special tokens. It achieved BLEU equal to 37.14, METEOR 0.4930, and BERT F1 Score 0.9021 on the full test dataset.

This first part of the experiment proves that our model can generate translations on the same level as some established controllable translation solutions. Now we need to check models on different domains included in the test set to check how all models distinguish different styles and to check if our model is able to beat separate specialized models for each domain.

VII. *Experiments. Measuring controllability*

We measured each metric for 3 domains individually for each model to compare their performance and to understand how well the proposed model distinguishes domains. The desired result for our proposed model would be to perform on par with specialized models for each domain or at least get a close score. We will start with official texts. Scores can be found in Table 4.

The proposed model gives better results for all 3 metrics in comparison to all other models and most importantly it overcomes model trained only for the official style translations. It surpasses 50 by BLEU, which indicates that it is capable to provide fluent law translations. As it was said a few times before this style contains lots of difficult cases like uncommon words or strict structure of the sentence. Metrics show that model with provided semantic descriptors was able to capture these cases well enough.

Table IV.
Comparison by official texts domain

Model variant	BLEU	METE OR	BERT F1 Score
MarianMT tuned with official texts	49.48	0.6044	0.9247
MarianMT tuned with all special corpora	48.60	0.5987	0.9239
Original OPUS MT MarianMT	08.06	0.2444	0.7778
MarianMT with special token without tuning	9.10	0.2764	0.7862
MarianMT with special token tuned	51.93	0.6141	0.9285
Modified MarianMT with semantic descriptors	**53.25**	**0.6473**	**0.9303**

Measurements on general texts retain high quality too, as the proposed model still gets BLEU higher than 50. It overcomes all other models here and gives a significant boost to the translation quality. Also, it is interesting to see how a special token without tuning made results only worse for the initial model here as it was already trained to deal with general texts and here it gets an unknown entity, which only creates more errors in comparison to the target translation. Both models trained on all specialized corpora lost to the model trained only on general texts. Even style marker did not help the model distinguish other styles from image descriptions well enough to beat the specific model.

The results for general texts are represented in Table 5 (in this case image descriptions from Multi30k).

The last ones are abstracts from scientific articles. Results are represented in Table 6.

The proposed model works better than other ones for this domain too, however, the translation quality is still low. Such BLEU indicates that it still makes significant errors. METEOR and BERT Score show that probably the model still tries to replace original constructions with similar, synonymous ones. Such a decline in performance was probably provoked by the mentioned difference in the structure of English and Ukrainian counterparts. Also, it is interesting how the model tuned with all texts overcomes the one with abstracts only, which can be explained by a high diversity of abstracts in terms of their topics. Additional texts provide the model with more knowledge of some less-represented subdomains. It can be seen in Fig. 1, where a subset of scientific texts divides into 2 categories. We clustered these texts additionally and obtained 3 large clusters, which mainly can be described as articles about laws in spheres of economics and education, mechanics articles, and ones about biology and chemistry. The number of clusters was found via the silhouette method. Fig. 5 shows 2D projections of sentence embeddings of scientific texts clustered into 3 categories (where blues points are laws articles, green ones are about mechanics, and red ones are about chemistry and biology). So laws domain should help with the first

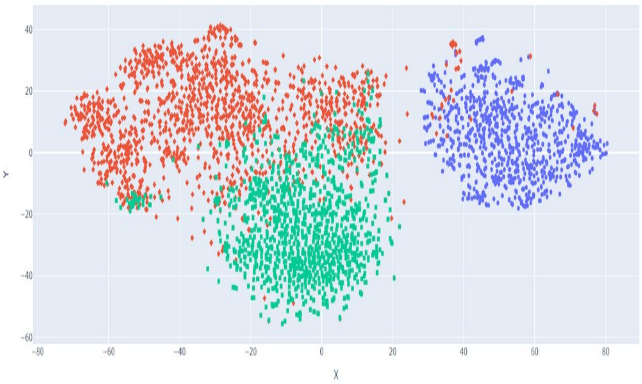

Fig 5. Scientific articles clusters

Table V.
Comparison by general texts domain

Model variant	BLEU	METE OR	BERT F1 Score
MarianMT tuned with general texts	42.40	0.4083	0.9181
MarianMT tuned with all special corpora	40.06	0.3948	0.9128
Original OPUS MT MarianMT	22.90	0.3264	0.8599
MarianMT with special token without tuning	22.022 3	0.3730	0.8428
MarianMT with special token tuned	40.89	0.4029	0.9164
Modified MarianMT with semantic descriptors	**53.46**	**0.5301**	**0.9264**

Table VI.
Comparison by scientific texts domain

Model variant	BLEU	METE OR	BERT F1 Score
MarianMT tuned with scientific texts	21.93	0.4127	0.8495
MarianMT tuned with all special corpora	23.42	0.4291	0.8548
Original OPUS MT MarianMT	10.94	0.2710	0.7956
MarianMT with special token without tuning	10.89	0.2736	0.7952
MarianMT with special token tuned	25.22	0.4523	0.8648
Modified MarianMT with semantic descriptors	**26.64**	**0.4686**	**0.8618**

TABLE VII.
EXAMPLES OF CONTROLLABLE TRANSLATION

№	Original	Translation	Modifications of text descriptor	Cosine similarity score (original to translation)
1	acquire ownership of intellectual property rights	набуття права інтелектуальної власності	Absent	0.9714
	This translation is close to the original meaning, but does not fully stick to the law language style. The issue here is that both “ownership” and “rights” can be translated as “власність” here, which would be a more correct translation. “право” and “власність” can be used as a more general style options.			
2	acquire ownership of intellectual property rights	набути право власності на інтелектуальну власність	Linear combination with official domain (=3.5)	0.9748
	Here we get “ownership” translated as “право власності”, which would be a more correct translation of this sentence according to laws terms. So model correctly used one word to translate two English ones in the same sentence and preserved the official style.			
3	I began asking the students themselves to compile multiple translations of a single poem for class presentation.	Я почала просити студентів скласти кілька перекладів одного вірша для презентації класу.	Absent	0.9810
	Just a correct translation with general style words used.			
4	I began asking the students themselves to compile multiple translations of a single poem for class presentation.	Я почав просити самих студентів скомпілювати кілька перекладів одного вірша для презентації класу.	Linear combination with a subset of a casual domain where the subject is male (=4.5)	0.9849
	Same style, but model captured the change of subject gender in provided examples and changed words forms (like “почав” instead of “почала”).			
5	I began asking the students themselves to compile multiple translations of a single poem for class presentation.	Я почав вимагати від студентів складання декількох перекладів єдиного вірша для презентації класу.	Previous modification + official domain with =3.5	0.9854
	Official style made the request “began asking” sound more as a requirement (“почав просити” became “почав вимагати”). English-like word “скомпілювати” got replaced by Ukrainian original word “складання” and the form became closer to English passive voice.			
6	In case you broke something you must pay for this	Якщо ти щось зламав, ти повинен заплатити за це	Absent	0.9812
	Just a normal translation with correct meaning			
7	In case you broke something you must pay for this	Якщо ви розбили що-небудь, ви повинні відповісти	Linear combination with official domain (=7)	0.9683
	Combination with official domain, which mostly consists of juridical documents and laws, made “pay for this” translation sound more like “carry responsibility” instead of paying money, which could be used one of more interpretations			
8	why don’t you come sit down with me?	чому б тобі не присісти зі мною?	Absent	0.9766
	Straightforward, correct translation			
9	why don’t you come sit down with me?	чому ви не приєднаєтеся до мене?	Official domain with coefficient 5.5	0.9137
	“you” gets translated as a more formal address and the sentence gets interpreted as “why don’t you join me”, which could be one of the possible translations depending on a larger context			
10	Do you want to hear a dirty joke? Ok. A white horse fell in the mud.	Ви хочете почути брудний жарт? Гаразд. Білий кінь впав у грязюку.	Absent	0.9692
	-			
11	Do you want to hear a dirty joke? Ok. A white horse fell in the mud.	Хочете почути грязну анекдоту? Гаразд. У грязюку впав білий кінь.	Old literature domain with coefficient value 4.5	0.9720
	By combining the source text with old literature we change the word “жарт” into “анекдота”, which would be an outdated way to translate “joke”. This word can still be used, but more as a joke genre name.			
12	Excuse me. Do you know the way to the zoo?	Вибачте, ви знаєте шлях до зоопарку?	Absent	0.9715
	This translation is correct and would be understood by a native Ukrainian speaker, but it copies the structure of the English source instead of adapting it.			
13	Excuse me. Do you know the way to the zoo?	Вибачте, ви знаєте, як пройти до зоопарку?	Casualness domain with coefficient 5.5	0.9702
	Here we get a more correct adaptation of “Do you know the way to the zoo” phrase, which would be a more common way to build this phrase in Ukrainian.			

cluster and technical documentation can provide more insight into terms from the second cluster, which can also be seen in Fig. 1, where a subset of scientific articles gets placed right between laws and documentation.

These measurements proved that our proposed model is able to translate 3 different domains with high quality and it distinguishes their features well by using information obtained from semantic descriptors. So these vectors can really help the model find enough examples of necessary translations among learned examples and they can be used to control translation style.

VIII. *Controllability examples*

We created 4 domain descriptors to test the proposed model. Each one of them was calculated as a mean embedding vector of texts corresponding to each domain. We encoded only English input texts, so the model searches for pairs close to the descriptor vector and uses their features to decode embeddings with the proposed style.

- Casual domain was calculated from 1000 image descriptions from the Multi30k dataset;
- Official domain was calculated from 1000 laws sentences;
- Instruction domain was calculated from 1000 documentation sentences;
- Old literature domain was calculated from 1000 sentences gathered from English literature from Project Gutenberg.

So now we have 4 domain descriptors with 384 elements each. We conducted some experiments on controllability to find optimal values of the transformation coefficient . Values below 3.5 usually do not change output text at all or change it slightly (as an example the only change can be the form of a single word). However, values lower than 3.5 can be used when we use multiple domains at once. Values higher than 7 shift descriptor values too much, so most of them become more than 1 or less than -1. It breaks the decoding process, so we get just a single word repeated as many times as the maximum number of output tokens allows or we just get some random symbols.

We show some examples of controllable translation in Table 7.

The model still can make some significant errors during style transfer. For example, we caught some errors with high coefficient values for the official domain. If we set it to 6.5 or higher it transforms some texts too much and literally changes their meaning. The input text was “Excuse me. Do you know the way to the zoo?”. Translation with official domain and coefficient equal to 7.0 was “Вибачте, чи знаєте ви шляхи до участі у виборчому окрузі”. In our opinion, it could be solved by using just one example of the desired style, so transfer could happen without setting of transformation coefficient.

We tested mentioned style transfer without transformation coefficient or creation of domain descriptors. We just pass another text as an example of the desired style and create its descriptor. It is then passed to the model instead of the input translation text descriptor. However, currently, the model does not make any changes based on just one example. It translates the text as if nothing was passed at all. In our opinion model needs more tuning to start working in a one-shot learning mode and transfer style from just one example instead of a whole set.

So the model can be used for controllable machine translation task but needs some precalculated domain descriptors to transfer the style of certain text set.

IX. *Conclusion*

In this research we proposed a solution to increase the controllability of machine translation models by using style transfer. We proposed a modified encoder-decoder architecture, which concatenates text semantic descriptor to each token embedding before decoding it into the target translation. This way we can point the model towards texts with necessary features, which we want to transfer into the final translation. The proposed solution was compared to established approaches like domain fine-tuning and the addition of a style marker by token and embedding metrics. Models were compared on a full multi-style test dataset and on each style separately. Examples of style transfer from a set of references were provided and a hypothesis for working in a one-shot learning mode was tested. Currently model needs more tuning to transfer style from just one example.

During our experiments, we tested the proposed solution only for 3 domains for English-Ukrainian translation. Also, we chose the optimal values range for the transformation coefficient by checking the changes after tweaking its value. The proposed model can be tuned further to learn new domains better. This solution can be scaled to a larger number of languages by changing the external model, which generates semantic descriptors.

As a further development, we propose to tune the model enough to finally run it in a one-shot learning mode. Also, we would like to interpret semantic descriptors in more detail to provide better control over text features and get a better understanding of each value influence. It can be done by using the sparse embeddings approach. Also, we would like to further modify the proposed architecture by trying other semantic encoders or changing the structure of the dimensionality reduction module.

Abstract—**The importance of federated information retrieval (FIR) is growing in humanities research. Unlike traditional centralized information retrieval methods, where searches are conducted within a logically centralised collection of documents, FIR treats each information system as an independent source with its own unique characteristics. Searching these systems together as a centralised source results in lower precision in humanities research, even when the research data itself is structured and stored according to standardised guidelines such as EpiDoc, and requires the need to be able to trace the origin of records to avoid incorrect historical conclusions. Matching of queries against all data sets in each source is proving less effective. A global search index that enables traceable matching of key values deemed relevant would provide a more robust solution here. In this article, we propose a solution that introduces a novel EpiDoc data matching procedure, facilitating traceable FIR across distinct epigraphic sources.**

I. Introduction

IN THE field of humanities, the need for federated information retrieval (FIR) is becoming increasingly important [5], [13], [20], [21]. FIR refers to the process of searching for relevant information across distributed and autonomous information systems within a database federation. A database federation provides a logical centralisation of data without the need to change the physical implementation of databases and maintain the identity of autonomous developed databases.

Information systems have emerged in some humanities projects, e.g., the epigraphy projects “Epigraphische Datenbank zum antiken Kleinasien” (EDAK) [23] and “Collection of Greek Ritual Norms” (CGRN) [3], they are not collaboratively searchable because these information systems run in heterogeneous hardware and software environments, and have different data models. Although both projects use an epigraphy-specific XML format called EpiDoc [7], a customized version of TEI (Text Encoding Initiative) [22], is additionally provided to exchange research data. The purpose of the EpiDoc format is to enhance machine-readability, and effectively searching for specific information within EpiDoc files relies on correctly matching the research data extracted from these files across different sources.

Although an EpiDoc schema was developed in each of the two projects, in Fig. 1 it is shown that the general structure is similar, however, in detail the XML tags are applied differently. In an example, according to the TEI guidelines, the XML tag “origDate” is used to represent dates. In practice, concrete date specifications for “origDate” vary. In CGRN a date presents a century and in EDAK an epoch (see Fig. 1). When specifying the place, mapping from both sources becomes even more difficult because the semantics of the place terms are different. While in CGRN the place name is specified in the XML tag “ref”, in EDAK the tag “placeName” is used (see Fig. 2). Only an expert in this field can say exactly how the places can be mapped onto each other. For an efficient FIR, a correct matching of data sets from different sources must be defined in advance to provide precise IR results.

In the humanities, mapping of data from different sources is still done manually. The manual procedure is necessary

The research was funded by the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation) under Germany´s Excellence Strategy – EXC 2176 ‘Understanding Written Artefacts: Material, Interaction and Transmission in Manuscript Cultures’, project no. 390893796.

due to the need to achieve a high degree of precision in semantic evaluation, which is crucial to avoid making false statements about cultural artefacts. The current challenge is to automatically match the data, which is stored in various EpiDoc formats. Searching through hundreds upon thousands of EpiDoc files can be challenging, so it can be advantageous to transfer data represented in EpiDoc to a relational database. The advantages of transforming data from EpiDoc into a relational database are:

- (i) higher query answering performance because relational databases are optimized for query answering,
- (ii) scalability which makes relational databases a good choice for large data sets, and
- (iii) opportunity to use pre-defined data types and to define relationships between data elements.

In the CGRN and EDAK projects, relational mappings exist beside the XML representations. We use both, the existing relational mappings and the XML tags, to compute relevant key values and use these values for our new indexing approach for a precise and performant EpiDoc data matching. If the relational mappings are missing, it is possible to use large language models such as Generative Pre-trained Transformer 2 (GPT-2) [24] or other versions to generate the required relational mappings. Computing the relational mappings is done by entering the specific EpiDoc schemas into the language model, which can then generate the required mappings.

This article presents a novel method to overcome the difficulties of automatically matching epigraphic data from different sources with different EpiDoc schemas while ensuring semantic precision. The proposed method offers potential benefits for humanities scholars by maintaining precision while minimising heterogeneity caused by differences in data semantics. Furthermore, the proposed EpiDoc data matching approach can be applied to an FIR to offer scholars in the humanities access to a wider range of information from distributed and autonomous sources.

The remaining article is structured as follows: Section II gives an overview of some work on the representation of epigraphic data, as well as selected approaches to match these data. Section III describes a new matching process for epigraphic research data to enhance correct semantic mapping. This process provides the basis for enabling FIR, which is described in Section IV. Section V concludes this article and gives an outlook.

II. Related Work

Studies emphasise the need for careful selection of repositories in federated search to avoid describing objects that are not searchable. A prototype federated search engine [17] or cross-domain information system [11] has been developed to address this problem by integrating selected repositories. However, manual mapping is usually required to link different content with high precision. This article proposes an automatic data mapping that eliminates the need for manual mapping.

Data in EpiDoc.XML is syntactically represented as XML documents. Existing work on XML matching can be applied for schema matching and mapping. These methods typically begin with element-level similarity assessment [1] and then extend to data set level comparison [10]. For comparing EpiDoc data sets, this article suggests adopting similarity functions used for XML elements, such as Levenshtein distance [14] or the Soundex algorithm [9]. The overall similarity between data sets can be evaluated using metrics like Jaccard distance [8].

Applications processing semi-structured data often require schema matching for tasks like schema integration and schema clustering. Previous research, such as [10] and [18], has defined similarity functions for semi-structured data (DTDs) and schema fragments (from XSD) to address these needs. In our approach, we can focus specifically on matching different variants of EpiDoc, assuming that all input data are in this format. This eliminates the need to rely on general schema matching algorithms and allows us to treat the different EpiDoc variants as dialects of the same language.

III. Matching of Epigraphic Research Data

Matching data sets involves the process of comparing two or more data sets to identify similar elements. In the following the general process of matching data and the process of matching EpiDoc data are presented (cf. [4] and see Fig. 3).

A. General Process of Matching Data

a) Data pre-processing: The initial step in data pre-processing involves preparing the data sets for matching. This involves cleaning, formatting, and standardizing the data sets to ensure compatibility and effective comparison. This may also include removing duplicates and identifying missing data.

b) Indexing: The complexity of matching records increases with the number of records to be matched. Indexing is a strategy to pre-select potential matches and leads to a reduction in the number of matches. Indexing usually involves identifying the key variables that will be used to match the data sets. These variables may include unique identifiers, such as the titles of editions, dates, or places. A traditional indexing

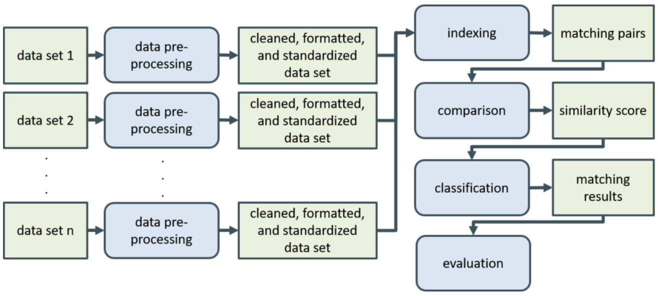

Fig. 3. The general process of matching n data sets. Based on [4] (extended)

method has the name blocking [2]. The method compares only those records that are based on the same so-called blocking criteria. In this article, we present an advanced blocking method that considers both the XML and relational structure of databases created based on the XML files to determine the matching criteria and then identify the candidate pairs for comparison.

c) Comparison: In this step, the data sets are compared to identify matches. For this purpose, the similarity between the key values used during indexing, but also additional other values, will be calculated.

d) Classification: Based on the data set comparison, the matching records are classified as match or non-match.

e) Evaluation: The final step involves validating the matched data sets and reviewing the results for accuracy and completeness. This may involve checking for errors, inconsistencies, or missing data and making any necessary adjustments.

B. Process of Matching EpiDoc Data

1) Data Pre-processing: As a starting point, we use the EpiDoc files from the projects EDAK and CGRN. The EpiDoc data are transformed into a relational database using the so-called databasing on demand (DBoD) approach [12], [19]. The DBoD approach is used for building project-specific information systems on demand in a few hours and with few resources. The DBoD process consists of the following steps:

1) Transformation of all EpiDoc files into one CSV file. The mapping of the EpiDoc XML elements into a canonical mapping was carried out via the widely used EpiDoc XSLT stylesheets [6] as defined by epigraphers (cf. data representations on the websites: [3], [23]).
2) Insert all the data from the CSV file in a database instance.

From the website it could be inferred that both projects have different relational representations. The EDAK project has the column names “Edition”, “Inscription type”, “Obejct type”, “Region”, “Place”, “Date (epoch)”, “Text”, . . ., while CGRN has the column names “Edition”, “Provenance”, “Place”, “Date (century)”, “Text”, ...

To ensure comparability between centuries and epochs, we have transformed them into a starting time (notBefore) and an ending time (notAfter). For instance, the “imperial” epoch was converted to notBefore=1 and notAfter=300. This conversion allows for a standardized representation of time periods, facilitating analysis and comparison across different historical eras.

In [4] it is suggested to standardize tables, so that the relational models consist of the same entity types, and thus facilitates the data matching process. Since in our case the mapping rules are given (defined by epigraphers), it is not necessary to use the same database models for all databases, especially since in practice this form of database entry would not be accepted by the users due to the diverse requirements. In the indexing step, it is shown that mapping rules, rather than standardisation of databases, are sufficient to successfully perform data matching. If the structure of the relational database is already known, mapping EpiDoc data sets directly to a database instance using XSLT or a similar transformation language may be easier and more efficient. However, if these mapping rules are missing, our hypothesis is that large language models can be useful to define such mapping rules if the input data are the EpiDoc schemas and the EpiDoc guidelines. We tested our hypothesis with the use of ChatGPT [16], which has statistical knowledge, acquired through its extensive training on large data sets. We gave ChatGPT the EpiDoc guidelines as input and the two EpiDoc schemas, and asked it to provide us with the mapping for transforming EpiDoc data into a relational database. As output, we received tables that correspond to the hierarchical structure of the XML file. In total, ChatGPT delivered more tables than needed, but all contents remain taken into consideration.

2) Indexing: Indexing includes identifying the key variables for an efficient schema matching process. For existing relational databases, it can be assumed that the column names belong to the key variables and are used for their project-specific analysis. Therefore, the column names are regarded as key variables. Since matching all key variables is inefficient, a blocking procedure is traditionally used [4]. This reduces the number of comparisons and improves performance. This article employs an alternative approach to existing blocking methods by utilizing the XML schema to identify matching candidates. For seen data (mapping rules known), XSLT is used, while ChatGPT is used for unseen data (mapping rules are not known). The identification of matching candidates is described in the next paragraph.

If two sets A and B of XML tags, where the sets A and B are from different EpiDoc schemes, are mapped to the same element, then that element is a matching candidate to be added to the matching candidate set C. Let $A = \{a_1, \dots a_i\}$ and $B = \{b_1, \dots b_j\}$ be sets of XML tags, and let f be a function which represents a mapping from A to B: $f : A \rightarrow B$, then the matching candidates C are given by:

$$C = \{b \in B : \exists a \in A \text{ with } f(a) = b\} \qquad (1)$$

In the given example, the EpiDoc schema “EDAK” belongs to set A and “CGRN” to set B. Table I displays the column names used in the respective projects and the

TABLE I
OVERVIEW OF MATCHING CANDIDATES DERIVED FROM THE EPIDOC SCHEMES AND RELATIONAL REPRESENTATION OF THE EPIDOC CONTENT

EpiDoc Schema	Column name	XML tag	matching candidate C
EDAK	Edition	title	no
EDAK	Inscription type	term	no
EDAK	Object type	objectType	no
EDAK	Region	placeName	yes
EDAK	Place	placeName	yes
EDAK	Date (epoch)	origDate	yes
EDAK	Text	div	yes
CGRN	Edition	idno	no
CGRN	Provenance	placeName	yes
CGRN	Date (century)	origDate	yes
CGRN	Text	div	yes

TABLE II
MATCHING DATA OF EDAK AND CGRN

project	ID	placeName	Sndx-PN
EDAK	a_1	Pisidia	P230
EDAK	a_1	Antiochia	A532
EDAK	a_2	Ephesus	E120
CGRN	b_1	Ephesos	E120
CGRN	b_2	Tomis	T520
CGRN	b_3	Athens	A352

corresponding XML tags. The matching candidates are $C = \{\text{placeName}, \text{origDate}, \text{div}\}$.

a) Matching: The data also includes words that sound similar and can also be judged semantically similar, e.g. “Ephesus” and “Ephehos.” In the simple comparison, the terms are evaluated as different, even though they are the same place.

The commonly used phonetic coding algorithm Soundex is employed to find a match despite minor differences. Each word is coded into a letter and a three-digit number sequence, words with the same coding are scored as similar. That means for our example that “Ephesus” coded as E120 and “Ephehos” coded as E120 are semantically similar. For more details of the Soundex algorithm is given in [15].

For data represented with the data type “Text” or “Date”, the Soundex procedure is not applied as it maps to strings and numeric values. Although “Date” is also a numeric value, it represents a period of time, and the comparison of time periods differs from that of strings and numeric values. This is not considered in the indexing procedure, but in our comparison step.

Using the matching criteria Soundex for the matching candidate “placeName,” then the indices and record pairs are presented as shown in Table II. The matching key values P230, A532, and E120 are identified. The only record pair that was identified is (a_2, b_1) for E120.

Formally, the set of matching pairs are computed as follows:

$$f_{\text{Sndx}} : C_{A_{\text{Sndx}}} \to C_{B_{\text{Sndx}}}$$

$$\begin{aligned} P = &\{(a \in C_{A_{\text{Sndx}}}, b \in C_{B_{\text{Sndx}}}) : \exists a \in C_{A_{\text{Sndx}}} \\ &\text{with } f_{\text{Sndx}}(a) = b\} \end{aligned} \tag{2}$$

When comparing the EDAK data set with the CGRN data set, there is only the overlap with one region. This result was to be expected, as it is common in the humanities for research to be conducted in a very specialised area, and it can be assumed that there is little overlap. Nevertheless, in the humanities one is interested in finding other interpretations of texts or even the same data sets. Our next application example shows that our algorithm can also handle larger data sets and that more similar data sets are to be expected in the context of a humanities project. We split one part of the EDAK data set into two so that we have 199 entries in one data set and 201 in the other. Of these, 159 matching candidates were identified based on the same region. The two comparisons (CGRN + EDAK; EDAK part 1 + EDAK part 2) provide the results, as expected, with a high degree of precision.

If comparison is made with the tables or columns provided by ChatGPT, the difference is that there is a larger number of tables or table columns that would have to be compared with each others. As a result, as the number of tables grows, more key candidates emerge and more matches are made than would be necessary. However, if there are no mapping rules, this approach is still helpful because precise results can still be shown.

3) Comparison: The comparison process in schema matching indicates the degree of similarity between two record pairs to determine whether they are a match or not.

The comparison function $c(a_i, b_j)$ maps the matching pairs values of a_i and b_j as well as the pairs with the data type “Text” to a similarity score in the range $[0, 1]$, where 0 indicates no similarity and 1 indicates a perfect match. The comparison function can be defined using different similarity metrics, such as the Jaccard coefficient, cosine similarity, or edit distance, depending on the characteristics of the schema elements and the matching criteria.

In this article, the Jaccard similarity is used to compare the sets of matching terms from P associated with a_i and b_j defined as follows:

$$c(a_i, b_j) = \left| \frac{P(a_i) \cap P(b_j)}{P(a_i) \cup P(b_j)} \right| \tag{3}$$

where $|.|$ denotes the cardinality of a set. For dates, the similarity is computed in the following way. Assuming d_1 and d_2 represent the time periods d_{a_1} to d_{a_2} and d_{b_1} to d_{b_2}, the date similarity is given by:

$$sim_{\text{date}}(a_1, b_1) = \begin{cases} 1 & d_{a_1} \leq d_{b_2} \text{ and } d_{b_1} \leq d_{a_2} \\ 0 & \text{otherwise} \end{cases} \tag{4}$$

If there is a temporal overlap, the similarity score is 1, otherwise 0.

For “placeName”, the similarity score sim_{place} is also 1 if there is a match, otherwise 0.

TABLE III
COMPARISON

ID	placeName	Date	div	sim_{all}
a_1	Ephesus	0001 - 0300	[text]	
b_2	Ephesos	-550 - 500	[text]	
	1	1	0.5	2.5

The comparison function can be used to rank the candidate matches based on their similarity scores:

$$\begin{aligned}\text{sim}_{\text{all}}(a_i, b_j) = {} & sim_{\text{place}}(a_i, b_j) \\ & + sim_{\text{date}}(a_i, b_j) \\ & + c(a_i, b_j) \end{aligned} \tag{5}$$

and to select the best match(es) according to a given threshold or ranking criteria.

The comparison between the two EDAK data sets revealed a similarity score ranging between 2.00 and 2.25. The determination of whether this score indicates a match is explained in the following step.

4) Classification: Classifying the compared record pairs based on their summed similarities is a two-class (binary) classification task. Each compared record pair is classified to be either a match (1) or a non-match (0) depending on a threshold value θ.

The classification of each compared record pair can be based on either the full comparison vectors or on the summed similarities. Based on the summed similarity score, a match is defined as:

$$\text{match} = \begin{cases} 1 & \text{sim} \geq \theta \\ 0 & \text{otherwise} \end{cases} \tag{6}$$

In the context of the project, a good value for θ is between the "number of attributes" divided by 2 and the total "number of attributes" to achieve matching results between approximately 50% and 100%. Formally:

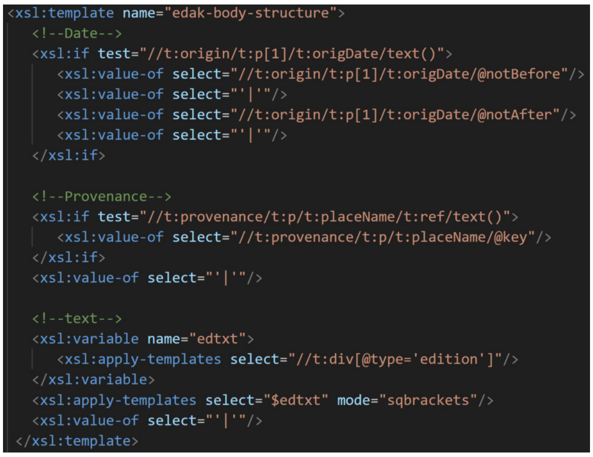
$$\frac{\text{number of attributes}}{2} \leq \theta \leq \text{number of attributes}. \tag{7}$$

If $\theta =$ "number of attributes" (100% similarity), then it could indicate a duplicate. It is important to note that, in general, the optimal value for θ may depend on the specific characteristics of the data sets being compared and the desired level of similarity between them. Now the matching results can be evaluated by experts.

5) Evaluation: In the EDAK project some dates are marked as "Unknown". In this case, the date should have been cleaned up in the pre-processing step or should have been taken into account in the algorithm with another θ value. After we adjusted θ, the similarity score increased.

IV. Federated Information Retrieval

FIR is an approach used in information retrieval (IR) systems where multiple autonomous and distributed information sources are integrated to provide a unified and comprehensive search experience. Unlike traditional centralized IR methods, which rely on a single collection of documents, FIR treats each information system as an independent source with its own unique characteristics.



```
<xsl:template name="edak-body-structure">
   <!--Date-->
   <xsl:if test="//t:origin/t:p[1]/t:origDate/text()">
      <xsl:value-of select="//t:origin/t:p[1]/t:origDate/@notBefore"/>
      <xsl:value-of select="'|'"/>
      <xsl:value-of select="//t:origin/t:p[1]/t:origDate/@notAfter"/>
      <xsl:value-of select="'|'"/>
   </xsl:if>

   <!--Provenance-->

   <xsl:value-of select="'|'"/>
 </xsl:template>
```

Fig. 4. XSLT code shows that the EpiDoc data is read from the project CGRN

A federation of database systems is called federated database system (FDBS) and integrates multiple autonomous database systems into a single database system. However, the identity of the individual databases is not lost in the merging process. In general, the constituent the physically decentralized databases are interconnected via computer networks.

We have implemented a prototype to integrate the new indexing procedure into an FDBS and thus enable FIR. For this purpose, we have written a Python script combined with the XSLT stylesheets for each project (EDAK and CGRN) that first transforms the EpiDoc data into a relational database model. To do this, it was necessary to adapt the existing XSLT stylesheets to transfer the project-specific mappings from XML to a relational database. Fig. 4 shows the representative XSLT source code representing how the EpiDoc data (date, provenance, and text) is read from the CGRN project.

A further Python script was written for the presented matching process of epigraphic research data to compute the similarity score for the three selected attributes: "Place", "Date" (splitted into "notBefore" and "notAfter" to represent a period), "Text". The result of our script is a tabular listing of all selected attributes that are ranked according to the similarity score. CGRN and EDAK did not provide any results for the area for the place name "Ephesus" and the period 1-300 (notBefore-notAfter). This result was almost to be expected, since research in the field of the humanities is designed in such a way that the projects are usually distinct in terms of content and detail.

As evidence of the applicability of the new data matching process, we generated two data sets from the EDAK project and compared them with each other. In Table IV the top 10 results with the highest similarity are presented. In sum, we have an overall similarity of 39.75% within the result set, which was to be expected.

TABLE IV
TOP 10 RESULTS OF THE EPIDOC DATA MATCHING PROCESS

Edak 1	Edak 2	notBefore	notAfter	Sndx-PN	Sim_Score
TAM V 2, 1152	TAM V 2, 868	1	300	L356	2,25
TAM V 2, 1152	TAM V 2, 1151	1	300	L356	2,21
TAM V 2, 1075	TAM V 2, 1151	1	300	L356	2,20
TAM V 2, 1024	TAM V 2, 987	1	300	G430	2,19
MAMA VII, Nr. 67	Robinson, TAPhA 57 (1926) , Nr. 7	1	300	L250	2,19
Laminger-Pascher, Inschriften Lykaoniens (1992) , Nr. 303	Robinson, TAPhA 57 (1926) , Nr. 7	1	300	L250	2,19
TAM V 2, 1075	TAM V 2, 868	1	300	L356	2,19
TAM V 2, 1026	TAM V 2, 987	1	300	G430	2,17
TAM V 2, 1085	TAM V 2, 1061	1	300	G430	2,17
TAM V 2, 1024	TAM V 2, 1061	1	300	G430	2,17
MAMA VIII, Nr. 315	Robinson, TAPhA 57 (1926) , Nr. 7	1	300	L250	2,17
TAM V 2, 1182	TAM V 2, 868	1	300	L356	2,16

The current implementation so far only supports a search by the three selected categories (attributes). We have also prototypically implemented our new EpiDoc data matching method as an FIR in such a way that a user can enter the attributes “placeName”, “notBefore”, “notAfter”, and “text.” As a result, the user receives a list with the matching candidates and the similarity score such as presented in Table IV.

V. SUMMARY AND OUTLOOK

This article is about the increasing importance of federated information retrieval (FIR) in the field of humanities. An FIR, unlike traditional centralised information retrieval methods, treats each information system as an autonomous resource with unique properties. The article proposes a novel EpiDoc data matching procedure which uses the XML schema representations and relational representations to identify the matching candidates, so that on the one hand the number of data matches is reduced and on the other hand the precision is maintained. The new procedure was successfully implemented as a prototype and will be evaluated in the future by transferring it to the productive system at the Universität Hamburg.

***Abstract*—In cybersecurity, accurate and timely prediction of attacks plays a crucial role in mitigating the risks and impacts of cyber threats. However, traditional attack prediction methods that rely on training Machine Learning (ML) algorithms directly on raw data often suffer from high false alarm rates and low detection rates, leading to inaccurate and unreliable results. To overcome these limitations, this paper presents a novel approach that integrates attack prediction with self-supervision using variance-invariance-covariance regularization (VICReg). The proposed method harnesses VICReg to enhance raw data and generate representations while leveraging self-supervision to learn meaningful features without supervision. Training classic ML algorithms on these refined representations improves prediction accuracy and enhances the robustness of the learning process. We provide a comprehensive description of the proposed method and present an evaluation of its performance on several benchmark datasets. The experimental results demonstrate the superiority of the proposed method over classic ML algorithms.**

***Index Terms*—Self-supervised learning, Deep Learning, Structured Data, Attack Prediction, Wireshark**

I. Introduction and Related Work

CYBERSECURITY is a major concern for businesses, governments, and individuals, as the damage caused by worldwide cybercrime is expected to reach $10.5 trillion annually by 2025. The global cybersecurity workforce is projected to be short 1.8 million people by 2022, with 66% of respondents reporting that they don't have enough capacity to address current threats. Predictive analysis has the potential to give organizations an advantage by allowing them to allocate their defence resources more effectively and automate the process of attack forecasting and prediction.

Some of the most actively studied problems include Network Risk Scoring (NRS) [1], Threat Detection and Classification (TDC) [2], Attack Prediction [3], phishing detection [4], web shell classification and automating security pipelines.

A. Attack Prediction

The number and sophistication of cyberattacks are constantly increasing, making it increasingly difficult for organizations to protect themselves against all likely threats. By predicting and preparing for potential attacks, risks and losses can be minimized. Attack prediction refers to the process of identifying and forecasting potential security threats or vulnerabilities in a system or network. This is a critical aspect of cybersecurity, as it helps organizations to proactively protect themselves against future attacks and to minimize the impact of any breaches that do occur.

TABLE I
Example of Wireshark captured data in table format

6	0.14	192.168.1.1	HTTP	903	HTTP/I.1 200 0K

B. Prediction Logic

One of the key tools in addressing cybersecurity threats is the use of network packet analyzers. These tools are designed to capture, analyze, and interpret network traffic, to identify potential security breaches and malicious activities. Among these tools, Wireshark [5] is a free and open-source (GNU General Public License) platform independent tool that serves as a packet analyzer. It is used for network issue resolution, examination, the development of communication protocols and educational purposes. Wireshark intercepts packets and presents them in a table format, with each row representing a single packet and each column displaying various details about the packet.

The captured packets can be filtered and sorted using various criteria, such as the protocol used, the source and destination addresses, or the specific type of data being transmitted. Table I-B shows an example of Wireshark data displaying six packets in table format. The columns include the time, source IP address, protocol, packet length, and a brief description of the packet

C. Self Supervised Learning

Self-supervised learning (SSL) [6] is a machine learning approach that seeks to acquire data representations without explicit supervision, thereby eliminating the need for labeled data. Through this method, the model autonomously learns valuable features and representations, which can be utilized for downstream tasks. SSL holds significant potential for enhancing the efficiency and effectiveness of learning algorithms in scenarios where labeled data is limited or costly to obtain.

One of the earliest works in SSL was the autoencoder [7], a neural network architecture that learns to reconstruct its input by training on an unlabeled dataset. Another popular SSL technique is contrastive learning [8] which is a method of training a model to distinguish between different representations of the same data.

SSL has been applied to a wide range of tasks such as computer vision [9], natural language processing [10] and speech recognition. SSL is still an active area of research and many questions remain open. For example, there is currently no consensus on the best way to evaluate the quality of the representations learned by SSL methods [11]. Additionally, the effectiveness of SSL for certain tasks or domains is still being explored. The issue of collapsing problem [12] in learning architecture is often mitigated by the presence of hidden biases, which may not have a transparent explanation or interpretation. This ensures that the learning process remains stable and effective. However, the underlying reasons or justifications for these biases may not always be readily apparent or easily interpretable.

D. VICReg

VICReg [13] a study by Meta Research introduced an approach that explicitly addresses the collapse problem by incorporating a straightforward regularization term on the variance of the embeddings along each dimension independently. VICReg, combines this variance term with a decorrelation technique that focuses on reducing redundancy and covariance regularization. By integrating these strategies, VICReg achieves state-of-the-art results on a range of downstream tasks, effectively overcoming the collapse problem and enhancing the quality and diversity of the learned embeddings.

While Self-Supervised Learning (SSL) has garnered substantial interest and recognition in the domains of computer vision and natural language processing (NLP), where large-scale datasets of unlabeled images are readily available (e.g. ImageNet), there has been very less research behind the adoption of SSL to tabular data. We apply self-supervision to predict attacks from tabular data using VICReg in this paper. Following are some of the significant observations:

1) Self supervision using VICReg on tabular data before applying Machine Learning (ML) algorithms helps in improving prediction accuracy.
2) When it comes to attack prediction, swap noise, a complementary approach to existing augmentation techniques in the tabular data setting, proved to be effective.
3) VICRA improves attack prediction accuracy compared to traditional Machine Learning (ML) methods.

Our key contributions can be summarized as follows:

1) We address the problem of Attack Prediction on wireshark features as a Machine Learning (ML) problem. We present the problem as an anomaly detection task for tabular data.
2) We propose a novel technique called VICRA (Variance-Invariance-Covariance Regularization for Attack Prediction) which uses self-supervision to enhance the tabular embeddings using swap noise and show significant increase in performance.
3) By leveraging the inherent structure of data and regularizing the learning process, the method is able to improve prediction accuracy and robustness.
4) We present a pipeline to train attack prediction models on wireshark data using VICRA.
5) We investigate the performance of VICRA attack prediction on popular datasets by comparing it with the current ML approaches.
6) Our VICRA technique improves the accuracy by over 2.48% for NSL KDD, 0.90% for UNSW NB15 and 7.17% for AWID2 than traditional ML approaches.

The rest of the paper is organized as follows. Our proposed approach is described in Section 2. Performance evaluation and findings of the work are shown in Section 3, Section 4 concludes the finding of the work.

II. Proposed Approach

In this section, we formally introduce our proposed VICRA system and highlight the specific areas of the problem that we aim to solve. The architectural overview of the proposed system is shown in Figure II.

The system takes Wireshark features as input and predicts if it's an attack or not. The overall procedure includes the following steps: (1) data preparation, (2) self-supervised learning, (3) embedding cloud generation, and (4) attack prediction. The primary focus of this research is to use self-supervision to enhance the feature embeddings while improving metrics for attack prediction. The processes are then thoroughly explained.

A. Data Preparation

As seen in Figure 1 the dataset is in the form of raw Wireshark features. To obtain useful information from the raw features we clean the data using standard data preparations methods which are mentioned below.

1) Missing Values: The data collected might have a lot of missing features. There are many proposed approaches on handling missing data in Wireshark data. For our approach, we perform List-wise Deletion [14] on categorical and binary features followed by Simple Mutation on continuous features. In List-wise Deletion, every case that has one or more missing values is removed whereas in Simple Mutation the missing value is replaced by the mean of the values in that feature.

2) Feature Selection: The Wireshark data that was recorded includes incorrect fields and extra information. In this step, feature selection methods reduce the number of features. In the process of attribute selection, information gain and gain

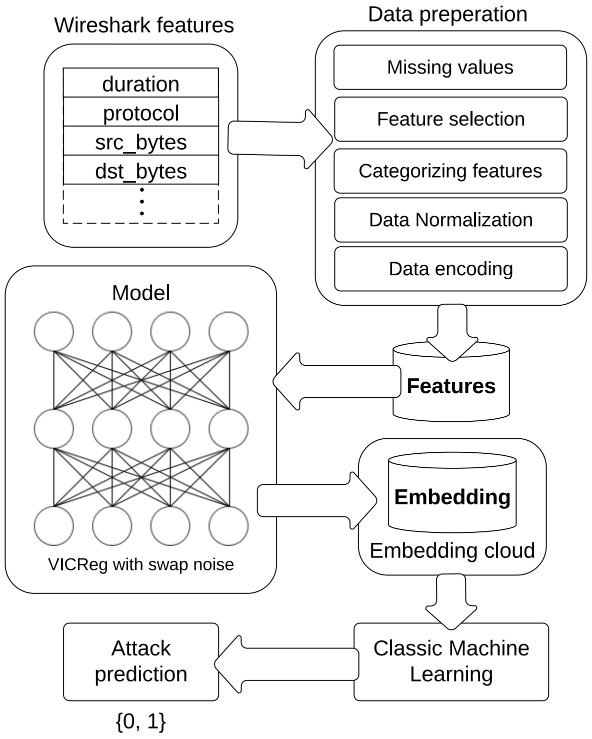

Fig. 1. System architecture of the VICRA System

ratio are commonly employed techniques for assessing the relevance of variables with respect to the target variable [15] [16]. Some columns like IPv4/IPv6 addresses are also removed since the model tends to overfit on these features.

3) Categorizing Features: The features are now categorized into continuous, categorical, discrete and binary for further pre-processing. Categorizing features is a crucial step in pre-processing data for attack prediction. Features are categorized into continuous (e.g., time duration), categorical (e.g., protocol type), discrete (e.g., number of packets), and binary (e.g., event occurred or not) types. By categorizing features, appropriate pre-processing techniques can be chosen for each type.

4) Data Normalization: Continuous features are either normalized or standardized. Log-transformation is performed on skewed data. Log transformation helps mitigate the effect of skewness by reducing the variability in the data and bringing it closer to a normal distribution.

5) Data encoding: Categorical features are one-hot encoded, and discrete features are treated as categorical or binned into ranges. Binary features require no pre-processing.

The output of this phase (given T) is clean and structured data which is fed into the VICReg model for self supervision.

B. Self Supervision

Figure II-B provides an illustration of the VICReg architecture, which encompasses variance, invariance, and covariance regularization. The process begins with a batch of features T obtained from the Data preparation step. From this, two sets of noisy features X and X' are generated and encoded into representations Y and Y'. These representations are then passed through an expander, resulting in the production of embeddings Z and Z'.

To ensure the effectiveness of the embeddings, several regularization techniques are applied. Firstly, the distance between embeddings from the same feature is minimized. Additionally, the variance of each embedding variable within a batch is maintained above a specified threshold. Furthermore, the covariance between pairs of embedding variables over a batch is attracted to zero, promoting decorrelation between the variables. It is worth noting that the two branches in the architecture do not necessarily share the same architecture or weights, although in most experiments, they consist of shared weight Feed Forward Layers (FFL).

To generate the noisy features X and X', swap noise is introduced to the original features, a process that is elaborated upon in Section III-C. After training, the model is then utilized for inference on the features obtained in the previous step. The resulting embeddings are generated and subsequently stored in the embedding cloud for further analysis or downstream tasks.

C. Embedding Cloud

The embeddings generated from the self-supervised inference are combined to form an embedding cloud as mentioned in [17]. The embedding cloud is a permanent storage of preprocessed embeddings which are used while training. Once the embedding cloud is generated and saved, we can proceed to train the model on the embeddings for attack prediction.

D. Attack Prediction

The embeddings stored in the embedding cloud, along with the ground truth labels, are utilized to train the Machine Learning (ML) model instead of training the model on the raw features. The self supervision performed regularizes the learning process and leverages the inherent structure of the data. The proposed method is found to yield improved prediction accuracy and greater robustness compared to traditional feature-based approaches. The use of self-supervised learning for generating embeddings has been demonstrated to be a promising approach for training ML models in a variety of applications. Our results suggest that this approach has the potential to be a useful tool in the field of cybersecurity for predicting and mitigating cyber attacks. While the proposed approach shows promising results for attack prediction, further research is required to fully explore its potential and assess its applicability to various types of attack prediction tasks.

III. Evaluation

A. Dataset

For our evaluation, we used three benchmark datasets commonly used in the field of cybersecurity: AWID 2 [18], NSL KDD [19], and UNSW NB15 [20] [21] [22]. These datasets provide a diverse range of attack scenarios and network traffic patterns, allowing us to assess the performance of our proposed approach across different contexts. The AWID 2

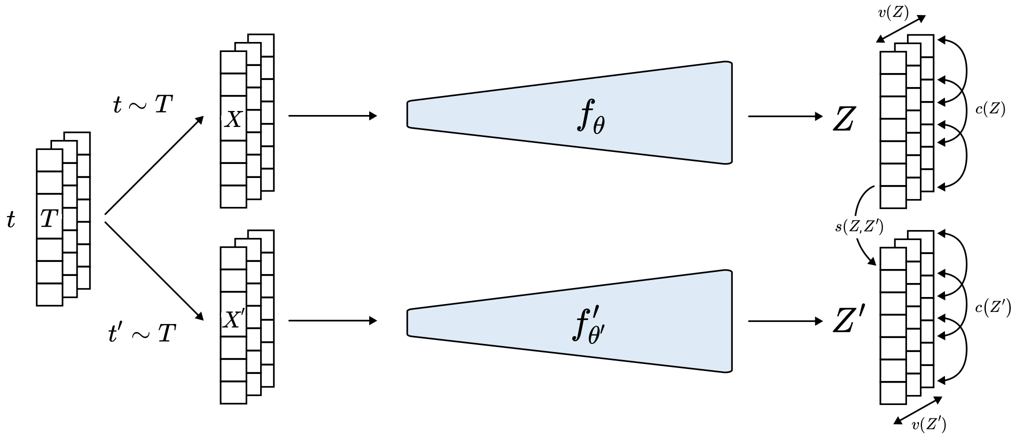

Fig. 2. VICReg architeture chosen for the wireshark data.

dataset contains wireless intrusion detection system (WIDS) data, the NSL KDD dataset is derived from the KDD Cup 1999 dataset, and the UNSW NB15 dataset includes network traffic data with various attack types. Table III-A provides an overview of the dataset distribution for three different datasets: AWID2, NSL KDD, and UNSW NB15. It is also clear from the distribution that in AWID2 dataset close to 97.15% of the data is from the “Normal” label, whereas in NSK KDD and UNSW NB15 datasets, the “Normal” label is only 53.46% and 31.94% respectively.

In order to evaluate the proposed approach, a binary classification scenario was created for each dataset. In this scenario, the "Normal" label was assigned the binary value of 0, while all other attack labels were grouped together and assigned the binary value of 1. This binary classification setup allows for the examination of the model’s performance in distinguishing between normal instances and instances associated with various types of attacks. By treating normal instances as the negative class (0) and attacks as the positive class (1), the model can be trained and tested to assess its ability to correctly classify instances as either normal or attack-related. This approach simplifies the problem by focusing on differentiating between normal behavior and malicious activities, enabling the evaluation of the model’s effectiveness in detecting and classifying attacks within the given datasets.

1) Data preparation: Prior to applying self supervision and learning algorithms, the dataset is cleaned using the techniques mentioned in Section 2.1. This includes handling missing values, selecting and categorizing features, data normalization for numerical features and data encoding for categorical features. The post processed data (T) is fed in batches to the self supervised VICReg model after adding noise.

2) Swap noise: Our proposed framework offers a complementary approach to existing augmentation techniques employed in the tabular data setting. As such, we conducted experiments involving the introduction of noise to randomly selected entries within each subset. This was achieved by overwriting the value of a chosen entry with another value randomly sampled from the same column. This augmentation technique is referred to as ’swap-noise’. In a previous study conducted by Michael Jahrer (MJ) [23], a noise creation method known as ’swap noise’ was introduced. This method involves randomly swapping a small portion of columns between two samples in order to generate noisy samples for training purposes. In the following section, we present our implementation of the swap noise technique, based on MJ’s original approach.

B. Baseline

To evaluate the performance of VICRA, we compared it against several methods commonly used in attack prediction tasks. These methods include traditional machine learning algorithms such as logistic regression, decision trees, and support vector machines, as well as deep learning models such as feed-forward neural networks. Additionally, we implemented our own baseline model that directly trained on the raw features without the self-supervised learning step.

C. Experiment Setup

To conduct the experiment, we first preprocess the AWID2, NSL KDD and UNSW NB15 datasets using the approach mentioned in Section 2.1. The features are then run through the VICReg model for self supervision. The VICReg model is a multi-layer perceptron architecture with stacked layers of linear transformations, batch normalization, and ReLU activation functions. The model consists of an expander module that is responsible for expanding the input features. It takes in features and applies a linear transformation followed by batch normalization and ReLU activation. This process is repeated n times in the expander module. The model is trained for 50 epochs and the representations are generated for each wireshark feature in the dataset. The generated representation

is stored in the embedding cloud as a json object before using it for attack prediction.

As seen in [18] we choose four Machine Learning approaches, Decision Tree, Logistic Regression, Multi Layer Perceptron (MLP) and Support Vector Machines (SVM) for attack prediction. As a way to demonstrate the importance of self supervision and test whether it works, we train attack prediction models both on raw features T and representations Z. For each dataset four such models are trained on raw features and the self supervised representations and the metrics are logged for comparison.

D. Evaluation Metrics

The most commonly deployed performance metrics for validating the performance of ML and DL methods for attack prediction are Accuracy, F1 Score, Precision and Recall.

- Precision is defined as the ratio of total number of correctly predicted packets by total number of predicted packets.
- Recall is defined as the ratio of total number of correctly predicted packets by the sum of correctly predicted packets and the number of missed packets.
- F1-score: Given precision and recall, F-score is defined as the Harmonic mean of precision and recall
- Accuracy is defined as the ratio of the total number of correctly predicted packets to the total number of packets in the dataset.

E. Results

The results are shown in Table III. It can be observed that the models trained on self supervised VICReg embeddings perform better in the given metrics compared to the models trained on raw features. The experiment was done using four different approaches for attack prediction to show that self supervision helps improve prediction metrics regardless of the choice of the model. On an average across the four methods, self supervision improves the accuracy by over 2.48% for NSL KDD, 0.90% for UNSW NB15 and 7.17% for AWID2 than training the models on raw features. It is also to be noted that for datasets like AWID2 with over 97.15% data labeled as normal the improvement in accuracy is significantly higher compared to datasets like NSL KDD and UNSW NB15 where the percentage of data labeled as normal is 53.46% and 15.97% respectively.

IV. Conclusion

We tackle the challenge of Attack Prediction on wireshark features as a Machine Learning (ML) problem by framing it as an anomaly detection task for tabular data. To address this, we introduce a novel technique called VICRA (Variance-Invariance-Covariance Regularization for Attack Prediction). VICRA leverages self-supervision to enhance tabular embeddings using swap noise, resulting in a significant performance boost. By incorporating the underlying data structure and applying regularization during the learning process, VICRA improves prediction accuracy and robustness. We present a comprehensive pipeline for training attack prediction models on wireshark data using VICRA. To evaluate the effectiveness of VICRA, we conduct extensive experiments on popular datasets and compare its performance with existing ML approaches. Our results demonstrate that VICRA achieves substantial accuracy improvements, surpassing traditional ML approaches by over 2.48% for NSL KDD, 0.90% for UNSW NB15, and 7.17% for AWID2 datasets. Overall, VICRA offers a promising solution for enhancing attack prediction capabilities in the context of Wireshark data analysis.

***Abstract*—The problem of vine disease detection (VDD) was addressed in a number of research papers, however, a generic solution is not yet available for this task in the community. The region of interest segmentation and object detection tasks are often complementary. A similar situation is encountered in VDD applications as well, in which crop or leaf detection can be done via instance segmentation techniques as well. The focus of this work is to validate the most suitable methods from the main literature on vine leaf segmentation and disease detection on a custom dataset containing leaves both from the laboratory environment and cropped from images in the field. We tested five promising methods including the *Otsu's thresholding*, *Mask R-CNN*, *MobileNet*, *SegNet*, and *Feature Pyramid Network* variants. The results of the comparison are available in Table I summarizing the accuracy and runtime of different methods.**

I. Introduction

VINE DISEASE DETECTION plays an important role in the overall vineyard management allowing the loss reduction and the overcome of the pesticide overuse. The early stage VDD allows the degree of contamination reduction, which implicitly implies a positive economic impact as well.

Remote sensing plays an important role in precision agriculture, allowing the detection of different diseases, estimation of yield, or the computation of the fertilizer rates [29]. With the widespread of Unmanned Aerial Vehicles (UAV) in agriculture as well, close-range remote sensing expanded the range of applications for precision agriculture. The classical image processing algorithms were replaced by deep learning-based variants also for segmentation and object detection.

The most currently available solutions based on convolutional neural networks (CNN) are based on a sliding window approach, which allows the operations on smaller-sized image patches in favor of computational speed. However, for segmentation and detection purposes the whole image view could improve the segmentation boundaries and the accuracy of the detection.

In this paper, we propose to compare the already existing segmentation methods for masking diseased spots on grapevine leaves. For this, we create a mixture of datasets, which contains images from a laboratory environment as well as leaves cropped from images captured in the field from proprietary and publicly available datasets. Our proprietary dataset is captured with a mid-range commercial drone at low-altitude flight using a high-resolution (4K) camera.

The main contribution of this paper is the overview of the existing methods for this particular scenario with close-range remote sensing and the conclusions of the experimental finding in challenging datasets from various vineyards. The paper is organized as follows: the state of the art is presented in Section II, the dataset and method in Section III, and the comparison of the methods in Section IV.

II. State of the Art

Being an important aspect of precision viticulture, disease detection has a wide range of solutions in the literature. Many researchers seek a new way to stop the spread of diseases as early as possible, to reduce the chances of plant disposal and decreased quality. As far as the domain, multiple approaches exist. The first way to compare these approaches is to specify if the used images are from a laboratory environment or from the field. The approaches focusing on field image processing can be further split into proximal sensing, mainly using a conventional RGB camera, and remote sensing, using a variety of different mediums, such as RGB, multispectral, or hyperspectral. In this section, we provide a brief overview of the existing disease detection methods.

Cruz et al. [8] use transfer learning to detect grapevine yellow disease on single-leaf images while comparing multiple architectures. They experiment with numerous architectures, to conclude that *ResNet-50* [26] has the best *accuracy-to-complexity* ratio.

Similarly, Liu et al. [16] detect grapevine diseases using images of grapevine leaves. The images are either from a laboratory or from the field, however, an image contains only one leaf in both cases. The different leaf sizes are resolved using *dense inception convolutional neural network* from *GoogLeNet* [26] and *asymmetric factorization approach* [27].

While Gutiérrez et al. [10] capture their images in the field, they manually segment their images, to contain only one leaf, which either represents *downy mildew* and *spider mite*

Fig. 3: Samples from datasets: *Ab_data*, *Al_data*, *S3_data*

symptoms. The RGB data is converted into HSV color space. The authors claim this color space change ensures robustness for their *hue thresholding*-based method.

Morellos et al. [20] detect (*esca* and *powdery mildew* using transfer learning. Comparing multiple architectures, *Inception v3* [27] provides the overall best classification accuracy.

Mousavi and Farahani [21] base their work on the mixture of *VGG16* [25] and *Faster R-CNN* [23]. This method captures images of grapevines using a drone, however, the leaves are individually segmented before disease detection and localization.

Although all of these methods detect diseases, they do not create a binary mask to segment the diseased spots on the leaves. One example of this can be the work of Abdelghafour et al. [2], who detect *downy mildew* by capturing the images using a high-power flashlight, similar to Liu et al. [17], which causes an instantaneous segmentation, then converting the images into L*a*b color space. *Local structure tensor* [14] is used to extract geometric features

III. Material and Methods

In this section, we provide a brief description of the used datasets, and methods.

A. Datasets

Data is a highly valuable asset in computer vision. It is used to calibrate and evaluate the model, therefore we need a dataset with high variability. In this section, we describe the used datasets.

As the primary dataset, we use the *PlantVillage* dataset created by Hughes et al. [13], with the codename: *PV_data*. Other versions of this dataset also exist, for example by Cruz et al. [8], however, ultimately we chose the one available on GitHub[1], because in this case the background of the images is already blackened, Figure 1, unlike other versions, where the background is a gray table surface.

Additionally, we create an *infield-dataset*, which contains cropped images from vineyards from various locations. This ensures a wide variety of camera angles and lighting conditions. The first two such datasets are the ones we have access to, each of them located in Romania, courtesy of the University of Agricultural Sciences and Veterinary Medicine. Our main vineyard is located in Cluj-Napoca (codename: *Cj_data*), then less data is from Apoldu de Sus (codename: *Ap_data*). These images are captured using a DJI Mini 2 drone, using the onboard 4K camera.

The next dataset is from Abdelghafour et al. [1] (codename: *Ab_data*). This is a vineyard near Bordeaux. The uniqueness of this dataset is that while the images are captured from a camera mounted on a tractor, the creators use a high-power flashlight, Figure 3a. The result is a highly detailed canopy, with a dark, almost invisible background, all this with consistency, independently from weather or time of day.

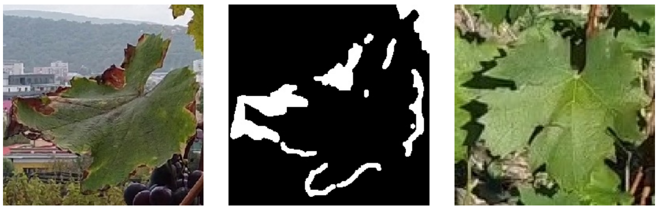
The fifth dataset is created by Alessandrini et al. [4] (codename: *Al_data*), using an Italian vineyard, focusing on leaves with *esca* disease, from different distances and angles, Figure 3b.

The last dataset is created by Casado et al. [7], named S3CavVineyardDataset (codename: *S3_data*), based on a swiss vineyard, Figure 3c. The images are perpendicular to the vines, captured from a tractor.

1) Data Organization: Since the task in this work is disease detection on single-leaf images, we need to have a ground truth mask for each image, which is created by us manually using GIMP [28].

From the dataset, we use 648 images of leaves with some sort of disease (*black rot*, *esca*, and *grapevine yellow*, or *dry leaf*), and 433 images of healthy leaves. Additionally, we crop leaves from other datasets: *Cj_data*, *Al_data*, *Ab_data*, *Ap_data*, and *S3_data*. We call this latter group *infield* images, hence their background is not black, but the real environment, Figure 4. In the *infield* group, 118 diseased leaves, and 100 healthy leaves are included. The task is disease detection, hence in the case of healthy images, the mask is just a black image, meaning that no diseased parts are present. The *PV_data* images are considered as *group1*, with an 80-20 train-test image ratio. The *infield* images are considered *group2* with

[1] https://github.com/shreyansh-kothari/Grapes-Leaf-Disease-detection



(a) Diseased sample. (b) Binary mask. (c) Healthy sample.

Fig. 4: Samples cropping *infield* leaves for disease detection.

a 20-80 train-test image ratio. We plan three test cases. In the first case, we train only on the images from *group1* and test only on *group1*. In the second test, we train only on the images from *group1* and test on *group2*. In the third test, we train on images from *group1* and *group2* and test on *group2*. All of these images are sized 255×255 pixels.

B. Methods

The disease detection task segments a region of interest, for this we choose both neural network-based methods, as well as a classical method to analyze their performance. We choose different architectures, to provide a wider analysis.

1) Mask R-CNN: The first machine learning algorithm that we include is the *Mask R-CNN* [11], which is used for precision viticulture by many researchers, for example, Ghiani et al. [9] and Santos et al. [24]. This is a well-known method, together with its other variants, such as *Faster R-CNN* ([23]). The base for implementing this method can be found at the link[2].

2) MobileNetV3: The idea of using *MobileNetV3* [12] comes from Aghi et al. [3], who use it for canopy segmentation and row detection. The base for implementing this method is available[3]. The main advantage of this model is its simplicity and lightness, making it more suitable for running on embeded devices.

3) Feature Pyramid Network: The Feature Pyramid Network FPN [15] architecture stands as a middle-ground between the lightness of *MobileNetV3* and the accuracy of *Mask R-CNN*. We have seen the FPNs perform decently in surface normal estimation application [18], and canopy segmentation [19], since different support sizes are analogous on some levels to vine leaves. The base for implementing this method can be found at the link[4].

4) SegNet: As the name suggests, *SegNet* [5] is a neural network designed for segmentation. Similarly to *Mask R-CNN*, *SegNet* is also well-known and widely used. Since it is based on an encoder-decoder architecture, the latent space could be helpful in encoding the diseased parts. The base for implementing this method is available[5].

5) Otsu's thresholding: Otsu's thresholding [22] is a dynamic thresholding application, meaning that instead of choosing a static value, and masking the image according to this value, *Otsu's thresholding* analyses each image, and chooses a thresholding value that is more decisive. The main drawback of this method is that despite the RGB color space using 3 channels, *Otsu's thresholding* only works with monochromatic images. One solution would be to mimic the work of Abdelghafour et al. [2], who convert the input signal into HSV color space and apply *Otsu's thresholding* only on the hue channel. However, because RGB does not have a hue value, we conduct a series of tests, to define the best solution. This phase is similar to the training phase in the case of a neural network since we use the training data for estimating an optimal set of parameters, which are later applied to the test data.

We run the thresholding method for each channel, which results in 3 binary masks. Then we combine these masks with each other, achieving a total of 7 masks. Then we do the same thing, but this time inverting the binary masks, since it is possible, that the region of interest might fall into the lower end of the thresholding. We compare the binary masks with the ground truth masks to determine the combination which gives us the best accuracy. Additionally, we create another set of estimation masks, where each individual channel is either inverted or not, depending on the previous results, and then combine these masks to determine the best combination. The ideal combination is noted for each case, and this parameter is used at the time of evaluation. Rather interestingly, from these initial tests, the optimal combination is between the red and blue channels, while the green channel results in slightly worse accuracy. The base for implementing this method is the OpenCV library [6].

IV. Evaluation

In this section, we show the results of the conducted tests. For each task, the accuracy is calculated on the percentage of the pixels correctly estimated, compared to the ground truth. At first sight, this task might seem trivial, because of the small images, yet, the shade difference and the varying spot shapes add a layer of complexity to it. As we described previously, we conduct 3 tests: 1) train on *PV_data* (864 images), test on *PV_data* (217 images); 2) train on *PV_data* (864 images), test on *infield* images (174 images); 3) train on *PV_data* with added infield images (908 images), test on *infield* images (174 images). The last test case is to see how much the accuracy rises by adding 5% more images from the test domain. Accuracy can be seen in Table I, and the range of false positives and false negatives in Table II.

From our tests, we can see that *SegNet* is not suitable for understanding healthy leaves, where it should not extract any region of interest, yet it does, which pulls back the performance by at least 20%. Furthermore, *Otsu's thresholding* is extremely unstable. On the other hand, both of these methods are the fastest. On the first test, *Mask R-CNN* performs the best, although, it is the slowest, while *MobileNetV3* and FPN

Otsu	35	2	48	6	48	6
Mask R-CNN	3	3	38	1	10	3
MobileNetV3	0	16	11	8	3	14
FPN	8	1	48	2	4	12
SegNet	35	2	40	0	31	4

perform relatively well, in a much shorter time, which can be important for real-time applications on the field.

Another aspect that we want to check is the amount of increase in accuracy if a few *infield* images are added to the training. In the case of *Otsu's method*, we find virtually no difference, while for the other methods, we see an increase in accuracy between 10-20%, which is significant for such little data. This test is an indication, that it is worth pretraining a model with general images, from various grape leaves, and then training a few epochs with a few additional images from the domain of application. However, we think that in the case of *MobileNetV3* we see an anomaly in the second test because the result is too accurate.

Additionally, we also observed, that on average the number of false positives is higher for *Otsu's method*, *Mask R-CNN*, FPN, and *SegNet*, while for *MobileNetV3* the false negatives are higher. We generally prefer false positives, because in VDD an image flagged as infected should be further investigated by a specialist, therefore, be corrected, however, an infected leaf that is not flagged is unnoticed.

V. Conclusion

In this work, we compared the performance of existing segmentation algorithms from the state of the art for vine disease leaf segmentation and detection. Overall, the CNN-based methods performed well except for *SegNet*, while the *Otsu's thresholding* gave poor results, even if it is the fastest method. We also proved, that adding just a few images from the target domain to the general dataset, yields significantly better performance. While *Mask R-CNN* provides relatively good accuracy, the FPN-based method offers much faster execution without an increased loss of accuracy and an overall smaller memory footprint for the model. The latter aspect is relevant for the embedded implementation of the methods.

For future work, we would like to experiment with different color spaces, as the color spaces can affect the performance of the CNN methods. Although, our raw data is in RGB, a neural network could be capable of optimizing the data in a latent layer better than a simple color conversion.

The disease segmentation can be extrapolated on entire grapevine canopies, which removes the necessity for individual leaf extraction. Additionally, further tests should be done using more variable datasets, including synthetic datasets, and more vine species captured from different angles from different vineyards.

***Abstract*—An approach to speaker's age classification using deep neural networks is described. Preliminary signal features are extracted, based on mel-frequency cepstral coefficients (MFCC). For gender classification an MLP network appears to be a satisfactory lightweight solution. For the age modelling and classification problem, two network types, ResNet34 and x-vectors, were tested and compared. The impact of signal processing parameters and gender information (both theoretic perfect realistic imperfect) onto the age classification performance was experimentally studied. The neural networks were trained and verified on the large "Common Voice" dataset of English speech recordings.**

I. Introduction

ALTHOUGH work on speaker age recognition dates back to the 1950s [1], this problem is still difficult to solve in practice. Several reasons for this state of affairs can be listed. The speaker's perceived age and his/her chronological age can differ significantly. To train the age classifier well, a very large database of recordings labeled with the age of the speakers will be required. By its nature, the sound of the same speaker's speech depends on many factors independent of age, such as gender, weight, temperament, mood, ethnicity. The first systems with relatively good efficiency in estimating the age of the speaker were developed some 20 years ago [2], [3]. Currently developed systems for estimating the age of the speaker are based on acoustic modeling used in the speaker recognition (speaker identification and verification) systems [4]. The basic classic machine learning methodologies used for this problem are UBM-GMM (Universal Background Model - Gaussian Mixture Model) and "i-vectors" [5], [6], [7]. An early solution based on deep neural networks is the "x-vector" [8], [9], [10] network. Other deep network architectures, such as LSTM [11] or ResNet [12], were also proposed for this purpose.

In this paper, we propose a gender-informed approach to speaker's age classification using the large "Common Voice" database [13] for neural network training and testing. In section 2, this database is introduced in more details. The implemented system SAR (speaker's age recognition) is presented in section 3. Here, we already present results of initial experiments, aimed to find optimal settings of two signal processing parameters. The main experiments and a summary of age classification performance, follows in section 4. At the end, in section 5, we conclude the work with a summary of results.

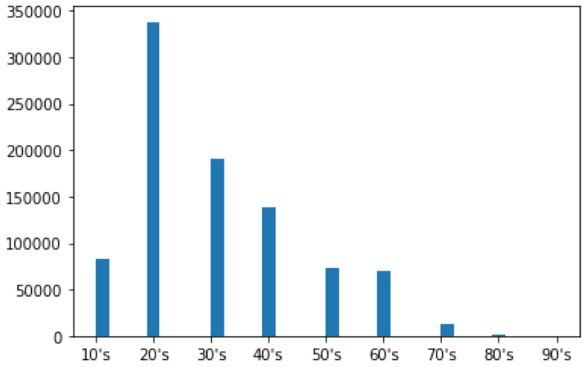

Fig. 1. Statistics of the English language subset of "Common Voice" recordings according to age groups

II. Datasets

A. "Common Voice"

Two large databases of tagged recordings were analyzed for the speaker's age recognition (SAR) system. The first one is "Age-VOX-Celeb" [14], which contains age tags of celebrity recordings, downloaded from "YouTube". The second base is "Common Voice" [13], a Mozilla project, dedicated to record the speech of ordinary Internet user. Everyone can register and record his voice. Other users can listen to the recordings and evaluate their correctness. The tags included speaker's accent, age and gender. The content of the database is growing every day – it contains over 37 million audio files with speech samples in many languages. The "Common Voice" database was chosen here, due to its easy accessibility and a large containment of almost 900,000 recordings in English from over 18,000 people (Fig. 1).

The database contains recordings of voices ranging from teenagers to people in their nineties, but the distribution of age groups is significantly uneven. There are only few participants over the age of seventy. Therefore, for the first series of experiments we decided to limit the age classification to the

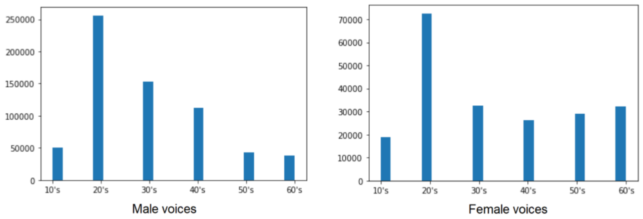

Fig. 2. Distribution of the English subset of "Common Voice" recordings according to speaker's gender and age

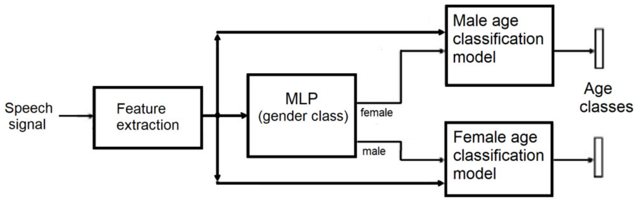

Fig. 3. Structure of SAR

first six age groups. The number of recordings from females is around 200,000 and are much lower than the number of recordings from males, which are over 650,000 (Fig. 2). This leads to our separate treating of age classes for women and men.

This large number of speakers supports extensive speaker classification studies but it also requires extensive computational resources for training and testing neural network models. As a tradeoff solution, we decided to select a training subset of 25,000 recordings of men from each age group and 15,000 recordings of women from each age group. The test set consisted of thousand recordings for each age group, regardless of gender. In total, 12 classes were distinguished, which resulted from taking into account the 6 age groups and 2 gender of the speaker.

III. Solution SAR

The overall structure of the speaker's age recognition (SAR) system is shown in Figure 3. There are three processing stages: feature extraction, gender classification and age group classification.

A. *Feature extraction*

Standard speech features were chosen based on ”mel frequency cepstral coefficents” (MFCC), delivered by popular audio processing library - the LibRosa library [15]. A feature vector is generated for every signal frame. It consists of 70 coefficients, i.e. 3×23 MFCC-based (i.e., MFCCs, delta MFCCs and delta-delta MFCCs) plus 1 energy coefficient.

Nevertheless the standard MFCC-based signal parametrization, some signal segmentation parameters still need to be set optimally. We experimented with different settings of two parameters: the window length (n_fft) and the delay between consecutive windows (hop_ length).

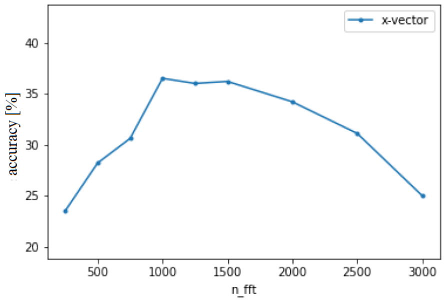

Fig. 4. Experiments with different window lengths

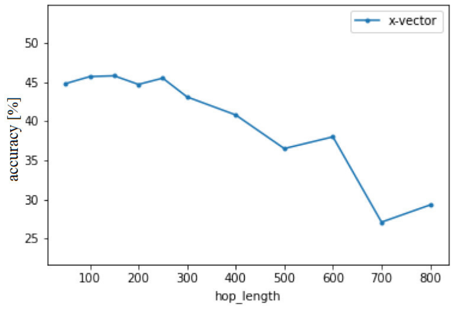

Fig. 5. Experiments with different hop lengths

In the first type of experiments various window lengths, have been set, the x-vector network was trained and its test performance was evaluated. In this test series, the hop_length was set to half of n_fft. The classification performance as a function of window length is shown in Figure 4. The highest quality of results is observed for n_fft in the range between 1000 and 1500 signal samples. (i.e., 45 – 68 ms). Both for smaller and larger windows, the performance is deteriorated. Hence, we selected a window size of 1000 samples, using a FFT of order 1024.

In experiments with different hop lengths, the window size was fixed. The delay parameter was studied in the range from 50 to 800 (Figure 5). As expected, the results show a tendency of increased classification accuracy with decreased hop length. The best performance was stable obtained for delays between 50 and 250 samples (i.e., ca 2 – 11 ms). Among them, we have chosen 250 samples for reasons of computational efficiency. The accuracy of the x-vectors network was 45.5%, only slightly worse than 45.7% and 45.8% for 100 and 150 samples, respectively. Please note, that already with this optimal setting of the hop length parameter, the multi-class classification accuracy of the x-vectors network has been increased by 9% (from 36.5% to 45.5%).

B. *Gender classification*

For the purpose of gender classification, the feature vectors of all the frames of given recording, are combined into a single vector. This constitutes the input of a multi-layer perceptron (MLP) with two hidden layers. The network is trained on samples annotated with gender information. We evaluated the

Layer	Layer context	Total context	Input x output
Conv1D	[t-2,t+2]	5	210x512
Conv1D	{t-2,t,t+2}	9	1536x512
Conv1D	{t-3,t,t+3}	15	1536x512
Conv1D	{t}	15	512x512
Conv1D	{t}	15	512x1500
stat pooling	[0,T]	T	1500Tx3000
linear	{0}	T	3000x512
linear	{0}	T	512x512
softmax	{0}	T	512xN

Fig. 6. The x-vectors network [8]

trained model on a small database, containing recordings of 24 speakers (the RAVDESS database), and its accuracy was 98.7%.

C. x-vectors

X-vectors is a very popular speech recognition network, recently proposed in [8] and already ighly cited in the literature. The architecture of the x-vector network is summarized in Figure 6. The discussed architecture uses a one-dimensional convolution layer - the filter kernel operates along the time domain, while each feature is treated separately. The first five layers operate in this way. Statistical data (mean and deviation) are extracted from the last convolutional layer for each output feature (each channel). This operation is to ensure a fixed length of the output vector, which will later be processed by two dense layers. Finally, there is a softmax layer that maps their outputs to 12 age classes.

D. ResNet34

The second, much more complicated neural network used in our work, is ResNet34 (Figure 7). This architecture also enjoys popularity [16], [17]. It is based on convolutional networks and residual connections. It starts with a convolutional layer with 64 output channels and a 3×3 reception area. Then, there is a ResNet block of 3 layers, each one composed of 2 convolutional layers, with a 3×3 area and 64 outputs. Next, three more ResNet blocks follow, with same kernel size but growing number of outputs. An average pooling layer, a dense layer and softmax complete the network.

We conclude, that the main difference between the two considered architectures is the use of different convolutional layers. X-vectors is using a lightweight 1-D convolution along time axis, whereas ResNet34 applies a true 2-D convolution along time and feature indices.

IV. Results

The technological stack of the system implementation consists of: the Python 3.9.6 language, Jupyter Notebook 8 interactive code editor Librosa 9 library in Python for audio signal processing. PyTorch 10 library for neural network tools and utility libraries, like NumPy and Pandas.

3 classes x two separate models - gender information	77,3%	86,1%

Fig. 8. Summary of age classification results obtained on the "Common Voice" subset

A. Age classification

In Figure 8, we give results of several training and test series of the two considered network architectures for the class-balanced subset of the „Common Voice" English dataset. Both x-vectors and ResNet34 were applied in the same way - they were trained in 15 epochs with the feature set. The second model is more complex than x-vectors (one needs ca. 10 times more parameters to train) but it shows a better performance than the first one in all experiments.

B. Age classification without gender information

Consider first a 6-class problem, when there is one model for both male and female speakers and no gender information controls the classification process. Both networks perform poorly (25,5% x-vectors, 32,7% ResNet34). If perfect gender information is available to the system, one can expect better results.

C. Age classification with perfect gender information

Consider first a single network model created for a 12-class problem (2 gender $\times 6$ age groups), with the additional information about gender, that allows to select the most likely output from the proper 6-class subset. The ResNet34 shows a better total accuracy of 67,1% in this classification case, compared to an accuracy of 53,8% of the x-vectors.

Now, remember our proposed architecture, shown in Figure 3, with two separate models, trained separately on the two gender samples. Each of the two models is classifying a

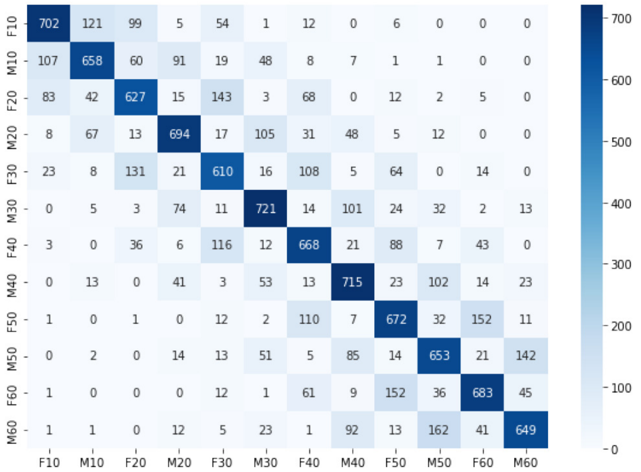

Fig. 9. Confusion matrix of age classification into 12 classes under known gender information, obtained on the "Common Voice" dataset using the ResNet34 network

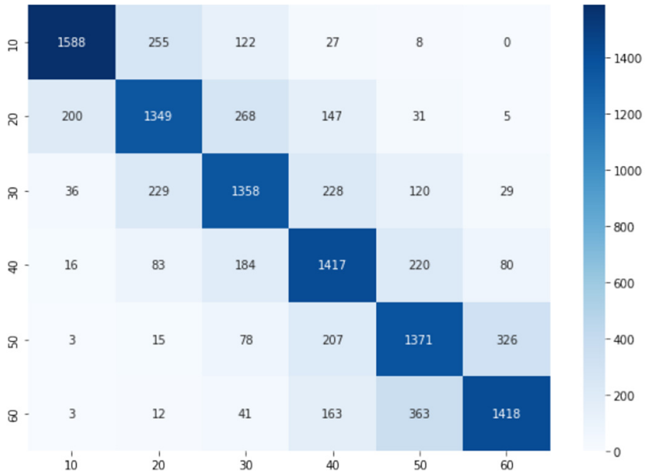

Fig. 10. Confusion matrix of age classification for separate networks, each created for 6 classes, under known gender information (presenting combined results of the two networks), obtained on the "Common Voice" dataset using the ResNet34 network

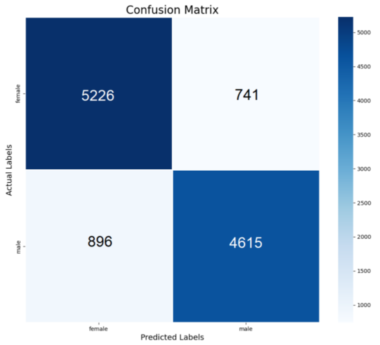

Fig. 11. Confusion matrix of gender classification in the gender-and-age experiment

speaker into one of 6 age classes. In this solution, the performance of both model types is again increased - ResNet34 achieves 70,8% and x-vectors achieves 59,6%.

D. Grouping of age classes

An obvious way further to improve the results is to decrease the number of classes, by grouping difficult-to-distinguish classes. In many applications, the speaker's age classification problem can be reduced to three age classes: teenagers (class "10"), adults (classes "20", "30", "40") and senior adults (classes "50", "60"). In this case, the x-vector-based solution has shown increased accuracy from 59.6% (for 6 classes) to 77.3% (for 3 classes), and the ResNet34 - from 70.8% (6 classes) to 86,1% (3 classes).

E. Confusion matrices

The above results can be justified, when confusion matrices are studied. Such a matrix for results on 12 classes, obtained with ResNet34, is presented in Figure 9. Already a general view leads to the conclusion, that main errors happen between neighbour age groups, as the "errors" (represented by big numbers outside the diagonal) concentrate in the direct neighborhood of the diagonal axis. For example, a misclassification of a teenager as a 60+ senior is practically excluded. Similar observation comes from an error matrix created for a 6-class problem, with gender information, were the results for the same ages classes of man and women are combined (Figure 10).

F. Real gender and age classification

In the second series of experiments, we simulated the realistic case of imperfect gender information. We divided 25000 recordings into three sets: a) for training the age model (now for 8 age classes), b) for training the gender model, c) for coupling age and gender into 16 age/gender classes, i.e., class 10_male, 20_male, ... , 80_male, 10_female, 20_female, ... , 80_female. The results on the test subsets, obtained for models created after 30 learning epochs, are presented by two confusion matrices, given in Figures 11 and 12.

The gender success rate (Recall) for females is 87.58% and for males – 83.74%. Thus, the weighted gender-average success rate is 85.74%. The overall age success rate (average Recall) of the combined gender–and–age classifier is 41%, which applies to a 16–classes problem. Interestingly, an increasing age is correlated with growing success rate. The oldest age groups of people 70+ and 80+ are recognized very well.

V. Conclusions

The proposed three-stage approach to speaker's age classification has been trained and tested on a large dataset containing recordings of a high number of speakers. Presented results have shown the positive impact of perfect gender information onto age classification performance. We have also received realistic performance scores under non-perfect gender information. The "heavy-weight" ResNet34 network models

***Abstract*—The focus of this study is on the optimal use of high performance computing in the area of environmental security (air pollution transport, in particular). Contemporary mathematical models of air pollution transport should include a fairly large set of chemical and photochemical reactions to be established as a reliable simulation tool. The investigations and the numerical results reported in this paper have been obtained by using a large-scale mathematical model called the Danish Eulerian Model (DEM).**

For optimization of some applications of the Danish Eulerian Model in various important scientific, social and economic areas, it is of great importance to simplify the model as much as possible, preserving the high reliability of its output results. A careful sensitivity analysis is needed in order to decide how to do such simplifications. On the other hand, it is important to analyze the influence of variations of the initial conditions, the boundary conditions, the rates of some chemical reactions, etc. on the model results in order to make right assumptions about the possible simplifications, which could be done. The sensitivity analysis version of the Danish Eulerian Model was created for these purposes. Its complexity is of higher order, a real challenge for the top performance supercomputers nowadays. The sensitivity analysis version of DEM (SA-DEM) has been implemented on the new Bulgarian petascale supercomputer DISCOVERER. It is a part of the European High Performance Computing Joint Undertaking (EuroHPC), which is building a network of 8 powerful supercomputers across the European Union (3 pre-exascale and 5 petascale).

The results of some scalability experiments with SA-DEM on the new Bulgarian petascale supercomputer DISCOVERER are presented here. They are compared with similar experiments performed on the Mare Nostrum III supercomputer at Barcelona Supercomputing Centre – the most powerful supercomputer in Spain by that time, upgraded currently to the pre-exascale Mare Nostrum V, also part of the EuroHPC JU infrastructure.

Keywords: sensitivity analysis, air pollution, numerical model, supercomputer, parallel algorithm, scalability

I. Introduction

Environmental security is rapidly becoming a significant topic of present interest all over the world. It is necessary to carry out many comprehensive scientific studies and to analyze carefully the most important physical and chemical processes during the transport, and transformations under the transport of air pollutants. An effective performance of such complicated procedures requires a joined research and collaboration between experts in the field of environmental modeling, numerical analysis and scientific computing.

The aim of the present work is to propose a new mechanism for investigation the sensitivity of the calculated concentration levels of important pollutants (like nitrogen dioxide NO_2 and especially ozone O_3) due to variation of rates of the involved chemical reactions in a real-life scenario of air pollution transport over Europe with the Unified Danish Eulerian Model (UNI-DEM).

In investigation of various highly complex engineering, physical, environmental, social, and economic systems it is important to measure relations that describe the effect on the output results when the conditions for the input change.

Sensitivity **a**nalysis (SA) is the study of how uncertainty in the output of a model can be apportioned to different sources of uncertainty in the model input [20]. Two classes in sensitivity analysis are considered in the existing literature: local SA and global SA. Local SA studies how some small variations of inputs around a given value change the value of the output. Global SA takes into account all the variation range of the inputs, and apportions the output uncertainty to the uncertainty in the input factors.

In general, several sensitivity analysis techniques are available [20]. Most existing methods for providing SA rely heavily on special assumptions connected to the behavior of the model (such as linearity, monotonicity and additivity of the relationship between input factor and model output). Among quantitative methods, variance-based methods are the most often used [19]. The main idea of these methods is to evaluate how the variance of an input or a group of inputs contributes into the variance of model output.

Computational tasks arising in the treatment of large-scale air pollution models are enormous. It is highly desirable to simplify as much as possible the model, keeping high level of reliability of models' results. Sensitivity analysis is rather helpful in order to decide where and how simplifications can be made. On the other hand, it is important to analyze the influence of variations of the initial conditions, the boundary conditions and/or the chemical rates on the model results in order to make right assumptions about the simplifications which have to be implemented. Such an analysis can give valuable information about the performance of reliable and reasonable simplifications or to identify parameters and mechanisms the accuracy of which should be improved, because the model results are very sensitive to variations of these parameters and mechanisms. Thus, the goal could be: (i) improving the model, (ii) increasing the reliability of the results, and (iii) identifying processes that must be studied more carefully.

The rest of the paper is organized as follows: In Section II the general concept of global sensitivity analysis is introduced in terms of ANOVA high-dimensional model representation. In Section III the Danish Eulerian Model is described, including its high-performance parallel code UNI-DEM and its special sensitivity analysis version SA-DEM. In Section IV numerical results from some scalability experiments with SA-DEM on two of the most powerful supercomputers in Europe are given. Finaly, some conclusins are drawn.

II. Sensitivity Analysis Concept

A. Global Sensitivity Indices

When the sensitivity of the concentrations calculated by UNI-DEM (or any other deterministic mathematical model) is studied, it is convenient to introduce some stochastic variables and equations.

It is assumed that the mathematical model can be presented as a model function

$$\mathrm{u} = f(\mathrm{x}), \qquad \mathrm{x} = (x_1, x_2, \ldots, x_d) \in U^d \equiv [0;1]^d \tag{1}$$

is a vector of input parameters with a joint **p**robability **d**ensity **f**unction (p.d.f.) $p(\mathrm{x}) = p(x_1, \ldots, x_d)$. In general, real problems are characterized by multiple outputs. Here it is assumed that a scalar output is given. It is also assumed that input variables are independent (non-correlated input variables) and the density function $p(\mathrm{x}) = p(x_1, x_2, \ldots, x_d)$ is known, even if x_i are not actually random variables. This implies that the output u is also a random variable, as it is a function of the random vector x, with its own p.d.f.

It is reasonable to introduce an indicator that measures the importance of the influence of a given input parameter onto the output. The main indicator referred to a given input parameter $x_i,\ i = 1, \ldots, d$ (normalised between 0 and 1) is defined as

$$\frac{\mathbf{D}[\mathbf{E}[\mathrm{u}|x_i]]}{\mathbf{D}_\mathrm{u}}, \tag{2}$$

where $\mathbf{D}[\mathbf{E}[\mathrm{u}|x_i]]$ is the variance of the conditional expectation of u with respect to x_i and $\mathbf{D}_\mathrm{u}$ is the total variance according to u. This indicator is named *first-order sensitivity index* by Sobol' [23] or *correlation ratio* by McKay [13]. A brief review of measures of importance used in variance-based methods for sensitivity analysis is given in [3].

The *total sensitivity index* [10] provides a measure of the total effect of a given parameter, including all the possible joint terms between that parameter and all the others. The **t**otal **s**ensitivity **i**ndex (TSI) of input parameter $x_i,\ \ i \in \{1, \ldots, d\}$ is defined in the following way [10], [23]:

$$S_{x_i}^{tot} = S_i + \sum_{l_1 \neq i} S_{il_1} + \sum_{l_1, l_2 \neq i, l_1 < l_2} S_{il_1 l_2} + \ldots + S_{il_1 \ldots l_{d-1}} \tag{3}$$

where S_i is called *the main effect (first-order sensitivity index)* of x_i and $S_{il_1 \ldots l_{j-1}}$ is the j-th order sensitivity index (respectively *two-way interactions* for $j = 2$, *three-way interactions* for $j = 3$ and so on) for parameter x_i $(2 \leq j \leq d)$. The higher-order terms describe the interaction effects between the unknown input parameters $x_{i_1}, \ldots, x_{i_\nu},\ \nu \in \{2, \ldots, d\}$ on the output variance. Usually for practical computations the set of input parameters is classified according their TSI [3]: *very important* if $0.8 < S_{x_i}^{tot}$, *important* if $0.5 < S_{x_i}^{tot} < 0.8$, *unimportant* if $0.3 < S_{x_i}^{tot} < 0.5$, and *irrelevant* if $S_{x_i}^{tot} < 0.3$. In subsection II-B we will show how sensitivity indices $S_{l_1\ \ldots\ l_\nu}$ are defined via the variances of conditional expectations $\mathbf{D}_{l_1} = \mathbf{D}[f_{l_1}(x_{l_1})] = \mathbf{D}[\mathbf{E}(\mathrm{u}|x_{l_1})]$, $\mathbf{D}_{l_1\ \ldots\ l_\nu}, 2 \leq \nu \leq d$ (see, equation (8)). It is often reasonable to assume (see [12], [17]) that relatively small subsets of input variables in high-dimensional models have the main impact on the output. The high dimensional sums can be neglected when many practical problems are studied. This means that one can use low-order indices preferably, but should be able to control the contribution of higher-order terms.

B. The Sobol' Approach

The Sobol' method is one of the most often used variance-based methods. To our best knowledge the Sobol' sensitivity measure [23] was first published in [22]. An important advantage of this method is that it allows to compute not only the first-order indices, but also indices of a higher-order in a way similar to the computation of the main effects. The total sensitivity index can be calculated with just one Monte Carlo integral per factor.

The method for global SA applied here is based on a decomposition of an integrable model function f in the d-dimensional factor space into terms of increasing dimensionality:

$$f(\mathrm{x}) = f_0 + \sum_{\nu=1}^{d} \sum_{l_1 < \ldots < l_\nu} f_{l_1 \ldots l_\nu}(x_{l_1}, x_{l_2}, \ldots, x_{l_\nu}) \tag{4}$$

where f_0 is a constant. The total number of summands in equation (4) is 2^d (see [25]) and, in general, this so called high dimensional model representation [23] is non-unique. But, if each term is chosen to satisfy the following condition

$$\int_0^1 f_{l_1 \ldots l_\nu}(x_{l_1}, x_{l_2}, \ldots, x_{l_\nu}) \underset{\cdot}{\mathrm{x}}_{l_k} = 0, \quad 1 \leq k \leq \nu \leq d \tag{5}$$

then (4) is unique. The representation (4) is called **ANOVA-representation** of the model function $f(\mathrm{x})$ [24]. Here and hereafter the variables of integration are markeed by a dot below in the integration formulae.

The functional decomposition of $[0;1]^d$ ANOVA (meaning: **ANalysis Of VAriance**) -representation has been studied by many authors [2], [9], [21], [26]. Sobol' has proven [22] that the decomposition (4) is unique on the assumption (5) and the functions of the right-hand side can be defined in a unique way by multidimensional integrals [24]:

- $f_0 = \displaystyle\int_{U^d} f(\mathrm{x})\underset{\cdot}{\mathrm{x}}$;
- $f_{l_1}(x_{l_1}) = \displaystyle\int_{U^{d-1}} f(\mathrm{x}) \prod_{k\neq l_1} \underset{\cdot}{\mathrm{x}}_k - f_0,\ l_1 \in \{1,2,\ldots,d\}$;
- $f_{l_1 l_2}(x_{l_1},x_{l_2}) = \displaystyle\int_{U^{d-2}} f(\mathrm{x}) \prod_{k\neq l_1,l_2} \underset{\cdot}{\mathrm{x}}_k - f_0 - f_{l_1}(x_{l_1}) - f_{l_2}(x_{l_2}), l_1, l_2 \in \{1,\ldots,d\}$.

An additional essential property of the terms in the ANOVA-representation is their mutual orthogonality:

$$\int_{U^d} f_{i_1\ldots i_\mu}(\mathrm{x}) f_{j_1\ldots j_\nu}(\mathrm{x})\ \underset{\cdot}{\mathrm{x}} = 0,$$
$$(i_1,\ldots,i_\mu) \neq (j_1,\ldots,j_\nu), \quad \mu,\nu \in \{1,\ldots,d\}.$$

It follows from the assumption that the above subsets of indices differ from one another at least one element and the corresponding integral vanishes for this index due to (5).

The quantities

$$\mathbf{D} = \int_{U^d} f^2(\mathrm{x})\underset{\cdot}{\mathrm{x}} - f_0^2 \qquad (6)$$
$$\mathbf{D}_{l_1\ \ldots\ l_\nu} = \int f^2_{l_1\ \ldots\ l_\nu}(\mathrm{x})\underset{\cdot}{\mathrm{x}}_{l_1}\cdots\underset{\cdot}{\mathrm{x}}_{l_\nu}$$

are called variances (total and partial variances, respectively) and have been obtained after squaring and integrating over U^d the equality (4) on the assumption that $f(\mathrm{x})$ is a square integrable function (thus all terms in (4) are also square integrable functions). Therefore, the total variance of the model output is partitioned into partial variances [22] in the analogous way as the model function, that is the unique ANOVA-decomposition:

$$\mathbf{D} = \sum_{\nu=1}^{d} \sum_{l_1<\ldots<l_\nu} \mathbf{D}_{l_1\ldots l_\nu}. \qquad (7)$$

It is obvious that the use of terms of probability theory is based on the following interpretation: in general, the input parameters are random variables distributed in U^d that defines $f_{l_1\ \ldots\ l_\nu}(x_{l_1}, x_{l_2},\ldots,x_{l_\nu})$ also as random variables with variances (6). For example f_{l_1} is presented by a conditional expectation:

$$f_{l_1}(x_{l_1}) = \mathbf{E}(\mathrm{u}|x_{l_1}) - f_0$$

and respectively

$$\mathbf{D}_{l_1} = \mathbf{D}[f_{l_1}(x_{l_1})] = \mathbf{D}[\mathbf{E}(\mathrm{u}|x_{l_1})].$$

Based on the above assumptions about the model function and the output variance, the following quantities

$$S_{l_1\ \ldots\ l_\nu} = \frac{\mathbf{D}_{l_1\ \ldots\ l_\nu}}{\mathbf{D}}, \quad \nu \in \{1,\ldots,d\} \qquad (8)$$

are called Sobol' global sensitivity indices [22], [24]. This formula coincides for $\nu = 1$ with (2) and the so defined measures correspond to the main effect of input parameters as well as the interactions effect. Using the definition of these measures as ratios of variances and dividing (7) by $\mathbf{D}$, it is easy to show that the following properties hold for the Sobol' global sensitivity indices: $S_{l_1\ \ldots\ l_\nu} \geq 0$, and

$$\sum_{\nu=1}^{d} \sum_{l_1<\ldots<l_\nu}^{d} S_{l_1\ \ldots\ l_\nu} = 1. \qquad (9)$$

Based on the results discussed above it is clear that the mathematical treatment of the problem of providing global sensitivity analysis consists in evaluating total sensitivity indices (3) and in particular Sobol' global sensitivity indices (8) of corresponding order. And that leads to computing of multidimensional integrals: $I = \int_\Omega g(\mathrm{x})p(\mathrm{x})\,\underset{\cdot}{\mathrm{x}},\ \Omega \subset \mathbf{R}^d$, where $g(\mathrm{x})$ is a square integrable function in Ω and $p(\mathrm{x}) \geq 0$ is a probability density function, such that $\int_\Omega p(\mathrm{x})\,\underset{\cdot}{\mathrm{x}} = 1$. This means that in general case one needs to compute 2^d integrals of type (6) to obtain $S^{tot}_{x_i}$. As we discussed earlier the basic assumption underlying representation (4) is that the basic features of the model functions (1) describing typical real-life problems can be presented by low-order subsets of input variables [12], [17], that are constants, terms of first and second order. Thus, the high-dimensional sums (referred to higher-order interactions effects) in (4) can normally be neglected. Therefore, based on this assumption, one can assume that the dimension of the initial problem can be reduced.

Nevertheless, the calculating of the integrals defined by formulas (6) requires integration of different integrands that is not effective according to the computational cost. The procedure for computing global sensitivity indices measuring effect (main or otherwise) of the input parameters that is overcoming this disadvantage has been proposed by Sobol' [24]. Consider an arbitrary set of m variables ($1 \leq m \leq d-1$): $\mathrm{y} = (x_{k_1},\ldots,x_{k_m}),\ 1 \leq k_1 < \ldots < k_m \leq d,$ and let z be the set of $d-m$ complementary variables. Thus $\mathrm{x} = (\mathrm{y},\mathrm{z})$. Let $K = (k_1,\ldots,k_m)$.

The variances corresponding to the subsets y and z can be defined as

$$\mathbf{D}_\mathrm{y} = \sum_{n=1}^{m} \sum_{(i_1<\ldots<i_n)\in K} \mathbf{D}_{i_1\ \ldots\ i_n}, \qquad (10)$$
$$\mathbf{D}_\mathrm{z} = \sum_{n=1}^{d-m} \sum_{(j_1<\ldots<j_n)\in \bar{K}} \mathbf{D}_{j_1\ \ldots\ j_n},$$

where the complement of the subset K in the set of all parameter indices is denoted by $\bar{K}$. The first sum in (10) is extended over all subsets $(i_1,\ldots,i_n)$, where all indices $i_1,\ldots,i_n$ belong to K. Then the total variance corresponding to the subset y is $\mathbf{D}^{tot}_\mathrm{y} = \mathbf{D} - \mathbf{D}_\mathrm{z}$ and it is extended over all subsets $(i_1,\ldots,i_\nu),\ 1 \leq \nu \leq d$, where at least one $i_l \in K,\ 1 \leq l \leq \nu$.

The procedure for computation of global sensitivity indices is based on the following representation of the variance $\mathbf{D}_\mathrm{y} =$

$\int f(\mathrm{x})\ f(\mathrm{y},\mathrm{z}')\d{\mathrm{x}}\d{\mathrm{z}}' - f_0^2$ (see [24]). The last equality allows to construct a Monte Carlo algorithm for evaluating $f_0, \mathbf{D}$ and $\mathbf{D}_{\mathrm{y}}$, where $\xi = (\eta, \zeta)$:

$$\frac{1}{N}\sum_{j=1}^{N} f(\xi_j) \xrightarrow{P} f_0,$$
$$\frac{1}{N}\sum_{j=1}^{N} f(\xi_j)\ f(\eta_j, \zeta_j') \xrightarrow{P} \mathbf{D}_{\mathrm{y}} + f_0^2,$$
$$\frac{1}{N}\sum_{j=1}^{N} f^2(\xi_j) \xrightarrow{P} \mathbf{D} + f_0^2,$$
$$\tfrac{1}{N}\textstyle\sum_{j=1}^{N}\ f(\xi_j)\ f(\eta_j', \zeta_j) \xrightarrow{P} \mathbf{D}_{\mathrm{z}} + f_0^2.$$

For example, for $m = 1, \mathrm{y} = \{x_{l_1}\}, l_1 \in \{1, \ldots, d\}$ and $\mathrm{z} = \{1, \ldots, d\}\backslash l_1$:

$$S_{l_1} = S_{(l_1)} = \mathbf{D}_{(l_1)}/\mathbf{D},\ S_{l_1}^{tot} = \mathbf{D}_{l_1}^{tot}/\mathbf{D} = 1 - S_{\mathrm{z}}.$$

It is important to estimate the computational cost for computing the sensitivity indices in order to be able to compare this approach with other existing approaches. The computational cost of estimating all first-order ($m = 1$) and total sensitivity indices via the scheme proposed by Sobol' can be defined as $N(2d + 1)$ model function evaluations (N model runs for f_0, dN model runs for the first-order terms, and dN model runs for the total effect terms), where N is the sample size and d is the number of input parameters. It should be noted that the most frequently used variance-based methods as Sobol' method and FAST (Fourier Amplitude Sensitivity Test) (and their improved versions) have a computational cost proportional to dN of estimating all main and total effects of input parameters (see [18]).

The computing of higher-order interactions effect can be performed by an iterative process. For example,

$$S_{(l_1 l_2)} = \mathbf{D}_{(l_1 l_2)}/\mathbf{D} = S_{l_1} + S_{l_2} + S_{l_1 l_2},$$

and $S_{l_1 l_2}$ can be obtained assuming that the corresponding first-order sensitivity indices have already been computed.

III. Description and Parallel Implementations of the Danish Eulerian Model (DEM)

DEM is a powerful large scale air pollution model, with more than 30-year development history [28], [15], [16], [29]. Over the years it was successfully applied in different long-term environmental studies in various areas. processes in the atmosphere should be taken into account, which are mathematically represented by a complex PDE system. To simplify it a proper splitting procedure is applied. As a result the initial system is replaced by several simpler systems (submodels), connected with the main physical and chemical processes. These systems should be calculated in a large spatial domain, as the pollutants migrate quickly on long distances, driven by the atmosphere dynamics, especially on high altitude. Here they are exposed to temperature, light and other condition changes in extremely wide range, so does the speed of most chemical reactions. One of the major sources of difficulty is the dynamics of the atmospheric processes, which require small time-step to be used (at least, for the chemistry submodel) in order to get a stable numerical solution of the corresponding system. All this makes the treatment of large-scale air pollution models a tuff and heavy computational task. It has always been a serious challenge, even for the fastest and most powerful state-of-the-art supercomputers. [7], [29].

The Danish Eulerian Model (DEM) [27], [28] is mathematically represented by the following system of partial differential equations:

$$\begin{aligned}\frac{\partial c_s}{\partial t} = &-\frac{\partial(uc_s)}{\partial x} - \frac{\partial(vc_s)}{\partial y} - \frac{\partial(wc_s)}{\partial z} + \\ &+\frac{\partial}{\partial x}\left(K_x\frac{\partial c_s}{\partial x}\right) + \frac{\partial}{\partial y}\left(K_y\frac{\partial c_s}{\partial y}\right) + \\ &+\frac{\partial}{\partial z}\left(K_z\frac{\partial c_s}{\partial z}\right) + \\ &+E_s + Q_s(c_1, c_2, \ldots, c_q) - (k_{1s} + k_{2s})c_s\ ; \\ &\qquad s = 1, 2, \ldots, q\ ;\end{aligned} \tag{11}$$

where the following notation is used:

q - number of equations = number of chemical species,
c_s - concentrations of the chemical species considered,
u, v, w - components of the wind along the coordinate axes,
K_x, K_y, K_z - diffusion coefficients,
E_s - emissions in the space domain,
k_{1s}, k_{2s} - coefficients of dry and wet deposition respectively ($s = 1, \ldots, q$),
$Q_s(c_1, c_2, \ldots, c_q)$ - non-linear functions that describe the chemical reactions between the species.

A. Splitting into submodels and domain decomposition

The above rather complex system is split into three subsystems (submodels), according to the major physical and chemical processes as well as the numerical methods applied in their solution (marked by different colors in the right-hand-side of the system). These are (i) the horizontal advection and diffusion, (ii) chemistry, emissions and deposition and (iii) vertical exchange submodels, respectively. The discretization of the spatial derivatives in the right-hand-sides of these submodels results in forming three large systems of ordinary differential equations.

Chemical reactions play a significant role in the model. Moreover, both non-linearity and stiffness of the equations are mainly introduced by the chemistry (see [30]). On the other hand, this is one of the models of atmospheric chemistry, where the chemical processes are described with great detail in a very accurate way. The chemical scheme used in the model is the well-known condensed CBM-IV (Carbon Bond Mechanism; the scheme was proposed in [8], but some enhancements have been obtained in [28] by adding several reactions for handling the ammonia-ammonium transformations in the atmosphere). It includes 35 pollutants and 116 chemical reactions, where 69 are time dependent and the rest 47 are time-independent. The scheme is suitable and adequate to study cases of high concentrations of chemical species.

Another crucial point on the way towards efficient numerical solution of the sub-models is the domain decomposition technique. This is a natural way to achieve distributed memory parallelization of any numerical problem over a large spatial domain. In some cases, however, like the advection-diffusion equations in particular, there is always certain overhead due to the boundary conditions treatment. Minimizing this overhead is a key point towards efficient optimization. On the other hand, optimization should not restrict the portability of the parallel implementation, as the intensive development in the computer technology inevitably leads to regular updates or complete replacement of the outdated hardware. Standard parallel programming tools as MPI and OpenMP (for distributed / shared memory models) are used in order to preserve portability of the code. An important issue towards efficient parallel optimization is also the load-balance. Sometimes the MPI barriers, used to force synchronization between the processes in data transfer commands, do not allow good load-balance. This obstacle can be avoided to some extent by using non-blocking communication routines from the MPI standard library.

More details about the numerical methods, applied to solve these systems, can be found in [1], [11], [28].

B. Parallelization strategy

The MPI standard library is used as a main parallelization tool. The MPI (Message Passing Interface) was initially developed as a standard communication library for distributed memory computers. Later, proving to be efficient, portable and easy to use, it became one of the most popular parallelization tools for application programming. Now it can be used on much wider class of parallel systems, including shared-memory computers and clustered systems (each node of the cluster being a separate shared-memory machine). Thus it provides high level of portability of the code.

In the case of DEM, MPI parallelization is based on the space domain partitioning [15], [16]. The space domain is divided into sub-domains (the number of the sub-domains is equal to the number of MPI tasks). Each MPI task works on its own sub-domain. On each time step there is no data dependency between the MPI tasks on both the chemistry and the vertical exchange stages. This is not so with the advection-diffusion stage. Spatial grid partitioning between the MPI tasks requires overlapping of the inner boundaries and exchange of certain boundary values on the neighboring subgrids for proper treatment of the boundary conditions. The subdomains are usually too large to fit into the fastest cache memory of the corresponding CPU. In order to achieve good data locality, the smaller calculation tasks are grouped in chunks (if appropriate) for more efficient cache utilization. An input parameter CHUNKSIZE is provided, which controls the amount of short-term reusable data in order to reduce the transfer between the cache and the main (slower access) memory. It should be tuned with respect to the cache size of the target machine.

More detailed description of the main computational stages of DEM and the parallelization techniques used in each of them can be found in [1], [4], [15], [16], [28], [29], [30].

IV. Numerical experiments with SA-DEM on the petascale supercomputer IBM MareNostrum III in Barcelona, Spain and Discoverer EuroHPC in Sofia, Bulgaria

Results of scalability experiments with the 2-D fine-resolution grid version of SA-DEM on two of the most powerful supercomputers in Europe are shown in Tables I and II in this section. Some values of the user-defined parameters of SA-DEM used in the experiments on both machines are as follows:

- Grid-version: $(480 \times 480 \times 1)$;
- Time period of modelling: 1 year;
- Time step: 90 sec. (both in advection and chemistry stages);
- Cache utilization parameter: `NSIZE` = 32 .

A. Numerical experiments on the IBM MareNostrum III supercomputer at BSC - Barcelona, Spain

Characteristics of the system IBM MareNostrum III

- 3028 nodes IBM dx360 M4, 16-core, 32 GB RAM per node;
- 48488 cores in total (Intel SandyBridge-EP E5-2670, 2600 MHz);
- Total RAM $>$ 94 TB; Disk storage 1,9 PB;
- Interconnection networks: Infiniband / Gigabit Ethernet;
- Theoretical peak performance $\sim$ 1 PFLOPS.

B. Numerical experiments on the EuroHPC JU supercomputer DISCOVERER in Bulgaria

Below are described some of the most important technical characteristics of the DISCOVERER supercomputer, installed 2 years ago in Sofia Tech Park. by Atos company. The machine is part of a new network of 8 powerful supercomputers in the the European Union, build up and governed by the European High Performance Computing Joint Undertaking (EuroHPC JU).

System properties:

- System model type: ATOS BullSequana XH2000;
- The system consists of 12 racks, 376 blades, 1128 nodes (18 of them – Fat nodes), 2 login nodes (for public access to the system);
- There are 2256 processors and 144384 cores in total;
- Total RAM: 302592 GB (128 GB per node); total disk storage: $\sim$ 12 PB;
- Interconnection: Dragonfly+ with 200 Gbps (IB HDR) bandwidth per link;
- Sustained max. performance: 4.518 PFLOPS (on Linpack standard benchmark tests);

– Theoretical peak performance: 6 PFLOPS, ratio (max to peak): 0.753;
– TOP500 ranking: # 91 in the world, # 27 in EU by the time of instalation (June 2021).

Computing node design:

– CPU type: AMD EPYC 7H12 (code name Rome), 64-core, frequency 2.6 GHz, power consumption 280W;
– CPU sockets per node: 2, CPU Cores per node: 128;
– Main memory per node : 256GB (Each of the 18x Fat nodes has 1024GB Memory);
– Memory type and frequency : 16GB DDR4 RDIMM 3200MT/s DR, (The fat nodes are equipped with 64-GB DDR4 RDIMM 3200MT/s DR);
– Node DP TeraFlop/s peak performance: 5.325TFlops;
– Node sustained performance on Linpack tests: 3.940TFlops;
– DP ratio TeraFlop/s – peak vs Linpack: 0,74 ;
– Linpack node power consumption: 665.1 W per 256 GB compute node; 747.0 W per Fat compute node (Cooling subsystem power consumption excluded);
– Number and bandwidth of network interfaces : 1x 200Gbps HDR.

High performance network properties:

– Interconnection family: IB HDR;
– Interconnection bandwidth per link: 200 Gbps (IB HDR);
– Expected latency (worst case for a 1 kB message): 520ns;
– Interconnection topology: Dragonfly+ ;
– Number of compute nodes per isle (2 Racks): 192;
– Blocking factor within isle : 2:1;
– Number of links to I/O partition: 120;
– Performance: 40 X HDR 200Gb/s ports in a 1U switch, 80 X HDR100 100Gb/s ports in a 1U switch;
– Aggregate switch throughput: 16 Tb/s;
– Up to 15.8 billion messages-per-second;
– Switch latency: 130 ns.

Management network properties:

– Network family: Ethernet;
– Network bandwidth : 10GbE/1GbE.

Storage system and I/O capacity:

– Total net capacity of data: 2031.89 TB;
– Total net capacity for metadata storage + home/apps – 15.25 TB; User home folders and application binaries will be in Data drive; The useable capacity of the filesystem will be 1 to 2
– Aggregated performance: 20 GB/s;
– Number of data modules: 164 HDD;

– Number of metadata modules: 11 SSD;
– Data module details: Net capacity provided (PB): 2.03 PB, Performance provided: 20 GB/s, Number and type of storage elements: 164 HDD + 11 SSD, Size per storage element: 6 TB + 1.92 TB, CPU Cores per server: 10, Main memory per server: 150 GB, Memory type and frequency: DDR4 2666 MT/s, Number and bandwidth interfaces to control data network: 4 x GigE RJ45 for OS access and hardware management, Number and bandwidth interfaces to bulk data network (RDMA): 4x HDR100 IB / 100GbE ports (same ports as for metadata).

V. Conclusions

Sensitivity analysis and particularly the results, reported in this work, have an important twofold role: for mathematical models verification and/or improvement, and/or on the other hand, for a reliable interpretation of experts of main effect, interaction and higher-order interaction effect of input parameters on model output. Variance-based analysis is an useful tool for an advanced investigation of relationships between model parameters, output results and internal mechanisms regulating the system under consideration. Specifying the most important chemical reactions for the model output the specialists from various applied fields (chemistry, physics) may obtain valuable information for an improvement of the model and thus it will lead to an increase of reliability and robustness of predictions.

The results of numerical experiments performed show that:

- The parallel MPI implementation of SA-DEM is well balanced, portable and runs efficiently on some of the most powerful supercomputers in Europe, including the Bulgarian Petascale supercomputer Discoverer, part of the EuroHPC JU network.
- The efficiency and speed-up is higher in the computationally-intensive stages. In particular, the chemistry stage (which does not need any communication between the tasks) has almost linear overall speed-up. The advection stage scales pretty well too, taking into account that there is some unavoidable computational overhead due to overlapping boundaries of the partitioning.
- The time for the computationally-intensive stages is additionally reduced in relation with the number of threads in the hybrid MPI-OpenMP code with the OpenMP lower level of parallelism switched on, which can be exploited on core level within a node.
- Further attention should be payed on the optimization of the I/O processes in order to reduce the slowdown of the execution on large number of nodes.

Acknowledgments

This research was supported in part by the Bulgarian NSF project "Efficient methods for modelling, optimization and decision making" (contract # KP-06-N52/5), and by the European High-Performance Computing Joint Undertaking via the Discoverer Fast Track & Benchmark Access project "Installing, benchmarking, performance and scalability analysis of the UNI-DEM package for air pollution modelling".

***Abstract*—From an analysis of ethical paradoxes based on the inscrutability feature of AI algorithms and resulting from recent advances in this field, this paper emphasizes the pressingness of dedicating research to the potential consequences on societal organization and interactions. With reference to Critical Theory that needs to be recombined with other socio-technical theories, new perspectives on future research is offered and discussed in light of privacy and labor market, their mutual influence as well as limitations.**

I. Introduction

[6] OUTLINE possible challenges of managing human-centered Artificial Intelligence (AI). In the proposed model, the "frontiers of AI" (pp. 5, 14) are placed in a two dimensional space of scope and performance, which set the boundaries of three identified facets: autonomy, learning, and inscrutability. Moreover, the authors suggest further challenges likely to be relevant in the future; among them a reuniting frontier, i.e. ethical issues. In a wealth of literature, the later are referred to as the prevalent concern of the digital age and a major research gap that needs to be occupied on a much larger scale [8], [19], [14]. More specifically, violation of privacy, deep fakes, and accountability are burning issues evolving with AI and at the same time revealing different views on AI technology as well as conflicting at least partly with the prevalent value system established in the non-digital world.

In the digital world, the right for anonymity and the right of forgetting can no longer be guaranteed because algorithms are enabled to establish chains of correlations between pieces of information that can neither be foreseen nor fully understood by a human brain. Consequently, effective barriers to predict and protect these rights cannot be set up including the idea that AI is also employed to discover privacy violations itself. Similar to a trapdoor-one-way function in mathematics, the integrity of data can be manipulated by neural nets in such a way that it becomes impossible to clearly identify fake video clips and pictures from true material. Both, deep fakes and backtracking to a specific person, is realized but not prevented with AI. In other words, the issue at stake is the inscrutability condition as outlined in [6], which creates a paradox. On the one hand, humans have found a method that really helps them in getting work done; yet they are not capable of understanding how it really works. This inscrutability feeds back on the privacy of users. On the other hand, the lack of understanding AI methods also accounts for undermining fundamental rights mainly due to the inscrutability property, which is, by the same token, accountable for more job efficiency elsewhere. Thus, deep neural nets produce advantages and disadvantages that directly conflict each other. In analogy to nuclear fission, today it is still unclear if the advantages of AI outweigh the disadvantages. And this applies to the digital as well as to the analogous world.

The aforementioned paradox really consists of several ethical issues. Due to the inscrutability feature of AI systems, violated privacy has at least a direct and an indirect consequence. The direct consequence consists in massive collections on personality traits and unique identification vectors unknown to the users and future use. The indirect consequence is a substitution effect of human labor. AI algorithms collect data from users granting insights into processes and best practices on their work expertise while pretending help. The gained knowledge can then be used to oust human labor.

In this study, a critical perspective on these paradoxes will be provided. First the background of the theoretical framework, in which the identified AI paradoxes can be embedded, is given. Second, the nature of the paradoxes is analyzed and discussed. Last, the study closes with possible limitations and a short summary of the outcome.

II. Theoretical Framework for Analysis

The aim of the Frankfurt School was to scrutinize and challenge the existing power relations in questioning their underlying (often not explicitly known, but subconsciously assumed) preconditions, how these evolved over time and if these are still valid under the actual conditions that persist at present [24], [2], [17], [15]. Now, we find ourselves in a constantly readjusting societal value system. Socio-economic elites of a society have the power to influence belief and values in their favor and interests. Although elites cannot predict the outcome of their actions with certainty and must not consciously do so, the degree of impact is higher than for other societal groups. Put briefly, the area of influence is not absolute, yet it is higher, especially if considering the number of its members. These sociological findings form the theoretical backbone of what is referred to as Critical

IEEE Catalog Number: CFP2385N-ART ©2023, PTI

Theory under the additional constraint that technology itself establishes and strengthens power relations, i.e. it is tantamount to the means of production, capital goods, and financial assets in classical Marxian thinking. The two ethical paradoxes to be elaborated on in section III are model cases for this theoretical set up since technology is abused to (again) substitute labor. The substitution alone must not be negative. What is disadvantageous is how the socio-economic elite finds a way to keep the productivity gain from the substitution for themselves. From a sociological point of view, the substitution of white collar workers is especially demanding because it may reveal a difference to the first wave of machine automation, which stroke blue collar workers only.

At this point, it is necessary to extend Critical Theory by yet another explanatory variable, that is, proximity, i.e. the degree of similarity to the interests of the socio-economic elite. The hypothesis here would be: The closer a socio-economic group is to the socio-economic elite; the more concessions are made. Within this approach, one would have to observe that the substitution of white collar workers by AI technology comes along with political action that pays more tribute to the well-being of e.g. office workers compared to what the industrial workers experienced in the first wave of machine automation in the last decades of the last century. For the German case, one may speculate how the “Hartz IV” acts differ from the more recent legislation called “Bürgergeld”, which may have construed towards possible future firings coming along with AI engagement in public administrations. At the European level, new AI legislation (AI act) is in preparation, which also includes concessions in this direction [30], [21]. This alone may not be evidence enough for including proximity in Critical Theory, but it gives the incentive to carry out research in this direction.

A different perspective on the challenges revealed by the proposed paradoxes is laid out in Socio-Technical Theories [25], [31], [32], [33], [1]. Here the focus is on the organization and the question of how socio-technical change is analyzed towards the optimal way taking into account employees and their values. There are some more theories tying into the ethics of AI and society, which should be considered and be integrated into future research in this direction. These include *Privacy Calculus Theory* [23], [7], [20] to validate the assumptions of the preset theoretical material. This would offer an IS perspective on privacy issues if extended by findings of *Technological Network Analysis*. In addition, *Information Asymmetry Theory* [3] and certainly also as a cascade of several very influential theories, the *Unified Theory of Acceptance and Use of Technology* [40], are needed to further add on explanatory potential. One of its inputs can be contrasted to the simpler *Technology Acceptance Model* [12], [13], that in a similar manner modifies its predecessor. By the same token these theories could be enriched by or contrasted to old classics such as *Rational Choice Theory* or *Prospect Theory*, but also by more recent findings prevalent in *Organizational Culture Theory*, *Psychological Ownership Theory*, and *Work Systems Theory*.

III. Analyzing AI Ethics Paradoxes

This study is supposed to reveal a contrastive view on two seemingly ethical paradoxes that are selected purposefully for their differing contents, assumptions, and consequences for the society, but at the same time make interconnectedness visible, that is, the inscrutability paradox provokes the "‘AI versus labor"’ dilemma. A stepwise comparison will also reveal the methodological set up of analyzing the two paradoxes. Roughly, the dynamic equilibrium model [37] serves as an orientation. Yet the differentiation of paradox and dilemma applies to the economic context that appreciates logical paradoxes, but not to ethics per se for that moral dilemmas and paradoxes are synonymously used. An ethical paradox is recognized in situations, in which important values or norms are violated no matter how an individual behaves [11].

While the questions on “AI versus labor” need a quantitative analysis of secondary sources, the “inscrutability paradox” is for the most part a qualitative investigation of network designs and algorithms as well as a collection of results in the literature. For the former, to check the assumptions implicitly made by the claim AI substituted labor, data on the branches of unemployment and correlations with branches of dismissal are available by the federal Statistical Office and the Census Bureau. Additionally, data of recruiting branches, expatriates and qualified immigration needs to be aggregated (cp e.g. [22]). From there, it becomes clear for which qualifications organizations aim at. Last, programs of work creation schemes are considered. More particularly, the duration and number of programs that are aligned to AI technology can here be determined. And to evaluate the quality of these programs, they are compared to educational tracks typically present at university curricula.

The second method addressing the “inscrutability paradox” is qualitative. As a starting point, a short collection of acknowledged results of big data analyses could be laid out (e.g. [26]). Some popular findings include results that happen to be technically correct, but are neither causal nor plausible, yet valid with respect to the algorithmic short cut through the data (e.g. of the form: people with green shirts, long hair, and . . . have an 80 percent chance of getting a heart attack). If made public, some of these findings may feedback into future analysis and change the final result with unfair consequences for independent parties (e.g. sellers of green shirts). By use of these examples, an analysis of the algorithmic construct of a limited number of networks used for big data analysis will reveal that the inscrutability feature rather erodes privacy than enhancing it. Now, the same is done for net privacy issues (integrity, authentication, anonymity) and contrasted with e.g. profiling or fingerprinting. Last, privacy and inscrutability is brought together by showing what the application of the respective other algorithmic set up would mean for inscrutability and privacy.

The interrelatedness of privacy and the labor market is revealed when looking at the forecasted consequences on the white collar labor market. Now knowledge jobs, sales agents, law consultants, and the like are affected on a large scale and much will depend on how fast respective AI technologies will be introduced in public and private organizations and if labor forces have sufficient time to shift to other areas of high-quality jobs. The average education time for these vocations are estimated to be five years. It is likely to depend on the age of the learner, too. This line of argumentation hints at the supposition of the paradox: the advantages of human-centered AI technologies in the service sector that are supposed to assist and add value to employed staff are traded off against the cost of their labor, that is, human workforce is potentially substituted by machine power whereas the profit of this substitution is roughly the cost of the employed. But different from the first wave of the machine revolution, which massively reached out to blue collar workers, the ethical paradox could be seen again in the inscrutability of deep learning. Without consciously knowing, service workers grant worldwide petabytes of data on processes, best practices, behaviors. Now, AI algorithms use this naturally grown knowledge, derive new patterns and routines from it. In fact, optimization functions produce even better results than their human counterpart would do. Put briefly, the human employee helps the machine to learn the specifics and secrets of its job. By doing so employees downsize and cut their own jobs while AI tools pretend to assist them, which they do, but in the background collect valuable data to get rid of the human workforce in the long run, which is prevented from transparency by the asynchronous inscrutability property. The knowledge gathered here is most of the time not even explicitly accessible to any human understanding (cf [35]).

This shows how human-centered AI technology in the digital sphere produces ethical paradoxes that further replicate serious consequences, even if unintentionally brought forward, for the interaction in the analogous world. First, it brings together the characteristics of inscrutability acknowledged as inherently preconditioned in all deep net's AI technology, on the one hand, and privacy issues, deep fakes, and accountability, on the other hand. Second, an ethical problem may also be seen in promoting the advantages of AI for the existing workforce while really exploiting their knowledge and preparing its substitution without making it transparent. This is not, as one may think at first glance, an inscrutability issue per se, but mediated by privacy violations since the inscrutability of the inner workings of a deep net are not what is hidden from the public, but the fact that more or less sensitive knowledge is gained from its aid. As a first working hypothesis it looks as though the first paradox seems to be inbuilt as the property of inscrutability that produces a dilemma no matter how it is framed. Inscrutability fosters anonymity, but conflicts with accountability and, at the same time, it discloses privacy (big data correlations), but facilitates disguise (deep fakes). The second paradox, however, is concerned with the social context, for which it is possible to make additional assumptions and find additional factors of influence. As such these assumptions and factors of influence should be modifiable towards the value system of our society. AI may disguise spying on labor skills while pretending support, but it is still the decision of the members of the society to accept its consequences. In other words, if a machine substitutes human labor, we may decide that the substituted workforce continues to receive the full payment and may have more leisure time.

To validly evaluate possible consequences and developmental trends, it is to be further examined if additional assumptions could be made. They have to stand the test of plausibility and if possible have to be derived from the theoretical basis or should be included as a given fact. The latter is the case when the exact employment figures from Census of federal statistical offices, respective branches, and significant workforce shifts are taken into consideration. An example for a theoretical finding that could counterbalance an ethical evaluation is that in times of a high labor demand, the dismissed workforce is even better off if employed in newly created and emerging AI technology branches. This is the case in a Schumpeterean understanding. Yet, what could not be foreseen in the 1930ies, not even up until the turn of the century, was the velocity, in which these changes take place, and its unpredictable consequences for the societal set up (labor, wealth, values). As we have learned from the last burst of the Internet bubble in the early 2000th, interest rate reversals, or the financial crises with a 10-year recession of the American employment market later on that public institutions such as educational systems do not keep pace with the necessary requirements dictated by a digital world economy.

As a consequence, for an ethical evaluation, it is not enough to show one positive path out of dilemmas, but to take into account all (thinkable) possible scenarios and a plausible estimation of their occurrence probability. Indeed, a scenario is more likely if a theoretical claim or a claim derived from a theoretical basis has proven right by past events, which harbor similar assumptions. Paraphrased as a research question, one could ask what are the ethical paradoxes that follow from the assumptions given in the literature, i.e. inscrutability and privacy, task automation and labor market? What is the nature of these paradoxes? Under which costs and assumptions could they be resolved? The answer of an ethical question needs to be contextualized in a social context, in which a set of values prevail. Typically, these values neither are of equal importance ("speaking about the dead" vs. murder) nor do they stay constant over time (adultery, piousness). Some values may change rather drastically if power relations or other dynamics overcome a critical limit (euthanasia, right of succession, role of men and women), others are more rigid and seem to be static (theft, right of possession, piety).

Societies (as groups of people of different sizes [38]) happen to converge on values and its members show an intuitive understanding [27], [18], [16]. Values are key to social cohesion. It implies bottom-up learning processes that emerge over long time spans and they consolidate subconsciously in the collective memory of a community. Also, an intuitive and entrenched understanding of values is necessary to rank values [36], [5], [10], [4], [28], [29]. It is this ranking together with changes in the understanding of values that leads to conflicts and ethical paradoxes whereas changes are often driven by technological innovations (such as AI) or major scientific findings (evolution, solar system, relativity).

Hence to understand ethical paradoxes, it is essential to guarantee social cohesion and thus this research directly offers its practical usefulness. Adjustments in the value system is an ongoing process in all societies and if made transparent, it becomes more robust. The humble scientific value comprises two aspects. First, it consists of the systematic proof of the underlying assumptions and balancing the ranking of values, i.e. how can AI as a new driver of technological innovation and its consequences be embedded into the existing value system. Second the correct derivation of action alternatives from the AI placement must be considered.

There are no clear cut solutions for ethical problems, otherwise they would not be any. Solutions are sketched as appraisals of all alternatives, a careful balancing of all known pros and cons while taking into account the value system prevalent at the time of evaluation. This modus operandi is common in Ethics in general and in Ethics in Information Science in particular. And it has been done for several Topics in AI research [39]. However, along the lines of inscrutability in the condensed form of the frontiers model [6], there is no systematic ethical investigation deriving privacy violations from the inherently given inscrutability feature and arguing for a causal relation to effects on the labor market.

IV. Limitations

When viewed through the lens of Critical Theory, the "Labor versus Automation" paradox could turn out to be not a real ethical paradox because there seem to be legislative solutions that do not contradict to ethical values. Yet the entire chain of arguments cannot be overlooked from a superficial assessment. So the legislature in favor of white collar workers could have negative effects for others, e.g. blue collar workers. The assessment could turn out to be different if considering Socio-technical theories that focus on organizations. Other theoretical groundwork may come forward with ideas not yet considered. All of them need to be accounted for the final evaluation.

For the case of the "inscrutability versus privacy" paradox, there exist at least no obvious solution from which a major drawback on the values could be denied. So no matter what is done, it will always be ethically questionable. Both, inscrutability and privacy, reinforces the weaknesses of the respective other. As a preliminary thought experiment: Increasing transparency, i.e. decreasing inscrutability, also raises the negative effects on privacy. Strengthening privacy (e.g. Thor browsing) enhances inscrutability even further. In addition, it would further lead to a bias towards users unfamiliar with the technology. As identified in the above argument, technology is seen on the same analytical level as financial assets or means of production. So it feeds back into supporting distorted power relations.

A possible limitation for the examination of labor and automation could be seen in the general economic situation on the labor market. Throughout all service branches, organizations report a high deficit on qualified employees. If this situation continues as some outlooks suggest, the labor-automation dilemma would lose its ethical grasp. In this case, the net effect of automation is very likely to be positive with respect to labor substitution. And it would only be relevant for Critical Theory for other aspects such as the traditional thinking in this field, that is, alienation of the human being from nature, but no longer the machine human substitution as the source of societal unfairness.

Concerning the limitations of inscrutability and privacy issues, it is not possible to take into consideration all prevalent architectures of neural nets for a technical analysis. Due to lack of evidence, it is still open if the inscrutability feature of neural nets could also be used to enhance privacy without paying off on accountability (e.g. by widely establishing cryptographic solutions [9]), so that inscrutability is not misused as a data collector, but as a data protector. However, there are no references in the relevant literature that really makes this theoretical possibility plausible.

V. Summary

The paper at hand set out to identify two relevant ethical paradoxes that come along with human-centered AI technology. It turns out that the inscrutability property of AI technology as produced by deep neural nets and by an increasing blurring of the ground truth input, invokes privacy violations. Privacy violations, on the other side, make it possible to collect huge amounts of data, which enable a machine view on services and processes that is not accessible to a human brain. These views are exploited as shortcuts bearing large efficiency gains for carrying out these services and thus making human work obsolete with seemingly dramatic consequences for the labor market. From this situation new paradoxes emerge from the very moment that humans allow machine exploitation without being able to grasp the full account of such decision. The consequences cannot be understood for the inscrutability argument; privacy stretches out over observations as to what is clicked, when and where. In fact, we see some kind of a cascade following from inscrutability over privacy to the engagement of labor. In addition to identifying the paradoxes, a specific theoretical context, in which these phenomena could best be studied is given and some obvious limitations to these approaches are also outlined.

***Abstract*—The permutation flow-shop scheduling problem (PFSP) is an important problem in production industry. The problem has been a subject of many research and various algorithms to solve PFSP have been developed over the years. The newly developed algorithms are usually tested on Taillard and VRF benchmarks and their results are compared using various measures that assess the size of error made by an algorithm and the computation time. In this paper, we propose two new measures to assess the quality of results of algorithms for solving PFSP with the makespan criterion. The first ARD.NEH measure gives similar results as the well known ARPD measure but is robust to updates of the best known solutions of benchmark problems. The second ARID measure is an interval-based measure which is able to assess whether the good quality of an algorithm results stems from its good behavior of this algorithm for a few instances or from its good behavior for most instances. The computational experiments confirm the usefulness of the proposed quality measures.**

I. Introduction

The permutation flow-shop scheduling problem (PFSP) is one of the most studied combinatorial optimization problems, rooted in the manufacturing industry. It can be defined as follows: given a finite set of m machines $\{M_1, \ldots, M_m\}$ and a finite set of n jobs $\{J_1, \ldots, J_n\}$, each of which should go through all the m machines in the same order, the goal is order the jobs so as to minimize the assumed optimization criterion (e.g., makespan, total tardiness, flow time, cost, energy consumption).

The PFSP with makespan criterion, commonly referred to as $Fm|prmu|C_{\max}$ [1], is undoubtedly the most frequently investigated scheduling problem. Garey and Johnson [2] proved that $Fm|prmu|C_{\max}$ is NP-hard if $m \geqslant 3$. Therefore, various heuristics have been developed to solve this problem in a reasonable amount of time. Among them, the Navaz, Enscore and Ham (NEH) construction heuristic [3] plays an important role; for a long time NEH has been regarded as the best heuristic for solving $Fm|prmu|C_{\max}$.

Since optimal solutions are generally not known for some instances, the only way to asses the results of new methods is to compare them with the best solutions known so far. The well-known measure of solution quality, initially referred to as the increase over optimum (IOO) [4] and later as the relative percentage deviation (RPD) [5], is defined as:

$$\mathrm{RPD} = \frac{S - Best}{Best} \times 100\%, \tag{1}$$

where S is the solution of the evaluated algorithm and $Best$ is the best solution known so far for a given instance of the problem. For a group of instances, a synthetic solution quality measure, called the average relative percentage deviation (ARPD), is calculated as:

$$\mathrm{ARPD} = \frac{1}{I}\sum_{i=1}^{I} \frac{S_i - Best_i}{Best_i}, \tag{2}$$

where I is the number of instances, S_i is the solution of the evaluated algorithm on the instance i of a given size, and $Best_i$ is the best solution known so far for this instance.

The quality of solutions is obviously not the only aspect of algorithms evaluation – the running time is also an important feature (we often face the trade-off between the quality of results and computational time). Literature research shows that the computational time is often reported in time units (usually in milliseconds) [6], sometimes, especially in case of simpler algorithms, the computational complexity is provided. Given several algorithms to be compared and various instances, the computational effort is usually measured by using the average CPU time (ACPU) computed as follows:

$$\mathrm{ACPU}_j = \frac{1}{I}\sum_{i=1}^{I} \mathrm{CPU}_{i,j}, \tag{3}$$

where $\mathrm{CPU}_{i,j}$ is the CPU time consumed by algorithm j on instance i. However, the running time scheduling algorithms strongly depends on the size of the problem instance, therefore Fernandez-Viagas and Framinan [7] proposed to measure the average relative percentage time (ARPT) consumed by algorithm j:

$$\mathrm{ARPT}'_j = \frac{1}{I}\sum_{i=1}^{I} \mathrm{RPT}_{i,j}, \tag{4}$$

where $\mathrm{RPT}_{i,j}$ (relative percentage computation time of algorithm j for instance i) is computed as:

$$\mathrm{RPT}_{i,j} = \frac{\mathrm{CPU}_{i,j} - \mathrm{ACT}_i}{\mathrm{ACT}_i}, \tag{5}$$

This study was conducted under a research project funded by a statutory grant of the AGH University for maintaining research potential.

and ACT_i (average computational time for instance i) is computed as:

$$\mathrm{ACT}_i = \frac{\sum_{j=1}^{J} \mathrm{CPU}_{i,j}}{J}. \tag{6}$$

Since ARPT'_j can yield negative values ($\mathrm{ARPT}'_j > -1$), Fernandez-Viagas and Framinan [8] proposed to compute $\mathrm{ARPT} = \mathrm{ARPT}' + 1$, which allows the graphics to be shown in logarithmic scale.

The above described features of ACPU and ARPT make these two measure not very authoritative and quite cumbersome in practice. In [9], we have proposed the ART.NEH (the Average Relative Time over NEH) indicator defined by the following formula:

$$\mathrm{ART.NEH} = \frac{\sum_{i=1}^{I} \frac{\mathrm{CPU}_i}{\mathrm{CPU}_{i,\mathrm{NEH}}}}{I}, \tag{7}$$

where I is the number of considered instances, CPU_i is the CPU time of a considered algorithm for the instance i, and $\mathrm{CPU}_{i,\mathrm{NEH}}$ is the CPU time of NEH for the instance i. ART.NEH indicates how many times, on average, the evaluated algorithm is faster (ART.NEH<1) or slower (ART.NEH>1) than the classical NEH. Following this idea, we propose in Section II several new measures to compare the quality of results produced by algorithms for solving PFSP with the makespan criterion. Numerical experiments showing the usefulness of the proposed measures are described in Section III. The paper ends with concluding remarks.

II. New measures of algorithms efficiency

New algorithms are expected to be better than existing ones, but a fair comparison of algorithms is quite difficult (due to implementation issues and hardware used). However, most of papers on solving PFSP with the makespan criterion provide the results produced by NEH. So, it seems quite natural to use this well-known heuristic as a computational benchmark.

The ARPD indicator given by formula (2) is by far the most popular measure for assessing the quality of scheduling algorithms taking into account the size of the error. It has, however, some drawbacks which led to the development of alternative measures. An important drawback, we want to emphasize, is that the value of ARPD can change when new better solutions are found for an analyzed instance. In this regard, the ARPD value of an algorithm can change significantly over the years. A good example can be the most known PFSP benchmark – Taillard's benchmark [10] published in 1993. Though it is now 30 years since its publication, better solutions are still found for various instances [11]. Thus, since the ARPD factors change, the whole measure change as well. In that case, it is difficult to compare the new results with existing (published) ones due to different reference values (the results of such a comparison may not be reliable). To get rid of this drawback, in this paper we propose a new measure ARD.NEH (Average Relative Deviation over NEH) which will not change in time thanks to the use of the NEH results as reference results. The proposed ARD.NEH measure is computed from the following formula:

$$\mathrm{ARD.NEH} = \frac{1}{I}\sum_{i=1}^{I} \frac{\mathrm{NEH}_i - S_i}{\mathrm{NEH}_i}, \tag{8}$$

where I is the number of instances, S_i is the solution of the evaluated algorithm on the instance i, and NEH_i is the solution obtained using the NEH algorithm for this instance.

The main reason for developing this measure was to make it easier to compare the results produced by new algorithms with the results available in the literature. The advantage of ARD.NEH over ARPD is that it does not change over time. This particular feature of ARD.NEH is due to the fact that ARD.NEH does not depend on the best solutions known so far, but on the results of NEH. So, the measure is especially useful to deal with those problems for which the optimal solution is not know yet. Since ARD.NEH indicates how far the results of an algorithm are from the results of NEH, the greater is ARD.NEH the better.

Another new measure to assess the quality of the results, we propose in this paper, is the $\mathrm{ARID}(\inf, \sup)$ (Average Relative Interval Deviation) measure. $\mathrm{ARID}(\inf, \sup)$ is different from existing quality measures in that it is based on the interval $[\inf, \sup]$ (it is assumed that the interval $[\inf, \sup]$ can be improper) instead of a single value (reference point). By taking different intervals, we can obtain various quality measures. The concept behind this measure is to equalize the impact of each benchmark instance on the final value of the evaluation measure. The value of $\mathrm{ARID}(\inf, \sup)$ is computed from the following formula:

$$\mathrm{ARID}(\inf, \sup) = \frac{1}{I}\sum_{i=1}^{I} \frac{\max(\inf, \sup) - S_i}{\sup - \inf} \tag{9}$$

where S_i is the solution for the instance i.

Proposition 1: ARPD and ARD.NEH measures are a special case of the ARID measure.

Proof: Let I be the set of instances, and Best_i, NEH_i, and S_i the best known solution, the solution produced by NEH, and the solution for the instance i, respectively. It holds that

$$\mathrm{ARID}(\mathit{Best}, 0) = \frac{1}{I}\sum_{i=1}^{I} \frac{\max(\mathit{Best}_i, 0) - S_i}{0 - \mathit{Best}_i} =$$

$$= \frac{1}{I}\sum_{i=1}^{I} \frac{\mathit{Best}_i - S_i}{-\mathit{Best}_i} = \frac{1}{I}\sum_{i=1}^{I} \frac{S_i - \mathit{Best}_i}{\mathit{Best}_i} = \mathrm{ARPD}$$

$$\mathrm{ARID}(0, \mathrm{NEH}) = \frac{1}{I}\sum_{i=1}^{I} \frac{\max(\mathrm{NEH}_i, 0) - S_i}{\mathrm{NEH}_i - 0} =$$

$$= \frac{1}{I}\sum_{i=1}^{I} \frac{\mathrm{NEH}_i - S_i}{\mathrm{NEH}_i} = \mathrm{ARD.NEH}$$

■

In what follows, we set $\inf = \mathit{Best}$, $\sup = \mathrm{NEH}$, where *Best* means that we use the best solutions (makespans) known so far for benchmark instances, and NEH means that we use the solutions produced by NEH for the respective instances. Then, ARID(*Best*,NEH) (further referred to as simply ARID), similarly as ARPD, uses the best know solutions, so ARID is recommended to be used for problems with $Best = Opt$. ARID allows to equalize the impact of different instances on the final result. For example, the ARPD value for Taillard benchmark is the most influenced by the instances having the best solutions far from the optimum and the less influenced by the instances having the best solution close to the optimum. Making each instance to have comparable impact on the final evaluation of an algorithm, allows to compare different algorithms in terms of the stability of their results in relation to the dynamically determined value, which in this case is the result of NEH. The result of NEH can therefore be considered as a kind of assessment of the difficulty of a given instance. The stability of an algorithm should be understood here as a possibility to obtain better results than NEH for as many instances as possible. Let us note that the value of ARID, similarly as the value of ARD.NEH, should be maximized. The next section presents the experiments that aim to show the usefulness of the proposed measure of the algorithms quality.

III. Computational experiment

The measures proposed in Section II were used to assess the results of various algorithms for Taillard benchmark [10] and VRF Large benchmark instances [12]. Best solutions provided by the authors of the benchmarks are updated with the recent results presented in [11] (Taillard) and [13] (VRF Large).

Tables I and II show the values of the ARPD, ARD.NEH and ARID measures obtained for, respectively, Taillard and VRF Large benchmarks by using selected deterministic algorithms for solving PFSP (cf., [14], [15], [16], [17], [18], [7], [8], [19], [20], [21], [22], [9]). As can be seen from the tables, only two algorithms (RAER and RAER-di) achieved negative values of ARD.NEH measure, which means that their average results were worse than the average result of NEH. It can be seen as well that only FRB and N-list technique-based algorithms (the latter will be further referred to as N-algorithms) achieved the results that are better than NEH results by more than 1 percent, for both benchmarks. As for the ARID measure, only FRB algorithms and N-algorithms achieved the values greater than 15%. Moreover, only 3 algorithms (for Taillard benchmark) and 2 algorithms (for VRF Large benchmark instances) achieved the results greater than 50%, which means that only 3 algorithms were able to improve the results of NEH by, on average, more than a half distance between the best solution produced by NEH and the best solution known so far for a given instance.

Figures 1 and 2 show the rank (y-axis) of each algorithm with respect to the specific quality measure. As we can see, the ranks with respect to ARD.NEH and ARPD coincide for all algorithms. This means that the ARPD measure can be successfully replaced with the ARD.NEH measure. If we take a look at the ARID measure, we can see that this measure ranks the algorithms in a different manner than the other two measures. Those algorithms that are ranked below the line determined by the ARPD and ARD.NEH measures can be considered as more stable. The results produced by these algorithms are less due to the fact of significant improvements of NEH results for single instances, and more due to improvements of NEH results for more instances. Due to the design of the measure, large improvements for single instances are less promoted than frequent but less significant improvements. Hence the deterioration of the results of individual algorithms,

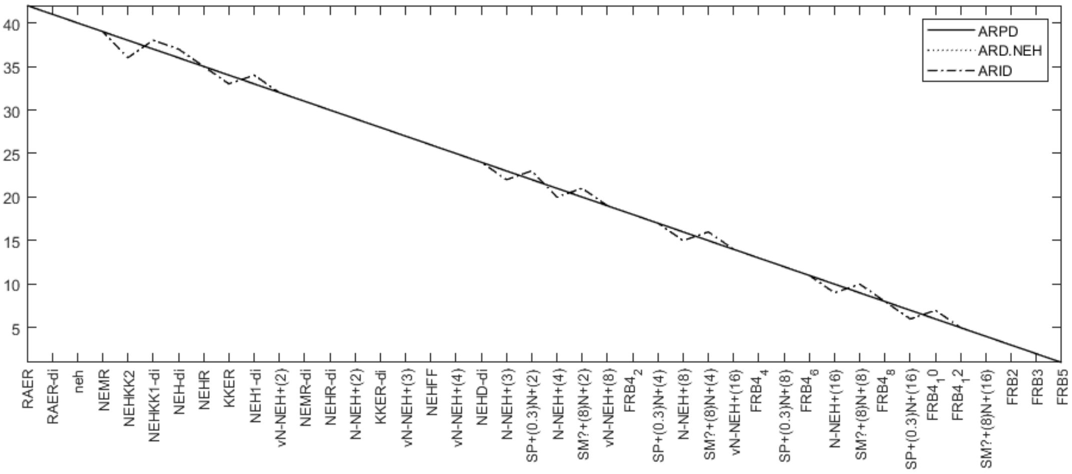

Fig. 2. Ranking of algorithms based on ARPD, ARD.NEH and ARID values for VRF Large instances

for which the position for the ARID measure deviates upwards from the line ARPD/ART.NEH.

IV. Conclusion

This work proposes two new measures for assessing the quality of results produced by algorithms for solving permutation flow-shop problems with the makespan criterion. The first ARD.NEH measure has the very useful feature of elimination of the dependency of the quality assessment from the best known results which, as shown by the performed analysis, change over time, and therefore the comparison of new results with the older one might be cumbersome. The second ARID measure is to our best knowledge the first interval-based measure. It is worth to underline that the ARID measure with properly selected intervals is equivalent to ARPD or ARD.NEH measures. The proposed new measure have been tested on 42 selected deterministic algorithms for solving PFSP run on Taillard and VRF Large benchmarks. Based on the obtained results it can be concluded that ARPD and ARD.NEH measures coincide, i.e., they rank the algorithms in a very similar manner. The ARID measure, in turn, is useful in assessing the stability of the algorithms, i.e., it indicates whether a good (average) quality of results stems from good results for a few instances of from good results for most instances. The numerical experiments show that the proposed measures are very useful for more reliable comparison of algorithms for solving PSFP with the makespan criterion.

***Abstract*—In the field of Materials Science, tomographic images play an important role in the analysis of composite materials. We present a computational environment that helps specialists in the field to carry out analysis and evaluation of samples of composite materials. This environment takes the form of a tailored Problem Solving Environment (PSE) and builds upon the SCiRun PSE. Its implementation is driven primarily by four major attributes: modularity, flexibility, interactivity and performance. Users can easily assemble networks of modules, with some of the modules being specifically designed for materials science analysis. These modules are flexible in terms of configuration, so yielding more flexibility to the setup of the networks, as well as in relation to the user interaction upon them once running. The implementation of data processing algorithms supporting critical modules rely on parallel programming. Furthermore, the quality of tomographic images under analysis is an issue of concern.**

I. Introduction

RESEARCHERS in the field of materials science use X-ray micro/nanotomography (mCT) for studying composite materials, namely for 3D geometrical characterization of the material's constituent phases. The tomographic image that is reconstructed using specialized software corresponds to a 3D matrix, where each voxel in space is usually represented by an integer corresponding to its grey-level.

On that basis, it is important to provide materials science specialists with proper software to accomplish the research goals set. In particular, researchers are mainly interested on:

- Visualizing data in 3D;
- To perform different image processing operations in order to remove any artifacts present in the image;
- To exclude irrelevant objects to the ongoing analysis;
- To perform image processing operations that label each of the distinct objects under consideration;
- To obtain geometric information that establishes a statistical description of the entire population of objects under consideration.

In this article we describe a framework for building flexible environments for the analysis of tomographic images of composite materials. Besides the normal operations we may expect to use in tools of this category, this framework is mostly concerned with usability and data quality issues that materials science specialists might face. They are:

- Modularity and flexibility, as the system must support an easy way of specifying the processing steps, and should allow to easily perform testing and reconfiguration tasks;
- Interactivity, in the sense that individual processing and visualization operations should be carried out faster since specialists want to see the outcome of those operations as quickly as possible, and also to allow a smooth steering of the computations;
- Tomographic image quality, since it should not be taken for granted that all images will show high contrast.

The organization of the paper is as follows: Section II presents related work that has been developed in the area of computational environments for analysing scientific data. Then, in Section III, we introduce a framework alongside guidelines to build a computational environment to process and analyse scientific data, followed in Section IV by an implementation with focus on data collected from material science experiments. In order to validate our proposal, we discuss a case-study in Section V, in particular concerning tomographic images with low contrast, so difficult to process, and finally Section VI wraps up with conclusions.

II. Related Work

Computational environments to process tomographic images can broadly be split into two major categories: environments that allow users to apply processing algorithms to tomographic images on a one-o-one basis, that is, with the simple paradigm *read-transform-visualize* in sight, and the so-called visual programming environments, more friendly but complex, which allow users to set up a network of processing modules via graphical deployment in a canvas, with related computations following the data-flow model [1].

This work was partially funded by National Funds through FCT – Portuguese Foundation for Science and Technology, Reference UID/CTM/50025/2019 and NOVA LINCS (UIDB/04516/2020) with the financial support of FCT.IP.

As inferred from above, visual programming environments allow specialists to specify a sequence of processing steps by choosing a set of modules available in a menu, including obviously reading tomographic images, and interconnects them. An example of those is the commercial software Avizo/Amira [2].

On the other hand, one can prefer to use the other category of environments, like the image processing and visualization software ImageJ/Fiji [3] or Paraview [4]. Worth pointing out that we can always follow the route of developing dedicated software, like the case of spam mentioned in [5].

In respect to visual toolkits mentioned above that rely on the data-flow model, sometimes referred to as PSEs due to its usability in various scientific areas, it is clear that a major advantage they present is that they can be tailored to the specific needs of a particular scientific area, yielding to dedicated environments. One example is SCIRun [6] from the University of Utah, USA. The toolkit has been very successful regarding the development of dedicated PSEs. For example, it is the case of BioPSE [7], which is specifically tailored for running bio-electric field simulations on top of SCIRun.

III. Framework

Given the information provided by practitioners in the materials science field, our understanding is that we should have an integrated software solution, embracing both image processing algorithms and visualization capabilities, but underlying a clean and easy-to-use approach. On that basis, the proposed solution will address primarily the following requirements:

- Open-source desktop solution but providing users interactivity and computational steering;
- Processing of tomographic images, including the ones with low contrast;
- Availability of various processing algorithms, even the complex ones requiring higher computational resources;
- Providing adequate data formats in accordance to the processing operations of concern.

We borrow the idea from the concept of PSE, sustained by the data-flow model [1], upon which SciRun is a prominent example. Hence, our solution provides four distinct categories of modules: data readers, filters, mappers and renders. Fig. 1 depicts the processing model we advocate.

Specialists will have at their disposal such modules to create networks, that ultimately will solve their problems. The networks will be managed by the specialists themselves. This includes the setting of control parameters and of both data and images to/from modules via input/output ports.

IV. Implementation

All the developed modules were built on top on SciRun. Notice that the interactivity and steering requirement is delivered by SciRun. Next, we will introduce new implemented modules, yielding to an open-source solution that works on desktops.

A major concern is that tomographic images showing up low-contrast between matrix and particles are challenging to identify and characterize objects – let us focus hereafter on particles. Common approaches sometimes fail to to so and some take too much time to deliver results. That is why we have taken a careful approach while designing those modules that are related the most. For example, modules belonging to the category *Filter* have been implement using OpenMP or CUDA, so a parallelization approach targeting both CPUs and GPUs. Operations that do occur at voxel level will take advantage of data parallelization.

In respect to visualization functionalities, we take advantage of native SciRun visualization modules, mostly for general 3D visualization. But for specific purposes, like visualizing and analysing particle features, specialists are able (i) to automatically launch external viewers and, importantly, (ii) to use a new 2D visualization module to check features on a image plane basis, regardless of its orientation in the 3D space. Also, for a better understanding, specialists can playback the outcomes of image operations that were applied, in sequence.

In relation to image operations, and among the various modules that have been implement, there are some operations that deserve to be singled out. They are: edge detection, segmentation, erode and dilate, and crucially particle identification and subsequent characterization.

Edge detection. This operation basically creates conditions to correctly identify particles. Examples of filters that relate to this task are *Unsharp* (mask to unsharping to enhance high-frequencies like boundaries), *Gradient* (first derivatives), *Laplacian* (second derivatives to enhance tiny boundaries), *Sobel* (Sobel derivatives to give direction of intensity variations) and *ZeroCrossings* (location based on 2nd derivatives).

Segmentation. The goal in this operation is to highlight particles within the raw image. This is carried out via the *Thresholding* filter: Assuming that we have a raw image defined in a gray scale, by applying the filter we get a black-and-white image. Also, we can chose to apply bi-segmentation, meaning that we end up with black, or white, or unchanged voxels. Crucially, this operation requires setting critical cut-off levels, usually inferred with the help of image histograms.

Erode and Dilate. These two operations working together help to achieve particle separation. It happens when somehow the boundaries of particles touch to each other, that is, it seems there are contiguous voxels but belonging to different particles. Notice that the given image is already in black-and-white. *Dilate* implies enlarging the border of a particle (white to black), whereas *Erode* is the converse operation. When there is a sequence *Erode* then *Dilate*, it is called *Open* operation. The reverse sequence is called *Close* operation.

Particle Identification. This crucial task implies the use of various filters supporting a bi-segmentation process, which is even more critical when the raw tomographic images show low contrast between matrix and reinforcements. It also relies on two modules: *ParticleLabelling* and *PoissonReconstruction*. The first one is based on a labelling algorithm [8] but implemented with OpenMP or CUDA, (there are two versions available, meaning it is up to the specialist to decide which version is going to be used) yielding to a fine-tuned parallel implementation to reduce execution times. The second module uses

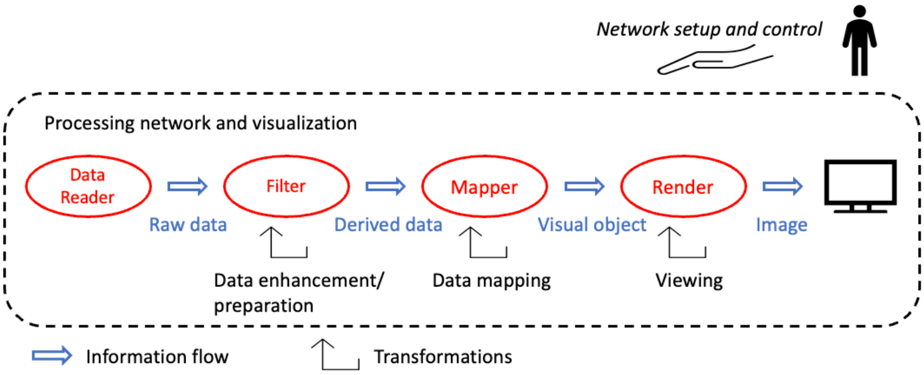

Fig. 1. Processing model based on the data-flow visualization paradigm.

the Possion surface reconstruction algorithm [9] available in the Point Cloud Library (PCL) library. (https://pointclouds.org) While the first module produces sets of interconnected voxels, (parts of potential particles) the second module takes a cloud of points as input (those voxels) and properly reconstructs the surfaces of the particles. Then, as output, polygonal meshes are generated to depict the reconstructed surfaces.

Particle Characterization. Once particles have been geometrically identified, specialists still have to further evaluate the outcome as it is presented to them. Notice that we may end up with clusters of particles or even *fake* particles. But in the end, the final decision about accepting or rejecting a particular particle rests on the specialists. The outcome will be a set of particles of interest and their characterization – the location within the sample, the geometric profile such as volume, area and bounding box, among other similar concepts.

Worth pointing out that the way data is organized affects the performance of applied algorithms. That is why it has been also implemented a set of rapid but robust data formats converters. Then, in a particular situation, specialists will decide which ones to use in order to achieve better efficiency and performance. Also, because the visual appearance of particles is helpful in the characterization process, specialists have at their disposal various visualization functionalities.

V. Evaluation

In order to validate the extended PSE, we discuss now a case-study concerning samples of aluminum as the base material (matrix) and tungsten carbide as reinforcements but showing low contrast between them. That is, if we were to draw an histogram of densities, it will not show two clear peaks – one corresponding to the matrix and another one to the reinforcements – as we were expecting to obtain in a clear bi-segmentation process.

The samples were collected at the European Synchrotron Radiation Facility in Grenoble and were defined in a regular grid. For evaluation purposes, we use a subset corresponding to a uniform 3D cube lattice of dimension $[512\times512\times432]$, with each voxel corresponding to one μm^3 approximately [10].

Looking at the raw tomographic images, they show low contrast between the base material and reinforcements, and contain various porous. (See Fig. 2) Furthermore, information gathered during the collecting process hinted that the particles were showing a cone-shaped, convex geometry, they could be broken, and the average size is about 35 μm.

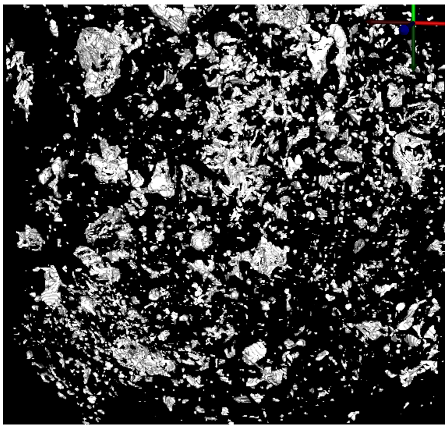

Fig. 2. Glimpse of a raw tomographic image prior to any processing.

Overall, the goal is to identify particles inside the sample an then to characterize the ones of interest. The sequence of operations works as follows:

1) Removal of porous;
2) Increasing contrast between particles and base material;
3) Particles labelling;
4) Particles detection;
5) Particles characterization.

The initial two operations are mostly supportive of the particles labelling process. Hence, and given the modules available, a typical workflow to accomplish the tasks mentioned can be split into three sequential stages: particles labelling, particles detection and finally particles characterization. In the following we will provide further details about these three stages.

A. Particles labelling

The goal here is to figure out potential locations of particles in the volumetric sample. It starts by smoothing the raw data, that is, reducing the noise in the tomographic image and then, in sequence, applying band pass filters, labelling the image, followed again with enhancement using pass filters.

For example, Fig. 3 shows a circular air porous that is going to be removed by first painting its interior with the colour of the matrix so once bi-segmentation is applied later on, it will be converted into matrix. At this point we are able to get an initial identification of reinforcements.

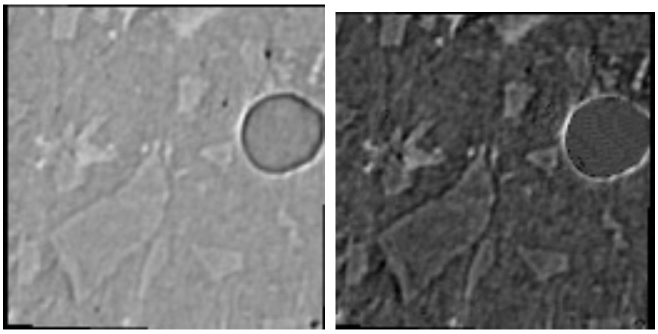

Fig. 3. Circular air porous (left) that will be removed once bi-segmentation is applied, but only after pre-painting its interior as matrix (right).

Then, it follows a bi-segmentation process using high and low pass filters, alongside operations to erode/dilate the outcome. The outcome will be regions of connected voxels that in the end may be considered as particles.

In this experiment we have identified 1 239 connected voxel regions at this stage, that is, 1 239 particle candidates.

Fig. 4 shows a network of modules to support the labelling process. Notice that some modules, like those related to pass filters, also output information to visualization modules so specialists can figure out the results of intermediate operations. This includes drawing histograms.

B. Particles detection

At this stage the goal is to figure out the proper boundaries of the real particles. It implies carrying out careful analysis in relation to potential regions of particles that have been considered in the previous stage, so we will end up with particles of potential interest, with proper closed boundaries.

As shown in Fig. 5, particles boundaries are not continuous at the beginning. Therefore, first it is required a reconstruction of the boundaries, which is done using the Poisson surface reconstruction algorithm. Only then we can compute the exact number of particles and respective size.

In this case-study, some of the 1 239 regions of connected voxels originated in the previous stage can still be considered as noise. Therefore, we have used a module to discard those *fake* particles. The cut-off size value set was 100 voxels, which is a value somehow derived from the pre-understanding and knowledge of the specialist about the sample. As result, there were 202 particles with acceptable size, that were then submitted to the Poisson surface reconstruction algorithm. The final outcome was a set of particles, described via a set of *Ply* files and representing polygonal meshes that can be visualized.

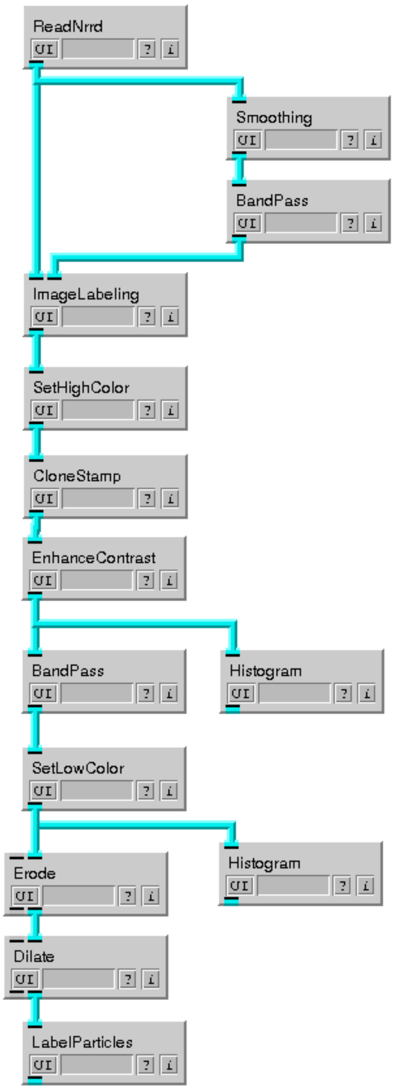

Fig. 4. Network of modules set by a specialist with the purpose of supporting particle labelling.

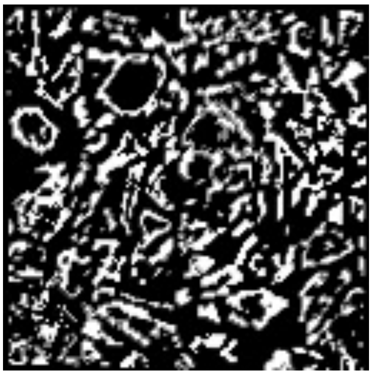

Fig. 5. Initially, particles boundaries are not continuous so proper identification and reconstruction is required.

C. Particles characterization

At this final stage, the goal is to deliver the set of particles the specialist is interested on, and with detailed characterization, mostly based on the geometric profile. It matters not only the selection itself but the quality of characterization.

As depicted in Fig. 6, given the detected particles from the previous stage (Ply files), which may not be entirely correct from a semantic point of view, we enter into an iterative process where, at each iteration, the specialist can accept a particular particle, or reject it, or else submit it to a enhancement process, likewise in the previous stage.

The decisions made are also supported by the viewing of particles, as highlighted in Fig. 7.

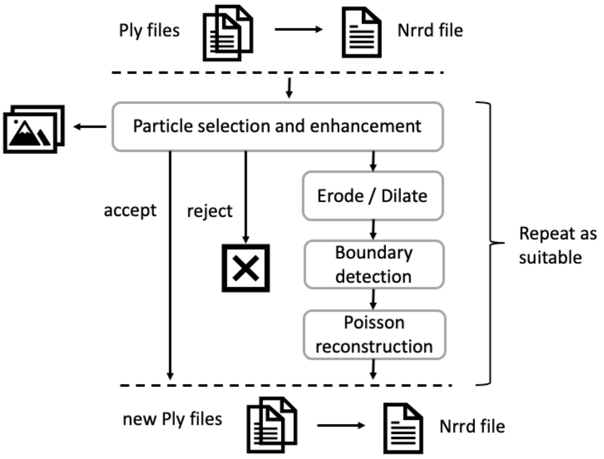

Fig. 6. Iterative process to select and enhance particles of interest for further characterization.

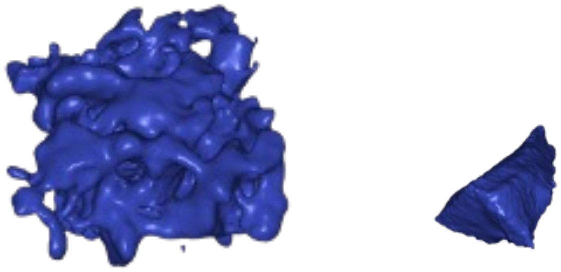

Fig. 7. Visualization to help selecting and enhancing particles of interest: From cluster requiring further processing (left) to accepted particle (right).

Also, the geometric profiles of the particles of interest are computed and stored in a SQLite database. Among other features, it includes the location within the sample, surface area, volume, bounding box, etc. It is worth noting that specialists have general pre-understanding about the samples they are working with, namely in relation to shape and average particle size.

The information stored in the database can be exported to files for further usage with other tools of convenience. Nonetheless, the implemented *FeatureVisualizer* module is tailor-made for the purpose of visualizing particle features within the context of the PSE itself. The underlying thinking is that it is important to provide extra flexibility to specialists.

VI. Conclusions

We have presented a dedicated PSE to help material science specialists to carry tasks of analysing tomographic images. The proposed solution fits into the list of requirements set by specialists, who were keen on having an environment where (i) they could easily use a wide range of algorithmic strategies to carry out their experiments, (ii) the build up of the processing network was done in a flexible manner and (iii) they should experience human-computer interactivity as much as possible, alongside fast and effective visualizations.

As highlighted in the discussion about particles identification in Section V, tomographic images with low contrast pose additional demands as far as type and number of operations that have to be included in the processing network. In the case-study introduced, the system delivered the results specialists were looking for from a scientific perspective. Also, the network of modules was relatively easy to set up and its steering afterwards was effective.

As a final note, once particles are properly identified and stored in a database, and having various data formats at disposal, a specialist can also use external tools to further analyse the outcome of the experiment, all but in a cohesive working environment.

***Abstract*—Circuit prototyping on multi-FPGA (Field Programmable Gate Arrays) platforms is a widely used technique in the VLSI (Very-Large-Scale Integration) context. Due to the ever-increasing size of circuits, it is necessary to use partitioning algorithms to place them on multi-FPGA platforms. Existing partitioning algorithms focus on minimizing the cut size but do not consider the critical path length, which can be degraded when mapping long paths to multiple FPGAs. However, recent studies try to consider the degradation of the critical path and the target topology but these works still use cutting minimization algorithms. In this work, we propose a mathematical model as an integer program (IP) based on the Red-Black Hypergraph model that considers the minimization of the critical path degradation and the target topology. We compare our partitioning results with KHMETIS, a min-cut algorithm, and show a better critical path for many circuit instances.**

I. INTRODUCTION

OUR work concerns practical improvements of the electronic circuit design chain. The typical hardware design flow includes different steps, such as floor planning, placement, and routing, that may concern very large logic circuits. To deal with such large circuits, the methods involved may benefit from divide-and-conquer approaches that allow for working locally on separate parts of the circuit, greatly reducing the work on the global circuit. Such a divide-and-conquer approach also enables circuit prototyping on a multi-FPGA platform, where the circuit is too large (in terms of resource consumption) to be implemented on a single FPGA. In such cases, a strong constraint is to mitigate a possible increase in the signal propagation delay of the longest combinatorial path, known as the *critical path*. Indeed, in synchronous circuits, the critical path length determines the maximum frequency at which the circuit may operate; mapping long paths across several FPGAs is likely to degrade the critical path.

Circuit partitioning is both an essential step in the design flow of electronic circuits, and a challenging multi-constraint optimization problem. It must address both the multi-resource issue (i.e., capacity limits on each FPGA and their interconnection links) and the minimization of the critical path degradation.

Traditional partitioning tools use the now classic multi-level scheme (see Fig. 1) consisting of three phases: *coarsening*, *initial partitioning*, and *refinement* [1]. The coarsening phase uses a recursive clustering method to transform the circuit model, a hypergraph, into a smaller one. During the second phase, an initial partitioning is computed on the smallest coarsened hypergraph. Finally, for each coarsening level, the solution for the coarser level is extended to the finer level and then refined using a local refinement algorithm. The initial partitioning algorithm presented in this paper concerns the first step of the multilevel framework described above.

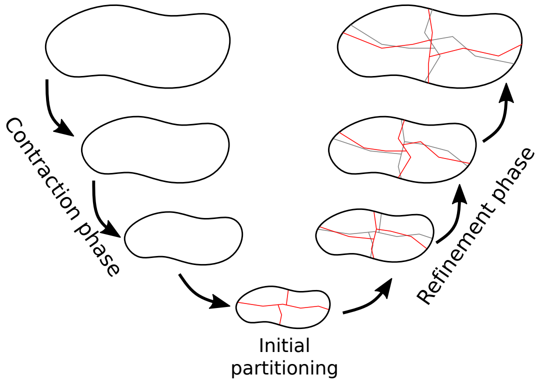

Fig. 1. Multi-level scheme

Our work focuses on balanced hypergraph partitioning, in which our objective functions are both *path-cost* minimization and the classical *min-cut* objective that is still relevant to us. The hypergraph model we consider in our research context consists of a union of directed acyclic hypergraphs (DAH) [2]. The global hypergraph is assumed to be connected; otherwise, its disconnected components are processed independently. The source and sink vertices of each DAH (which represent registers and I/O ports) are labeled red, while other vertices are black. Red vertices can be shared by multiple DAHs, which makes the global hypergraph connected. A *path-cost* function models the impact of a cut on the red-to-red paths during partitioning. Each partition of a hypergraph will result in cuts along some paths, inducing additional traversal costs. Our aim is to find a partition of minimum path cost, such that the size of the cut is also minimized. Our research context only considers the paths between two red vertices and a non-uniform cut cost between parts.

The classical approach is to model this problem with a hypergraph, using cost functions that minimize cut size. However, it has been shown in [3] that the cut size does not address the path cost efficiently during the hypergraph partitioning procedure. This is why several authors proposed pre- and/or post-processing steps in order to reduce the degradation of cut paths [3], [4], [5]. In this paper, we devise a dedicated integer programming model that minimizes path cost degradation during partitioning, based on the red-black hypergraph structure, which can be used as an initial partitioning method in a multilevel framework.

The remainder of the paper is organized as follows: Section 2 presents a reminder of our red-black hypergraph structure as well as previous works. Section 3 describes our coarsening scheme before the initial partitioning and the integer programming model. Our experiments are outlined in Section 4. We conclude and give perspectives in Section 5.

II. Preliminaries

In this part, we define the notations and definitions used in this work.

A. Definitions and Notations

Let $\mathcal{H} \overset{\text{def}}{=} (\mathcal{V}, \mathcal{A}, \mathcal{W}_v, \mathcal{W}_a)$ be a directed hypergraph, defined by a set of vertices $\mathcal{V}$ and a set of hyperarcs $\mathcal{A}$, with a vertex weight function $\mathcal{W}_v : \mathcal{V} \to \mathbb{R}^+$ and a hyperarc weight function $\mathcal{W}_a : \mathcal{A} \to \mathbb{R}^+$. Every hyperarc $a \in \mathcal{A}$ is a subset of vertex set $\mathcal{V}$: $a \subseteq \mathcal{V}$. Let $s^+(a)$ be the source vertex set of hyperarc a, and $s^-(a)$ its sink (destination) vertex set. We consider here, without loss of generality, that each hyperarc has a single source, so $\forall a, |s^+(a)| = 1$. As hyperarcs connect vertices, let $\Gamma(v)$ be the set of neighbor vertices of vertex v, and $\Gamma^-(v) \subseteq \Gamma(v)$ and $\Gamma^+(v) \subseteq \Gamma(v)$ the sets of its inbound and outbound neighbors, respectively.

In the model we propose, hypergraphs that model circuits are be represented as sets of interconnected DAHs, according to a red-black vertex coloring scheme. Red vertices correspond to I/O (Inputs/Outputs) ports and registers, and black vertices to combinatorial circuit components. Let $\mathcal{V}^R \subset \mathcal{V}$ and $\mathcal{V}^B \subset \mathcal{V}$ be the red and black vertex subsets of $\mathcal{V}$, such that $\mathcal{V}^R \cap \mathcal{V}^B = \emptyset$ and $\mathcal{V}^R \cup \mathcal{V}^B = \mathcal{V}$. A hypergraph or sub-hypergraph $\mathcal{H}$ is a DAH iff its red vertices $v_R \in \mathcal{V}^R$ are either only sources or sinks (*i.e.*, $\Gamma^-(v_R) = \emptyset$ or $\Gamma^+(v_R) = \emptyset$), and no cycle path connects a vertex to itself.

Using this definition, we can represent circuit hypergraphs as *red-black hypergraphs*, *i.e.*, sets of DAHs that share some of their red vertices. Let $\mathbf{H}(\mathbf{V}, \mathbf{A}) \overset{\text{def}}{=} \{\mathcal{H}_i, i \in \{1 \ldots n\}\}$ be a red-black hypergraph, such that every $\mathcal{H}_i$ is a DAH and an edge-induced sub-hypergraph of $\mathbf{H}$. Consequently, $\mathbf{V} = \bigcup_i \mathcal{V}_i$, $\mathbf{A} = \bigcup_i \mathcal{A}_i$, $\mathbf{V}^R = \bigcup_i \mathcal{V}_i^R$, and $\mathbf{V}^B = \bigcup_i \mathcal{V}_i^B$. Moreover, $\forall i, j$ with $i \neq j$, if $\mathcal{V}_{i,j} = \mathcal{V}_i \cap \mathcal{V}_j \neq \emptyset$, then $\mathcal{H}_i$ and $\mathcal{H}_j$ share source and/or sink vertices, *i.e.*, $\mathcal{V}_{i,j} \subset \mathbf{V}^R$.

In this model, the paths in $\mathbf{H}$ to consider when addressing the objective of minimizing path-cost degradation during partitioning are only the paths interconnecting red vertices, as these red-red paths represent register-to-register paths in combinatorial circuits. Since only red vertices are shared between DAHs in $\mathbf{H}$, red-red paths only exist within a single DAH and can never span across several DAHs.

Let us define $\mathbf{P}$ as the set of red-red paths in $\mathbf{H}$, such that $\mathbf{P} \overset{\text{def}}{=} \{p | p \text{ is a path in } \mathcal{H} \in \mathbf{H}\}$. From these paths and a function $d_{\max}(u, v)$, which computes the maximum distance between vertices u and v of some DAH $\mathcal{H}$, we can define the longest path distance for $\mathcal{H}$ as: $d_{\max}(\mathcal{H}) \overset{\text{def}}{=} \max(d_{\max}(u, v) | u, v \in \mathcal{H})$ and, by extension, for $\mathbf{H}$, as: $d_{\max}(\mathbf{H}) \overset{\text{def}}{=} \max(d_{\max}(\mathcal{H}) | \mathcal{H} \in \mathbf{H})$.

A partition Π of $\mathbf{H}$ is a splitting of $\mathbf{V}$ into vertex subsets π_i, called parts, such that:

(i) all parts π_i, given a capacity bound M, respect the capacity constraint:

$$\sum_{v \in \pi_i} \mathcal{W}_v(v) \leq M$$

(ii) all parts are pairwise disjoint:

$$\forall i \neq j, \pi_i \cap \pi_j = \emptyset$$

(iii) the union of all parts is equal to $\mathbf{V}$:

$$\bigcup_i \pi_i = \mathbf{V}$$

Consequently, in our model, the distance between two vertices u and v may increase during partitioning due to the additional cost of routing paths between two (or more) parts. Let $D_{kk'}$ be the penalty associated with parts k and k' such that if u is in part k and v is in part k', then:

$$d_{\max}^{\Pi}(u, v) \geq d_{\max}(u, v) + D_{kk'} \tag{1}$$

For a given partition Π of $\mathbf{H}$, the *path-cost* is defined by the function: $f_p(\mathbf{H}^{\Pi}) = \max(d_{\max}(\mathcal{H}^{\Pi}) | \mathcal{H} \in \mathbf{H})$.

Let a red-black hypergraph $\mathbf{H}$ and a partition Π, the connectivity $\lambda_{\Pi}(a)$ of some hyperarc $a \in \mathcal{A}$ is the number of parts connected by a. If $\lambda_{\Pi}(a) > 1$, then a is said to be cut; otherwise, it is entirely contained within a single part and is not cut. The cut of partition Π is the set $\omega(\Pi)$ of cut hyperarcs, *i.e.*, $\omega(\Pi) \overset{\text{def}}{=} \{a \in \mathcal{A}, \lambda_{\Pi}(a) > 1\}$. The cut size is defined as $f_c \overset{\text{def}}{=} \sum_{a \in \omega(\Pi)} \mathcal{W}_a(a)$. If all hyperarcs have the same weight (equal to 1), the cut size is equal to $|\omega(\Pi)|$. Another cut metric used by some partitioning tools to measure the quality of partitioning is called *connectivity-minus-one* [6]. The connectivity-minus-one cost function f_λ of some partitioned hypergraph $\mathbf{H}^{\Pi}$ is defined as: $f_\lambda = \sum_{a \in \mathbf{A}} (\lambda_{\Pi}(a) - 1) \times \mathcal{W}_a(a)$.

B. Previous work

Several approaches in the literature have been attempted to improve the performance of circuit partitioning. We present some recent work on circuit partitioning for rapid prototyping that considers performance constraints. Many of these works attempt to tweak existing *min-cut* partitioning tools, which are used as black boxes, to consider additional constraints. For example, [3] presents a multi-objective approach based on hMetis. The authors compute the K most critical paths at each partitioning step, using a metric cost that considers the critical path length, the cut number along critical paths, and the weight of the hyperarcs associated with the critical paths. Reference [4] compares a classical method using hMetis for partitioning followed by a placement algorithm with a derived approach consisting of placement and routing during the partitioning step. The results show better critical path values compared to the two-step approach. More recently, [5] performs some pre- and post-processing on the hypergraph to capture the critical path minimization objective within the cut-size metric, using hMetis as the partitioning tool. Reference [7], presents an IP model to address the hypergraph partitioning problem. The model is not dedicated to mapping and critical path minimization but to minimize the cut cost.

III. Contributions

We now present our core contribution. The first part consists of a coarsening algorithm to reduce the size of the hypergraph. In the second part, we present our IP model used as initial partitioning.

A. Coarsening method

The heavy-edge matching (HEM) approach for graph coarsening presented in [8] is widely used in hypergraph and graph partitioning tools [9], [10] and yields efficient results in many cases. Our coarsening algorithm is based on a heavy-edge matching approach. It consists of reducing the instance's size while minimizing the merged vertices' weight differences as much as possible. The risk in merging vertices is to end up with disproportionate weights of vertices, which may prevent the initial partitioning from exploring different solutions. However, in the context of critical path minimization, it may be interesting to merge all vertices along the critical path into one large vertex. This method is not necessarily interesting when the circuit contains many critical or semi-critical paths. It is, therefore, necessary to find a compromise between creating a large vertex by securing the cut along the critical path and balancing the fusion to allow a more practical exploration search during the initial partitioning phase. The vertex criticality model the value of the longest path traversing the vertex. Our algorithm groups vertices by criticality to favor the grouping of critical paths. Vertices with a smaller weight are selected to favor balanced coarsening.

TABLE I
Indices and set definitions

Set	Definition
$\mathbf{V}$	set of vertices
$\mathbf{E}$	set of hyperedges
J	set of jobs
O_l	ordered set of operations of job l, ($i \in O_l$), where O_{l1} and $O_{ln'}$ are the first and the last elements of O_l
i,i'	vertices/operation index (i, $i' \in \mathbf{V}$)
j, j'	hyperedges index ($j, j' \in \mathbf{E}$)
l, l'	job index ($l, l' \in J$)
k	part index

TABLE II
Parameters definitions

Parameter	Definition
n	number of vertices
m	number of hyperedges
h_{ij}	1 if vertex i is connected to hyperedge j, 0 otherwise
c_{kr}	capacity of part k for resource r
q_{ir}	quantity of resource r, required by i
d_i	propagation time of vertices (operation) i
$D_{k,k'}$	delay between part k and k'
$\mathcal{W}_v$	vertex weight
$\mathcal{W}_a$	hyperedge weight

B. Integer Program

The objective of the IP model is to minimize the degradation of the critical path, so we need to calculate the maximum degradation among all possible degradations. We also need to model the target topology to consider the different delays between each part. Cut minimization tools do not address these two aspects: path length and topology. Cut minimization tools only limit the connections between parts. As this objective is still essential in practice, we add a second objective to our model: minimizing the connectivity minus one. As the paths between two red vertices do not contain cycle, it is possible to see the chain of black vertices in a path as a sequence of operations/tasks i associated with a job l. In our model, we consider scheduling constraints to minimize the impact of partitioning on the critical path. Given a path (job) $p = v_0, v_1, v_2$, the critical time associated with the path equals $\sum_{v \in p} d_v$. If vertices (tasks) belonging to p are placed in different parts, then a time penalty must be added to the total time of p. A summary of the integer model can be found in Table I, the parameters in Table II, and the variables in Table III. Below is the integer program with two objectives 2a for critical path minimization and 2b for connectivity cost minimization:

$$\min z_{\max} \tag{2a}$$

$$\min \sum_j \mathcal{W}_a^j \left(\sum_k y_{jk} - 1 \right) \tag{2b}$$

$$\text{subject to} : \sum_k x_{ik} = 1, \quad \forall i \tag{2c}$$

$$h_{ij} x_{ik} \leq y_{jk}, \quad \forall i, j, k \tag{2d}$$

$$\sum_i q_{ir} x_{ik} \leq c_{kr}, \quad \forall k, r \tag{2e}$$

$$\sum_{i,i' \in O_l} d_i + x_{ik} x_{i'k'} D_{kk'} \leq z_l, \quad \forall k, k', l \tag{2f}$$

$$z_l \leq z_{\max}, \quad \forall l \tag{2g}$$

$$x_{ik}, y_{jk} \in \{0, 1\}, z_l \in \mathbb{N} \quad \forall i, j, k, l \tag{2h}$$

Constraint 2c states that each vertex is mapped onto one part. Constraint 2d guarantees that y_{jk} equals the connectivity cost

TABLE III
VARIABLES DEFINITIONS

Variable	Definition
x_{ik}	1 iff the vertex i is mapped onto part k, 0 otherwise
y_{jk}	1 iff the hyperedge j has a vertex placed on part k
z_l	completion time of job l
$z_{\max}$	maximum completion time of jobs

associated with hyperedge j. The constraint 2e ensures the capacity constraint is respected. The constraints 2f and 2g determine the value of the delay of the job (path) and the maximum delay (*critical path*). The constraint 2h are the non-negativity and integrity conditions on the variable.

There are symmetries in the solution space in hypergraph partitioning for cut size minimization. Indeed, if there are ω hyperedges between parts, ω remains unchanged regardless of the labels of the parts. On the other hand, in our problem, we are trying to minimize the path cost, which is degraded by routing paths between parts that are not always fully connected. There are models for partitioning graphs and hypergraphs with symmetry-breaking constraints [11]. However, these constraints are too restrictive for the solution space associated with path cost. In our problem, the target topology defines a time penalty associated with path routing. As a result, we cannot consider all partitions with the same subset of vertices but different labels, identical, from a routing point of view. An example can be found in Figure 2. Note that some symmetries exist, for example: if we take the partition a, shown in Figure 2. It is possible to create a partition a' by swapping the vertices of π_0 and π_3 and of π_1 and π_2. Future work will involve improving the model to remove these symmetries.

IV. EXPERIMENTAL RESULTS

To validate our models and algorithms, we have performed experiments on benchmarks [12] of logic circuits. These circuits consist of acyclic combinatorial blocks, bounded by their input and output registers. Every combinatorial block can therefore be modeled as a DAH. Their computation time is conditioned by their critical path, defined as the longest path between two registers (*i.e.*, two red vertices). Our work aims at minimizing the degradation of the critical path during partitioning according to the target topology. For each instance, we use topology data to define a traversal cost $d(v)$ for each vertex v, corresponding to the traversal time of a logic element. As the degradation between the parts can be non-homogeneous, we have defined several architecture topologies composed of four elements. The test architecture is a chain $\pi_0, \pi_1, \pi_2, \pi_3$. We did not consider the fully connected topology to highlight the advantage of our topology-aware algorithms over regular partitioners like KHMETIS. To solve the initial partitioning problem, we use Gurobi Optimiser version 9.1.2 with a time limit set to $600s$. During the refinement phase, we use the DKFM [2], a local search algorithm dedicated to minimizing path length. This algorithm is inspired by FM [13], a local search algorithm for minimising the number of hyperedges between two parts. We use KHMETIS rather than HMETIS because HMETIS is based on recursive bipartitioning methods, which often do not respect the balance constraint. We use the maximum criticality as a weight for the hyper-edges as [2] to guide KHMETIS to minimise the number of cuts along the critical path as much as possible.

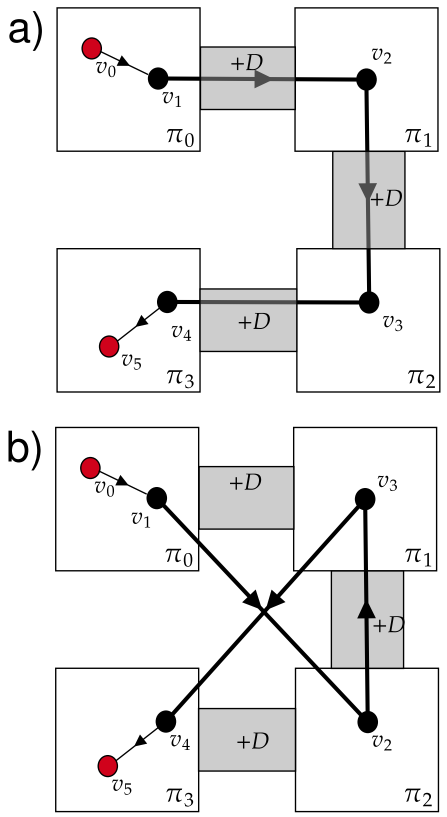

Fig. 2. In this example, the path $p = v_0, v_1, v_2, v_3, v_4, v_5$ is partitioned into 4 parts. In partition a, the path admits a routing penalty of $3D$, where D is the traversal time between parts. In partition b, the routing penalty is $5D$. Since there is no route between π_0 and π_2, we must necessarily pass through π_1 to get there, which gives a cost of $2D$ to get from π_0 to π_2. The same goes for π_1 to π_3. From the point of view of the size of the cut, partition a allows a cost of 3 cut edges, as does partition b. Partitions a and b are identical and symmetrical for cut minimization.

A. Results

Table IV shows that our approach gives better results. Indeed, the first coarsening step allows the grouping of the most critical vertices while maintaining a balance in the reduced hypergraph. Finally, since the initial partitioning considers the topology, it allows for finding an appropriate placement before the refinement phase. For instances B14 and B17, the time limit is not sufficient for Gurobi to find a good solution. A method needs to be found to better reduce the size of the instance while retaining sufficient criticality information for the integer program. Table V shows us a better performance

V. CONCLUSION

In this paper, we present a multilevel approach to the problem of red-black hypergraph (circuit) partitioning on not fully connected topologies. Our approach consists of exploiting the vertices' criticality to group the critical paths in the same part during the coarsening phase. Finally, we propose a mathematical model considering the two objectives: f_p and f_λ for the initial partitioning. For the refinement, we use the DKFM algorithm. Our results show that our approach is better at minimizing f_p than a min-cut partitioning tool, even if it is oriented towards the criticality of hyperarcs. It may be interesting to test our approach on other more extensive benchmarks, as well as to test other coarsening algorithms to improve the results of initial partitioning based on our IP.

***Abstract*—Electronic devices in the 21st century have numerous network components, including wireless or wired Internet access modules. Connecting devices to networks and cloud services enables them to access new functionalities and unlock system updates and device security enhancements. The article presents the concept of an intelligent laundry management system based on RFID and cloud computing. The Internet connection not only unlocks additional features of the washing machine, such as different washing modes, but also allows for selecting the appropriate detergent level and washing parameters based on the textile material being washed. Additionally, the paper presents the solution and measurement studies on the accuracy of textile identification.**

I. Introduction

Technological development can be observed in many aspects of human life. Modern solutions can be seen all around, for example, controlling home facilities from a smartphone [1], shopping online using a phone, computer, or even autonomously by a refrigerator. The use of technology facilitates work, life, and provides more opportunities for self-focus. Solutions based on the Internet of Things (IoT) are gaining significant popularity, as well as the increasingly popular idea of the Internet of Everything (IoE) [2]. The concept of IoT devices is to establish a stable connection to both home and public computer networks, as well as the cloud, which enables remote administration of the device, whether it's a refrigerator, car, or a home automation system. The wide availability of services and possibilities can influence living conditions if one knows how to use them physically and safely. However, in many cases, the solutions proposed by manufacturers are unsafe [3], [4]. IoT security measures are often minimal, limited to simple mechanisms. Such solutions provide significant opportunities for hackers who can, for example, gain access to a building by attacking a home appliance, thus gaining entry to the main home network. The analysis of IoT devices from a cybersecurity perspective is particularly emphasized in the era of a very large number of IoT devices in residential buildings. Research allows for the detection of new methods of authentication and security measures used in various IoT device [5],[6].

IoT devices are most commonly equipped with WiFi modules or, in the case of specialized devices, Ethernet modules, which, when connected to the global network, unlock additional functionalities. These devices can be based on less advanced controllers such as NodeMCU [7],[8], ESP [9],[10], Raspberry Pi [11], as well as more advanced modules like PLC controllers [12]. Such solutions can utilize artificial intelligence algorithms for efficient management of electricity consumption [13],[14] and [15], or heating systems [16],[17],[18], not only in individual buildings but also in a cluster of buildings managed from the cloud [19],[20] and [21]. Due to the availability of components and a substantial base of online tutorials, it is possible to build custom Smart Home solutions using popular microcontrollers such as Arduino, ESP, etc. However, a key element is securing the entire system against external attacks.

As mentioned, IoT devices unlock most of their functionality through connection to the cloud computing. Devices equipped with a series of cameras can analyze their content and react accordingly, for example, by notifying the user that it's time to go shopping. Cars equipped with temperature sensors can inform the user through a push notification on their phone, via a dedicated application, that the car is heated or cooled and ready to drive. The amount of data required for processing and the memory needed to store the database is often so large that it is impossible to store all the requested information locally. Thus, in the case of many devices working together, the communication requires a connection to the cloud computing in order to properly manage the data exchange.

An example of such a solution can be a system of intelligent washing devices currently under development, as presented in this paper. It is assumed here, that the washing appliances have additional modules that allow for management and adjustment of washing parameters for textile materials using an RFID system. The concept of integrating washing devices with the

IEEE Catalog Number: CFP2385N-ART ©2023, PTI

cloud computing is demonstrated using the example of the Microsoft Azure IoT Hub service and its services, RFID system, and proprietary laundry management software. Research on information reading in washing devices is also presented. The last section summarizes the research results and presents potential paths for the project's development.

II. Smart Laundry in the Era of IoT and Cloud Computing

Despite the large access to household washing machines, laundries are still popular and used not only for traditional everyday clothes, but especially for textiles that require specialized treatments. Each fabric requires appropriate washing agents to be used without damaging the material. Some clothes require more specific measures, while for others they can be more universal. The idea of an intelligent laundry system is to adapt the chemical agents, their dosage, and grouping based on the fabric inserted into the washing machine.

Considering the wide range of laundry detergents available and the constant emergence of new liquids and powders, storing their information along with the clothing would be an outdated solution. This means that whenever new products appear, the information for each garment would require updating. A much flexible and future-proof solution is to store the data in the cloud, where the database can be updated at any time. This allows for the utilization of products that have recently entered the market in a very short time.

The idea of operation of an intelligent cluster of washing devices is presented in Fig. 1

As seen, each device is equipped with an Ethernet module or a WiFi module for communication with the network. When a washing machine connects to the Internet, it immediately unlocks the connection to the cloud by retrieving necessary data, such as pending software updates, new washing programs. The device may also send data to the manufacturer regarding the current status of the machine or informing the operator about the current washing process. An offline mode must be provided in case of a network connection problem. However, when appropriate fabrics are detected, the offline data is overwritten with information obtained from the cloud.

The RFID (Radio Frequency IDentification) system was used to recognize the textiles. They contain RFID tags with information about the product [22].Typical data is shown in Fig. 2.

The RFID identifier has security keys and a write-lock feature, preventing the introduction of incorrect materials/components into the washing device, thus avoiding damage. An important element is the `Cloth_code` - a special string of characters assigned, for example, by manufacturers during production, confirming that it is a suitable material for washing. This key is verified against a database to confirm the material after reading its content. The UUID serves as a unique product identification number. It can be checked in the database for existence and based on it, the ideal washing conditions can be selected, taking into account the manufacturer's recommendations available in the cloud database. In

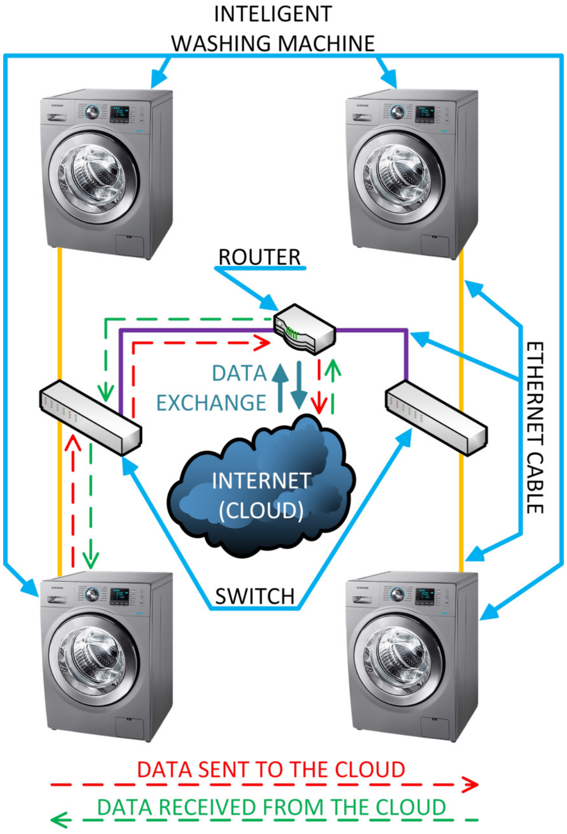

Fig. 1. A cluster of intelligent washing devices

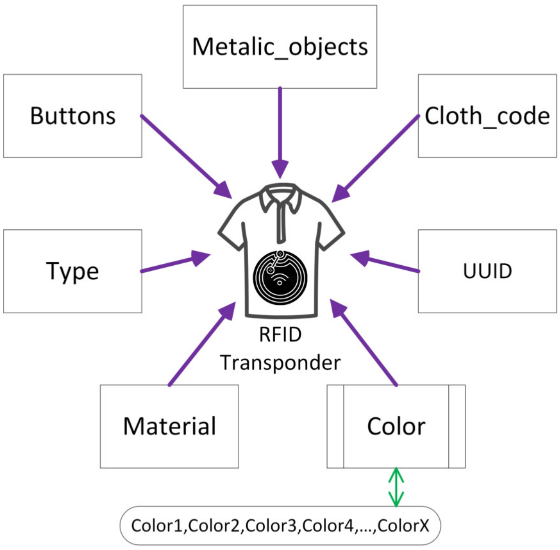

Fig. 2. Data structure in the memory of the RFID identifier

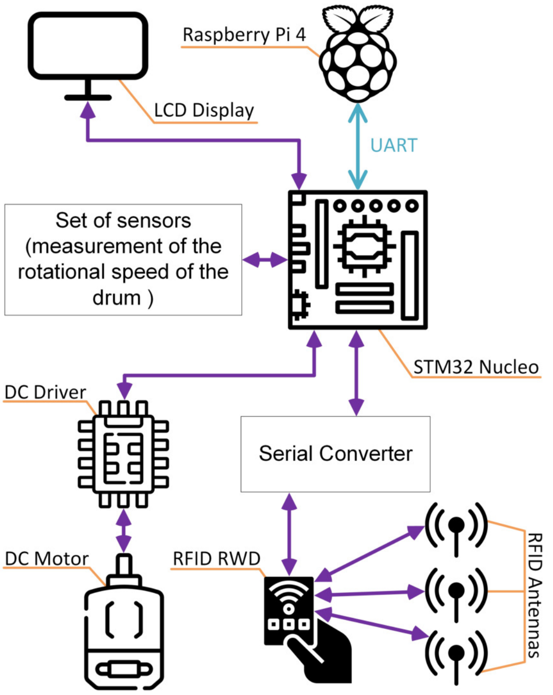

Fig. 3. Diagram of connections and communication between electronic components

the absence of records associated with a particular material, other parameters such as type, fabric, and color are taken into consideration.

To conduct the tests, a device was developed that contains 3 FEIG RFID read/write readers (RWDs). The entire device is controlled using an STM32 microcontroller embedded in the Nucleo board, which features a 32-bit M4 processor with 512KB flash memory and 128KB RAM. The Nucleo board is connected to a touch LCD display, FEIG reading/writing devices, and DC motors for drum rotation control. Since the Nucleo board does not have wireless or wired network modules for internet communication, the Raspberry Pi 4 microcomputer was used. It runs Raspberry Pi OS Lite, which does not have a graphical interface. The Raspberry Pi is connected to the STM microcontroller via the UART interface. The functional diagram is presented in Fig. 3.

After placing clothes equipped with RFID identifiers, the drum rotates to read the data from memory using RWD. In the next step, the information is retrieved and aggregated by a dedicated Python script running on the Raspberry Pi. The data is adjusted accordingly and transmitted to the Azure cloud using Raspberry Pi's wireless (WiFi) or wired (Ethernet) modules.

The project utilized the Azure IoT Hub service, which provides the necessary sub-services to fully leverage the potential of the intelligent cluster of washing machines. In the cloud, the uploaded data is compared with the records in the database, and after successful verification, the device receives instructions on the specific washing parameters for the given fabric. Each incoming data originates from a dedicated device identified by a unique identifier assigned by Azure. This enables the aggregation and processing of a large volume of data from multiple devices simultaneously. When sending data to the cloud, the device must authenticate itself in the service before transmitting any information to the database. To authenticate a device in the cloud, it is necessary to include it in the Azure IoT Hub settings, which will generate the required connection string along with login credentials. Each device is provided with access keys and individual character string, allowing for its identification in the cloud. All steps are presented in the diagram shown in Fig. 4.

The data obtained from the cloud computing (Azure IoT service) is transmitted to Raspberry Pi, which modifies the incoming information accordingly. It then sends the information via the UART interface to the STM32 microcontroller, along with laundry-related details such as detergent dosing, drum rotation settings, and the amount of powder to be dispensed. Additionally, the LCD screen displays information related to the recommended detergent and laundry powder provided by the manufacturer.

III. Reading textile data

As part of the research work, accuracy analyses were conducted on the detected objects in the smart washing device. For this purpose, 30 RFID identifiers simulating clothes were used to determine the number of scans required to correctly read all the identifiers inside the washing machine. The results are presented in Figure 5, divided into the number of scans as 1-3 and 4-6, respectively.

As can be observed in Fig. 5 on the left chart, during a single full drum rotation with the identifier scanning, the accuracy of reading individual identifiers decreases as the number of clothes in the drum increases. In the case of a small quantity of 1-2 clothes, a 100% reading accuracy can be determined. In the range of 3 to 15 identifiers (clothes), the success rate of scanning ranges from 93% to 97%, which seems a pretty good result for a single rotation. Unfortunately, with a larger quantity of clothes, the level of accuracy decreases. This is due errors in reading data from the identifiers or a lack of power supplied to the identifier memory during a single rotation. It is worth noting that the device is equipped with 3 antennas for reading identifiers, which are activated during one rotation, resulting in good reading accuracy even with a large number of clothes.

In the case of two full drum rotations, a significant improvement in reading the fabric information can be observed. The reading accuracy is 100% for a range of 1 to 16 clothes inside the washing machine. The accuracy starts to decrease from 17 clothes, but within the range of 17 to 21 identifiers, the accuracy level still remains above 90%, which is a satisfactory result. The lowest value, 60%, appears only at 30 clothes, whereas in the case of a single rotation, the lowest value appeared at 29 clothes and was 44%.

Another measurement was conducted by performing 3 scans, which means 3 full drum rotations. As can be seen, the measurement accuracy increased for a larger number of clothes. The scanning achieved a 100% value even for 21 RFID identifiers. The accuracy level remained above 90% for 22 and 24 identifiers. In the case of measuring 23 identifiers, the value reached 88%. This may be related to a lack of power supplied to the memory of the RFID identifiers, which reduced the accuracy measurement results. It is worth noting that even for 30 clothes inside the washer, the reading accuracy level was above 70%.

The right chart of figure 5 presents measurements conducted for 4 to 6 drum rotations to verify the influence of rotations on reading accuracy. Although the previous results showed a significant increase in accuracy level, the readings were still below 80% in the most challenging case. As can be observed, the accuracy level for 4 drum rotations, up to 21 clothes, does not deviate from the results presented on the left chart. In the case of values 20-21, there is a slight decrease to approximately 99%. However, it is worth noting the change in reading results for the range of 27-30 clothes. The reading accuracy significantly improved for 4 rotations, resulting in over 80% accuracy for 30 RFID identifiers. For further analysis, two additional scans were conducted, namely 5 and 6 drum rotations. For the 5 scans (5 rotations), another accuracy leap can be observed for the final values. In the case of 30 clothes inside the intelligent washing device, the accuracy level reached over 90%, as well as for all the remaining cases. However, it can be noticed that an increase in the number of drum rotations did not significantly affect the values in the range of 23-26 RFID identifiers. To validate the results, a 6-fold drum rotation was performed, and the results are presented in Fig. 5. It can be observed that the accuracy for 30 clothes did not change significantly, with only a 1% increase. However, the reading levels for the range of 23-28 RFID identifiers slightly improved. The last two scans show that the accuracy level stabilized, and subsequent rotations do not significantly affect the data readings from the memory of the identifiers inside the drum of the device. Additional scans may cause changes at a maximum of 1-2%, which does not bring significant changes considering the lowest value of 92%.

For each identified textile, parameters stored in the Microsoft Azure cloud database are analyzed. Dedicated washing parameters for individual materials are retrieved. Then the data is processed to select the best possible washing agents and recommendations. In the case of a different fabrics inside the washing machine, averaged washing conditions are selected to avoid damaging any of the materials.

IV. Conclusion

The presented paper showcases a prototype of an intelligent laundry management system connected to the cloud. Parameters and washing configurations are retrieved from the database in the Microsoft Azure service. As part of the research, an analysis of textile recognition accuracy was conducted. This is crucial for washing automation, especially in public laundries, where each fabric should be correctly identified. The analyses demonstrated high accuracy in reading data from the identifiers after performing 5 and 6 scans, which correspond to full drum rotations, at a level exceeding 90%.

In further work, the authors aim to examine the selection of washing parameters for incompatible materials and introduce the ability to adjust material information in the washing machine before starting the washing process. Additionally, they plan to develop a mobile application that allows managing the washing machine, including reading the current materials inside the device. The development of the application will enable further advancement of the project towards an intelligent virtual wardrobe with enhanced material control and storage capabilities.

Acknowledgment

This project is financed by the Minister of Education and Science of the Republic of Poland within the “Regional Initiative of Excellence” program for years 2019–2023. Project number 027/RID/2018/19, amount granted 11 999 900 PLN.

Text embeddings and clustering for characterizing online communities on Reddit

Jan Sawicki
0000-0002-8930-7564
Warsaw University of Technology
Email: jan.sawicki2.dokt@pw.edu.pl

***Abstract*—This work analyses Reddit, the largest public, topic-centered social forum. In the experiments, contextualized text embeddings, obtained using DistilBERT, represented subreddit content. Next, clustering was performed, using an unsupervised K-means algorithm and evaluated with multiple clustering metrics. The obtained clusters were analyzed. Moreover, changes of cluster structure, between 2019 and 2022 have been examined.**

I. Introduction

REDDIT is the largest, public, topically-separated forum [1]. Its unique structure allows users with common interest to find their place for discussion, i.e. a subreddit; a subforum dedicated to a particular topic. The platform policy, and Reddit administration, put no restrictions on the topic of subreddits (except for the rules regarding illegal content). Moreover, any user with at least 30-day old account and a non-negative "karma score" (reputation metric) can create a subreddit. This allows "communities" to blossom, with little-to-no supervision. There are subreddits, which are very close thematically, e.g. r/worldnews or r/news (news and information), or r/leagueoflegends and r/Overwatch (video games). There are also subreddits with distant, or even opposite, topics, e.g. r/Conservative and r/Libertarian.

The freedom and scale of subreddits raise multiple research questions, e.g. what are the most popular topics? Are there topically similar subreddits? Can subreddits be reasonably grouped into clusters? Are there, and if so what are, migrations of subreddits between clusters? This contribution explores these questions, for a Reddit dataset spanning 2019-2022, using natural language processing and data clustering.

II. Related works

Reddit's communities have been analyzed with different methods and from different perspectives. The main inspiration for this work are the results of a 2015 study [2] clustering 15,000 subreddits, from the first half of 2013 using scale-free backbone graph networks. The subreddits were grouped into 57 clusters and further, manually, annotated into 10 metaclusters (categories) such as: Electronic Music, Fitness, Sports, Soccer, Video Games, my Little Pony, LGBT, Pornography, Programming, Guns. Captured relations were based on interactions of over 800,000 users. However, the actual content of the posts, or comments, were not analyzed.

Two years later, "community2vec" [3], was introduced. This study also focused on users, by encoding post authors and user co-occurrences and applying PCA . Additionally, post content was encoded with static GloVe embeddings [4]. The main result was showing that vector representations of communities can encode meaningful analogies and semantic relationships, similarly to what has been previously seen for words.

A 2020 study of Reddit and Twitter [5] focused exclusively on texts of 54.5 million Reddit comments and 23,684 tweets. Its goal was to compare text embedding methods: TF-IDF Word2Vec [6] and Doc2Vec [7] applied to topic modelling, with document clustering using k-means, k-medoids, hierarchical agglomerative clustering and non-negative matrix factorization (NMF). For these, different settings and hyperparameters have been tested. It was established that combining Doc2Vec and K-means achieved the best results.

Finally, in [8], instead of static clustering, community evolution over time was analyzed. Here, active users and textual content, processed with LIWC analysis , has been applied. The results represent patterns of user engagement at different stages of community lifespan. However, they do not show how the subreddit topic clusters evolve over time.

To summarize, over time, a shift from user-based to content-based embeddings can be observed. Additionally, since 2018, an influence of NLP advancements [9] is noticeable; from basic text processing (e.g. LIWC, TFIDF, PCA) and static embeddings (e.g. GloVe, Word2Vec and Doc2Vec), to contextualized text embeddings (e.g. BERT [10] and BERT-like models, e.g. DistilBERT [11]). Here, note that older techniques underperform, against BERT-like models (e.g. LIWC [12]).

Moreover, Reddit continues to grow, since its launch in 2005, with past studies completed in 2015, 2017 and 2020. Therefore, a Reddit structure study needs to be revisited, applying modern approaches, to understand what the subreddits communities look today like and how they change in time. Therefore, this contribution presents results of explorations based on a dataset spanning four years (2019-2022), while applying contextual text embeddings with a BERT-like model, with the goals of analysis of subreddit community structure and its evolution over time.

III. Methodology

Let us now briefly discuss (1) dataset, (2) text embedding method, (3) clustering approaches, and (4) cluster quality assessment methods used in this contribution.

A. *Dataset*

Reddit consists of over 3.5 million communities (and over 1.5 billion monthly visitors). The most popular Reddit data source is the Pushshift database [13], [14]. The subreddit data was extracted from Pushshift subreddit dumps. Furthermore, Pushshift REST API could not have been used due to an outage that happened in early 2023. Overall, content of 3090 "largest" subreddits, i.e. subreddits with at least 100,000 subscribers, has been extracted.

Overall, Reddit is a subject to the 1% rule that appears in the majority of social networks [15]. The majority of posts gain little-to-no attention ("upvotes"), while a small fraction "goes viral" and appears on the frontage of Reddit (the main Reddit forum r/all). Hence, to reduce the computational cost, while capturing subreddit structure, 1000 posts with the highest *scores*, have been extracted from each subreddit. The *score* is the Reddit's measure of "appraisal by a community of Reddit subscribers of an item" [16]. Finally, the dataset spans 4 years: 2019-2022, to allow the analysis of subreddits cluster evolution over time. The resulting dataset consisted of over 12 million unique user posts.

B. *Text embedding*

After gathering, text embeddings has been applied to the posts. Since the introduction of BERT (in 2018), multiple models, for different NLP goals, were introduced [17], [18]. This work needs a general feature extraction models that deliver multipurpose text embeddings. The model should be "general" and multipurpose, because input data originates from over 3000 communities, and covers topics from politics and news (r/politics, r/news), through video games (r/DOTA, r/gaming), memes (r/hmmm, r/me_irl), drug usage (r/LSD, r/shrooms), to plants (r/Bonsai, r/gardening), fishkeeping (r/Aquariums, r/PlantedTank) or military (r/military, r/guns).

Moreover, the NLP part takes the longest processing time (over 50% of total runtime). Therefore, a general multipurpose and fast, but efficient model is required. In 2019 a "smaller, faster, cheaper and lighter" version of the BERT model has been introduced, the DistilBERT. It retains 97% of the original BERT performance on downstream tasks, while being 40% smaller and 60% faster [11]. Therefore, to reduce computation time, DistilBERT has been selected.

Here, it should be noted that different Reddit communities have different posts "styles". For example, r/politics consists mostly of links to news websites, while r/AbruptChaos contains mostly GIFs or short videos. There is, however, one part of posts that is forced by Reddit – the post's title, which has to be present on every posts regardless of subreddit. While there are ways to overcome this (Reddit post, over 99% of posts in the dataset have a textual title. Overall, DistilBERT embedded posts titles to 768 dimensional vectors, which were clustered.

C. *Clustering*

Use of K-means for clustering followed results found in [19], [20]. However, the biggest downside of K-means is that it requires specification of the number of clusters. This problem can be overcome by using unsupervised clustering metrics [21], [22] to find "best" clustering. In this context, Silhouette Score (previously used on Reddit [23]), Davis-Bouldin score , Caliński-Harabasz score and k-means inertia (sum of squared distances of samples to their closest cluster center) have been tried. The most suitable cluster size has been sought by evaluating clustering results for cluster sizes: 10, 20, 30, ... 1530, 1540, where 1540 is half o the number of subreddits. Davis-Bouldin metrics is the only metric where lower values are better (for others, higher is better). For easier interpretability of the results, presented in Figure 1, Davis-Bouldin metrics is presented with a minus sign. Interestingly, the metrics were practically identical for considered time periods (annually for 2019-2022). Hence, it can be stated that the number of subreddit clusters, and hence the topical dispersion, does not change much over time (see, also, Section IV).

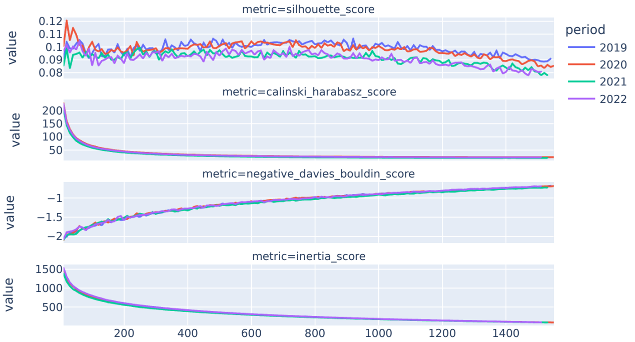

Fig. 1. Cluster evaluation with different metrics (Davis-Bouldin score is actually negative score, to keep up with "higher is better" interpretation.

The choice of the cluster number was a challenge since not all metrics have been consistent (see, Figure 1). The Silhouette Score differed a lot. This is related to the fact that the Silhouette Score ranges from -1 to 1, where the best value is 1 (all points assigned to the right cluster) and the worst value is -1 (all points assigned to the wrong cluster), while scores near 0 indicate cluster overlap. All Silhouette Scores were close to 0, indicating existence of overlaps. To find a compromise between Davis-Bouldin, Caliński-Harabasz and inertia metrics, the Elbow Method was applied, as previously used in similar settings [24], [25] (also on Reddit [26]). Overall, any number between 180 and 450 represented a "good fit". However, to achieve interpretability of results, 200 clusters were selected. Here, note that smaller numbers of clusters were checked (e.g. 100), but they produced clusters with "not-fitting" topics. Larger numbers (e.g. 300), on the other hand, resulted in fragmented topics.

After clustering, the subreddit groups were manually assigned to meta groups (categories). For example, subreddits related to games (r/LeagueOfLegends, r/DOTA, r/Overwatch, r/gtaonline) or subreddits related to politics (r/Conservative, r/politics, r/Libertarian, r/Political_Revolution, r/geopolitics). These groups are further described in Section IV-A.

D. Cluster similarity and time-evolution

To automatically detect cluster dynamics, they were compared annually using the Jaccard Index [27]. Each cluster from a period was compared to each cluster from the next chronological period. The pair of sets with the highest Jaccard Index is considered a transition, from the predecessor to the successor. Note that the predecessor and the successor may be the same, i.e. the cluster did not change from period to period. This way, ordered lists of cluster transitions were created. Then for each list a generalized multi-set Jaccard index was calculated for all sets (2019, 2020, 2021, 2022). The results are discussed in Section IV.

IV. Results and their analysis

Let us now discuss the key experimental findings.

A. Subreddit clusters characterization

Let us first look into clusters of subreddits established for year 2022. Table I presents number of subreddit by manually annotated categories. Most categories are obvious, but some require some explaining.

"**Pictures**" aggregates subreddits dedicated to posting pictures, GIFs and videos. The themes range from wallpapers (r/wallpapers), to content that is supposed to amaze on-lookers (r/nextfuckinglevel, r/woahdude) or disquiet/scare them (r/cursedcomments, r/cursedimages, r/cursedvideos).

Some subreddits do not have a "theme", and are extremely broad, such as r/gif, r/gifs, r/pics. Interesting is a group of "X_Porn" subreddits, where X is some subject. Here, the term "porn" is a synonym to "amazing", "beautiful", "wonderful" (not pornography). Subreddits in this group (r/CabinPorn, r/CityPorn, r/EarthPorn, r/InfrastructurePorn) showcase pictures of things, places or phenomena that are to be perceived as "porn", i.e. most spectacular of its kind. There are also "meta-themes", such as r/BetterEveryLoop, where the author of a post claims that the more times a GIF/video is watched, the better it gets. The actual content is discretionary. Finally, there are also subreddits with random pictures, e.g. r/nocontextpics.

In the "**states**" category, there are subreddits related to individual US states and cities, e.g. r/Atlanta, r/Austin, r/Calgary, r/California, r/Dallas, r/Denver, r/LosAngeles.

Interestingly, while the applied NLP model is meant for English, it clustered subreddits in other languages into the category "**language specific**". There are also separate clusters for: German subreddits (r/de, r/de_IAmA), the Polish subreddit r/Polska, the Netherlands, containing r/thenetherlands and a cluster related to Scandinavian subreddits, containing r/norge, r/svenskpolitik, r/swedishproblems.

The "ask" category contains subreddits with questions. Here, questions can be general (r/AskReddit), topic specific (r/morbidquestions, r/AskRedditAfterDark), or answerer specific (r/AskMen, r/AskMenOver30, r/AskWomen, r/AskEurope, r/AskUK).

There was a group that was separated from "pictures" were "**animals**". This group contains clusters of subreddits about (mostly) dogs and cats and other small animals. It appears that the similarity between some "animals" subreddits and some "pictures" is in the feelings that the pictures are supposed to invoke, i.e. happiness, or cuteness. For example, subreddits: r/aww (described as: "Things that make you go AWW! Like puppies, bunnies, babies, and so on... A place for really cute pictures and videos!" and r/MadeMeSmile ("A place to share things that made you smile or brightened up your day. A generally uplifting subreddit." . On the "other side", one can find "animals" in subreddits dedicated to brutality and violence in animal kingdom (r/natureismetal, r/Natureisbrutal).

Next, there is the "**irl**" group, standing for "in real life". It contains subreddits, such as: r/meirl, r/2meirl4meirl, r/bi_irl, r/discord_irl, r/egg_irl, r/anime_irl, r/gay_irl, r/me_irlgbt, r/woof_irl, r/ich_iel . All of them contain pictures with strict post title policy. Depending on the subreddit, the titles are always "meirl" (r/meirl), "2meirl42meirl4meirl" (r/2meirl42meirl4meirl), etc. It was clear how to characterize the content of these subreddits, other than it being memes. Interestingly, even though r/ich_iel is a German subreddit, it got clustered with other English "irl" subreddits.

Let us now consider "**social chatting**" group. Here, clusters include both general (r/CasualConversation, r/MakeNewFriendsHere) and specialized chatting topics (r/BreakUps, r/LongDistance, r/Marriage). There are also subreddits where users explicitly ask for an advice: r/Advice, r/askwomenadvice, r/dating_advice or seek approval/disapproval of their actions: r/AmItheAsshole (the latter with a dedicated study, from 2023 [28]).

Moving to smaller subreddits, there is the "**NSFW**" (Not Safe For Work) group. Here, confirmation that the user is an adult is required. However, these are different from "pornography", since they discuss adult topics, such as fetishes, fantasies and other sex-related issues. The examples are: r/BDSMAdvice, r/BDSMcommunity, r/Swingers, r/polyamory, r/DeadBedrooms, r/NoFap, r/bigdickproblems. There are also subreddits devoted to looking for other people with similar interests. These often use the acronym "r4r" (Redditors for Redditors): r/DirtySnapchat, r/Kikpals, r/dirtykikpals, r/dirtyr4r, r/exxxchange, r/r4r, r/snapchat, r/swingersr4r.

The "**Reddit meta**" category contains Reddit administration (r/announcement) and technical support subreddits (r/help). Next, "Deals" category contains subreddits about free goods, or goods on sale, e.g. r/GameDeals, r/NintendoSwitchDeals, r/PS4Deals, r/deals, r/eFreebies, r/freebies, r/googleplaydeals. Finally, "**Help me find**" is the group of subreddits where users ask others to help them find something, or find what something is, e.g. r/HelpMeFind, r/RBI (Reddit Bureau of Investigation), r/Whatisthis. Here, subreddits for identifying pornographic performers or scenes r/pornID, r/sources4porn, r/tipofmypenis are included.

What is clearly visible in Table I, is that the most of the clusters are related to pornography, pictures with vague themes, video games, memes and technology. These themes also aggregate the biggest number of subreddits.

TABLE I
CLUSTERING EVALUATION

category	subreddits count	cluster count
pornography	692	33
pictures	253	22
games	215	6
memes	201	8
mixed	195	13
tech	135	9
social chatting	119	6
tv series	99	3
animals	95	5
politics	92	5
music	64	6
sports	64	3
finance	58	4
NSFW	52	4
hate	48	1

deals	11	3
writing	11	2
crime	11	1
religion	11	1
anime	10	1
trading	9	3
help me find	7	1
hiring	5	1
surveys	1	1

B. Subreddit clusters findings

Let us now report key findings regarding the clustering.

1) Subreddit naming: There are naming patterns and conventions of subreddits. Reddit's users employ multiple acronyms, e.g. "IRL" (In Real Life), "AMA" ("Ask Me Anything") or "NSFW" ("Not Safe For Work"). These 3 alone materialize in 42 subreddits. There are also subreddits acronym names, e.g. r/ATBGE ("Awful Taste But Great Execution"), including the longest name: r/UNBGBBIIVCHIDCTIICBG ("Upvoted Not Because Girl, But Because It Is Very Cool; However, I Do Concede That I Initially Clicked Because Girl."). As noted, common is using the word "porn" to name content that is supposed to be beautiful, aesthetically pleasing, interesting, well-made, etc. Moreover, only 10 out of 71 "X_porn" subreddits contain actual pornography.

Finally, while many subreddits are descriptive of the topic (e.g. movie or TV series title, music genre, area of science or name of a video game), multiple subreddits focus on describing a general phenomenon/feeling (r/aww, r/INEEEEDIT, r/iwanttobeher). This shows how important it is to analyze the content of the subreddits instead of just the names.

2) Country subreddits: There is a group of subreddits, in English, dedicated to countries, e.g. r/UnitedKingdom, r/russia, r/China, r/canada. Interestingly, they appear in *different* clusters, but all in the category "politics". Interestingly, r/russia and r/China appear in a single cluster, consisting of: {r/ANormalDayInRussia, r/China, r/MapPorn, r/PropagandaPosters, r/imaginarymaps, r/russia, r/vexillology, r/vexillologycirclejerk}. This suggests that text embeddings of map-related subreddits and a propaganda poster subreddit, are similar to the content of r/russia and r/China. Subreddits r/canada, r/europe, r/unitedkingdom are in the same cluster with political and general news subreddits: {r/CanadaPolitics, r/Conservative, r/DemocraticSocialism, r/canada, r/Economics, r/Libertarian, r/Political_Revolution, r/europe, r/Republican, r/news, r/The_Mueller, r/democrats, r/geopolitics, r/politics, r/ukpolitics, r/unitedkingdom, r/worldnews}.

Note that even though the US is the third-largest country by population, and has the highest number of users on Reddit, it does not have a dedicated subreddit. However, as noted (in Section IV-A), there exist subreddits dedicated to US states and cities, and they form a separate cluster.

3) Technology + Finance = Cryptocurrencies: There is an interesting overlap between subreddits in "finance" and "tech". There is a cluster containing both investment subreddits (r/algotrading, r/pennystock, r/RobinHoodPennyStocks), cryptocurrencies subreddits (r/BitcoinMarkets, r/btc, r/ethereum, r/ethtrader) and technology subreddits (r/tech, r/technews, r/technology). This captures that fact that cryptocurrencies became a "middle-ground" conversation joining finances and technology.

4) Real life and gaming: In the cluster dedicated to crafts, there is a subreddit with "digital craftsmanship". It is r/Minecraftbuilds, containing building concepts created in the game Minecraft. It appears in the cluster with subreddits such as: {r/HomeImprovement, r/Justrolledintotheshop, r/Tools, r/electricians, r/longboarding, r/redneckengineering, r/whatisthisthing, r/woodworking}. Similarly, among "fashion" subreddits there is one related to the Animal Crossing video game fashion designs (r/ACQR): {r/AsianBeauty, r/Embroidery, r/Makeup, r/MakeupAddiction, r/RedditLaqueristas, r/crafts, r/crochet, r/femalefashionadvice, r/knitting, r/malefashion, r/malefashionadvice}. This illustrates interfusion of real life craftsmanship and fashion with in-game craftsmanship and fashion.

5) Are you eating? Watch a documentary.: There exists a relatively small cluster: {r/Documentaries, r/mealtimevideos}, where the first subreddit is about a documentary movie and the second contains video suggestions for watching during lunch or dinner. It appears that both of them have similar content, meaning that documentary videos would be a good suggestion for watching during mealtime.

6) Pornography mix: As visible previously in Table I, most of the clusters are dedicated to pornography. There are subreddits dedicated to fetishes, body parts, looks activities performers, sexual preference (e.g. heterosexual, homosexual etc.), amateur vs professional or performers. However, all of their content seems alike, as there are no particular patterns in pornography clusters, except for one. The subreddits dedicated to particular performers have similar content (often about praising a particular performer), e.g. {r/AdrianaChechik, r/AlexisTexas, r/AngelaWhite, r/DaniDaniels, r/KimmyGranger, r/Miakhalifa, r/RileyReid, r/abelladanger, r/leahgotti}.

The lack of any other patterns when it comes to clustering pornography subreddits shows that their content is extremely overlapping and similar regardless of the subreddit.

C. r/worldpolitics in NSFW subreddits

There is an interesting anomaly in one of the clusters. Subreddit r/worldpolitics appears in a cluster nearly exclusive to NSFW content, e.g. {r/BDSMAdvice, r/Rapekink, r/SexWorkers, r/Swingers, r/mbti, r/bigdickproblems, r/bisexual, r/lgbt, r/polyamory, r/sexover30, r/BDSMcommunity}. At first, this looks like a clustering error, since r/worldpolitics should be in a political cluster with subreddits such as r/politics. Due to permissive rules of this subreddit it is full of all kinds of posts. Its description states "reddit's anything goes subreddit, no topic imposed or opposed by the mods" . Additionally, when posts are sorted by Reddit's "top of all time", the first 100 are marked NSFW, even though they do not include adult content. Overall, r/worldpolitics seen from the perspective of text-embedding, is very close to other adult-content subreddits, i.e. it is either very chaotic, or contains adult content.

1) Current clustering vs. previous studies: As mentioned, the study from 2015 [2] performed similar clustering and manual annotation into "meta clusters". Let us compare meta-clusters from 2015 with these from 2022.

First, the 2015 groups: "Fitness", "Sports", "Video Games", "Pornography" all map one-to-one to cluster groups established in 2022. Second, "Electronic Music", "Programming", "Soccer" and "Guns" map to wider/similar cluster categories, which are "music", "tech", "sports", and "military", respectively. Third, there are 2 groups of clusters with no one-to-one correspondence: "my Little Pony" and "LGBT". Subreddits marked as "LGBT" in 2015 appear in clusters of "NSFW" (e.g. {r/BDSMAdvice, r/Rapekink, r/SexWorkers, r/Swingers, r/mbti, r/bigdickproblems, r/bisexual, r/lgbt, r/polyamory, r/sexover30, r/BDSMcommunity}). This can be a question of the naming convention. Moreover, it seems that LGBT issues are close to NSFW, which is logical, since many of them involve sexuality and sex. "My Little Pony" subreddits were completely absent in this analysis. Even though they are large enough (over 100,000 subscribers), they did not appear in the Pushshift dumps, probably due to inconsistencies in the Pushshift database. Hence, this cluster has no mapping to 2022 clusters.

Similarly to the original work, a dimensionality reduction of the embeddings has been performed with the t-SNE method, to create a two-dimensional visualization. Figure 2 shows the clusters in the top 20 categories, by subreddit count in cluster. T-SNE reduced the dimensions of vectors 768 to 2, Even in two dimensions the clusters such as "pornography", "sports", "music" or "tech" appear close within the group and far between the groups. This is consistent with the 2015 study. Hence, it supports quality of embeddings and category annotations reported in current contribution.

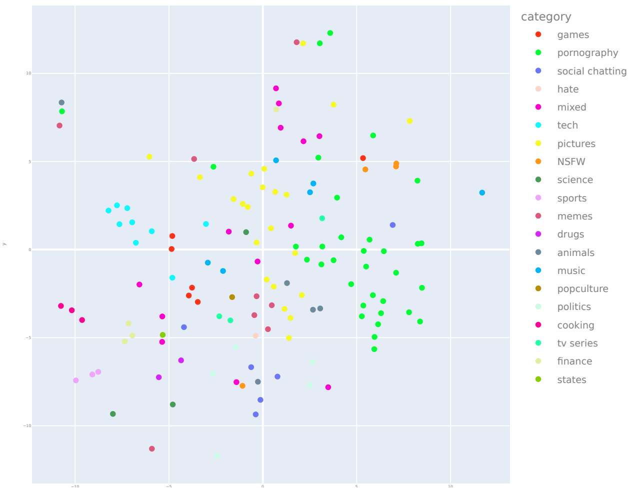

Fig. 2. The clusters in the top 20 categories by subreddit count in cluster. The X and Y axis are insignificant due to dimensionality reduction with t-SNE

D. Subreddit cluster transitions

The second group of results focuses on cluster evolution between 2019 and 2022. Due to space limitations, only selected key findings are presented.

1) Gardening, hair, writing and vehicles stay unchanged: The highest Jaccard index (0.78) between subreddit clusters is achieved for clusters about plants, gardening and fish tanks.

Here, almost no change has been observed for 4 years. The cluster lost one subreddit: r/shrooms, and gained 3 new ones: r/snakes, r/thingsforants, r/whatsthisbug. Interestingly, in 2021, the r/shrooms subreddits migrated to a drug-related cluster. Similarly, between 2019 and 2022, the hair-related cluster (Jaccard index of 0.7) went through a couple changes, but finally lost one subreddit (r/FancyFollicles) and gained one (r/beauty).

With Jaccard index of 0.61 there is also the writing cluster, which moved closer to it's writing theme by dropping r/MovieSuggestions, r/TrueFilm and gaining r/stephenking.

Another barely changed cluster concerns vehicles. In 2019, it was mostly related to cars, but in 2020 it gained and retained r/MTB (mountain bike), r/bicycling and r/cycling subreddits. Interestingly, the r/Cartalk and r/MechanicAdvice subreddits, in 2022 formed a completely new cluster. The main difference between these two and other clustered subreddits is that they focus on discussions rather than showcasing vehicle models.

2) COVID-19: As expected, COVID-19 pandemic is noticeable in subreddit evolution. A cluster that, in 2019, contained general science, health and chemistry subreddits ({EverythingScience, r/Health, r/physicsgifs, r/science}) was extended, in 2020, with r/COVID19, r/China_Flu, r/Coronavirus. It remained unchanged until 2022.

3) Pornographic subreddits migrations: Over time, significant migrations between pornographic clusters have been observed. "Pornography" category has the second-lowest mean, 4-year, Jaccard index of about 0.02. There even was one cluster in 2019 of 30 subreddits which finally got reduced to a single-subreddit cluster (containing only r/sarah_xxx). However, similarly as described in Section IV-B6 these cluster migrations are chaotic and random, and no pattern was detected.

V. Concluding remarks

This work is devoted to study of structure of and time evolution of the Reddit platform. Current text-embedding methods have been applied to the dataset covering 2019-2022 period. Overall, Reddit is a place containing content and discussion on various topics, with both very wide and very narrow scopes. Majority of the most popular subreddits are dedicated to pornography, pictures and videos about "anything and everything". Furthermore, popular are video games, memes and technology subreddits. While some of the topical clusters stay unchanged over the years, there are subreddit migrations between most of the clusters. Future studies will focus on more particular groups of subreddits and researching new methods for inter-subreddit topical modelling, such as crossposts.

***Abstract*—In Numerical Weather Prediction (NWP) models we need to model the dynamics of the atmosphere and the physical variables that take place in a moment. In grid point models the temporal evolution of the model variables are calculated in a 3D grid which covers the atmosphere from the surface up to the model top. NWP models include two import routine namely Runge-Kutta method and microphysics scheme WSM6. This paper describes advances in the performance of the Runge-Kutta method and WSM6 microphysics by exploiting multi-level parallelism using CUDA-based GPU on hybrid parallel platform. We applied pipeline parallelism technique, workload balancing and asynchronous data exchange strategy each demonstrating be useful to improve performance. Our experiments show that the solution is scalable. We also realized an analysis of the accuracy of our implementation with good results.**

***Index Terms*—Runge-Kutta Method, WSM6 microphysics, Hybrid Parallel Algorithms, Multi-GPU Algorithms, High performance Computing**

I. Introduction

WEATHER prediction systems assess atmospheric changes. They have diverse uses, from aiding agriculture, aviation, navigation, to assisting in natural disaster prevention. Weather prediction, a complex system, requires modeling atmospheric dynamics and physical variables such as pressure, temperature, wind, water vapor, clouds, and precipitation. Outputs typically include future temperature, humidity, and rainfall based on initial conditions. Some small-scale processes, like cloud formation, which can't be resolved numerically, are incorporated into models through parameterization schemes.

There are several numerical prediction systems based on sets of physics-based equations which weather can be predicted from atmospheric data as temperature, radiation, air pressure, wind speed, wind direction, humidity, and rainfall, and how they behave in the atmosphere [1], [2].

Among them, Model for Prediction Across Scales (MPAS) [3], Global/Regional Assimilation and PrEdiction System (GRAPES) [4] and Weather Research Forecasting (WRF) model [5] are popular tools used for both research and operational purposes. The Runge-Kutta third order method (RK3), used to time integration, and the Single-Moment 6-Class Micro-physics (WSM6), which calculates several hydrometeors variables, are tasks present in important models of weather prediction. Moreover, they are the most time-consuming tasks in a weather forecasting system.

The main goal of this paper is to present some enhancement for the RK3 and for the WSM6 using multi-level parallelism and pipelining on hybrid parallel platform. Our tests show that we achieved speedup ranging from 10 to 39 for the RK3 and from 5 to 26 for the WSM6 when compared to a 12-thread CPU. The pipelining and asynchronous data exchange strategies improved the runtime by up to 37%.

II. Background and related Works

There are several works that implement RK3 method and the WSM6 using parallel platforms. Korch and Rauber [6] investigated the RK3 method They compare the RK3 implementation using MPI, Pthreads and Java on Sun SMP and on Cray T3E. The speedup ranged from 3 to 10 with 8 processors. The authors of [7] show an enhancing of twelve-fold of a CUDA RK4 implementation on a Tesla compared to an OpenMP implementation. Murray [8] describes an OpenMP RK4 implementation for physics simulation that achieved a speedup of 2 on a 4-core CPU. Wo *et all* [9] achieve a speedup of 2 on a Geforce GT450M. The authors of [10] achieved a gain of 45 times on 2x Xeon Phi versus the same implementation using OpenMP on 2x Intel Xeon.

An implementation of WSM6 on CUDA [11] obtained a speedup of up to 246 using a K40 GPU and up to 295 using two GPUs when compared to a single-threaded CPU. Kim *et al* [12] implemented the WSM6 using OpenACC for Model for Prediction Across Scales (MPAS) [1]. They achieved a speedup of 5.7 running on a V100 GPU compared to a multi-thread version executed on 48 CPUs. More recently, Silva *et al* [13] improved those results and reached speedup of 371 using four V100 GPUs compared to single-thread CPU e 108 fold compared to 24-thread CPU.

III. Weather Prediction: RK3 and WSM6

The dynamic core of an NWP is responsible for discretization in space. Variables such as temperature, pressure, wind, humidity are time integrated by this dynamic core model. RK3 method is responsible for this time integration. However, many processes cannot be spatially discretized. Therefore, these processes are parameterized in terms of other variables available in the a model time-step state. Among these processes is the microphysics scheme.

The equations of the Runge-Kutta are formulated using the pressure vertical coordinate $\eta = (P_p - P_{ht})/\mu$, where $\mu = (P_{hs} - P_{ht})$, P_p is the hydrostatic component of the pressure, P_{hs} and P_{ht} are representing the pressure at surface and top boundaries. The transport equations in the flux form can be written as:

$$\frac{\partial \mu_d \phi}{\partial t} = -\nabla_\eta \cdot \mu_d \mathbf{v_h} - \frac{\partial \mu_d \omega \phi}{\partial \eta} \tag{1}$$

The quantity μ_d is the mass of the dry-air column (between the bottom and the top of the atmosphere for a vertical coordinate of mass type $s = [\pi_d - (\pi)_t]/\mu_d$, with $\mu_d = \partial \pi_d / \partial s$. Moreover, $\mathbf{v_h} = (u, v, \omega)$, which is the zonal, meridional and covariant vertical velocities, respectively. $\phi = (u, v, w, \theta, q_m)$, where w is the vertical movement, θ is the potential temperature, and q_m represents the scalar quantities, such as water vapor, hydrometeors and aerosol mixing ratio.

The WRF use third order Runge-Kutta for temporally discretized [14], which can be described by the equations:

$$\Phi^{*} = \Phi^{n} - \frac{\Delta t}{3} \nabla_\eta \cdot (\mu_d \mathbf{v_h} \phi)^{n} - \frac{\Delta t}{3} \frac{\partial (\mu_d \omega \phi)^{n}}{\partial \eta} \tag{2}$$

$$\Phi^{**} = \Phi^{n} - \frac{\Delta t}{2} \nabla_\eta \cdot (\mu_d \mathbf{v_h} \phi)^{*} - \frac{\Delta t}{2} \frac{\partial (\mu_d \omega \phi)^{*}}{\partial \eta} \tag{3}$$

$$\Phi^{n+1} = \Phi^{n} - \Delta t \nabla_\eta \cdot (\mu_d \mathbf{v_h} \phi)^{**} - \Delta t \frac{\partial (\mu_d \omega \phi)^{**}}{\partial \eta} \tag{4}$$

where $\Phi = \mu_d \phi$.

Now, the WSM6 scheme is based on six classes of cloud particles: water droplets, ice crystals, snow, hail, aggregates of ice crystals, and raindrops. In an NWP system, the WSM6 is a module that is coupled with other parameterization schemes which are described by differential equations that can be seen in more detail by Hong *et al* [15]. The WSM6 also considers the interactions between the different classes of hydrometeors.

IV. Hybrid Parallel platform

A Hybrid Parallel platform consists of a set of computer nodes which each node has a multi-core CPU and a many-core GPU. Each CPU as well GPU in the set can be heterogeneous. Under this model, we use MPI [16] to dispatch two threads by nodes using massage passing. One of them containing the code that will be executed on the multi-core CPU using OpenMP [17] and another thread containing CUDA [18] code that will be executed on GPU.

V. Multi-level Parallelism

Our weather model enables to use various levels of parallelism. The first level employs the MPI for coordinating various computer nodes. This level helps the task distribution across several nodes and their intercommunication, allowing concurrent execution of tasks. The second level is the division of tasks between different CPUs using shared memory. The last level is the use of CUDA-based GPUs to accelerate the processing. Each GPU executes the pipeline, which allows the model to run faster and more efficiently.

In our implementation of the method RK3 on CUDA, we performed a reorganization of the original code due to the different features between the Fortran compiler and CUDA. The first step in the implementation process involved consolidating all the subroutines into a single subroutine. The main goal of this initial stage is to identify sections that can be optimized and subsequently translated into CUDA. This strategy also helps avoid unnecessary copying of data from the CPU to the GPU. Besides, the consolidation of subroutines contributes to reducing the number of kernel calls.

Our CUDA WSM6 employs parallel optimization techniques similar to those used in the RK3. However, there is a distinction between the two implementations: WSM6 exhibits lower dependency on its operations. This feature enables the WSM6 to be executed in parallel over different portions of the data. We leverage this inherent characteristic of microphysics scheme to execute multiple WSM6 kernels simultaneously. This facilitates a better workload balance, improving distribution of tasks. Moreover, we distribute a workload to each node proportionally to its computational power.

A. Parallel Runge-Kutta

Take as input a grid of $nx \times ny \times nz$ of points which are the starting points of RK3, a function $f'(x, y)$ and a timestamp h. Moreover, it is given the computational power of each node and an integer N representing the total number of steps.

```
1.   - Let $T_f$ be the total of Gflops of the platform and let $T_i$
       be the computational power of the compute node $i$. Send
       to node $i$ $(nz * zy * nz) * (\frac{Ti}{Tf})$ points.
2.   - If node $i$ is a CPU then perform the following steps:
2.1.   Suppose we have $t$ threads so that each thread computes
       $((nz * zy * nz) * (Ti/T_f))/t$ elements:
       Compute the new x and y based on Eq. 2, 3, and 4.
3.   - If node $i$ is a GPU then perform the following steps:
3.1.   Let $v$ be an array of points attributed to $i$. Transfer
       array $v$ to global memory of the device.
3.2.   Invoke the kernel RK3 with $((k_1 + k_2 + 4k_3)/6)/32$
       blocks and 32 threads per block.
3.3.   Set $e = blockIdx.x * blockDim.x + threadIdx.x$;
3.4.   For $n_i$ from 0 to $N - 1$ do:
       Compute the new x and y based on Eq. 2, 3, and 4.
```

B. Parallel WSM6

We developed the CUDA WSM6 to support multi-level parallelism and pipelining. Each equation responsible for calculating the transition from one hydrometeor to another (as described in details by [15]) can to be computed in parallel.

Let p be a partition of the domain points with $x \times y \times z$ points according to Fig. 1.

```
1.   For $i = 0$ to $x$, do:
1.1.   Let the set of blocks $B = (b_0, b_1 ... b_y)$ be such that
       each $b_i \in B$ has $z$ threads.
       Each thread $t \in b_i$ computes the hydrometeors droplets
```

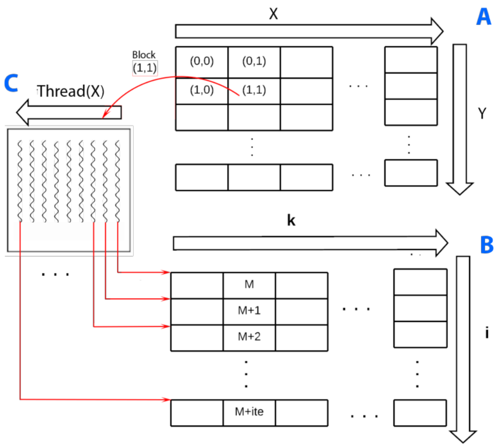

Fig. 1. GPU memory access of the M(k,i): (A) GPU blocks organized in two dimensions; (B) Matrix M(k,i), (C) A threads block of the (A) where each block thread accesses the matrix den with coalesced memory access.

(qc), ice particles (qi), rain droplet (qr), snow crystal (qs), graupel (qg) and water vapor (qv) as folows: Let k be the thread index and j the block index. For each (qc,qi,qr,qs,qg,qv) in $p(k,i,j)$ compute the transition considering the variables of that point.

VI. Pipeline Parallel

Pipelining is extensively utilized by hardware designers. Enhancement is accomplished by dividing each processed instruction into multiple stages. Below we describe how we apply the pipeline technique at the software layer, where the domain to be computed on the GPU is divided into partitions. Each partition represents a stage, allowing parallel processing.

We note that there are two main tasks of system working alternately, namely the dynamic RK3 and the microphysics WSM6. Each task is implemented in a different kernel. In this approach, as soon as a kernel finishes its job another kernel is launched. Hence, during some time the GPU is idle or wasting time with data exchange and, as result, reducing efficiency.

Firstly we identify data used by both RK3 and WSM6 and that may remain within the GPU memory during two consecutive call of different kernels avoiding data exchange.

Additionally, we noted that the idle GPU is the most important bottleneck to achieve better performance. To solve this problem the pipeline parallelism could be a interesting strategy. So, each part of the domain attributed to a GPU is divided into small partitions such that can be processed in parallel by the pipeline stages. Once a stage completes the WSM6 processing for its partition, that partition can start the task RK3 on it corresponding to the next stage in the pipeline. Similarly, as the next stage completes its RK3 processing for its partition it starts the WSM6 processing.

Each GPU executes its own pipeline independently. For clarity of presentation let us assume we have a two-stage pipeline. In this version we split the domain points given as input in two partitions p_1 and p_2: The RK3's and WSM6's kernels were implemented in such a way as to allow splitting the entry points into two partitions. Thus, we are able to execute RK3 with input p_2, while simultaneously, on the same GPU, we execute WSM6 with input p_2.

VII. Multi-Stages Pipeline RK3 WSM6

Using the same ideas of the previous section we may divide the domain in n blocks. Hence, we can generalize the pipelining for $2n$ stages considering n partitions of points.

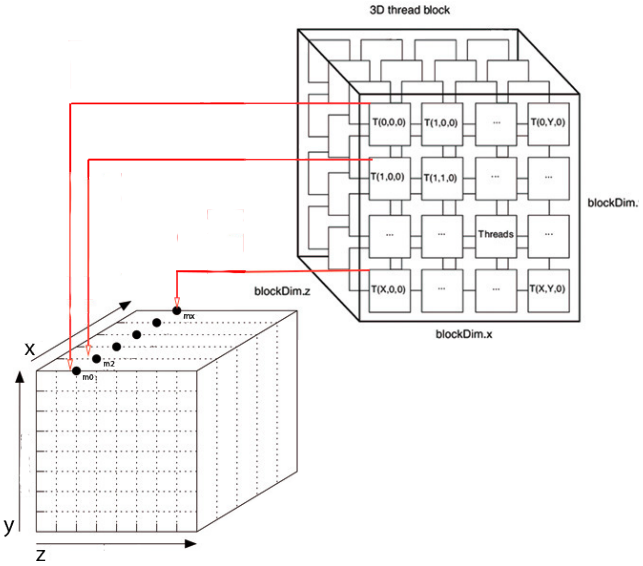

Fig. 2. GPU Memory access of the M(x,y,z): The thread (x,y,z) accesses the rank (x,y,z) of the M such that if the rank in the global memory of the element (x,y,z) is m, the rank of the element $(x+1,y,z)$ will be m+1.

The second step in implementing involves properly modeling the data structures to ensure coalesced access to the GPU's memory. This step is performed both in loops operating on three-dimensional (3D) portions of the domain and in two-dimensional (2D) portions. The way to map threads and blocks depends on the type of loop and its interaction with the data structure. In general, the structures are mapped as follows.

For 3D loops, threads in a block are mapped to a contiguous subset of elements in a specific dimension as can be seen in Figure 2, blocks are mapped to different portions of the 3D domain and for 2D loops, threads in a block are mapped to a contiguous rectangular region of the data in two dimensions, blocks are mapped to different sections of the 2D domain. The goal is to maximize coalesced access to the GPU's memory, allowing threads to simultaneously access data, taking advantage of the CUDA architecture.

We employed an optimization involving the use of constant memory and texture memory to variables and small arrays that remain constant during the execution. By storing these constant values in dedicated memory, we can benefit from their optimized access and reduce the memory traffic.

Shared memory is a valuable resource on GPUs. It is notably more limited than GPU global memory and is visible to threads within the same block. Due to this feature, we chose to rub this implementation with a configuration that prioritizes a wider cache over shared memory. Shared memory is firstly used for some loops that allow for blocking optimizations. Moreover, it is used to store some intermediate results and, when possible, loop invariants. This strategy maximizes the efficiency of shared memory utilization.

Our second implemented optimization is loop fusion. Since loops often iterate over the same data, they can be combined into a single loop without compromising the accuracy, depending on the operation. Along with loop fusion, we also strive to organize memory accesses to the same structure as closely as possible in the code whenever feasible.

Another optimization we used involved rewriting code snippets related to floating-point operations. It's important to exercise caution when applying this type of optimization to avoid introducing discrepancies between the CPU and GPU code. Taking care, we ensure that our CUDA implementation is both accurate and efficient.

Our last optimization creates a pipeline that splits RK3 processing into up to four stages. It works as follows: initially, a CPU thread is assigned for each stage and a master thread oversees operations. At the start, all threads are blocked. The master selects the thread responsible for processing the initial data and enters a busy-wait state. Once the kernel signals that more data can be processed, the master unblocks a thread. This process continues until no CPU threads are blocked. When a thread finish, it chooses a new data block and blocks itself, waiting for the master to unblock it.

A. *WSM6-RK3-Pipeline*

The joint execution of the RK3 pipeline and the multi-kernel implementation of WSM6 enables the creation of an integrated pipeline that performs the combined computation of both tasks. This implementation resembles the thread management described in the RK3 pipeline. Each of these stages is assigned to a thread on CPU. This mechanism has a similar principle to the RK3 pipeline. This case requires monitoring two distinct CUDA streams, one for RK3 and another for WSM6. Moreover, it is crucial to check for dependencies that arise between the stages of WSM6, thus ensuring proper synchronization between stages.

VIII. Experimental results

We performed a two-domains WRF simulation for March 4th of 2021, starting at 00UTC with duration of 12h. See Fig. 3 for details. The set of physical parameterization used in the simulation was: (a) WSM6 microphysics [15]; (b) longwave and (c) shortwave radiation schemes of Community Atmospheric Model 3 (CAM) [19]; (d) planetary boundary layer scheme of Yonsei University [20]; and, (e) Kain-Fritsch for cumulus parametrization [21].

A. *Experiments*

In our tests we first measured the time of the RK3 and WSM6 separately. After that, we measured the overall system performance considering both the stages.

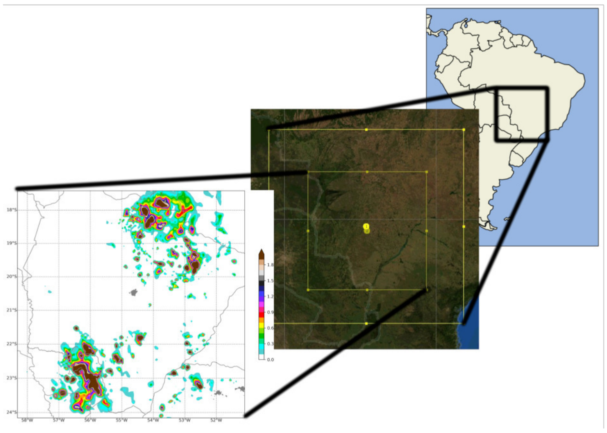

Fig. 3. Domains of the WRF simulation with 12 km of horizontal resolution: X-axis and Y-axis represent latitude and longitude, respectively. The 4 km horizontal resolution domain is represented by the highlighted square in the center of the 12-km resolution domain. The model is set to 34 vertical levels. Colors represent the vertical levels sum for q_c, q_i, q_r, q_s and q_g.

TABLE I
Time and acceleration of the RK3 and WSM6

	RK3		WSM6		WRF
Hardware	time(s)	speedup	time(s)	speedup	Total
12-thread-CPU	1335	-	2956	-	6156
1xP100	125	10.2	520	5.6	2857
1xP100+1xk80	96	13.9	436	6.7	2532
1xP100+2xk80	77	17.3	280	10.5	2410
2xP100	71	18.8	225	13.1	2337
1xP100+4xk80	53	25.2	169	17.4	2009
2xP100+4xk80	34	39.3	112	26.3	1776

With the CUDA-RK3, we achieved a speedup of 10.6 using one GPU P100 and 39.2 using 2x P100 + 4x k80 when compared to 12 thread version (see Table I). we also see the run-time and speedup of the CUDA-WSM6. We achieved speedups ranging from 5.6 on one GPU P100 to 26.3 on the 2x P100 + 4xk80 set. We note we obtained increasing speedup consistently with the growth of computational power.

TABLE II
Time (in seconds) of the RK3+WSM6 with pipeline stages

stages RK3+WSM6	1	2	4	8	16
12-Thread-CPU	6156	6156	6156	6156	6156
1x P100	3023	2802	2525	2420	2318
1x P100 + 1xk80	2736	2445	2212	2116	2048
1x P100 + 2xk80	2614	2343	2114	2022	1979
2x P100	2535	2214	1998	1911	1828
1x P100 + 4xk80	2213	1892	1707	1633	1502
2x P100 + 4xk80	1980	1698	1523	1463	1448

Table II show the overall performance when we increase the computational power(in each column). Besides, we notice the time gain when varying the number of pipeline stages.

Besides we apply the technique of overlapping transfer and processing through the use of asynchronous transfers. This enabled performance gains as can be seen in the Table III.

TABLE III
TIME (IN SECONDS) OF THE WSM6+RK3 WITH OVERLAPPING

stages RK3+WSM6	1	2	4	8	16
Ryzen 1600 12 Ths	6156	6156	6156	6156	6156
1x P100	2857	2613	2315	2216	2079
1x P100 + 1xk80	2532	2242	2009	1913	1844
1x P100 + 2xk80	2410	2140	1909	1818	1774
2x P100	2337	2014	1869	1728	1612
1x P100 + 4xk80	2009	1690	1502	1430	1300
2x P100 + 4xk80	1776	1493	1319	1260	1246

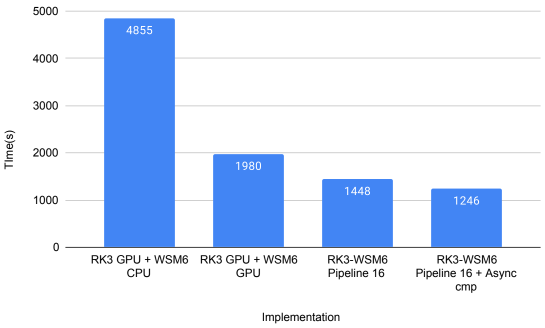

Fig. 4. Runtime of the implementation on platform 2xP100 + 4xK80.

Fig. 4 show the result using our load balance heuristic. We see that with each new device added, we have a performance gain nearly proportional to the increase in computational power, so that our implementation proves to be scalable.

B. Accuracy Analysis

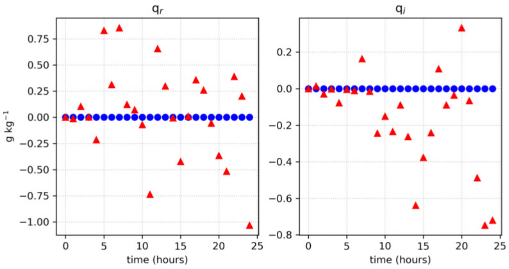

Fig. 5. The bias of the vertical profile in relation to the CPU simulation for mixing ratio of rain droplets (q_r) and ice particles (q_i) from 00UTC on March 4th to 00UTC on March 6th, 2021. The x-axis is in g kg^{-1} and the y-axis is in σ vertical coordinate. The blue and red markers are related GPU arithmetic optimizations off and GPU arithmetic optimization on, respectively.

To measure the accuracy of our GPU implementation, we used the results of the CPU implementation as a reference and analyzed the deviations of the GPU solution. We examined the results of the solution with the configuration 2xP100+4xK80.

The Fig. 5 show the time biases. We illustrate the output hydrometeors ice particles and rain droplets to compare the optimization levels. We can note a deviation between the GPU and the CPU implementation. We analyzed a version of the GPU implementation with enabled optimizations and another without optimizations. Note that when these optimizations are disabled, the deviation from the CPU implementation is negligible. When they are enabled, some points show a reasonable deviation compared to the CPU.

***Abstract*—Internet of things (IoT) has opened new horizons in connecting all sorts of devices to the internet. However, continuous demand for connectivity increases the cybersecurity risks, rendering IoT devices more prone to cyberattacks. At the same time, rapid advances in Deep Learning (DL)-based algorithms provide state-of-the-art results in many classification tasks, including classification of network traffic or system logs. That said, deep learning algorithms are considered computationally expensive as they require substantial processing and storage capacity. Sadly, IoT devices have limited resources, making renowned DL models hard to implement in this environment. In this paper we present a Residual Neural Network inspired DL-based Intrusion Detection System (IDS) that incorporates weight pruning to make the model more compact in size and resource consumption. Additionally, the proposed system leverages feature selection algorithms to reduce the feature-space size. The model was trained on the NSL-KDD dataset benchmark. Experimental results show that the proposed system is effective, being able to classify network traffic with an F_1 score of up to 98.9% before the pruning and an F_1 score of up to 97.5% after pruning 90% of network weights.**

I. Introduction

INTERNET of Things (IoT) is booming in markets, driving efforts for increasing device inter-connectivity. However, this strive for increased connectivity poses requirements related to provision of security protocols and measures that would secure communication between devices and build trust in users that their data is communicated privately [1]. In order to meet these requirements current security solutions typically endorse defense in depth approach [2] in which the security layers span across network perimeter, intranet and endpoint systems. Such security mechanisms involve many attack detection and prevention technologies. One of the most important class of these technologies, namely Intrusion Detection Systems (IDS) [3], come in various flavors. Host-IDS examines the actions of the users and compares them to decide which actions can be considered as malevolent and which are likely benign. On the other hand, Network-based IDS, examines the traffic traversing through the network and compares it with already known signatures to distinguish between normal and malevolent flow. Though popular, these systems still face various challenges, such as detection accuracy, high false-alarm rates or the inability to detect zero-day attacks [4].

Machine Learning (ML) and Deep Learning (DL)-based technologies recently enjoy numerous practical deployments, e.g., in speech recognition, object detection, natural language processing, etc. It is also increasingly used in the cybersecurity domain [5][6]. Consequently, ML- and DL-based IDS gained popularity in the recent years. In particular, they have proven to be more robust than their predecessors, having lower false-positive rates and higher accuracy [7]. However, this line of research often adopted renowned image classification algorithms [8] to the traffic classification tasks [9][10][11]. Consequently, the proposed systems tend to be computationally cumbersome. Accordingly, for IoT devices, which have limited storage and processing resources, research increasingly focuses on replacing such burdensome algorithms with much lighter solutions.

In this paper, we introduce a new DL-based IDS designed around lightweight residual network [12] architectures. Our solution is coupled with the Extra Tree classification algorithm, which allows us to extract the most important features from the dataset. This makes the proposed system compact, while retaining high accuracy and detection rates. The small computational footprint of the proposed system is suitable for inference on a CPU, instead of resource-hungry GPU accelerators. Thus, our results show that attaining high accuracy while substantially reducing the size of the model is achievable in IDS tasks.

The following sections begin with review of the state-of-the-art results in ML-based intrusion detection systems. Next, we present the proposed attack detection architecture. Subsequently we describe the experimental setup and report obtained results. Finally, we give conclusions from experiments and outline future work.

II. Related Work

Deep Learning-based intrusion detection systems enjoyed rapid advances in recent years. Some researchers utilized DL capabilities for categorical data classification, where the task is to recognize specific attack instances. Haddad Pajouh et al. [13] proposed a Long-Short Term Memory (LSTM)-based IDS. First, they extracted OpCodes from the traffic and assigned them to input vectors. Next, they leveraged Principal Component Analysis (PCA) to extract the most significant features from the vectors. The model was trained using Adam optimizer [14]. Dropout layers were used to avoid overfitting. The performance of the model was evaluated with 10-fold Cross Validation (CV). Swarna Priya et al. [15] proposed a DNN-based IDS that, similarly to Haddad Pajouh et al. approach, also used PCA as a feature extractor. The system also utilized feature scaling to normalize the input data before feeding it to the classifier. Furthermore, they used Grey Wolf optimization algorithm (GMO) [16] to construct a feature hierarchy. This hierarchy provided features' fitness values. McDermott et al. [17] proposed a Bidirectional LSTM-based IDS. Word embeddings were used to embed the captured packets' content in a vector space suitable for the model. Subsequently, they used word embeddings to establish a dictionary of tokenized words. Sigmoid function, Mean Absolute Error (MSE) and Adam were selected as the activation function, loss function and optimizer, respectively. Zhang et. al [18] proposed a Deep-Belief Network (DBN)-based IDS that employed an improved genetic algorithm. The algorithm incorporated improved crossover and elite retention strategies to prevent the loss of the best individuals. The proposed system was trained and evaluated on the NSL-KDD dataset. Another DBN-based IDS was proposed by Tama et al. [19]. The system incorporated a grid search strategy to select the most significant input features. Evaluation was carried out on three datasets, namely, UNSW-NB15 [20], CIDDS-001 [21], and GPRS [22] using 10-folds cross validation, Repeated Cross-Validation (RepCV) [23] and data sub-sampling. Their model was able to maintain the same detection rate after sub-sampling. Overfitting was prevented with L1 and L2 regulations and an adaptive learning rate. Muna et al. [24] proposed a Deep Autoencoder to reduce the features dimensionality. Their system also encompassed a deep feed-forward Neural Network to detect and classify traffic. It was trained and evaluated on the NSL-KDD dataset. Latif et al. [25] emphasized the importance of providing lightweight DL-based IDS solutions. To this end, they proposed an intrusion detection algorithm employing random neural networks, in which the Poisson distribution was used to estimate the probability of the signals that made the neurons either active or inhibited. The proposed system was evaluated on the DS2OS dataset [26]. Shone et al. [27] proposed a Non-Symmetric Deep Auto-Encoder for unsupervised feature learning. The system employed Random Forest [28] to classify the traffic between benign and malevolent. Both NSL-KDD and KDD Cup '99 datasets were used in training and evaluation. Min et al. [29] proposed a system which uses an ensemble of byte-level word embeddings and text convolutional neural networks. Skip-Gram algorithms was used to create the byte-level word embeddings. Text convolutional neural networks were constructed from one-dimensional convolutions that extracted word-based features. Similarly to Shone et al., Random Forest was chosen as a classifier. The system was trained and evaluated on the ISCX2012 dataset [30]. Zhou et al. [31] proposed Deep Feature Embedding Learning method that reduces input features' dimensionality, thereby decreasing the time needed to train the model. They trained and evaluated their model on the NSL-KDD and UNSW-NB15 datasets. Leaky ReLU was chosen as the activation function for the hidden layers, while Sigmoid function was used as an activation function in the classification layer. Additionally, Dropout was used to avoid overfitting.

Other researchers choose to use deep learning for binary classification, where the goal is to distinguish attack signatures from normal traffic, irrespective of specific attack classes. Diro et al. [32] proposed a DL-based IDS trained in a distributed optimization scheme which involved fog nodes, i.e. mini-clouds implemented as edge devices in the cloud [33]. To avoid overfitting, the parameters were collected in the fog coordinator, which was responsible for their updating and distribution for subsequent epochs. Diro et al. [32] evaluated their system on the NSL-KDD dataset [34]. Similarly, Abeshu et al. [35] proposed a novel DL-based IDS that takes its parameters from the master fog node, while performing system fine-tuning on the worker nodes. Again, NSL-KDD was chosen as training and evaluation dataset. Almiani et al. [36] proposed an RNN-based IDS. Their system employed data oversampling to balance the minority classes, a modified back-propagation algorithm, and the min-max normalization. Kasongo et al. [37] proposed a feed-forward Neural Network-based IDS that was coupled with a wrapper-based feature extraction unit. The wrapper used the Extra Tree algorithm to classify and specify which features are most significant. The proposed system was trained and evaluated on the NSL-KDD dataset. Devan et al. [38] proposed an XGboost DL-based IDS composed of three main steps, namely, input feature normalization, feature selection using a classifier based on a collection of decision trees that derive the significant features, and final classification. Their system also leveraged neural networks with ReLU and Softmax activation functions for the hidden and classification layers, respectively. Nagisetty et al. [39] proposed a DL-based IDS that incorporated three

DL architectures: Multi Layer Perceptrons (MLP), CNNs, and an Autoencoders. The proposed system was trained and evaluated on two datasets, namely, UNSW-NB15 and NSL-KDD99. The system employed Root Mean Square Root Error (RMSE) as the cost function. DNN was used mainly to sort the features and create a feature hierarchy. Zhihan et al. [40] proposed a hierarchical Supporting Vector Machine-based IDS. In addition, a stacked autoencoder was used to denoise the data. The system was evaluated on the NSL-KDD dataset.

In this paper we will benchmark our results with the papers that focus on the binary classification task. To this end, we will evaluate our algorithm with respect to the metrics that they have discussed in their papers as our goal is to see if our pruned networks could compete with the state-of-the-art.

III. Proposed Architecture

In order to protect devices from attacks, while preserving processing and storage resources, we propose an Intrusion Detection System based on pruned residual neural networks [12]. The proposed system is trained in several steps. First, input data is pre-processed, including encoding of symbolic features. The data is then fed to an Extra Tree Classifier [41], which selects the most important features from the feature set. In the next step, the data is normalized and used to train the proposed classification model. Finally, the model is pruned in fine-tuning steps, which minimizes its size and the inference cost.

We evaluate the final model with respect to precision, recall and F_1 score both before and after network pruning. Evaluation is carried on the NSL-KDD dataset.

A. NSL-KDD Dataset

The NSL-KDD dataset is the successor of the KDD'99 [42] dataset, which was introduced by DARPA in 1998. The dataset was firstly proposed by Tavallaee et al. [43] and is composed of 4 different attack classes, namely, Denial of Service (DoS), Probe, User-to-root (U2R), and Remote-to-Local (R2L). In DoS attacks the computing or network resources are exhausted, making the attacked system unable to serve the user's requests. Signatures of a DoS attack in the NSL-KDD dataset would be, e.g., the `Src_byte` and the `Wrong_fragment` features. Probe attacks are mostly used for surveillance, in order to to gain information on the potential victim system. The relevant signatures for probe attacks in the NSL-KDD dataset are the `Src_bytes` and the `Duration` features. User-to-root attacks attempt to grant superuser privileges to the attacker. One way of doing this is accessing the user's system via a normal account and then attempting to escalade privileges by exploiting a vulnerability. Relevant signatures for U2R attacks with respect to the NSL-KDD dataset are, e.g., `Num_file_creations` and `Num_shells` features. In Remote-to-Local attacks the attacker attempts to gain access of the user's system via a remote machine. Relevant signatures for R2L attacks in the NSL-KDD dataset are, e.g., `Duration`, `Service` and `Num_failed_logins` features.

TABLE I: NSL-KDD traffic statistics.

	NSL-KDD		
	Attack Type	***KDDtrain+***	***KDDTest***
1	DOS	45926	7458
2	Probe	11655	2421
3	R2L	995	2754
4	U2R	52	200
5	Normal	67345	9711
Total		125973	22544

The NSL-KDD dataset encompasses two subsets, namely, the KDDtrain+ and KDDtest. In standard classification setup, the proposed system should assign the signatures into four major categories, namely, `DOS`, `Probe`, `R2L`, `U2R`, and `Normal` traffic. Table I reports datasets statistics for these categories. Note that `DOS`, `Probe`, `R2L`, `U2R` and normal traffic makes 36.45%, 9.25%, 0.78%, 0.04% and 45.52% of the dataset instances, respectively. In binary classification setup the proposed system should be able to classify the traffic into two classes, namely, attack and non-attack. Note that classes in this case are balanced, with attack and non-attack traffic making 46.5% and 53.5% of the dataset, respectively.

The NSL-KDD consists of a total of 41 features that comes in four main categories: (a) intrinsic features that can be extracted from the packet's headers, (b) content features which reflect the data content of the packets, (c) time-based features which reflect the connection rates with the hosts, and finally (d) the host-based features. It is also worth mentioning that the KDDtrain+ subset has 3 categorical features, namely:

- `Protocol Type` which consists of 3 categories,
- `Services` which consists of 70 categories,
- `Flag` which consists of 11 main categories.

These features require preprocessing into one-hot encoding before they can be used in the subsequent steps.

B. Data Preprocessing

In this work we focus on a binary classification task, i.e., distinguishing normal network traffic from attacks. We therefore convert the provided labels into attack and non-attack classes before selecting the important features. Next, we remove data duplicates and rows that contain null values. The KDDtrain+ subset consists of both numerical and categorical data. We normalize the numerical features via z-scores:

$$Z = \frac{x - \mu}{\sigma} \tag{1}$$

where x represent the current instance of the feature while μ and σ represent the mean and the standard deviation of the feature respectively. The categorical features, on the other hand, are encoded in one-hot vectors.

In the next step we use Extra Tree classifier with 100 estimators (trees) to identify the most significant features. Specifically, we use the Gini coefficients [44] returned by the Extra Tree classifiers to select the most prominent features. Importantly, for one-hot-encoded features, the feature is retained if the Extra Tree classifier selects any of its dimensions according to the Gini coefficient. After a series of features selection iterations, the features listed in Table II were used to train the neural network for the binary classification task.

TABLE II: Features selected by the Extra Tree classifier.

Index	NSL-KDD Features	Index	NSL-KDD Features
1	count	12	protocol_type
2	same_srv_rate	13	logged_in
3	dst_host_count	14	rerror_rate
4	dst_host_same_srv_rate	15	same_srv_rate
5	dst_host_serror_rate	16	serror_rate
6	dst_host_same_src_port_rate	17	service
7	dst_host_same_srv_rate	18	flag
8	dst_host_rerror_rate	19	src_bytes
9	dst_host_srv_count	20	srv_rerror_rate
10	dst_host_srv_diff_host_rate	21	srv_serror_rate
11	dst_host_srv_serror_rate	22	dst_host_srv_rerror_rate

C. Pruning

We use pruning to reduce the overall size of the trained neural model. There are several pruning strategies that can be used to this effect:

- The classical approach in which the model is firstly trained with all parameters and then subset of the trained parameters is removed during additional fine-tuning epochs.
- Pruning at initialization, where parameters are pruned before the model is trained [45].
- Pruning during the main training run.

Furthermore, pruning can carried out globally, i.e., across the whole model, or locally, i.e., in each network layer [46].

In this work we use global, magnitude-based pruning which employs fine-tuning epochs after the main training run, during which weights with low magnitudes are gradually set to zero.

IV. Experimental Setup

Table III summarizes the hyper-parameters used in the experiments. These training hyperparameters were selected with few trial training runs. We evaluate variants of this architecture with varying widths. In particular, we vary the number of neurons inside the residual blocks while keeping a fixed network width of the skip-connection nodes. Furthermore, batch normalization layers [47] are used to improve the training. This architecture proved to work well, while saving on the number of model parameters. Each constructed model was run five times with different random seeds.

We also carried out evaluation of pruned variants of our models. To this end, a 20 epoch fine-tuning run with magnitude-based pruning was done. For each network instance the sparsity schedule started with 85% initial sparsity and increased with each iteration, until it reached a final sparsity of 90% by the end of the last fine-tuning epoch. For the performance numbers we report mean and variance of training time, test accuracy, precision, recall and F_1 score:

$$Precision = \frac{TP}{TP + FP} \tag{2}$$

TABLE III: List of training hyper-parameters.

Models width	1024, 256, 32, 8
Activation function	ReLU [48]
Optimizer	Stochastic Gradient Descend (SGD) with Nesterov accelerated gradient = 0.9 [49]
Loss function	Binary Cross Entropy [50]
Learning rate	0.1
Decay for unpruned models	1e-6
Decay for pruned models	Polynomial Decay
Batch size	120
Number of epochs (for both pruned and unpruned networks)	20

$$Recall = \frac{TP}{TP + FN} \tag{3}$$

$$Accuracy = \frac{TP + TN}{TP + FN + TN + FP} \tag{4}$$

$$F1 - Score = 2 \times \frac{Precision \times Recall}{Precision + Recall} \tag{5}$$

where TP is the true-positive count, FP is the false-positive count, TN is the true-negative count and FN is the false-negative count. Due to the substantial pruning rate, the sparse models of the same width tended to have the same performance across random seeds. Consequently, the variance estimates are not meaningful in this case and we don't report them.

V. Results

The proposed models were trained using the Google Collab environment. Table IV reports the results for unpruned networks. The model with the highest width achieved 98.96% accuracy, 99.39% precision, 98.38% recall and 98.91% F_1 score. Note that this is the most computationally expensive of our models. That said, the model with quarter the width preformed equally well up to the variance across random seeds. The remaining two models performed slightly worse, with F_1 score around 0.6% below that of the larger models. These models were, however, much more computationally efficient, with the training time stabilizing below width equal to 32 units. Our results also shows that the variance across the training runs is low for all models, which shows that the performance is not highly affected by the initial seeds.

Results for the pruned networks are reported in Table V. The F_1 score of the model with 1024-unit width dropped by about 1.5% after pruning, with performance decrease manifesting mostly in model's recall. For the pruned model with quarter the width, the performance metrics were about 0.5% below those of the larger pruned model and up to 2% below the unpruned network. The two smallest models scored the lowest after pruning, with an F_1 score approximately 2% below larger pruned networks. Overall, our results shows that even with aggressive pruning and small initiated models residual fully-connected networks perform well in this task, with precision recall and F_1 score above 95%.

TABLE IV: Performance metrics for unpruned models.

Model	Training Time(sec)	Accuracy	Precision	Recall	F1 Score
1024	360.6±35.7	98.96±0.03%	99.39±0.10%	98.38±0.11%	98.91±0.07%
256	155.4±6.5	98.91±0.05%	99.44±0.02%	98.22±0.08%	98.82±0.05%
32	72.9±7.1	98.38±0.07%	81.07±0.16%	97.45±0.23%	98.25±0.08%
8	73.7±8.5	98.38±0.07%	99.07±0.16%	97.45±0.23%	98.25±0.08%

TABLE V: Performance metrics for pruned models.

Model	Training Time(sec)	Accuracy	Precision	Recall	F1 Score
1024	471.3	97.67%	99.42%	95.59%	97.46%
256	217.9	97.31%	99.22%	95.01%	97.07%
32	118.6	95.82%	95.91%	95.13%	95.52%
8	119.3	95.82%	95.91%	95.13%	95.52%

TABLE VI: Performance metrics reported in related work.

Reference	Accuracy	Precision	Recall	F1 Score
[32]	99.20%	99.02%	99.27%	99.14%
[35]	99.20%	-	99.27%	-
[36]	92.42%	90.20%	-	92.29%
[37]	99.37%	-	92%	-
[38]	97.60%	97%	97%	97%
[39]	98.96%	-	-	92.28%
[40]	97.83%	-	-	-
Our unpruned 1024 model	98.96±0.03%	99.39±0.10%	98.38±0.11%	98.91±0.07%
Our pruned 32 model	95.82%	95.91%	95.13%	95.52%

To benchmark our results against the state of the art, we selected peer-reviewed papers which addressed the binary classification task with respect to the same NSL-KDD dataset. Some of these papers reported all the metrics mentioned earlier, while others took into consideration only a subset of them. Comparison between the benchmarks and our results is summarized in in table VI.

Comparing with the state-of-the-art for this benchmark dataset in binary classification setup, we observe that all of the proposed unpruned networks give competitive or better precision in detecting attacks (Table VI). More precisely, the models with 1024 and 256 widths achieved better accuracy compared to [36] [38] [39] [40], recall compared to [37] [38] and F_1 score compared to [36] [38] [39]. The pruned models achieved slightly lower results, but still maintained strong performance while requiring only 10% of the initial parameters.

VI. Conclusions and Future Work

Proliferation of IoT devices is making a huge impact on the communication sector. The increased interconnectivity comes not only with new business opportunities, but also increases security risks related to prevalence of network vulnerabilities and persistent cyberattack threats. Conventional IDS and firewalls deployed to counter cyber-threats are often inadequate for IoT environments, e.g., due to high false-positive rates or large resource requirements. In this paper we proposed an ML-based IDS that employs residual MLP networks and demonstrated that it provides strong results with respect to the precision and recall of attack detection, even when implemented with relatively small networks. We also demonstrated that it retains most of its accuracy after pruning of as much as 90% of its parameters.

In our future work we intend to extend this line of research with novel and promising neural architectures, e.g., transformer models. These models excel at text embedding and classification. We therefore intend to explore their ability to classify network and system logs. We also intend to explore more pruning strategies, e.g., unit-based pruning which removes entire neurons, rather than individual weights. Such pruning strategies may result in lower computational footprint, while still maintaining strong attack detection performance.

***Abstract*—In this paper, we introduce a domain-adapted machine translation (MT) model for intelligent virtual assistants (IVA) designed to translate natural language understanding (NLU) training data sets. This work uses a constrained beam search to generate multiple valid translations for each input sentence. The search for the best translations in the presented translation algorithm is guided by a verb-frame ontology we derived from VerbNet. To assess the quality of the presented MT models, we train NLU models on these multiverb-translated resources and compare their performance to models trained on resources translated with a traditional single-best approach. Our experiments show that multi-verb translation improves intent classification accuracy by 3.8% relative compared to single-best translation. We release five MT models that translate from English to Spanish, Polish, Swedish, Portuguese, and French, as well as an IVA verb ontology that can be used to evaluate the quality of IVA-adapted MT.**

I. Introduction

MULTILINGUAL natural language understanding (NLU) models are a major focus in natural language processing (NLP) as they enable virtual assistants to manage multiple languages. However, the scarcity of multilingual training data often leads to under-representation of some languages. While the manual translation of training sentences can address this problem, it is a time-consuming and costly process prone to errors and ambiguities that can compromise model quality. Moreover, manual translation struggles to adapt to language changes or the introduction of new languages to the virtual assistant.

In this context, using machine translation (MT) systems as a source of translations seems to be an attractive alternative for acquiring multilingual learning data. Creating multilingual NLU models by translating a learning sentence into multiple languages using MT models seems possible and promising.

MT systems, used to generate sentences for training NLU models, should produce multiple correct translation variants. This is crucial as languages often have numerous grammatical forms and ways of conveying information. For instance, English has various verb forms, such as regular, irregular, and modal verbs, with potentially different translations in other languages. If an MT system generates only one translation variant, the NLU model might not learn to recognize others, compromising the model's quality. Hence, MT systems should create multiple accurate translation variants to cover all possible patterns, enhancing the performance of NLU models.

Fig. 1. Example of multiple variants translations based on verb ontology and constrained beam search.

Fig. 1 presents the system schema proposed in this article. Source utterance is translated to the target language with the help of verb ontology. Translations generated by the system are rich in terms of verb coverage and improve NLU model generalization capabilities.

In this work, to the best of our knowledge, we present the first analysis of language (verb analysis) used in available IVA corpora. The results of this analysis are used to construct verb ontology, based on VerbNet and WordNet, that is later used to generate multiple correct hypotheses in the MT system designed to translate training resources of multilingual NLU.

II. Related Work

At first glance, our work conceptually resembles early machine learning efforts to introduce linguistic knowledge into neural network models. Our goal is different, however, as we aim to use methods that utilize semantic information and linguistic knowledge in the context of machine translation to explain better and analyze its results. Our research focuses on explaining how the model works and how to improve its output.

This work relates to the methods of generating multiple correct translations. Fomicheva et al. [1] used MT model uncertainty to generate multiple diverse translations. In our

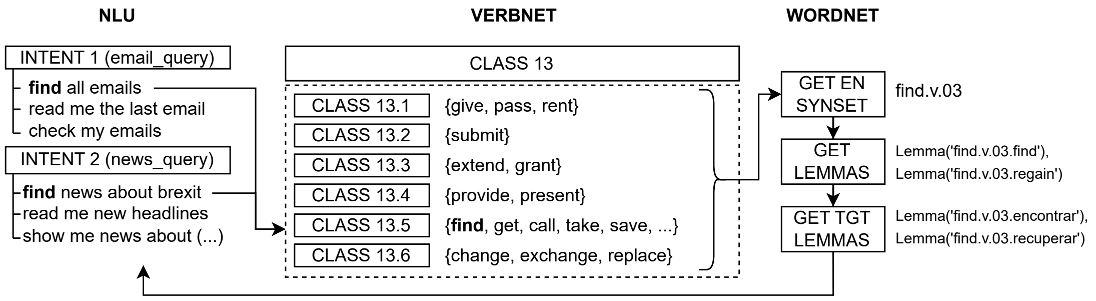

Fig. 2. Overview of the presented method. NLU verbs are matched to VerbNet, which consists of a WordNet synset from which a lemma in the target language can be extracted.

work, we used constrained beam search proposed by Anderson et al. [2] to generate multiple correct variants of translations.

Another area related to this work is using machine translation to translate training resources of NLU. Gaspers et al. [3] use MT to translate the training set of IVA and reported improvement in performance compared to grammar-based resources and in-house data collection methods. Abujabal et al. [4] used the MT model in conjunction with an NLU model trained for the source language to annotate unlabeled utterances reporting that 56% of the resulting automatically labeled utterances had a perfect match with ground-truth labels, and 90% reduction in manually labeled data.

We used VerbNet [5] and WordNet [6] to construct a dictionary to guide constrained beam search. WordNet is a linguistic resource that can be used to identify shallow semantic features that can be attached to lexical units. WordNet covers the vast majority of nouns, verbs, adjectives, and adverbs. It was initially developed for English, but more languages were recently added to the project Open Multilingual Wordnet. The words in WordNet are organized in synonym sets called synsets that share the same meaning. WerbNet is a verb lexicon with syntactic and semantic information based on Levin's verb classes. VerbNet is compatible with WordNet as verbs have links defined to WordNet synsets. VerbNet has been widely used in the context of NLU [7], [8].

Finally, this work relates to work that uses linguistic resources to improve the quality of NLU systems. Moneglia [9] created the ontology of action verbs to improve the performance of NLU and MT systems.

III. Method

In this work, we aim to build a multi-variant MT model that is guided by verb ontology, adapted to the IVA domain. Our secondary goal is that our ontology would be easy to edit, inspect and analyze by NLU developers. To do that, we extracted verbs from several VA corpora, matched them to their semantically equivalent class in VerbNet, and finally, using the link to WordNet, we extracted all their translations in the target language. In Fig. 2, we present steps of processing used to find verb equivalent in the target language to increase the variance of training resources. The proposed method consists of the following stages:

1) Creation of multilingual dictionary with verb translation for the IVA domain,
2) Creation of MT model (based on M2M100 architecture) from parallel corpora and creation of tools that guide decoding (constrained beam search) to generate multiple hypotheses,
3) Translation of NLU training resources, training of NLU model, and evaluation and analysis of the impact of MT on NLU quality.

A. Verb analysis of the NLU corpora

We start our investigation by analyzing verbs in NLU corpora. Verbs are carriers of key information about the event or action being described [10]. IVA commands semantics is composed of a verb and its parameters. In this work, we analyzed eight popular NLU corpora (listed in Table I) and extracted 374 English verbs. We then created a ranking list where the frequency of occurrences of verbs in all corpora is counted. The first verb on the list represents the most frequently used verb in all analyzed corpora.

In Table I, we present the top five positions on verb occurrence ranking. The highest-ranked verbs are: *set*, *show*, *remind*, *play* and *give*. Most analyzed NLU corpora consisted of calendar, alarm, and music domains which explain why given verbs are most popular.

While creating the ranking list, we noticed that each NLU corpus presents the same trend where the most frequent verbs can be found in around 20% of utterances. Fig. 3 illustrates that trend in IVA corpora follows the Zipf distribution. A similar trend can be found in other linguistic resources, for example, VerbNet [11].

B. Mapping IVA verbs to Levin classes and VerbNet

Most of the verbs we extracted from NLU corpora and analyzed are used in more than one domain. For example, a verb *set* can be used to set the alarm and the screen's brightness. For that reason, we decided to classify verbs of similar meaning. We used Levin verb classification [12] to investigate if IVA verbs are to be found there. In her work,

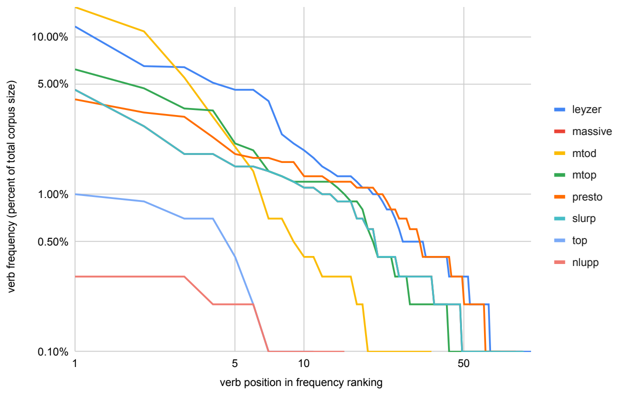

Fig. 3. Verb frequency and verb position on the ranking list for selected VA data sets presented in logarithmic scale.

Levin assigned 3,024 verbs to 48 broad and 192 fine-grained classes used in this article to find IVA verb frames.

Although verb classification can be automated [13], we found that research on language used in IVA is almost non-existent. Therefore, the automatic or semi-automatic methods will not perform well as they cannot be verified with certainty. For that reason, we decided to assign verbs to Levin classes manually. We first read each class description, including example verb frames, to decide if the same frame is used in the IVA context.

Out of 270 verbs, 14.88% could not be found in VerbNet or did not consist of WordNet class, making it impossible to use in our algorithm. 7.04% verbs matched more than one VerbNet class. 7.27% verbs belong to a VerbNet class where no other verb from NLU corpora belongs.

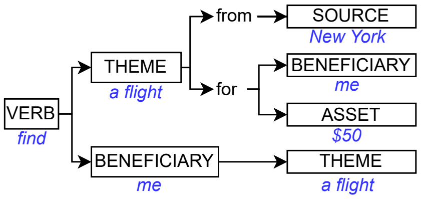

Fig. 4. Example of frames available in VerbNet for class 13 (Verbs of Change of Possession).

VerbNet defines semantic frames in which a given verb can be found. In the example presented in Fig. 4, we show four semantic frames belonging to class 13 where verb *find* appears. Verbs that belong to that class reflect the change of possession. From the frames presented in the example, we can construct several utterances belonging to the different IVA domains.

Below we present verbs found in NLU corpora that have been successfully matched to VerbNet classes. We can find other instances (verbs) of the same frame using those classes. We present the ten most frequent classes found in NLU corpora:

1) Class 13 (Verbs of Change of Possesion) where 10.73% of verbs belong with following sub-classes:
   a) 13.1 with *give*, *pass*, *rent*,
   b) 13.2 with *submit*,
   c) 13.3 with verbs such as *extend* and *grant* that relate to the change of possession that will take place in the future,
   d) 13.4 with *provide*, *present* that can be described as “X gives something to Y that Y needs or deserves”,
   e) 13.5 (Get and Obtain Verbs) with *find*, *get*, *call*, *take*, *save*, *order*, *keep*, *book*, *buy*, *select* and other,
   f) 13.6 with *change*, *exchange*, *replace* that relate to exchanging one thing for another,
2) Class 37 (Verbs of Communication) where 9.34% of verbs belong with the following sub-classes:
   a) 37.1 (Verbs of Transfer of Message) with *tell*, *read*, *write*, *ask*, *explain*, *dictate*, *summarize* that are verbs of type of communicated message,
   b) 37.2 with *remind*, *update*, *notify*, *inform*
   c) 37.3 with *call*, which is the verb of a manner of speaking and are distinguished from each other by how the sound is expressed. This is not a perfect match for IVA, but members are also not very far from IVA context,
   d) 37.4 with *email*, *phone*, *broadcast*, *ring* that relate to communication via these instruments of communication and are zero-related to the same noun,
   e) 37.5 with *speak*, *talk* that do not take sentential complement,
   f) 37.6 with *chat*
   g) 37.7 with *repeat*, *say*, *report*, *note*, *suggest*
   h) 37.8 with *complain* that specify the speaker’s attitude or feeling towards what is said,
   i) 37.9 with *alert*, *brief*
3) Class 26 (Verbs of Creation and Transformation) where 6.92% of the verbs belong. Members of that class are transitive verbs where one argument (agent) creates or transforms an entity,
4) Class 55 (Aspectual Verbs) where 5.19% of verbs belong. These verbs describe the initiation, termination, or continuation of an activity,
5) Class 45 (Verbs of Change of State) where 4.50% of the verbs belong. All of the verbs in this class relate to the change of state, with several sub-classes that define this state in more detail,
6) Class 9 (Verbs of Putting) where 4.15% of the verbs belong. These verbs refer to putting an entity at some location,
7) Class 29 (Verbs of Predicative Complements) where 4.15% of verbs belong,
8) Class 11 (Verbs of Sending and Carrying) where 3.81% of verbs belong,
9) Class 10 (Verbs of Removing) where 3.11% of verbs belong,
10) Class 51 (Verbs of Assuming Position) where 2.77% of verbs belong,
11) Remaining 30.45% consists of 38 verb classes.

pt-PT	188	3.76
sv-SE	116	2.46

C. Mapping VerbNet to WordNet

VerbNet maps each verb to the corresponding synset in WordNet. We used NLTK implementation of VerbNet and WordNet to find target language synsets.

As a result of mapping VerbNet to WordNet, we created verb ontology[1] that is represented by a dictionary where the key is an English verb, and values are verb translations in the target language as presented in the below examples. In Table II, we present how many English verbs and, on average, how many target verbs were extracted for them. In the case of Polish ontology, only 89 English verbs were matched as Polish WordNet has a small subset of the entire WordNet mapped, and we had to perform mapping manually.

1) en-es: {*find*: [*encontrar*, *recuperar*, *conseguir*]}
2) en-es: {*find*: [*encontrar*, *recuperar*, *conseguir*]}
3) en-fr: {*find*: [*retrouver*, *trouver*, *analyser*]}
4) en-pl: {*find*: [*znajdź*, *poszukaj*, *odnajdź*]}
5) en-pt: {*find*: [*achar*, *encontrar*, *atingir*]}
6) en-sv: {*find*: [*upptäcka*, *hitta*, *finna*]

D. Constrained variant generation using verb ontology

Verb ontology guides MT to generate translation variants that consist of the target verb. We use constrained decoding implemented in the Transformers library to generate a translation consisting of a target verb (force word). We choose a beam size equal to 5, translations cannot consist of n-grams bigger than two more than once, and a single translation is generated for each constrained verb. All translations with more than two tokens bigger or smaller than the first-best are removed. If the input sentences consist of slot annotation, then we expect constrained examples also to have slot annotations.

Our translator (multiverb_iva_mt[2]) generate translations using following algorithm:

1) First translation is always a result of unconstrained translation (single-best),
2) For each target verb from verb ontology, we replace the verb from the single-best translation with the target verb,
3) Finally, we add variants generated by constrained beam search.

The final result is a list of translations that consist of at least one translation, but in the case when the input verb is found in verb ontology, typically, three variants are generated.

IV. EXPERIMENTS

To demonstrate the impact of the proposed method on translation quality, we designed experiments in which we compared the baseline model with two different translation methods: single-best and multi-verb. We use a model trained and evaluated on an untranslated subset of the Polish data set as a baseline. In the second step, we translated the English subset of the same data set to Polish. In a typical scenario, one Polish translation is generated for one input utterance (English). We call this single-best translation as the typical MT model returns the best translation candidate using the beam-search algorithm. In contrast, multi-verb translation generates multiple translation variants using constrained beam search guided by the proposed verb ontology.

A. Data

We used the second version (0.2.0) of the Leyzer[3] data set to conduct the experiments. Leyzer is a multilingual data set created to evaluate virtual assistants. It comprises 192 intents and 86 slots across three languages (English, Polish, and Spanish) and 21 IVA domains. The corpus primarily consists of imperative commands uttered to a device, with most languages and utterances using subject-initial word order (Subject-Verb-Object and Subject-Object-Verb). We selected Leyzer to conduct our experiments because each intent comprises several verb patterns and levels of naturalness. For example, *ChangeTemperature* intent, which represents the goal of changing the temperature of a home thermostat system, distinguishes three levels of naturalness, where the most natural way (level 0) of uttering this goal by the user would be to say *change temperature on my thermostat*, less natural (level 1) would be *set the temperature on my thermostat*, and finally least natural (level 2) yet still correct would be *modify the temperature on my thermostat*. These two pieces of information that are also available in the test set of the Leyzer corpus allow us to measure the impact of the multi-verb translation better.

The training subset of Polish corpora that we used to measure baseline results includes 15748 train utterances, 4695 development utterances, and 5839 test utterances. The English subset of corpora that we used to translate and report results

[1] https://github.com/cartesinus/multiverb_iva_mt/tree/main/data/verb_translations

[2] Code available at: https://github.com/cartesinus/multiverb_iva_mt

[3] Data set available at https://github.com/cartesinus/leyzer

of single-best and multi-verb includes 17289 training and validation utterances. All training utterances were translated with the third version of verb ontology (v.0.3.0) available in the proposed system. We extracted 3997 utterances from translated training set for validation, ensuring at least one sentence is available for every intent, level, and verb pattern.

B. Machine translation

We used the M2M100 model [22] as a base for our MT model. It provides an excellent base for future expansion, especially when considering low-resource languages, as it was trained to translate 100 languages. Moreover, this architecture is considered state-of-the-art, and most systems participating in WMT-22 implemented similar, Transformer architecture.

The foundation model was already pre-trained on the MT task; therefore, we performed light adaptation for ten epochs on the MASSIVE data set [15]. Adam [23] was used for optimization with an initial learning rate of $2e-5$. We used all data available in the training part of the corpus. Each epoch was evaluated on the validation subset. The batch size was 4, which is a relatively small value, but in our experiments on A100 GPU (40GB VRAM), it was impossible to set a larger batch size due to insufficient memory.

C. Natural language understanding

We used multilingual XLM-RoBERTa [24] models for intent classification (IC) and slot-filling (SF) and fine-tuned the models on the Leyzer data set. We chose this architecture for NLU as it can be easily compared to models presented in MASSIVE and achieves better results in a multilingual setting when compared to multilingual BERT (mBERT).

The foundation model was trained on 2.5TB of filtered CommonCrawl data containing 100 languages. During fine-tuning on the Leyzer data set, we used Adam [23] for optimization with an initial learning rate of $2e - 5$.

The quality of the IC model was evaluated using the accuracy metric that represents the number of utterances correctly classified to given intent. SF model was evaluated using a micro-averaged F1-score.

D. Impact of multi-verb translation on NLU

In Table III, we present the impact of multiple variant generation on IC and SF model results. Baseline models achieve results above 95% for both IC and SF, which means that test set annotations are consistent with a train set, and if good translated training data are present, also good results can be obtained.

The proposed improvement to the translation generation positively impacts IC model results. The accuracy of multi-verb translation is 3.8% relatively better than single-best translation. However, it is 7.95% relatively lower than the baseline model. As presented in Table IV, each English sentence generates an average of 1.74 Polish translations. In our opinion, this is the main reason why multi-verb translation generates a better training data set for the IC model. Leyzer test set evaluates multiple variants in which given intent can be uttered, including different levels of naturalness and verb patterns; therefore, more variant training set improves results. Further, IC results could be improved if more variants were created in verb ontology. Polish ontology (Table II) consists of 89 verbs, which is the smallest of all presented languages.

TABLE III

COMPARISON OF NLU INTENT ACCURACY AND SLOT F1-SCORE BETWEEN BASELINE, SINGLE-BEST TRANSLATION, AND MULTI-VERB TRANSLATION ON LEYZER DATA SET.

Model	**Intent Accuracy [%]**	**Slot F1 [%]**
Baseline	95.48	98.07
Single-best	83.73	88.21
Multi-verb	87.53	88.15

TABLE IV

AVERAGE NUMBER OF TRANSLATIONS GENERATED FOR A SINGLE ENGLISH INPUT PER LANGUAGE.

Target Language	**Avg. Num. Translations**
es-ES	1.73
fr-FR	2.63
pl-PL	1.74
pt-PT	1.91
sv-SE	1.46

Multi-verb translation does not improve the results of the SF model. Our method does not generate different variants of slot values; therefore, during training, the SF model cannot generalize to new test cases. The difference in F1-score between single-best and multi-variant is not statistically significant.

V. CONCLUSION AND FUTURE WORK

In this paper, we proposed a method to create verb ontology for IVAs that can be used to generate multiple variants of translations. We tested our method on the NLU training set translation task, where we translated English corpora to Polish and trained NLU models from them. The results of our experiments show that verb ontology can significantly improve IC while maintaining SF results intact compared to single-best translation.

To the best of our knowledge, our MT models extended with verb ontology presented in this work are the first open-source models adapted to the domain of IVA that can return multi-variant translation. We released verb ontology, verb ranking list, and source code of IC and SF training codes to the research community. Data for the following five language pairs were published: English-Spanish[4], English-French[5], English-Polish[6], English-Portuguese[7], and English-Swedish[8]. In the future, we plan to extend our experiments to other languages.

***Abstract*—The aim of this paper is to study the performance of OpenACC implementations of sparse matrix-vector product for several storage formats: CSR, ELL, JAD, pJAD, and BSR, achieved on Intel CPU and NVIDIA GPU platforms to compare them with the performance of SpMV implementations using the BSR storage format provided by *Intel MKL* and *NVIDIA cuSPARSE* libraries. Numerical experiments show that vendor-provided BSR is the best format for CPUs but in the case of GPUs, the pJAD storage format allows to achieve better performance.**

I. Introduction

Sparse matrix-vector product (SpMV) is a central part of many numerical algorithms and its performance can have a very big impact on the performance of scientific and engineering applications [1], [2]. There are a lot of various sparse matrix storage formats and sophisticated techniques for developing efficient implementations of SpMV that utilize the underlying hardware of modern multicore CPUs and GPUs [3], [4], [5], [6], [7], [8], [9]. Unfortunately, these methods are rather complicated and usually depend on particular computer architecture, thus developing efficient and portable sparse matrix source code is still a challenge. However, the results presented in [10] and [11] show that simple SPARSKIT SpMV routines using various storage formats (CSR, ELL, JAD) [1] can be easily and efficiently adapted to modern CPU-based or GPU-accelerated architectures. Loops in source codes can be easily parallelized using OpenMP [12] or OpenACC [13], [14] directives, while the rest of the work can be done by a compiler. Such parallelized SpMV routines achieve performance comparable with the performance of the SpMV routines available in libraries optimized by hardware vendors (i.e. Intel MKL, NVIDIA cuSPARSE). OpenACC, a standard for accelerated computing, provides compiler directives for offloading C/C++ programs from host to attached accelerator devices. Such simple directives allow marking regions of source code for automatic acceleration in a portable vendor-independent manner. Moreover, OpenACC programs can be compiled using the `multicore` option, and then such programs can also be run on CPU-based architectures [15], [16], [17] without any changes in source codes.

Recently, the Block Compressed Row (BSR) format [18], [19], which is a generalization of the Compressed Sparse Row (CSR) format, has become very popular. Intel MKL and NVIDIA cuSPARSE provide optimized SpMV implementations for this format. Moreover, the other formats have been deprecated. Especially, BSR has replaced the HYB format in cuSPARSE. In this paper we compare the performance of portable OpenACC implementations of sparse matrix-vector product for CSR, ELL, JAD, pJAD, and BSR with the performance of SpMV implementations using the BSR storage format provided in *Intel MKL* and *NVIDIA cuSPARSE* libraries.

II. Sparse Matrix Representations

Let us assume that A is a sparse matrix with a significant number of zero entries, and $\mathbf{x}$, $\mathbf{y}$ are dense vectors. The SpMV operation is defined as follows:

$$\mathbf{y} \leftarrow A\mathbf{x}. \tag{1}$$

It is clear that if we do not multiply entries of $\mathbf{x}$ by zero entries of A, then (1) requires $2 \cdot n_{nz}$ floating point operations (one multiplication and one addition per nonzero entry of A). The structure of a sparse matrix can be characterized by n, n_{nz}, n_{nz}/n, and $\max_{nz}$, where n is the number of rows, n_{nz} is the total number of nonzero elements, n_{nz}/n the average number of nonzero elements per row, $\max_{nz}$ is the biggest number of nonzero elements per row. Table I shows values of these parameters for a set of test matrices, selected from *Matrix Market* [20] and *University of Florida Sparse Matrix Collection* [21]. It is clear that the performance of SpMV depends on the matrix storage format that utilizes the underlying hardware.

For description purposes of several possible sparse matrix storage formats, let us consider the following matrix as an example:

$$A = \begin{bmatrix} 7 & 0 & 1 & 0 \\ 0 & 4 & 2 & 3 \\ 1 & 8 & 0 & 0 \\ 0 & 9 & 0 & 0 \end{bmatrix}, \tag{2}$$

where $n = 4$, $n_{nz} = 8$, $n_{nz}/n = 2$, and $\max_{nz} = 3$. Now let us consider a few basic (ELL, JAD, CSR [1], [22]), as well as, more sophisticated (pJAD [11], BSR [18], [19]) storage formats for sparse matrices.

A. ELL

The ELL storage format was introduced in *Ellpack-Itpack* package. It assumes that a sparse matrix is represented by two arrays (Figure 1). Nonzero elements are stored in the first one called `a`. The second one called `ja` contains the corresponding column indices [23]. Both arrays are $n \times ncol$, where $ncol = \max_{nz}$. While ELL is simple and provides easy access to matrix entires, when $n_{nz}/n \ll \max_{nz}$, the number of stored zero entries of the matrix increases significantly.

9	*	*

`ja:`

0	2	*
1	2	3
0	1	*
1	*	*

Fig. 1: ELL format for (2)

B. JAD

The JAD (i.e. *Jagged Diagonal*) format storage is represented by three arrays (Figure 2). It is similar to ELL, but removes the assumption on the fixed-length rows [22]. Firstly, a sparse matrix needs to be sorted in non-increasing order of the number of nonzeros per row

$$PA = \begin{bmatrix} 0 & 4 & 2 & 3 \\ 7 & 0 & 1 & 0 \\ 1 & 8 & 0 & 0 \\ 0 & 9 & 0 & 0 \end{bmatrix}.$$

The arrays `a` and `ja` of dimension nz contain nonzero elements (i.e. jagged diagonals) and the corresponding column indices. The array `ia` contains the beginning position of each jagged diagonal. Additionally, we can add array `rlen` which contains the number of nonzero elements in each row. Entries of this array can be calculated (in parallel) using the following formula. Let $jdiag$ be the number of jagged diagonals. Then for each row, $i = 0, \ldots, n-1$, we have

$$\mathbf{rlen}[i] = |\{j : 0 \leq j \leq jdiag - 1 \wedge \mathbf{ia}[j+1] - \mathbf{ia}[j] > i\}|.$$

Note that this format is devoid of the inconvenience associated with the need to store zero elements in rows completed to the width of $\max_{nz}$.

Fig. 2: JAD format for (2)

C. pJAD

The pJAD storage format is an optimized version of JAD (Figure 3). This format assumes aligning (padding) columns of the arrays `a` and `ja` [11]. We add zero elements, thus the number of elements of each column should be a multiple of a given $bsize$ and rows of each block should have the same length. Entries of the array `brlen` contain widths of blocks of $bsize$ rows. Note that pJAD assumes to store at most $jdiag \cdot (bsize - 1)$ additional zero entries, where $jdiag$ is the number of jagged diagonals stored in `a`. Padding of jagged diagonals is important especially for GPUs. It allows *coalesced memory access* and reduces *thread divergence* within a block of threads [24].

`ja:`

1	2	3	0	2	0	1	*	2	*

Fig. 3: pJAD format for (2)

D. CSR

A sparse matrix in CSR (i.e. *Compressed Sparse Rows*) is stored in three arrays (Figure 4). The first array called `data` contains nonzero elements, and the second one called `cols` contains corresponding column indices of nonzero values. Indices of the beginning of rows in `data` array are stored at the `ptr` array.

`data:`	7	1	4	2	3	1	8	9
`cols:`	0	2	1	2	3	0	1	2
`ptr:`	0	2	5	7	8			

Fig. 4: CSR format for (2)

E. BSR

The BSR storage format can be treated as a generalization of CSR. A sparse matrix is represented by four arrays (Figure 5). Array `vals` contains column ordered values from blocks with nonzero values. Array `cols` stored columns indices of the first element per block. The `ptrB` and `ptrE` arrays contain the indices of the beginning and ending positions of the elements in the block row respectively.

`vals:`	7	0	0	4	1	2	0	3	1	0	8	9
`cols:`	0	1	0									
`ptrB:`	0	2										
`ptrE:`	2	3										

Fig. 5: BSR format for (2)

III. Algorithms

The SpMV operation for all storage formats presented in Section II can be implemented using OpenACC to be executed on both GPU-accelerated and CPU-based systems. OpenACC offers compiler directives for offloading selected computations from host to attached accelerator devices. It allows to indicate regions of source code for automatic parallelization in a portable manner. Algorithms 1, 2, 3, 4, and 5 show how to implement SpMV in C/C++ using OpenACC for all considered formats: ELL, JAD, pJAD, CSR, and BSR formats, respectively. OpenACC-specific parts of the implementation start with `#pragma acc` directives. The `parallel loop` directive defines a loop to be accelerated on GPU. Additional clauses, namely `gang` and `vector_length` tell that `gangs` (i.e. blocks of threads) should perform an iteration of loops. Threads within gangs work in vector or SIMD mode [13]. The `loop seq` construct placed before a loop within `parallel loop` says that such a loop should be executed sequentially by a single thread. The `present` clause says that indicated variables are previously allocated on GPU. It allows to avoid unnecessary data movements between host and device memory systems. OpenACC provides the `data` construct that can be used to specify such scope of data in accelerated regions. Data transfers can also be initialized using the `enter data` and `exit data` constructs [13]. Figure 6 shows output messages generated by the compiler using the `-acc=gpu` option.

Algorithm 1 SpMV using ELL in OpenACC

```
// auxiliary routine
double count_per_row(double *a, double *x, int *ja,
     int n,  int ncol, int i){
  double t = 0;
  #pragma acc loop seq
  for( int j = 0; j < ncol; ++j ) {
      t += a[j*n+i] * x[ja[j*n+i]];
  }
  return t;
}

// driver routine
void ELL_SpMV(int n, double *x, double *y, int ncol,
     double *a, int *ja){
  #pragma acc parallel loop gang vector_length(128)\
       present(y,x,a,ja)
  for(int i=0; i<n; i++) {
    y[i] = count_per_row(a, x, ja, n, ncol, i);
  }
}
```

Algorithm 2 SpMV using JAD in OpenACC

```
// auxiliary routine
double count_per_row(int rlen, int *ia, int i,
     double *a, double *x, int *ja){
  double t = 0;
  #pragma acc loop seq
  for(int j = 0; j<rlen; j++){
    int k = ia[j]+i;
    t+=a[k]*x[ja[k]];
  }
  return t;
}

// driver routine
void JAD_SpMV(int n, int *perm, double *a, int *rlen
     , int *ia, int *ja, double *x, double *y){
  #pragma acc parallel loop gang vector_length(128)\
       present(perm,a,rlen, ia, ja, x, y)
  for(int i = 0; i<n; i++){
    y[perm[i]] = count_per_row(rlen[i], ia, i, a, x,
         ja);
  }
}
```

When OpenACC programs are compiled using the `-acc=multicore` option, the compiler generates appropriate parallel regions to be executed in parallel on CPU cores (Figure 7). It should be noticed that if we omit OpenACC directives, we will get sequential implementations of SpMV.

IV. Performance of SpMV

All OpenACC implementations of SpMV have been tested on the computer equipped with two Xeon Gold 6342 @ 2.80GHz (48 cores) and NVIDIA A40 GPU (10752 cores, FP64 Peak perf. 584.6 GFLOPS), running under Linux Oper-

Algorithm 3 SpMV using pJAD in OpenACC

```
// auxiliary routine
double count_per_row(double *a, double *x, int *ia,
    int *ja, int brlen, int bsize, int i){
  double t = 0;
  #pragma acc loop seq
  for( int j = 0; j < brlen; ++j ) {
    int k = ia[j]+i;
    t += a[k]* x[ja[k]];
  }
  return t;
}

// driver routine
void pJAD_SpMV(int n_block, double *x, double *y,
    double *a, int *ja, int *ia, int *brlen, int *
    iperm, int bsize){
  #pragma acc parallel loop gang vector_length(128)\
       present(y,x,a,ja,ia,brlen,iperm)
  for(int i=0; i<n_block; i++) {
    #pragma acc loop
    for (int j=0; j<bsize; j++){
      y[iperm[i*bsize+j]] = count_per_row(a, x, ia,
          ja, brlen[i], bsize, i*bsize+j);
    }
  }
}
```

Algorithm 4 SpMV using CSR in OpenACC

```
// auxiliary routine
double count_per_row(int nz_in_row, int idx_start,
    int *cols, double *data, double *x){
  double t = 0;
  #pragma acc loop seq
  for(int j = 0; j<nz_in_row; j++){
     t+=x[cols[idx_start+j]]*data[idx_start+j];
  }
  return t;
}

// driver routine
void CSR_SpMV(int n, double *data, int *cols, int *
    ptr, double *x, double *y){
  #pragma acc parallel loop gang vector_length(128)\
       present(ptr,cols,x,y,data)
  for(int i = 0; i<n; i++){
    y[i] = count_per_row(ptr[i+1]-ptr[i],ptr[i],cols
        ,data,x);
  }
}

ating System with Intel OneAPI and NVIDIA HPC compiler suits. The results have been compared with SpMV implementations using the BSR storage format that are provided in *Intel MKL* and *NVIDIA cuSPARSE* libraries. Table II shows the performance (GFLOPS) obtained for all considered implementations for both CPUs and GPU and the set of sparse matrices from Table I calculated as follows:

$$perf = \frac{2 \cdot n_{nz}}{t \cdot 10^9} \text{ GFLOPS}, \tag{3}$$

where t is the execution time of SpMV (in seconds). It should be noticed that in the case of BSR, the table shows the best performance achieved for the optimal block size determined empirically. All experiments have been performed for FP64.

V. Results of Experiments

On CPU, the best performance for the majority of matrices is obtained for *Intel MKL* BSR implementation. For the smaller matrices, the best results are achieved by OpenACC implementation of SpMV using the CSR format. Other OpenACC implementations achieve worse performance than *Intel MKL* BSR. Especially, OpenACC BSR is much slower than its well-optimized counterpart. In most cases pJAD achieves better performance than JAD, however its performance is

still worse than the optimized BSR provided by Intel. The ELL format gives the worse performance for matrices with $n_{nz}/n \ll \max_{nz}$, when the number of stored zero entries increases significantly.

On GPU, we can observe that pJAD implementation achieves the best results for the largest number of matrices (eleven matrices). It outperforms JAD format for all matrices and *Nvidia cuSPARSE* BSR for almost all matrices. Moreover, for several matrices pJAD outperforms *Intel MKL* BSR significantly. The second best format is CSR. It gains the best results for seven matrices. For the others, the pJAD format is always better and the JAD format is almost always better. The ELL format achieves best results for five matrices (*cry10000, af23560, ecology2, thermal2, atmosmodl*), most of which have almost the same row length ($n_{nz}/n \approx \max_{nz}$). *Nvidia cuSPARSE* BSR gains the highest performance for only one matrix (i.e. *ldoor*), however for larger matrices it is much faster than OpenACC BSR. As with CPU, the difference between OpenACC and *Nvidia cuSPARSE* implementations of BSR is significant.

VI. Conclusions and Future Work

We have shown that sparse matrix-vector product using several formats can easily be implemented using OpenACC in order to utilize underlying hardware of modern CPUs and GPUs. Our implementations achieve reasonable performance on GPU and CPU, in some cases comparable with the performance of vendor optimized implementations using the BSR format, and sometimes even better.

It seems that the use of pJAD is very promising for GPUs. Its OpenACC portable implementation achieves much better performance than BSR optimized by the vendor. In the future we plan to provide non-portable optimized version of SpMV using pJAD.

***Abstract*—This paper addresses the issue of fake news detection, with a particular focus on solutions derived from graph theory. It covers identifying channels, which are sources of fake news, and identifying users spreading false information, considering users deliberately misleading their audience, forming clusters called ’troll farms’. It proposes a solution using graph theory, which includes classifying users based on the social context extracted in graph centrality measures built from user interactions or networks built from followers on the social network Twitter. The solution includes not only the identification of trolls but also potential unintentional users spreading false information, users exposed to false information, or automated scripts spreading information (bots). Thorough research on the efficiency of different features and classifiers is conducted on MIB and FakeNewsNet datasets. Conducted research confirms general conclusions from previous studies and offers some improvements.**

I. Introduction

WITH the rapid increase in accessibility to information caused by the development of the Internet, it has become much easier to manipulate and spread false information to any audience. Social media platforms have changed the way journalism can be conducted in the 21st century, causing anyone to be able to report on events to the masses. What is most commonly considered fake news is, in a broad sense, information that is not true, or in a more specific purpose, information that has been made available to mislead the recipient [1].

Information portals or social media enable targeting any audience, which, if used appropriately, can influence public sentiment and impact countries’ internal politics. It severely threatens a nation’s and its citizens’ stability and internal security. Examples of such events include the 2016 US presidential election campaigns, during which 20 of the most popular manipulated posts generated more shares and comments than 19 of the most prominent news sites [2]. ’Trolling’ can be defined as deviant, malicious, anti-social behavior aimed at destroying a conversation or creating conflict. The key features of this activity are deception, aggression, and negative disruptive actions, and the measure of success is to gain as much audience attention as possible [3].

An example of how vital the information domain is can be seen in the actions taken by Russia and Ukraine during the Russian-Ukrainian war that began on 24 February 2022. Building public support for an invasion of a neighboring country using manipulative techniques and a wide range of information channels preceded the Russian Federation’s attack on Ukraine [4]. This action also targeted the rest of the world – using messengers such as Telegram to release posts or videos distorting the picture of reality to present the Russian view of the conflict and gain support for its actions. While most Western countries did not succumb to disinformation, the manipulation work carried out domestically in the Russian Federation served its purpose and convinced most Russians that the war was necessary and consolidated citizens around the authorities.

II. Methods of fake news detection

Methods for detecting false information are classified as content-oriented, social context-oriented, and graph-based [5].

A. Content-oriented methods

Methods that use fact-checking, i.e., comparing the thesis presented in the news with external sources, are called knowledge-oriented methods. Manual fact-checking is poorly scalable and manpower-intensive. However, it allows for creating valuable datasets for developing automated solutions such as FakeNewsNet [6]. Fact-checking using ’crowd-sourcing’ has a high risk of obtaining biased results, but it is better scalable than the expert method [1].

Style-oriented methods are similar to knowledge-oriented methods, but in this case, the aim is not to assess the content’s veracity but to extract the author’s intentions and determine whether it was to mislead the audience [1].

Content-oriented methods also include linguistic analysis of the text [7]. It is based on analyzing the syntax and semantics of a sentence by extracting features that distinguish false information from accurate information, such as length of statements, word embedding, lexical context, discourse level, etc. [5]. This solution works in the case of longer forms of expression, but in social media, extracting these features proves difficult, or there are too few to determine the veracity of such information.

B. Social context-oriented methods

One method used is to analyze the life of information on the web. It allows one to observe how it evolves with each sharing and how information changes to form a 'rumor.' Analyzing the life cycle of such information over a period of time allows us to understand the diffusion patterns of rumors over time. Another way is to assess the information's veracity by analyzing the source's credibility [1][5]. The third popular solution for identifying fake news is to analyze the networks they form with other information, like social networks, friends, post sharing, interactions with other profiles, and profile data [1]. It allows for identifying the relationships between people spreading such information and extracting the characteristics of such interactions or profiles. An important aspect is the propagation pattern of such information, which differs between false and authentic information.

C. Graph-based solutions

Network and graph analysis is mainly based on studying features challenging to describe by standard data-averaging methods. In the case of graphs, there are often power relationships due to the uneven distribution of nodes or the high degree of links between data. Graph solutions allow the study of features such as the propagation speed of objects in the network, the relevance of individual nodes, or the way objects interact within the network and whether this can change.

Graph-based methods are used extensively in deep learning to detect internet trolls, fake news propagation channels, or fake news in general. Graph neural networks (GNNs) are characterized by the fact that they can encode the graph structure as well as the node features at the same time, which in the case of social networks or news propagation networks, dramatically increases the efficiency of classification [8][9].

To verify fake news, automatic fact-checking methods are often used, which consist of extracting facts from the content of the news and then comparing this fact with a knowledge base, the form of which can be a knowledge graph [1].

III. Dataset preparation and preprocessing

This paper decided to use graph centrality measures, which have served as features for machine learning algorithms. These measures were chosen because this area has yet to be fully explored despite some work on the subject.

Identifying 'fake' users based on a follower network is a method of detecting fake news based on social context. The source of false information can be identified in this way. When a new user arrives and 'adds' other users to his/her social network, there is a chance to identify whether he or she is an account that will spread false information. It creates a significant advantage because we can already take action, then – observe the user and start analyzing their content with other solutions to detect false information. References [10] and [11] examined follower networks and followed accounts using graph centrality measures. In addition, it was possible to classify online trolls from the 2016 US presidential campaign by creating a network of users who retweeted their posts [12]. Using graph algorithms, identifying Russian troll accounts extracted from a list provided by the US House Intelligence Committee from the 2016 US election was also feasible [13].

As part of this work, it was decided to use the centrality measures used in previous works, such as: centrality of agency, centrality of proximity (unnamed type), centrality of node degree (degree, in-degree, out-degree), PageRank centrality, centrality of eigenvector. In addition to this, the measures examined were: centrality of proximity (Wasserman-Faust), the centrality of harmonic closeness (harmonic closeness), ArticleRank, HITS (Hyperlink-Induced Topic Search).

A. Tools

Of the available tools for operating on graphs, it was decided to use Neo4j in the study because of the numerous previous uses of this tool for analyzing fake news and troll accounts [2][11][13]. This database is also fully adapted to operate on graphs. The research was performed on a computer with an Intel Core i7 7700HQ processor with 16GB RAM DDR5 and Google Colab. All collections were placed in the Neo4j database version 5.1.0. Additional libraries were used: APOC version 5.1.0 and Graph Data Science Library 2.2.5.

B. Datasets

The datasets used were those collected for the study of fake Twitter accounts [14]. This MIB dataset consists of five subsets: two sets of accounts run by humans (TFP and E13) and three sets of accounts with fake followers (INT, FSF, TWT). The data was collected before 2015. For machine learning, the collection was filtered, removing profiles with less than two edges due to their large number – they were considered noise. However, the complete set was used for feature extraction to capture the centrality features of all nodes as accurately as possible. In addition to the MIB collection, users extracted from the FakeNewsNet [6] collection were also used. This collection was created in 2018 and consisted of tweets spreading fake and real news, their retweets, the profiles of the users who sent them, and tweets from the users' timelines. The collection is based on manual fact-checking performed by the portals Gossipcop and Politifact.

Due to the known problems with the collection download and the Twitter limits [6][12][14][15], it was eventually possible to obtain 6 240 964 unique identifiers of users. Based on whether a profile was among the followers, or followers of an account that spread real or fake news, a label of true or false was assigned to that profile. Thus, profiles potentially at risk of seeing fake news were labeled as if they were spreading fake news. After filtering out the noise in the form of profiles that contained one or fewer relations and were irrelevant to the graph, 2 713 356 profiles were obtained. To speed up the Neo4j database feature extraction algorithms, once the collection was imported, the Random Walk with Restart algorithm was used to sample the collection at a ratio of 0.3. This algorithm preserves the structural features of the graph, which, in the case of centrality testing, is crucial for obtaining results close to the truth. Unfortunately, this procedure nevertheless introduced additional uncertainty into the study. The final result was 541 255 nodes labeled as potentially false and 272 743 as potentially genuine.

TABLE I: Size of follower datasets.

Dataset name	Number of profiles	Final number of profiles	Genuine/Fake accounts
TFP	240 961	198 621	Genuine
E13	996 438	147 955	Genuine
TWT	77 685	24 436	Fake
INT	57 266	17 578	Fake
FSF	20 173	5 914	Fake
FakeNewsNet #1	6 240 964	541 255	Fake
FakeNewsNet #2	-	272 743	Genuine
Sum	7 633 487	1 208 502	-

TABLE II: Size of user interaction sets from the FakeNewsNet skeleton and US Elections Trolls.

Dataset name	graphs (with fake news propagation)	profiles retweeting genuine news	profiles retweeting fake news
Politifact	314 (157)	18 042	23 012
Gossipcop	5 464 (2 732)	208 079	106 183
USElectionsTrolls	269 (269)	0	413
Sum	6 047 (3 158)	226 121	129 195

As the access to information about real troll accounts via the Twitter API was prevented, and the data contained in the Neo4j Sandbox about these accounts were small, another collection [1] from the GNN Fake News survey was used [8]. That survey used the FakeNewsNet dataset and provided the collection as a finished graph – the relationship between individual users who retweeted another user's post. The collection in this form contains much less memory because the original tweet identifiers have been mapped to unique numerical values starting from 0, and it does not contain additional information related to the user profile – it is a kind of skeleton. This processed collection yielded user profiles, with interaction in the form of retweeting a post. The original collection contained 425 842 profiles, but due to accounts being blocked, deleted, or unavailable, the authors obtained only 355 316. Tweet collection is a separate part of the MIB collection. It was created for the paper [15] on the study of spambots.

C. *Selection of characteristics of user interaction and followers sets*

To select features for machine learning algorithms, the following dependency measures were used: Pearson correlation, F-test, analysis of variance (F classifier), Mutual information, chi2 (chi-square test), tree classifier [16][17].

The feature selection analysis was started by determining the Pearson correlation matrix, identifying linearly dependent features, and then sifting them out. The selection was carried out on the complete set, with the awareness that some algorithms will show a linear relationship because they are similar in implementation – for example, closeness and harmonic closeness, or PageRank and ArticleRank.

The significance level of $\alpha = 0.1$ was assumed to reject the null hypothesis. Thus, for p > 0.1, we cannot reject the null hypothesis that the variables are independent. The choice to leave one of the two features was made when the linear Pearson correlation coefficient between the features exceeded the value of 0.3.

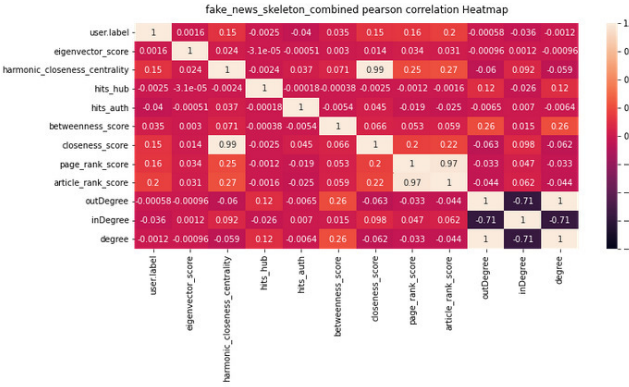

Fig. 1: Pearson correlation matrix of features extracted using graph algorithms for the FakeNewsNet skeleton - combined Politifact and Gossipcop sets.

Pearson correlation matrices were prepared for different cases: separate Politifact user interaction set, separate Gossipcop user interaction set, combined Politifact and Gossipcop user interaction set, MIB set of followers, and combined Politifact and Gossipcop set of followers. Results for different cases were similar. One of Pearson correlation matrices is shown in Figure 1. Based on them, selected features for user interaction sets were: eigenvector score, closeness score, hits auth, page rank, and inDegree. For the MIB set of followers and combined Politifact and Gossipcop set of followers, the following features were selected: eigenvector score, harmonic closeness score, hits auth, page rank.

IV. Classification

To roughly identify the classifiers that will bring the best effect, the extracted features were trained using the following algorithms:

- K-Neighbors Classifier, where k is set to n=3 by default;
- classifier with decision tree algorithm (Decision Tree Classifier);
- classifier with Random Forest Classifier, where the number of heuristic estimators was initially set at 300;
- adaptive boost classifier (AdaBoost Classifier);
- Gradient Boosting Classifier;
- Gaussian classifier with naive Bayes algorithm (GaussianNB);
- Linear Discriminant Analysis classifier;
- Quadratic Discriminant Analysis classifier;
- Support Vector Machines Classifier (SVC), with regularization parameter C=0.025, radial basis function kernel, and 5-fold cross-validation;
- Support vector classifier with support vector quantity control proposed by Bernhard Schölkopf (NuSVC - Nu Support Vector Machines Classifier) [18].

Algorithms with unspecified configurations used the default settings of the Sci-Kit Learn library. An initial test was carried out using the Accuracy index and the Log Loss function to determine the confidence with which the algorithm made the classification [19]. The sets were divided using the function

sklearn.model_selection.train_test_split from the sci-kit learn library, which split the set on a scale of 0.7 into training and test sets [17].

Finally, the following classifiers were subjected to further analysis: random forest, gradient boost, k-nearest neighbors, adaptive boost. These classifiers were subjected to a stratified 10-fold cross-validation study following a review of popular methods for testing the efficiency of classifiers [20]. Stratification is a good solution for unbalanced sets, and the K-fold method itself has already been used in previous works on this topic [10][11]. It is also widely used, and effective [21]. The study results are presented in Table VI.

Table VI shows that all models obtained a relatively low recall value, indicating many classifications of "fake" users as "real". A better result was obtained in the case of precision, which gives us information about how many "real" accounts were rated as "fake". Fewer false profiles in the set (Table II) could have contributed to obtaining a high value of the accuracy coefficient.

When detecting fake user accounts, it is essential to consider how much it will cost to recognize a user spreading accurate information when they are a "troll". This cost can be very high, making the built algorithm useless. Sometimes, however, the "forbearance" of the algorithm can be desirable.

The final proposed solution is a classifier based on the random forest algorithm, where the number of estimators n has been heuristically set to n=300. This classifier was tested on the set of Russian troll accounts described in Table II. This set consisted of 413 fake accounts and was used only as another measure of verifying the task's success. The final version of the random forest classifier learned from the Politifact and Gossipcop collections achieved an accuracy of 84.50%. This observation is consistent with previous conclusions for the set of low validity, but the obtained result is better than the tests would indicate.

A. Choosing a solution to detect fake propagation channels and bots by analyzing the network of followed users

The classifiers were studied for these sets by testing the best-performing algorithms using selected features. Studies for the

AdaBoost	84.504	0.870	0.950	0.908

sets were performed using 10-fold cross-validation to better compare the results with those in other studies. In addition, the results of training performed on one set and then testing the model on a second set were also examined.

Table VII shows that the classifiers obtained high confidence and accuracy on the MIB set. This may be because it consisted of accounts generated by bots, which may have resulted in more significant differences between the characteristics. An important fact is that this set is already about ten years old, so the algorithms creating the bots could have been less advanced then. Similar high accuracy was achieved for all algorithms except Gaussian naive Bayes and linear and quadratic discriminant analysis.

Other studies based on measures of centrality have yielded for this set:

- in 2016 - precision 89.0%, accuracy 100% and validity 95% [10];
- in 2021 - precision, accuracy, and validity of 99.5%[11].

The extracted features for this set allowed us to obtain results similar to the work [11] where closeness centrality was introduced. At the same time, it can be seen that betweenness centrality, in this case, does not play a significant role in classifying "fake" users. It was also possible to obtain better results with the KNN classifier than previous works did with the random forest.

Worse algorithm efficiency results were obtained for the set of FakeNewsNet followers, presented in Table VIII. In this case, the random forest classifier was the best, achieving the highest accuracy and the lowest Log Loss. The decision tree algorithm, KNN, and gradient boost also achieved high scores. Worse results could be obtained because accounts were classified as fake or genuine only because they had a person who tweeted false information to their followers or followed. However, achieving such accuracy means that we can identify people who may be potentially unwitting spreaders of fake news, and according to research, they constitute a large part of fake news propagation channels [1].

However, surprising results were obtained for the model trained on the FakeNewsNet set and tested on the MIB set containing bots. The results presented in Table IX show that both the decision tree algorithm and the naive Bayes classifier performed much worse in this case than before. An interesting result was obtained in the case of the adaptive gain algorithm, which turned out to be the best in terms of precision and in terms of accuracy. The gradient boost and random forest algorithms also performed well. The KNN method obtained a relatively high value of the Loss Log coefficient. This result was probably obtained because the MIB set profiles were relatively easy to detect. The model built on FakeNewsNet seems to be quite effective in this case. In the reverse situation, when the MIB model was used on the FakeNewsNet set, worse results were obtained – it can be assumed that the model built on this set will have a lower generalization ability.

The random forest, gradient boost, KNN, and adaptive boost classifiers were tested on a combined set of FakeNewsNet and MIB followers to maximize the efficiency. Table X shows the result of testing the effectiveness of classifiers using 10-fold cross-validation with stratification.

The obtained values are slightly worse than those obtained in the research from 2021 [11] on the exclusive MIB set. However, the MIB set allowed us to build a classifier and significantly lower ability to generalize in detecting fake users, in contrast to the set of FakeNewsFollowers obtained in this work. Building a classifier based on both sets significantly increases the generalization capabilities of the classifier.

Ultimately, the best overall results were obtained for the random forest, which confirms previous studies. At the same time, other algorithms have also been shown to be highly effective. Very high accuracy was obtained for the gradient boost, which may be beneficial in the case when a maximum "raw" classifier is needed in detecting fake users, even at the cost of considering some genuine users as fake.

V. Conclusions

The article presents graph techniques for detecting false information. An essential aspect of detecting fake news is combining knowledge from many disciplines and data from different contexts to get better results. Combining several methods gives better results, but creating a complete system that classifies information as genuine and false using content and social context analysis is time-consuming and complicated. Studying individual techniques of a complex solution, such as the one presented in the paper, requires much time and collecting appropriate training data for machine learning algorithms.

The problem of classification presented in both cases, for the analysis of connections between users based on retweeting posts and based on followers, turned out to be a complicated issue. In the case of the user interaction network, it was impossible to build an effective classifier to solve the problem. However, we created a classifier that dealt with accounts of Russian trolls from the 2016 US elections quite effectively, proving that research in this direction should be continued.

It is more difficult to determine whether a user is part of a fake news channel based on what users they retweet. In further research, the set should be enlarged with additional samples, more work should be done to remove potential outliers, and the set should be better balanced to avoid overfitting. An important area for improvement is set normalization, model regularization, and parameter tuning.

Classifier tests in the case of the follower network essentially confirmed the conclusions regarding the effective operation of the random forest from previous studies [10][11]. It turned out, however, that the KNN classifier on the same set of MIB followers achieved better results than the random forest used in previous studies. It is an important finding, considering that learning this algorithm took less time than in the case of a random forest for n=300 estimators. Also, learning on the set of FakeNewsNet followers and validation on the MIB set was reasonably practical – although it could have been more reliable among the algorithms, obtaining a considerable value of the Log Loss coefficient.

***Abstract*—This paper introduces a sophisticated multi-dimensional sensitivity analysis, incorporating cutting-edge stochastic methods for air pollution modeling. The study focuses on a large-scale long-distance transportation model of air pollutants, specifically the Unified Danish Eulerian Model (UNI-DEM). This mathematical model plays a pivotal role in understanding the detrimental impacts of heightened levels of air pollution. With this research, our intent is to employ it to tackle crucial questions related to environmental protection.**

We suggest advanced Monte Carlo and quasi-Monte Carlo methods, leveraging specific lattice and digital sequences to enhance the computational effectiveness of multi-dimensional numerical integration. Moreover, we further refine the existing stochastic methodologies for digital ecosystem modeling. The main aspect of our investigation is to analyze the sensitivity of the UNI-DEM model output to changes in the input emissions of human-induced pollutants and the rates of a number of chemical reactions.

The developed algorithms are utilized to calculate global Sobol sensitivity measures for various input parameters. We also assess their influence on key air pollutant concentrations in different European cities, considering the diverse geographical locations. The overarching goal of this research is to broaden our understanding of the elements influencing air pollution and inform potent strategies to alleviate its negative impacts on the environment.

I. Introduction

THIS paper focuses on conducting sensitivity analysis (SA) studies in the field of air pollution modeling [23], [26], [27], [28], [29], specifically using the Unified Danish Eulerian Model (UNI-DEM) as a case study. UNI-DEM is chosen for its accurate representation of relevant chemical processes in the atmosphere. The extensive output data generated by UNI-DEM has been utilized in various real-world applications, necessitating the accurate assessment of data reliability for specific uses. The research objective is to evaluate the dependability of the substantial volume of output data produced by the model. The study primarily examines the variations in hazardous air pollutant concentrations in relation to human-made emission levels and chemical reaction rates.

When it comes to making decisions, doubts arise regarding the reliability of large-scale mathematical models. To enhance their reliability, the sensitivity of model outputs to variations in model inputs caused by natural variability is studied and analyzed. Sensitivity analysis, as defined in this paper, is a procedure used to measure how sensitive mathematical model outputs are to variations in input data. The input data for sensitivity analysis in this study is obtained through simulations of a large-scale mathematical model known as the Unified Danish Eulerian Model (UNI-DEM). The model, developed at the Danish National Environmental Research Institute, covers a vast geographical area of 4800 × 4800 km, encompassing Europe and the Mediterranean fully and parts of Asia and Africa. It accurately represents the primary chemical, photochemical, and physical processes between the species considered and the emissions under rapidly changing meteorological conditions. The choice of this model for the case study is motivated by its precise treatment of chemical processes compared to other atmospheric chemistry models.

UNI-DEM is mathematically represented by the following system of partial differential equations (PDE) [22]:

$$\begin{aligned}\frac{\partial c_s}{\partial t} &= -\frac{\partial (uc_s)}{\partial x} - \frac{\partial (vc_s)}{\partial y} - \frac{\partial (wc_s)}{\partial z} + \\ &+ \frac{\partial}{\partial x}\left(K_x \frac{\partial c_s}{\partial x}\right) + \frac{\partial}{\partial y}\left(K_y \frac{\partial c_s}{\partial y}\right) + \frac{\partial}{\partial z}\left(K_z \frac{\partial c_s}{\partial z}\right) + \\ &+ E_s + Q_s(c_1, c_2, \ldots, c_q) - (k_{1s} + k_{2s})c_s, \quad s = 1, 2, \ldots, q,\end{aligned} \tag{1}$$

where c_s are the chemical species' concentrations; u, v, w are the wind components; K_x, K_y, K_z – the diffusion coeff.; E_s – the emissions; k_{1s}, k_{2s} – dry / wet deposition

Venelin Todorov is supported by the Bulgarian National Science Fund under Project KP-06-N52/5 "Efficient methods for modeling, optimization and decision making" and Project KP-06-Russia/17 "New Highly Efficient Stochastic Simulation Methods and Applications".

coeff.; $Q_s(c_1, c_2, \dots c_q)$ – non-linear functions used to depict the chemical reactions that occur between the species being studied.

The Carbon Bond Mechanism (CBM-IV) chemical scheme is utilized to account for both non-linearity and stiffness. [22], [25].

II. Global Sensitivity Analysis – Sobol Approach

Variance-based methods are frequently employed in quantitative global sensitivity analysis, with the aim of assessing the contribution of input variance (either individual or grouped) to the overall variance of model output. Among these methods, the Sobol approach is widely utilized [17], [5], [19]. This approach is based on the assumption that the mathematical model can be represented by a specific model function:

$$\mathrm{u} = f(\mathrm{x}), \tag{2}$$

where $\mathrm{x} = (x_1, x_2, \dots, x_d) \in U^d \equiv [0; 1]^d$ is the vector of input parameters with a joint **p**robability **d**ensity **f**unction (p.d.f.) $p(\mathrm{x}) = p(x_1, \dots, x_d)$.

The concept behind the Sobol approach involves decomposing the integrable model function f into terms of increasing dimensionality [18], [20]:

$$f(\mathrm{x}) = f_0 + \sum_{\nu=1}^{d} \sum_{l_1<\dots<l_\nu} f_{l_1\dots l_\nu}(x_{l_1}, x_{l_2}, \dots, x_{l_\nu}), \tag{3}$$

where f_0 is some constant.

According to Sobol [19], the ANOVA (Analysis of Variance) decomposition decompose the output variance of a mathematical model into components attributed to each input. The goal is to identify which inputs contribute most significantly to the output variance. Each input variable is given a sensitivity index, or Sobol index, indicating its relative contribution to the output variance.

In simple terms, the process involves running the model multiple times with different combinations of inputs and observing the changes in the output. The larger the change in output for a given change in input, the more 'sensitive' the model is to that input.

The expression (3), where each term is selected to fulfill the specified condition, is referred to as the ANOVA representation of the model function $f(\mathbf{x})$:

$$\int_0^1 f_{l_1\dots l_\nu}(x_{l_1}, x_{l_2}, \dots, x_{l_\nu}) \mathrm{d}x_{l_k} = 0, 1 \le k \le \nu, \nu = 1, \dots, d.$$

This condition ensures that the functions on the right-hand side of (3) have a unique definition and $f_0 = \displaystyle\int_{U^d} f(\mathrm{x})\mathrm{dx}$. The quantities

$$\mathbf{D} = \int_{U^d} f^2(\mathrm{x})\mathrm{dx} - f_0^2, \quad \mathbf{D}_{l_1 \ \dots \ l_\nu} = \int f^2_{l_1 \ \dots \ l_\nu} \mathrm{d}x_{l_1} \dots \mathrm{d}x_{l_\nu} \tag{4}$$

are referred to as total and partial variances, respectively. Similar is true for the total variance which is represented by the corresponding partial variances: $\mathbf{D} = \sum_{\nu=1}^{d} \sum_{l_1<\dots<l_\nu} \mathbf{D}_{l_1\dots l_\nu}$.

The definition of Sobol global sensitivity indices is the following[19], [17]:

$$S_{l_1 \ \dots \ l_\nu} = \frac{\mathbf{D}_{l_1 \ \dots \ l_\nu}}{\mathbf{D}}, \quad \nu \in \{1, \dots, d\}, \tag{5}$$

and the **t**otal **s**ensitivity **i**ndex (TSI) of an input parameter $x_i, i \in \{1, \dots, d\}$ defined by [19], [17]:

$$S_i^{tot} = S_i + \sum_{l_1 \neq i} S_{il_1} + \sum_{l_1, l_2 \neq i, l_1 < l_2} S_{il_1 l_2} + \dots + S_{il_1 \dots l_{d-1}}, \tag{6}$$

where S_i is named *the main effect (first-order sensitivity index)* of x_i and $S_{il_1\dots l_{j-1}}$ is the j^{th} order sensitivity index. The higher-order terms characterize the interaction effects between the unknown input parameters $x_{i_1}, \dots, x_{i_\nu}, \nu \in \{2, \dots, d\}$ on the output variance. Therefore comprehensive mathematical analysis of the global sensitivity analysis problem involves the calculation of total sensitivity indices (6) of the corresponding order. This calculation relies on the formulas (4)-(5), which require the computation of multidimensional integrals.

The authors of [9] discuss which formulation of

$$f_0^2 = \left(\int_{U^d} f(\mathrm{x})\mathrm{dx} \right)^2 \tag{7}$$

is better when calculating the total variance and the Sobol global sensitivity measures. The first approximation formula is

$$\hat{f_0^2} = \frac{1}{n} \sum_{i=1}^{n} f(\mathrm{x}_{i,1}, \dots, \mathrm{x}_{i,d}) \ f(\mathrm{x}'_{i,1}, \dots, \mathrm{x}'_{i,d}) \tag{8}$$

and the second one is

$$\hat{f_0^2} = \left\{ \frac{1}{n} \sum_{i=1}^{n} f(\mathrm{x}_{i,1}, \dots, \mathrm{x}_{i,d}) \right\}^2, \tag{9}$$

where x and x′ are two independent sample vectors. If one estimates sensitivity indices of a fixed order, the expression (8) is better (as it is recommended in [9]), and this is why we apply it here as well.

III. A new optimization method for SA

Let us take into account a multidimensional integration task in dimension s:

$$I(f) := I = \int_{U^s} f(x)\mathrm{d}x. \tag{10}$$

We introduce the quadrature formula

$$I_N(f) = \frac{1}{N} \sum_{i=1}^{N} f(x_i), \tag{11}$$

where $P_N = x_1, x_2, \dots, x_N, x_i \in [0, 1)^s$ are the nodes for the integration of the formula. The selection of these nodes is critical because it establishes the discrepancy of the sequence and the precision of the quadrature. For equation (11), the integration nodes that we will employ are [13], [14]:

$$x_k = \left(\left\{ \frac{kz_1}{N} \right\}, \left\{ \frac{kz_2}{N} \right\}, \dots, \left\{ \frac{kz_s}{N} \right\} \right), \ k = 1, 2, \dots, N, \tag{12}$$

where N represents the quantity of nodes, z is an s-dimensional generating vector of the lattice set and $a = a-[a]$ is the fractional part of a. Now, the equation (11) with nodes (12) and generators z is referred to as rank-1 lattice rules [2]. We will adopt a particular category of rank-1 lattice: the symmetrized lattice (SL).

We put forth a unique SL, defined in the following manner. In the unidimensional scenario, we set up a function, appropriate for periodic integrand functions, to be used with a non-periodic function F by applying the SL to the function

$$L(x) = \big(F(x) + F(1-x)\big)/2,$$

in a single dimension. For the two-dimensional situation, the function L is established as

$$L(x_1, x_2) = (F(x_1, x_2) + F(x_1, 1-x_2) + F(1-x_1, x_2) + F(1-x_1, 1-x_2))/4.$$

The definition of the function $L(x_1, \dots, x_s)$ is extrapolated for s dimensions:

$$L(x_1, \dots, x_s) = 2^{-s} \sum_{\varepsilon\in 0,1^s} F\big(\varepsilon_1 x_1+(1-\varepsilon_1)(1-x_1), \dots, \varepsilon_s x_s+(1-\varepsilon_s)(1-x_s)\big). \tag{13}$$

The terms over which the summation takes place can be envisioned as vertices of a parallelotope, with diagonals converging at the point $(1/2, 1/2, \dots, 1/2) \in [0, 1]^s$. Formula (13) is identical to

$$L(x_1, \dots, x_s) = \sum_{\varepsilon\in 0,1^s} F\left(x_1^{\varepsilon_1}(1-x_1)^{1-\varepsilon_1}, x_2^{\varepsilon_2}(1-x_2)^{1-\varepsilon_2}, \dots, x_s^{\varepsilon_s}(1-x_s)^{1-\varepsilon_s}\right).$$

The lattice we will use in our study are defined as follows. The first one is a rank one lattice rule with prime number of points and with product weights, which symmetrized version would be denoted by `SL-1pt`. The next lattice is a rank one lattice rule with prime number of points and with order dependent weights, which symmetrized version would be designated with `SL-1od`. These two lattice rules have variant with number of points, which is a prime power instead of prime itself, and we would denote them with `SL-1expt` and `SL-1exod`, respectively. The last lattice that would be used is a polynomial rank one lattice sequence in base two and with product weights, designated by `SL-2poly`.

IV. Sensitivity Studies with Respect to Emission Levels

In this section, we report the findings of the Sensitivity Analysis performed on the output of UNI-DEM, with particular attention paid to the monthly average ammonia concentrations in Milan, Italy. This analysis scrutinizes how alterations in anthropogenic emission data, employed as input, impact these concentrations.

The input is composed of 4 distinct constituents $\mathbf{E} = (\mathbf{E^A}, \mathbf{E^N}, \mathbf{E^S}, \mathbf{E^C})$:

$\mathbf{E^A}$ – ammonia (NH_3);
$\mathbf{E^S}$ – sulphur dioxide (SO_2);
$\mathbf{E^N}$ – nitrogen oxides ($NO + NO_2$);
$\mathbf{E^C}$ – anthropogenic hydrocarbons.

The domain under examination is the 4-dimensional hypercube $[0.5, 1]^4$.

The primary determinant of ammonia output concentrations is the emission of ammonia itself, accounting for approximately 89% in Milan. The next most influential factor is the emission of sulphur dioxide, contributing around 11% to ammonia output. This depiction of first- and second-order sensitivity indices for ammonia in Milan was established through the use of correlated sampling as part of Sobol's variance-based approach for multidimensional sensitivity analysis. This was done to compute all potential sensitivity measures and investigate the impact of the selected four groups of air pollutant emissions on the concentration of three key air pollutants.

This signifies the degree to which ammonia emissions directly affect ammonia concentrations, emphasizing the need for effective monitoring and management of these emissions. The role of sulphur dioxide emissions, albeit smaller, also needs to be taken into account due to their noticeable influence. Using multidimensional sensitivity analysis aids in comprehensively understanding the role of various emissions in air pollution, thereby enabling more targeted strategies to mitigate these issues. The results provide a foundation for future work aimed at improving air quality, informing policy decisions, and guiding future research into pollution control methods.

The relative error estimation for quantities f_0, the overall variance $\mathbf{D}$, the first-order (S_i) and the total (S_i^{tot}) sensitivity indices is exhibited in Tables I, II, III, correspondingly. f_0 is represented by a 4-dimensional integral, whereas the remaining quantities are denoted by 8-dimensional integrals, drawing upon the concepts of the *correlated sampling* technique to compute sensitivity measures in a robust manner (refer to [9], [20]). Four distinct stochastic methods utilized for numerical integration are displayed in separate columns in the tables.

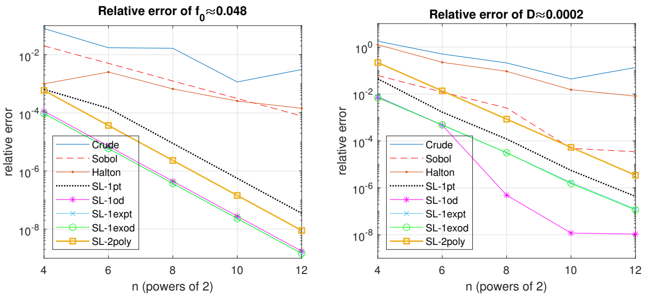

Fig. 1. Relative errors for the calculation of $f_0 \approx 0.048$ (left) and $\mathbf{D} \approx 0.0002$ (right)

When examining the model function f_0 with a sample size of $n = 2^{12}$, the most effective algorithm appears to be SL-1EXPT. This can be observed from the results given in Table I, which highlight outcomes for the maximum sample count.

When considering the total variance D for the same number of samples, SL-1OD comes out on top, as can be seen in Table II, which presents findings for the highest sample amount.

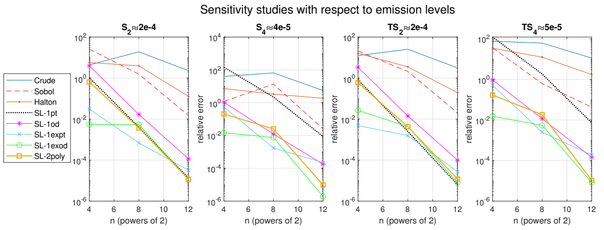

Fig. 2. Relative errors for the calculation of the small in value SIs

Regarding Sensitivity Indices (SIs), the optimal method is SL-1EXOD, as evident in Table III.

The efficiency and results of these algorithms can be further examined in Figures 1 and 2. The latter focuses particularly on SIs with smaller values, providing a more detailed look into their performance.

From the data displayed in Table III, it is evident that the SL-1EXOD algorithm enhances results in a majority of scenarios, particularly in determining the low-value sensitivity indices S_2, S_4, S_2^{tot}, and S_4^{tot}. These specific instances hold substantial significance as they play a crucial role in ascertaining the dependability of the model outcomes.

V. SENSITIVITY STUDIES WITH RESPECT TO CHEMICAL REACTIONS RATES

This section analyzes the sensitivity of the concentration levels of ozone in the atmosphere above Genova, Italy, with respect to modifications in the reaction rates of specific chemical reactions entailed in the condensed CBM-IV model ([22]). Notably, reactions # $1, 3, 7, 22$ (time-dependent) and # $27, 28$ (time independent) are the primary focus. The simplified formulas for the chemical reactions are as follows:

$$
\begin{aligned}
&[\#\mathbf{1}] \qquad NO_2 + h\nu \Longrightarrow NO + O;\\
&[\#\mathbf{3}] \qquad O_3 + NO \Longrightarrow NO_2;\\
&[\#\mathbf{7}] \qquad NO_2 + O_3 \Longrightarrow NO_3;\\
&[\#\mathbf{22}] \qquad HO_2 + NO \Longrightarrow OH + NO_2;\\
&[\#\mathbf{27}] \qquad HO_2 + HO_2 \Longrightarrow H_2O_2;\\
&[\#\mathbf{28}] \qquad OH + CO \Longrightarrow HO_2.
\end{aligned}
$$

The domain under examination is the 6-dimensional hypercube $[0.6, 1.4]^6$).

The findings from our analysis, with a focus on the reactions as described by the CBM-IV scheme, led to several important insights. Reaction rates #1, 3, and 22 have a profound impact on O_3 concentrations, making them extremely influential in this context. On the other hand, reaction rates #7 and 27, while not as dominant, still hold a noticeable significance. Contrarily, the influence of reaction rate #28 can be deemed negligible.

In other words, the study has found that there are clear relationships between specific reaction rates and O_3 concentrations. While the reactions #1, 3, and 22 play a leading role, reactions #7 and 27 still contribute to a certain extent. This information suggests that these specific reactions could be potential targets for strategies to reduce O_3 concentrations. However, the role of reaction #28 appears to be minimal, suggesting that efforts aimed at this reaction are likely to be less effective. These observations provide a better understanding of the dynamics involved in O_3 concentrations, paving the way for more effective and targeted air pollution control strategies.

The estimated relative error for the values f_0, total variance $\mathbf{D}$, and a subset of the sensitivity indices are detailed in Tables IV, V, and VI, correspondingly.

The parameter f_0 is depicted by a 6-dimensional integral, while the remaining quantities being examined are shown by 12-dimensional integrals, in line with the *correlated sampling* principle.

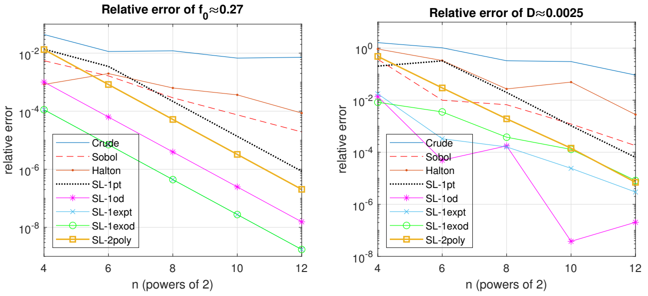

Fig. 3. Relative errors for the calculation of $f_0 \approx 0.27$ (left) and $\mathbf{D} \approx 0.0025$ (right)

In the case of the model function f_0, the optimal algorithm turns out to be the SL-1EXPT, with SL-1EXOD coming in as the second-best choice, as evidenced by the results displayed in Table IV. When dealing with a sample size of $n = 2^{12}$ for the total variance D, the top-performing algorithm is SL-1OD, as demonstrated by the results shown in Table V for the largest

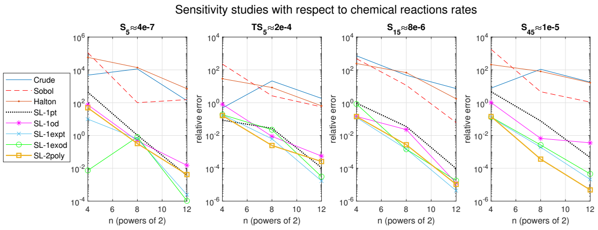

Fig. 4. Relative errors for the calculation of the small in value SIs

number of samples. In terms of the Sensitivity Indices (SIs), SL-1EXPT proves to be the most efficient method, closely followed by SL-1POLY and SL-1OD. This is clearly shown in Table VI. The algorithms' performance can be visually inspected through Fig. 3 and 4, with the latter emphasizing the SIs of smaller values.

As evidenced by Table VI, the SL-1EXPT algorithm improves outcomes in most instances, most notably for the lower-valued sensitivity indices S_5, S_5^{tot}, S_{15}, and S_{45}. These indices are particularly significant as they greatly impact the trustworthiness of the model's outcomes.

VI. CONCLUSION

We have examined the computational effectiveness of various stochastic methodologies for multi-dimensional numerical integration in relation to relative error and computational resources. The subject of this study is the sensitivity analysis of the output from the UNI-DEM model to changes in input emissions of anthropogenic contaminants and alterations in a selection of chemical reaction rates.

We scrutinize the impact of emission levels on key air pollutants, specifically ammonia, ozone, ammonium sulphate, and ammonium nitrate.

The computational experiments reveal that the optimization methods developed are amongst the most effective stochastic strategies currently available for determining sensitivity indices, particularly for the most challenging task – assessing the least value sensitivity indices, which are crucial for the dependability of the model's outcomes.

***Abstract*—We introduce large groups of quadratic transformations of a vector space over the finite fields defined via symbolic computations with the usage of algebraic constructions of Extremal Graph Theory. They can serve as platforms for the protocols of Noncommutative Cryptography with security based on the complexity of word decomposition problem in noncommutative polynomial transformation group. The modifications of these symbolic computations in the case of large fields of characteristic two allow us to define quadratic bijective multivariate public keys such that the inverses of public maps has a large polynomial degree. Another family of public keys is defined over arbitrary commutative ring with unity. We suggest the usage of constructed protocols for the private delivery of quadratic encryption maps instead of the public usage of these transformations, i.e. the idea of temporal multivariate rules with their periodical change.**

I. On Post Quantum, Multivariate and Noncommutative Cryptography

POST-Quantum Cryptography (PQC) is an answer to a threat coming from a full-scale quantum computer able to execute Shor's algorithm. With this algorithm implemented on a quantum computer, currently used public key schemes, such as RSA and elliptic curve cryptosystems, are no longer secure. PQC is subdivided into Coding based Cryptography, Multivariate Cryptography, Noncommutative Cryptography, Hash based Cryptography, Isogeny based Cryptography and Lattice based Cryptography. Each of these six areas is based on the complexity of certain NP-hard problem. Noteworthy that fundamental assumption of cryptography that there are no polynomial-time algorithms for solving any NP-hard problem remains valid. So all six directions are well justified theoretically.

The tender of US National Institute of Standardisation Technology (NIST, 2017) is dedicated to the standardisation process of possible real life Post-Qantum Public keys. Already selected in July of 2022 four cryptosystems are developed via methods of Lattice based Cryptography. This fact motivates researchers from other four core areas of Post Quantum Cryptography to continue design of new cryptographical primitives. Noteworthy that during the NIST project an interesting results on cryptanalysis of Unbalanced Rainbow Oil and Vinegar digital signatures schemes were found (see [1], [2], [3]). This scheme is defined via quadratic multivariate public rule, which refers to MiniRank problem. Examples of previously known multivariate quadratic public keys a reader can find in classical monographs [4], [5], [6].

Graph based multivariate public keys with bijective encryption maps generated via special walks on incidence graph of projective geometry were proposed in [7] this year. It can be count as attempt to combine methods of Coding based and Multivariate Cryptographies. Classical multivariate public rule is a transformation of n-dimensional vector space over finite field F_q which move vector $(x_1, \dots, x_n)$ to the tuple $(g_1(x_1, \dots, x_n), g_2(x_1, \dots, x_n), \dots, g_n(x_1, \dots, x_n))$, where polynomials g_i are given in their standard forms, i.e. lists of monomial terms in the lexicographical order. The degree of this transformation is the maximal value of $\deg(g_i)$. Traditionally public rule has degree 2 or 3.

We use the known family of graphs $D(n, q)$ and $A(n, q)$ of increasing girth (see [8], [9] and further references) and their analogs $D(n, K)$ and $A(n, K)$ defined over finite commutative ring K with unity for the construction of our public keys. Noteworthy to mention that for each prime power q, $q > 2$ graphs $D(n, q)$, $n = 2, 3, \dots$ form a family of graphs of large girth (see [8]). There is well defined projective limit of these graphs which is a q-regular forest. In fact if K is an integral domain both families $A(n, K)$ and $D(n, K)$ are approximations of infinite dimensional algebraic forests. Cubical transformation groups $GA(n, K)$ and $GD(n, k)$ of K_n (see [10], [11]), were used for the design of key exchange protocols of Noncommutative Cryptography (see [11], [12], [13]), elements of this groups were used for the creation of stream ciphers.

II. On graphs, groups and quadratic maps with the inverses of high degree

Let K be a commutative ring. We define $A(n, K)$ as bipartite graph with the point set $P = K_n$ and line set $L = K_n$ (two copies of a Cartesian power of K are used). We will use brackets and parenthesis to distinguish tuples from P and L. So $(p) = (p_1, p_2, \dots, p_n) \in P_n$ and $[l] = [l_1, l_2, \dots, l_n] \in L_n$. The incidence relation $I = A(n, K)$ (or corresponding bi-

This research is partially supported by British Academy Fellowship for Researchers at Risk 2022

partite graph I) is given by condition pIl if and only if the equations of the following kind hold:

$$\begin{aligned}
&p_2 - l_2 = l_1 p_1,\\
&p_3 - l_3 = p_1 l_2,\\
&p_4 - l_4 = l_1 p_3,\\
&p_5 - l_5 = p_1 l_4,\\
&\dots\\
&p_n - l_n = p_1 l_{n-1} \text{ for odd } n,\\
\text{or } &p_n - l_n = l_1 p_{n-1} \text{ for even } n.
\end{aligned} \tag{1}$$

We can consider an infinite bipartite graph $A(K)$ with points $(p_1, p_2, \dots, p_n, \dots)$ and lines $[l_1, l_2, \dots, l_n, \dots]$. We proved that for each odd n girth indicator of $A(n, K)$ is at least $2n + 2$.

Another incidence relation $I = D(n, K)$ is defined below. The following interpretation of a family of graphs $D(n, K)$ in case of general commutative ring K is convenient for the computations. Let us use the same notations for points and lines as in previous case of graphs $A(n, K)$. Points and lines are elements of two copies of the affine space over K. Point $(p_1, p_2, \dots, p_n)$ is incident with the line $[l_1, l_2, \dots, l_n]$ if the following relations between their coordinates hold:

$$\begin{aligned}
&p_2 - l_2 = l_1 p_1,\\
&p_3 - l_3 = p_1 l_2,\\
&p_4 - l_4 = l_1 p_3,\\
&\dots\\
&l_i - p_i = p_1 l_{i-2} \text{ if } i \text{ congruent to 2 or 3 modulo 4},\\
\text{or } &l_i - p_i = l_1 p_{i-2} \text{ if } i \text{ congruent to 1 or 0 modulo 4}.
\end{aligned} \tag{2}$$

Let $\Gamma(n, K)$ be one of graphs $D(n, K)$ or $A(n, K)$. The graph $\Gamma(n, K)$ has so called linguistic colouring ρ of the set of vertices. We assume that $\rho(x_1, x_2, \dots, x_n) = x_1$ for the vertex x (point or line) given by the tuple with coordinates $x_1, x_2, \dots, x_n$. We refer to x_1 from K as the colour of vertex x. It is easy to see that each vertex has a unique neighbour of the chosen colour. It means that the path in this graph is uniquely determined by initial vertex and the sequence of colours of the vertices. Let N_a and J_a be operators of taking the neighbour with colour a and jump operator changing the original colour of point or line for new colour a from K.

Let $[y_1, y_2, \dots, y_n]$ be the line y of $\Gamma(n, K[y_1, y_2, \dots, y_n])$ and $(\alpha(1), \alpha(2), \dots, \alpha(t))$ and $(\beta(1), \beta(2), \dots, \beta(t))$ are the sequences of colours from $K[y_1]$ of the length at least 2. We consider the sequence ${}^0v = y, {}^1v = J_{\alpha(1)}({}^0v), {}^2v = N_{\beta(1)}({}^1v), {}^3v = N_{\alpha(2)}({}^2v), {}^4v = N_{\beta(2)}({}^3v), \dots, {}^{2t-2}v = N_{\beta(t-1)}({}^{2t-3}v), {}^{2t-1}v = N_{\alpha(t)}({}^{2t-2}v), {}^{2t}v = J_{\beta(t)}({}^{2t-1}v)$. Assume that $v ={}^{2t} v = [v_1, v_2, \dots, v_n]$ where v_i are from $K[y_1, y_2, \dots, y_n]$. We consider polynomial transformation $g(\alpha(1), \alpha(2), \dots, \alpha(t), \beta(1), \beta(2), \dots, \beta(t))$, $t \geq 2$ of affine space K_n of kind $y_1 \to y_1 + \beta(t), y_2 \to v_2(y_1, y_2), y_3 \to v_3(y_1, y_2, y_3), \dots, y_n \to v_n(y_1, y_2, \dots, y_n)$.

It is easy to see that:

$$\begin{aligned}
&g(\alpha(1), \alpha(2), \dots, \alpha(t), \beta(1), \beta(2), \dots, \beta(t))\cdot\\
&\cdot g(\gamma(1), \gamma(2), \dots, \gamma(s), \sigma(1), \sigma(2), \dots, \sigma(t)) =\\
&= g(\alpha(1), \alpha(2), \dots, \alpha(t), \gamma(1)(\beta(t)), \gamma(2)(\beta(t)), \dots,\\
&\gamma(s)(\beta(t)), \beta(1), \beta(2), \dots, \beta(s), \sigma(1)(\beta(t)),\\
&\sigma(2)(\beta(t)), \dots, \sigma(s)(\beta(t))).
\end{aligned}$$

Proposition II.1. *[11] Transformations of kind* $g = g(\alpha(1), \alpha(2), \dots, \alpha(t), \beta(1), \beta(2), \dots, \beta(t))$*,* $t \geq 2$ *generate a semigroup* $S(\Gamma(n, K))$ *of transformations of* K_n*.*

Lemma II.1. *[11] The degree of transformation* g *of the II.1 is at least* $[\deg(\alpha(1)) + \deg(\alpha(1) - \alpha(2)) + \deg(\alpha(2) - \alpha(3)) + \dots + \deg((\alpha(t-1) - \alpha(t))] + [\deg(\beta(1) + (\deg(\beta(1) - \beta(2)) + (\deg(\beta(2) - \beta(3)) + \dots + (\deg(\beta(t-2) - \beta(t-1))]$.

Lemma II.2. *[11] Transformation* g *as in the II.1 is bijective if and only if* $\beta(t)(x) = a$ *has a unique solution for each* a *from* K*.*

Proposition II.2. *[11] Transformations of kind* ${}^n g = g(\alpha(1), \alpha(2), \dots, \alpha(t), \beta(1), \beta(2), \dots, \beta(t))$*,* $t \geq 2$ *such that* $\deg(\alpha(i)) = 0$ *and* $\beta(i) = y_1 + c(i)$*,* $c(i) \in K$ *generate a subgroup* ${}^2G(\Gamma(n, K))$ *of transformation of maximal degree* 2*.*

Remark II.1. *The inverse element of* ${}^n g = g(\alpha(1), \alpha(2), \dots, \alpha(t), \beta(1), \beta(2), \dots, \beta(t))$*,* $t \geq 2$ *as in the II.2 can be written as* ${}^n g(\alpha(t), \alpha(t-1), \dots, \alpha(1), \beta(t-1)(\beta(t) - 1), \beta(t-2)(\beta(t)^{-1}, \dots, \beta(1)(\beta(t)^{-1}), \beta(t)^{-1})$.

Remark II.2. *In the case of two quadratic transformations of* K_n *of "general position" their composition will have degree* 4*.*

We associate with the sequence $\alpha(1), \alpha(2), \dots, \alpha(t), \beta(1), \beta(2), \dots, \beta(t)$ of II.2 another quadratic transformation $h = H(\alpha(1), \alpha(2), \dots, \alpha(t), \beta(1), \beta(2), \dots, \beta(t))$ constructed via the sequence of vertices ${}^0v, {}^1v, {}^2v, \dots, {}^{2t-2}v = N_{\beta\times(t-1)}({}^{2t-3}v), {}^{2t-1}v = N_\alpha(t)({}^{2t-2}v)$. We compute ${}^{2t}v = J_{a(t)}({}^{2t-1}v) = v$ where $a(t) = (y_1)^2 + \beta(t)$ and define h as the quadratic map $y_i \to v_i$, $i = 1, 2, \dots, n$.

Theorem II.1. *(see [26], [11]) Let* K *be the finite field* F_q*,* $q = 2^r$*. Then transformation* $h = h(\alpha(1), \alpha(2), \dots, \alpha(t), \beta(1), \beta(2), \dots, \beta(t))$ *is a quadratic transformation of the vector space* $(F_q)^n$*. The polynomial degree of its inverse transformation is at least* 2^{r-1}*.*

Let us consider the linear projection $\tau : K_n + d \to K_n$ of deleting last d coordinates of the tuple.

The map $(p) \to (\tau(p)), [l] \to [\tau(l)]$ is an automorphism of the graph $\Gamma(n + d, K)$ onto $\Gamma(n, K)$. It induces the homomorphism θ of $S(\Gamma(n + d, K))$ onto $S(\Gamma(n, K))$ such that $\theta({}^2G(\Gamma(n + d, K)) = {}^2G(\Gamma(n, K))$.

Tame Homomorphism (TH) protocol (see [14]).

Alice selects ring K of kind F_q or Z_q where q is a prime power > 2 , parameters n and d, $d > 3$. She takes tuples of elements of K of kind $a(t_i) = ({}^i\alpha(1), {}^i\alpha(2), \dots, {}^i\alpha(t_i))$ and $b(t_i) = ({}^ib(1), {}^ib(2), \dots, {}^ib(t_i))$, $i = 1, 2, \dots, t$, $t \geq 2$ such that ${}^i\alpha(j) \neq {}^i\alpha(j + 1)$ and ${}^ib(j) \neq {}^ib(j + 1)$, $j = 1, 2, \dots, t_{i-1}$ together with affine transformation T from $AGL_{n+d}(F_q)$ and Y from $AGL_n(F_q)$.

Alice computes the standard forms of elements $a_i = T^{n+d}g({}^i\alpha(1), {}^i\alpha(2), \dots, {}^i\alpha(t_i), y_1 + {}^ib(1), y_1 + {}^ib(2), \dots y_1 + {}^ib(t_i))T^{-1}$ and $b_i = Y^n g({}^i\alpha(1), {}^i\alpha(2), \dots, {}^i\alpha(t_i), y_1 + {}^ib(1), y_1 + {}^ib(2), \dots y_1 + {}^ib(t_i))Y^{-1}$. She sends pairs (a_i, b_i), $i = 1, 2, \dots, t$ to Bob. Bob writes word $w(z_1, z_2, \dots, z_t)$ in formal alphabet $z_1, z_2, \dots, z_t$ of length at least t which uses each letter z_i. He computes the specialisations $w_A = w(a_1, a_2, \dots, a_t)$ and $c = w(a_1, a_2, \dots, a_t)$ in the groups of polynomial transformations of vector spaces $K^{n+d}$and K^n. Bob sends w_A to Alice and keeps c for himself. Alice computes $T^{-1}w_AT = {}^1c$, uses the homomorphism θ for getting $\theta({}^1c) = {}^2c$. She computes the collision map as Y^2cY^{-1}. Noteworthy that c is a quadratic map from the group of kind $y_1 \to c_1(y_1, y_2, \dots, y_n)$, $y_2 \to c_2(y_1, y_2, \dots, y_n)$,$\dots$, $y_n \to c_n(y_1, y_2, \dots, y_n)$.

Remark II.3. *Adversary has to decompose the standard form w_A into the word in the alphabet of generators $a_1, a_2, \dots, a_t$. Solution of this task in a polynomial time even with usage of Quantum Computer is unknown. So this is NP hard problem of Postquantum Cryptography.*

Remark II.4. *The complexity is determined by the complexity of computation of composition of two polynomial maps of degree 2 written in their standard forms. It is $O(n^7)$.*

Inverse TH protocol (see [14])

Alice selects the same data as in presented above protocol. She computes the standard forms of elements $a_i = T^{n+d}g({}^i\alpha(1), {}^i\alpha(2), \dots, {}^i\alpha(t_i), y_1 + {}^ib(1), y_1 + {}^ib(2), \dots y_1 + {}^ib(t_i))T^{-1}$. Instead of b_i Alice computes their inverses $c_i = b_i^{-1}$ and sends pairs (a_i, c_i) to Bob. He selects $j(1), j(2), \dots, j(r)$, $1 \le j(i) \le t$ and forms $w_A = a_{j(1)}a_{j(2)} \dots a_{j(r)}$ for Alice. Bob keeps $b = c_{j(r)}c_{j(r-1)}, \dots, c_{j(1)}$ for himself. Alice computes $T^{-1}w_AT = {}^1c$, uses the homomorphism θ for getting $\theta({}^1c) = {}^2c$. She computes the element a as Y^2cY^{-1}. It is easy to see that a and b are mutually inverse quadratic transformations of K^n.

Remark II.5. *Correspondents can use the protocol as a cryptosystem working with plaintexts from K_n. Alice can convert her message x to ciphertext $a(x) = y$. Bob decrypts y via the usage of his quadratic map b. After the usage of up to $[n^2/2]$ sessions they renovate their encryption/decryption tools via the new session of the inverse TH protocol.*

III. Cryptosystems with Quadratic Multivariate Rules

A. On the public key over F_q and its temporal form

Alice selects finite field F_q, $q = 2^r$, dimension n of the vector space over F_q, ${}^1T$ and ${}^2T$ from $AGL_n(F_q)$ defined by matrices with most entries distinct from zero.

She chooses parameter $t = O(n)$, elements $\alpha(1), \alpha(2), \dots, \alpha(t)$, $\beta(1), \beta(2), \dots, \beta(t)$ for which $\alpha(i) \ne \alpha(i)$, $\beta(i) \ne \beta(i+1)$, $i = 1, 2, \dots, n$ and compute the standard form of $F = {}^1Th(\alpha(1), \alpha(2), \dots, \alpha(t), \beta(1), \beta(2), \dots, \beta(t))^2T$. She presents F of kind $y_i \to f(y_1, y_2, \dots, y_n)$, $i = 1, 2, \dots, n$ as public map. Public user Bob use this transformation to encrypt his plaintext p in time $O(n^3)$. Alice knows the decomposition ${}^1Th^2T$ and sequences $\alpha(i)$ and $\beta(i)$, $i = 1, 2, \dots, t$. It allows her to decrypt in time $O(n^2)$.

Remark III.1. *II.1 insures that multivariate map ${}^1Th^2T$ has inverse of polynomial degree at least 2^{r-1}. So if $r \ge 16$ then the cryptosystem is resistant to a differential linearisation attacks. We implement the case with $r = 32$. We suggest this classical type multivariate public key as the object for standardisation studies.*

Remark III.2. ***Temporal** TH **public rule.** Alice creates bijective F according presented above method. Together with Bob she executes TH protocol to elaborate the collision map and sends C+F to his partner. So correspondents can use "public key rule" F in a private mode. The usage of F just $t(n) = [n^2/2]$ times for the message encryption or electronic signatures times does not allow adversary to make the restoration of F. After the exchange of $t(n)$ vectors correspondents can start the new session.*

B. On temporal multivariate public rules

Correspondents can execute the inverse TH protocol and get mutually inverse outputs a and b acting on the vector space. Alice generates the quadratic map F as it described in unit 3.1 with ${}^1T = Y$. She sends the composition Y of a and H to Bob. He restores F as bY. They can make $O(1)$ sessions of the inverse protocol and get several outputs ${}^1a, {}^2a, \dots, {}^sa$ and ${}^1b, {}^2b, \dots, {}^sb$. After that Alice or Bob can renovate their initial public key F via the following procedure. One of correspondents sends the the word $(i(1), i(2), \dots., i(t))$, $1 \le i(k) \le s$ to his/her partner. Bob uses $b^{i(t)}b^{i(t-1)} \dots b^{i(1)}F$ for the encryption. Alice gets $b^{i(t)}b^{i(t-1)} \dots b^{i(1)}F(p) = c$ from Bob. She computes $a^{i(1)}a^{i(2)} \dots a^{i(t)}(c) = d$ and solves the equation $F(x) = d$ with the usage of her knowledge on $\alpha(1), \alpha(2), \dots, \alpha(t), \beta(1), \beta(2), \dots, \beta(t))$ and affine transformations ${}^1T$ and ${}^2T$ of degree 1. Noteworthy that correspondents do not need to compute compositions of generators ${}^ia$ or ${}^ib$, they will apply them consecutively.

C. Modification with direct TH protocol

Correspondents can use s-times direct TH protocol with outputs ${}^1c, {}^2c, \dots, {}^sc$. Alice computes the standard form of kind $g_i = Yg(\alpha(1), \alpha(2), \dots, \alpha(t), \beta(1), \beta(2), \dots, \beta(t))Y^{-1}$, $i = 1, 2, \dots, s$ from $Y^2G(\Gamma(n, K)Y^{-1}$ and sends $c^i + g_i$ to Bob. Bob restores g_i in their standard forms. After the agreement on the word $(i(1), i(2), \dots, i(t))$, $1 \le i(k) \le s$ via open channel he encrypts with the consecutive usage of $g_{i(1)}, g_{i(2)}, \dots, g_{i(s)}$ and F. Recommended period of usage of words is $[n^2/2]$. It does not allow adversary to approximate the quadratic encryption transformation.

D. Remark on the implementation

We use computer simulation to generate maps of kind $y = \tau_1 h = h(\alpha(1), \alpha(2), \dots, \alpha(t), \beta(1), \beta(2), \dots, \beta(t))\tau_2(x)$

related to graphs $A(n, K)$ and $D(n, K)$. K is one of the commutative rings: Boolean ring $B(32)$, modular ring Z_2^{32} and finite field F_2^{32}. We have implemented three cases of invertible affine transformations. Tables and figures presenting simulation in all cases for F_2^{32} can be found in extended reprint version of this paper. The third case is presented in the following table.

1) τ_1 and τ_2 are identities, its just evaluation of time execution of core quadratic transformation,
2) τ_1 and τ_2 are of kind $x_1 \to x_1 + a_2x_2 + a_3x_3 + \cdots + a_nx_n$ (linear time of computing execution of τ_1 and τ_2),
3) $\tau_1 = A_1x + b_1$ and $\tau_2 = A_2x + b_2$, nonsingular matrices A_1, A_2 have nonzero entries and vectors b_1, b_2 with mostly all coordinates differ from zero standard forms of the maps in the cases 2 and 3.

The program is written in C++ and compiled with the gcc compiler. We used an average PC with processor Pentium 3.00 GHz, 2GB memory RAM and system Windows 7. Table I present the time of encryption with symmetric algorithm for commutative ring $F_{2^{32}}$.

IV. Trees of infinite forest $D(F_q)$ and obfuscations of quadratic multivariate rules

We suggest modification quadratic $D(n, K)$ transformations presented before which is based on the descriptions of the connected components of these graphs. The description uses the following alternative definition of them.

The family of graphs $D(n, K)$, $n = 2, 3, \ldots$ where K is arbitrary commutative ring defines the projective limit $D(K)$ with points

$$\begin{aligned}(p) = (&p_{10}, p_{11}, p_{12}, p_{21}, p_{22}, p'_{22}, \ldots,\\ &p'_{ii}, p_{i,i+1}, p_{i+1,i}, p_{i+1,i+1}, \ldots),\end{aligned} \tag{3}$$

and lines

$$\begin{aligned}[l] = [&l_{01}, l_{11}, l_{12}, l_{21}, l_{22}, l'_{22}, \ldots,\\ &l'_{ii}, l_{ii+1}, l_{i+1,i}, l_{i+1,i+1}, \ldots].\end{aligned} \tag{4}$$

which can be thought as infinite sequences of elements in K such that only finitely many components are nonzero.

A point (p) of this incidence structure I is incident with a line $[l]$, i.e. $(p)I[l]$, if their coordinates obey the following relations:

$$\begin{aligned} p_{i,i} - l_{i,i} &= p_{1,0}l_{i-1,i},\\ p'_{i,i} - l'_{i,i} &= p_{i,i-1}l_{0,1},\\ p_{i,i+1} - l_{i,i+1} &= p_{i,i}l_{0,1},\\ p_{i+1,i} - l_{i+1,i} &= p_{1,0}l'_{i,i}, \end{aligned} \tag{5}$$

These four relations are well defined for $i > 1$, $p_{1,1} = p'_{1,1}$, $l_{1,1} = l'_{1,1}$.

Let D be the list of indices of the point of the graph $D(K)$ written in their natural order, i. e. sequence $(1, 0), (1, 1), (1, 2), (2, 1), (2, 2), (2, 2)' \ldots$. Let ${}^kD$ be the list of k first elements of D. The procedure of deleting coordinates of points and lines of $D(k, K)$ indexed by elements of $D - {}^kD$ defines the homomorphism of $D(K)$ onto graph $D(k, K)$ with the partition sets isomorphic to the variety K^n and defined by the first $k - 1$ equations from the list (5).

Let $k \geq 6$, $t = [(k + 2)/4]$, and let $u = (u_i, u_{11}, \ldots, u_{tt}, u'_{tt}, u_{t,t+1}, u_{t+1,t}, \ldots)$ be a vertex of $D(k, K)$. We assume that $u_1 = u_{1,0}$ $(u_{0,1})$ if u be a point (a line, respectively). It does not matter whether u is a point or a line. For every r, $2 \leq r \leq t$, let $a_r = a_r(u) = \Sigma_{i=0,r}(u_{ii}u'_{r-i,r-i} - u_{i,i+1}u_{r-i,r-i-1})$ and $a = a(u) = (a_2, a_3, \ldots, a_t)$.

The following statement was proved in [17] for the case $K = F_q$. Its generalization on arbitrary commutative rings is straightforward, see [18].

Proposition IV.1. *Let K be a commutative ring with unity and u and v be vertices from the same connected component of $D(k, K)$. Then $a(u) = a(v)$. Moreover, for any $t - 1$ ring elements $x_i \in K$, $2 \leq i \leq \lfloor (k + 2)/4 \rfloor = t$, there exists a vertex v of $D(k, K)$ for which $a(v) = (x_2, x_3, \ldots, x_t) = (x)$.*

So the classes of equivalence for the relation $\tau = \{(u, v) \mid a(u) = a(v)\}$ on the vertices of the graph $D(n, K)$ are unions of connected components.

Theorem IV.1. *[18] For each commutative ring with unity, the graph $D(k, K)$ is edge transitive.*

Equivalences classes of τ form an imprimitivity systems of automorphism group of $D(k, K)$. Graph $C(n, K)$ was introduced in [9] as the restriction of incidence relation of $D(k, K)$ on a solution set of system of homogeneous equations $a_2(x) = 0$, $a_3(x) = 0$, $\ldots$, $a_t(x) = 0$. The dimension of this algebraic variety is $n - t = d$. Thus $d = [4/3n] + 1$ for $n = 0, 2, 3$ mod 4, $d = [4/3n] + 2$ for $n = 1$ mod 4. For convenience we assume that $C(n, K) = C_d(K)$. Symbol $CD(k, K)$ stands for the connected component of graph $D(k, K)$. The following statement holds.

Theorem IV.2. *(see [11] and further references).*

The diameter of the graph $C_m(K)$, $m \geq 2$, K is a commutative ring with unity of odd characteristic, is bounded by parameter $f(m)$ which does not depend on K.

Corollary IV.1. *If K is a commutative ring with unity of odd characteristics then $CD(n, K) = C(n, K)$.*

Let us rename coordinates $y_{1,0}, y_{1,1}, y_{1,2}, y_{2,1}, \ldots$ of symbolic line y of $D(n, K)$ accordingly to the natural order on them as $y_1, y_2, \ldots, y_n$ and write equations of the graph in the form 5. It allows as to write connectivity invariants of the line $y = [y_1, y_2, \ldots, y_n]$ as $a_i([y]) = a_i(y_1, y_2, \ldots, y_n)$ where $i = 2, 3, \ldots, t$. Similar notations we will use in the case of points. For the nonlinear map F of K^n with bounded degree given in its standard form we define trapdoor accelerator $F = {}^1TG_A{}^2T$ as the triple ${}^1T$, ${}^2T$, G_A of transformations of K^n, where ${}^iT$, $i = 1, 2$ are elements of $AGL_n(K)$, $G = G_A$ is nonlinear map on K^n depending on the piece of information A which allows to compute the reimage for nonlinear G in time $O(n^2)$ (see [20]). In this paper we assume that A is

TABLE I
Generation time for the map (ms) $D(n, F_{2^{32}})$,length of the word, case III

n	**16**	**32**	**64**	**128**	**256**
16	71	136	263	518	1030
32	1220	2324	4535	8962	17824
64	21884	40412	77476	151587	299839

given as a tuple of characters $(d(1), d(2), \ldots, d(m))$ in the alphabet K.

We use graphs $D(n, K)$ and $D(n, K[y_1, y_2, \ldots, y_n])$ to define family of quadratic multivariate maps F of kind $y_1 \to f_1(y_1, y_2, \ldots, y_n)$, $y_2 \to f_2(y_1, y_2, \ldots, y_n)$, $\ldots$, $y_n \to f_n(y_1, y_2, \ldots, y_n)$ with trapdoor accelerator $F = T_1 G_A T_2$, $T_1, T_2 \in AGL_n(K)$.

We take the line $[y_1, y_2, \ldots, y_n]$ of the graph $D(n, K[y_1, y_2, \ldots, y_n]$ for the colour α_1 from K we compute $[z] = J_{\alpha_1}([y]) = [\alpha_1 y_1, y_2, \ldots, y_n] = [z_1, z_2, \ldots, z_n]$ and compute $a_r = a_r([z]) = a_r(\alpha_1, y_2, \ldots, y_n)$, for $r = 2, 3, \ldots$. We form the quadratic expression $B = (y_1^s + C(y_2, y_3, \ldots, y_n)$ where $C(y_2, y_3, \ldots, y_n) = \lambda_2 a_2 + \lambda_3 a_3 + \cdots + \lambda_t a_t + \lambda_1$ with nonzero λ_i from K and $s = 2$ if the order of K^* is odd and $s = 1$ in all other cases. We form the walk in the graph $D(n, K[y_1, y_2, \ldots, y_n])$ starting from the line $[z]$ of colour α_1 and consecutive vertices of colours $y_1 + \beta_1, \alpha_2, y_1 + \beta_1, \alpha_3, \ldots, \alpha_{l-1}, y_1 + \beta l - 1, \alpha_l$ such that $\alpha_i \neq \alpha_{i+1}$, $\beta_i \neq \beta_{i+1}$ for $i = 1, 2, \ldots, l-1$.

We form the path with the starting line $v_1 = J_{\alpha_1}([y])$, $v_2 = N_{y_1+\beta_1}(v_1)$, $v_3 = N_{\alpha_2}(v_2)$, $\ldots$, $v_{2t-1} = N_{\alpha_t}(v_{2t-2}$ and consider $v_t = J_B(v_{2t-1}) = u$. The vertex u allows us to define the following transformation $G = G_A$, $A = (\alpha_1, \alpha_2, \ldots, \alpha_l; \beta_1, \beta_2, \ldots, \beta_{l-1}, B(y_1, y_2, \ldots, y_n))$ of K^n to itself

$y_1 \to (y_1)^s + C(y_1), y_2, \ldots, y_n)$,
$y_2 \to u_2(y_1, y_2)$,
$\ldots$
$y_n \to u_2(y_1, y_2, \ldots, y_n)$.

We identify $A = {}^1A$ with the array $(\alpha_1, \alpha_2, \ldots, \alpha_l; \beta_1, \beta_2, \ldots, \beta_{l-1}, \lambda_1, \lambda_2, \lambda_r, B(y_1, y_2, \ldots, y_n))$

Proposition IV.2. *Let T_1 and T_2 are bijective transformations from $AGL_n(K)$ and K is arbitrary commutative ring with unity. Then the standard form of $F = T_1 G_{l^A} T_2$, $l = O(n)$ has a trapdoor accelerator given by coefficients of T_1 and T_2 together with the array A described above.*

Proof. We have to justify that the reimage x of $v = G_A(x)$ can be computed in time $O(n^2)$. The procedure of its computation is the following:

1) Let the value v of G_A is given. We have to compute the connectivity invariants $a_2(u)$, $a_3(u)$, $\ldots$, $a_r(u)$ of the line $u = [\alpha_l, v_2, v_3, \ldots, v_n]$.
2) The computation of linear combination $b = \lambda_2 a_2(u) + \lambda_3 a_3(u) + \cdots + \lambda_r a_r(u) + \lambda_1$.
3) The computation of the solution $y_1 = c$ of the equation ${y_1}^2 + b = v_1$.
4) We form the parameters $d_1 = c + \beta_{l-1}$, $d_2 = \alpha_{l-1}$, $d_3 = c + \beta_{l-2}$, $d_4 = \alpha_{l-2}$, $\ldots$, $d_{2l-2} = \alpha_1$, of "reverse path" with the starting line $[u]$.
5) Conducting recurrent computations $N_{d_1}(u) = {}^1u$, $N_{d_2}({}^2u)$, $\ldots$, , $N_{d_{2l-1}}({}^{2l-2}u)$.
6) Computing of the reimage $J_c({}^{2l-2}u)$. The complexity of the algorithm is $O(n^2)$. So the map has a trapdoor accelerator.

The standard forms of transformations $F = T_1 G_A T_2$ can be used as a public keys. In fact this family is an obfuscation of quadratic multivariate public keys suggested in [15].

The idea of $D(n, K)$ based encryption with the usage of connectivity invariants was suggested in [16].

□

V. Conclusion

Multivariate Cryptography in wide sense is about constructions and investigations of Public Keys in a form of nonlinear Multivariate rule defined over some finite commutative ring K. These rule F has to be written as transformation $x_i \to f_i$, $i = 1, 2, \ldots, n$, $f_i \in K[x_1, x_2, \ldots, x_n]$ over commutative ring K. Bijective F can be used for the encryption of tuples (plaintexts) from the affine space K^n. Multivariate rules can serve as instruments for creation of digital signatures. In the case of bijective transformation decryption process can be thought as application of inverse rule G. The degree of G can be defined as maximum of degrees of polynomials $G(x_i)$, $i = 1, 2, \ldots, n$. For the usage of given publicly F as efficient and secure instrument its degree of has to be bounded by some constant c (traditionally $c = 2$) but the polynomial degree of the inverse G has to be high.

The key owner (Alice) suppose to have some additional piece T of private information about pair (F, G) to decrypt ciphertext obtained from the public user (Bob). Recall that family the family F_n, $n = 2, 3, \ldots$ has trapdoor accelerator ${}^nT$ if the knowledge of the piece of information ${}^nT$ allows to compute reimage x of $y = F_n(x)$ in time $O(n^2)$. Of course the concept of trapdoor accelerator is just instrument to search for practical trapdoor functions. As you know that the existence of theoretical trapdoor functions is just a conjecture. In fact it is closely connected to Main Conjecture of Cryptography about the fact that $P \neq NP$. Without the knowledge of T_n one has to solve nonlinear system of equations which generally is NP-hard problem. Finding of the inverse for F_n is an NP-hard problem if these maps are in so called "general position".

In the case of specific maps additional argumentation of the complexity to find inverses G_n can be useful.

We present such heuristic arguments in the case of $D(n,K)$ based encryption defined for arbitrary commutative ring K with unity with at least 3 elements and presented in previous section. Graphs $D(n,K)$ have partition sets K^n (set of points and set of lines) and incidence relation between points and lines is given by system of linear equations over K.

To define trapdoor accelerator for standard forms F_n, $n = 2, 3, \ldots$ we use special walks on graphs $(D(n,K)$ and and $D(n, K[x_1, x_2, \ldots, x_n])$.The constructed map F_n acts on the selected partition set K^n. In the case of trivial affine transformations T_1 and T_2 the relation $F_n(x) = y$ for $x = (x_1, x_2, \ldots, x_n)$ and $y = (y_1, y_2, \ldots, y_n)$ vertices x and $y = (f(y_1, y_2, \ldots, y_n), y_2, y_3, \ldots, y_n)$ are joint in the graph $D(n,K)$ by the path of length $> cn$, where c is positive constant and $f \in K[y_1, y_2, \ldots, y_n]$ is known quadratic expression. Finding the path will give us the trapdoor accelerator for the computation of preimages. This can be done by Dijkstra algorithm of complexity $v \log(v)$ where v is the order of graphs. It could not be done in polynomial time because of $v = 2|K|^n$ and $|K| \geq 3$. Noteworthy that the usage of nontrivial T_1 and T_2 will complicate the cryptanalysis.

We presented $D(n,K)$ based platform $H(n,K)$ of quadratic transformations. So correspondents Alice and Bob can use $H(n,K)$ protocols and elaborate collision map C, $C \in H(n,K)$. So Alice can create F_n and send $C + F_n$ to Bob instead of public announcement of this multivariate transformation. It gives the option to change the encryption tool periodically.

Alternatively Alice and Bob use the inverse $H(n,K)$ protocol to elaborate mutually inverse elements H and H^{-1} in their possessions. So Bob can change the rule F_n for the quadratic $H^{-1}F_n$ via left multiplication. These actions form a basis for algorithms with temporal public rules presented in the paper.

***Abstract*—Algebraic Constructions of Extremal Graph Theory were efficiently used for the construction of Low Density Parity Check Codes for satellite communication, constructions of stream ciphers and Postquantum Protocols of Noncommutative cryptography and corresponding El Gamal type cryptosystems. We shortly observe some results in these applications and present idea of the usage of algebraic graphs for the development of Multivariate Public Keys (MPK). Some MPK schemes are presented at theoretical level, implementation of one of them is discussed. Extended version of this article is available online at [31].**

I. Introduction

EXTREMAL algebraic graphs were traditionally used for the construction of stream ciphers of multivariate nature (see [19], [8] and further references). We introduce the first graph based multivariate public keys with bijective encryption maps. We hope that new recent results on algebraic constructions of Extremal Graph Theory [16] will lead to many applications in Algebraic Cryptography which includes Multivariate cryptography and Noncommutative Cryptography. Some graph based algebraic asymmetrical algorithms will be presented in this paper.

NIST 2017 tender starts the standardisation process of possible Post-Quantum Public keys aimed for purposes to be (i) encryption tools, (ii) tools for digital signatures (see [28]).

In July 2020 the Third Round of the competition started. In the category of Multivariate Cryptography (MC) remaining candidates are easy to observe. For the task (i) multivariate algorithm was not selected, single multivariate candidate is ”The Rainbow Like Unbalanced Oil and Vinegar” (RUOV) digital signature method. As you see RUOV algorithm is investigated as appropriate instrument for the task (ii). During Third Round some cryptanalytic instruments to deal with ROUV were found (see [20] and further references]). That is why different algorithms were chosen at the final stage. In July 2022 first four winners of NIST standardisation competition were chosen. They all are lattice based algorithms. They all are not the algorithms of Multivariate Cryptography.

Noteworthy that all considered multivariate NIST candidates were presented by multivariate rule of degree bounded by constant (2 or 3) of kind

$x_1 \to f_1(x_1, x_2, \ldots, x_n)$,
$x_2 \to f_2(x_1, x_2, \ldots, x_n)$,
. . .,
$x_n \to f_n(x_1, x_2, \ldots, x_n)$.

Classical results of Multivariate Cryptography can find in [25], [26] and [27].

We think that NIST outcomes motivate investigations of alternative options in Multivariate Cryptography oriented on encryption tools for

(a) the work with the space of plaintexts ${F_q}^n$ and its transformation G of linear degree cn, $c > 0$ on the level of stream ciphers or public keys

(b) the usage of protocols of Noncommutative Cryptography with platforms of multivariate transformations for the secure elaboration of multivariate map G from $End(F_q[x_1, x_2, \ldots, x_n])$ of linear or superlinear degree and density bounded below by function of kind cn^r, where $c > 0$ and $r > 1$.

Some ideas in directions of (a) and (b) are presented in [17].

We hope that classical multivariate public key approach i. e. usage of multivariate rules of degree 2 or 3 is still able to bring reliable encryption algorithms. In this paper we suggest new cubic multivariate public rules.

Recall that the density is the number of all monomial terms in a standard form $x_i \to g_i(x_1, x_2, \ldots, x_n)$, $i = 1, 2, \ldots, n$ of multivariate map G, where polynomials g_i are given via the lists of monomial terms in the lexicographical order.

We use the known family of graphs $D(n, q)$ and $A(n.q)$ of increasing girth (see [1]-[6] and further references) and their analogs $D(n, K)$ and $A(n, K)$ defined over finite commutative ring K with unity for the construction of our public keys. Noteworthy to mention that for each prime power q, $q > 2$ graphs $D(n, q)$, $n = 2, 3, \ldots$ form a family of large girth (see [1]), there is well defined projective limit of these graphs which is a q-regular forest. in fact if K is an integral domain both families $A(n, K)$ and $D(n, K)$ are approximations of infinitedimensional algebraic forests. The definitions of such

This research is partially supported by British Academy Fellowship for Researchers at Risk 2022 and by UMCS program UMCS Mini-Grants.

approximations are given in Section 3 together with short survey of their applications.

In Section 2 we present the known mathematical definitions of algebraic geometry for further usage of them as instruments of Multivariate Cryptography. In particular definition of affine Cremona semigroup of endomorphisms of multivariate ring $K[x_1, x_2, \ldots, x_n]$ defined over commutative ring K and affine Cremona group ${}^nCG(K)$ are presented there.

The concept of *trapdoor accelerator* of the transformation from affine Cremona semigroup ${}^nCS(K)$ is presented there as a piece of information which allows computation of reimage of the map in time $O(n^2)$.

This is a weaker version of the definition of trapdoor one way function. The definition of the trapdoor accelerator is independent from the conjecture $P \neq NP$ of the Complexity theory. Section 2 also contains some statements on the existence of the trapdoor accelerator with the restrictions on the degrees on maps and their inverses for families of elements of the affine Cremona group ${}^nCG(K)$.

Section 3 is dedicated to infinite forests approximations and their connections with Algebraic Geometry and Extremal Graph Theory.

The description of linguistic graphs $D(n, K)$ and $A(n, K)$ and some their properties are presented in Section 4, 5. These sections contain the descriptions of subgroups and subsemigroups of ${}^nCS(K)$ defined via walks in graphs $D(n, K)$ and their extensions $D(n, K[x_1, x_2, \ldots, x_n])$ and graphs $A(n, K)$ and $A(n, K[x_1, x_2, \ldots, x_n])$ respectively. Some statements about degrees of elements of these semigroups are given.

Section 6 contains examples of cryptographic applications of graph based trapdoor accelerators in the form of cubic multivariate public key.

Detailed description of multivariate public key related to one of presented families is presented in in the Section 7.

Remarks on security level connected with girth studies of tree approximations reader can find in section 8. Last Section 9 presents short conclusions.

II. On elements of Algebraic Geometry and trapdoor accelerators

Let K be a commutative ring with a unity. We consider the ring $K' = K[x_1,$ $x_2, \ldots, x_n]$ of multivariate polynomials over K. Endomorphisms δ of K' can be given via the values of $\delta(x_i) = f_i(x_1, x_2, \ldots, x_n)$, $f_i \in K'$. They form the semigroup $End(K[x_1, x_2, \ldots, x_n]) = {}^nCS(K)$ of K' known also as affine Cremona semigroup named after the famous Luigi Cremona (see [29]). The map $\tilde{\delta} : (x_1, x_2, \ldots, x_n) \to (f_1(x_1, x_2, \ldots, x_n), f_2(x_1, x_2, \ldots, x_n), \ldots, f_n(x_1, x_2, \ldots, x_n))$ is polynomial transformation of affine space K^n. These transformations generate transformation semigroup $CS(K^n)$. Note that the kernel of homomorphism of ${}^nCS(K)$ to $CS(K^n)$ sending δ to $\tilde{\delta}$ depends on the choice of commutative ring K.

Affine Cremona Group ${}^nCG(K) = Aut(K[x_1, x_2, \ldots, x_n])$ acts bijectively on K^n. Noteworthy that some elements of ${}^nCS(K)$ can act bijectively on K^n but do not belong to ${}^nCG(K)$. For instance endomorphism $x \to x^3$ of $R[x]$ acts bijectively on set R of real number but the inverse $x \to x^{1/3}$ of this map is birational element outside of ${}^1CG(R)$.

Recall that degree of δ is the maximal degree of polynomials $\delta(x_i)$, $i = 1, 2, \ldots, n$. The density of δ is a total number of monomial terms in all $\delta(x_i)$.

Assume that automorphism F from ${}^nCG(K)$ has constant degree d, $d \geq 2$. It is given in its standard form written as $x_1 \to f_1(x_1, x_2, \ldots, x_n)$, $x_2 \to f_2(x_1, x_2, \ldots, x_n)$, …, $x_n \to f_n(x_1, x_2, \ldots, x_n)$ where f_i, $i = 1, 2, \ldots, n$ are elements of $K[x_1, x_2, \ldots, x_n]$ and used as public rule to encrypt plaintexts from K^n.

The following definition was motivated by the idea to have a weaker version of trapdoor one way function.

We say that family $F_n \in^n CG(K)$ of bijective nonlinear polynomial transformations of affine space K^n of degree ≤ 3 has *trapdoor accelerator* ${}^nT$ of level $\geq d$ if

(i) the knowledge of piece information ${}^nT$ ("trapdoor accelerator") allows to compute the reimage x for F_n in time $O(n^2)$

(ii) the degree of ${F_n}^{-1}$ is at least d, $d \geq 3$.

Notice that if F_n are given by their standard forms and degrees of ${F_n}^{-1}$ are equal to d then the inverse can be approximated in polynomial time $f(n, d) = O(n^{d^2+1})$ via linearisation technique. One can see that the approximation task becomes unfeasible if d is "sufficiently large" like $d = 100$. Examples of cubic families F_n with trapdoor accelerator of high level t are given in the case of special finite fields F_q in the section 3.

III. On algebraic forest approximations and their applications

We define thick forest as simple graph without cycles such that each of its vertex has degree at least 3. In probability theory branching process is a special stochastic process corresponding to a random walk on a thick forest. A genealogy of single vertex is a tree. One of the basic properties of finite tree is the existence of a leaf, i. e. vertex of degree 1. Thus each thick tree is an infinite simple graph.

Let K be a commutative ring and K^n be an affine space of dimension n over K (free module in other terminology). A subset M in K^n is an algebraic set over K if it is a solution set for the system of algebraic equations of kind $f = 0$ or inequalities of kind $g \neq 0$ where f and g are elements of $K[x_1, x_2, \ldots, x_n]$. There are several alternative approaches to define dimension of M. In the case when K is a field these approaches are equivalent and dimension of M can be computed with the usage of Groőbner basis technique (see [21], [22], [23]).

We say that graph Γ is algebraic over K if its vertex and edge sets are algebraic sets over K

We investigate a possibility to define thick forest F by system of equations over some commutative ring K, i.e. construct F as a projective limit of algebraic over K bipartite graphs Γ_i, $i = 1, 2, \ldots$. Noteworthy that the girth $g_i = g(\Gamma_i)$, which is the length of minimal cycle in Γ_i tends to infinity when i is growing. In this situation we refer to F as algebraic forest over K.

We say that the family Γ_i is an algebraic forest approximation over the ring K. In the case $g_i \geq cn_i$, where n_i are dimensions of the algebraic sets $V(\Gamma_i)$ of vertices of the graph Γ_i and c is some positive constant we use term *algebraic forest approximation of large girth.* Note that algebraic forest approximations of large girth over finite field F_q, $q > 2$ are *families of graphs of large girth* in sense of P. Erdős'(see [15] and further references). The first algebraic forest approximation of a large girth was introduced by F. Lazebnik and V. Ustimenko (see [1], [2]) in the case of $K = F_q$.

The properties of trees of this algebraic forest and their approximations over F_q were investigated in the paper[30].

In 1998 more general algebraic graphs $D(n, K)$ defined over arbitrary commutative ring K were introduced [4]. It was stated that a girth of $D(n, K)$ is $\geq n+5$ in the case of arbitrary integrity domain K. This inequality insures that $D(n, K)$, $n = 2, 3, \ldots$ is algebraic forest approximation of large girth. The prove of the inequality reader can find in [5], simpler prove of this fact the reader can find in [18].

Noteworthy that in the case of integrity domain K together with $D(n, K)$, $n = 2, 3, \ldots$ one can consider another thick forest approximation $D(n, K[x_1,$
$x_2, \ldots, x_m])$ for each parameter m. Thus paper [5] opened a possibility to use extremal properties of these graphs in the Theory of Symbolic Computations and its various applications to Cryptography.

The paths of even length t on trees and their approximations can be used to induce multivariate transformations on varieties P_i and L_i of points and lines of $V(\Gamma_i)$. These transformations can serve as encryption maps acting on the potentially infinite space P_i of plaintexts (see [7], [19], [8] and further references). They form a group $G_i = G(\Gamma_i)$ which can be a platform for the protocols of Noncommutative Cryptography (see [9]-[14]). Noteworthy that if t is at most half of the girth of Γ_i then different paths produce distinct transformations. So, forest approximations of large girth are preferable for cryptographic applications.

Other tree approximation over the integrity domain K is formed by graphs $A(n, K)$ defined in [6]. In fact these graphs were defined earlier [5] as homomorphic images $E(n, K)$ of graphs $D(n, K)$ or their connected components $CD(n, K)$. As it was stated recently in short paper [24] for each integrity domain K, $K \neq F_2$ graphs $A(n, K)$ form a tree approximation of large girth.

Some encryption algorithms (stream ciphers) based on $A(n, K)$ and $D(n, K)$ were already introduced (see [7], [19], [8], [16]).

IV. On Linguistic Graphs $A(n, K)$, Related Semigroups and Groups and Symmetric Ciphers

Regular algebraic graph $A(n, q) = A(n, F_q)$ is an important object of Extremal Graph Theory. In fact we can consider more general graphs $A(n, K)$ defined over arbitrary commutative ring K.

This graph is a bipartite graph with the point set $P = K^n$ and line set $L = K^n$ (two copies of Cartesian power of K are used). It is convenient to use brackets and parenthesis to distinguish tuples from P and L.

So, (p) $= (p_1, p_2, \ldots, p_n) \in P_n)$ and [l] $= [l_1, l_2, \ldots, l_n] \in L_n$. The incidence relation $I = A(n, K)$ (or corresponding bipartite graph I) is given by the following condition.

pIl if and only if the equations

$p_2 - l_2 = l_1 p_1, p_3 - l_3 = p_1 l_2, p_4 - l_4 = l_1 p_3, p_5 - l_5 = p_1 l_4,$ $\ldots$, $p_n - l_n = p_1 ln - 1$ hold for odd n and $p_n - l_n = l_1 p_{n-1}$ for even n.

In the case of $K = F_q$, $q > 2$ of odd characteristic graphs $A(n, F_q)$, $n > 1$ form a family of small world graphs because their diameter is bounded by linear function in variable n (see [6]).

Recall that the girth of the graph is the length of its minimal cycle. We can consider an infinite bipartite graph $A(K)$ with points $(p_1, p_2, \ldots, p_n, \ldots)$ and lines $[l_1, l_2, \ldots, l_n, \ldots]$ which is a projective limit of graphs $A(n, K)$ when n tends to infinity. If K, $|K| > 2$ is an integrity domain then $A(K)$ is a tree and the girth g_n of $A(n, K)$, $n = 2, 3, \ldots$ is bounded below by linear function cn for some positive constant c [24].

As a byproduct of this result we get that $A(n, q)$, $n = 2, 3, \ldots$ for each fixed q, $q > 2$ form a family of large girth in sense of Erdős'. In fact graphs $A(n, K)$ were obtained in [5] as homomorphism images of known graphs $CD(n, K)$ of large girth (see [1], [2], [3]).

Let K be a commutative ring with a unity. Graphs $A(n, K)$ belong to the class of linguitic graphs of type $(1, 1, n - 1)$ [19], i.e. bipartite graphs with partition sets $P = K^n$ (points of kind $(x_1, x_2, \ldots, x_n)$, $x_i \in K$) and $L = K^n$ (lines $[l_1, l_2, \ldots, l_n]$, $l_i \in K$) and incidence relation $I = I(n, K)$ such that $(x_1, x_2, \ldots, x_n)I[y_1, y_2, \ldots, y_n]$ if and only if $a_2 x_2 + b_2 x_2 = f_2(x_1, y_1)$, $a_3 x_3 + b_3 x_3 = f_3(x_1, x_2, y_1, y_2)$, $\ldots$, $a_n x_n + b_n x_n = f_n(x_1, x_2, \ldots, x_n)$, where a_i and b_i are elements of multiplicative group K^* of K and f_i are multivariate polynomials from $K[x_1, x_2, \ldots, x_{i-1}, y_1, y_2, \ldots, y_{i-1}]$ for $i = 2, 3, \ldots, n$.

The colour of $\rho(v)$ of vertex v of graph $I(K)$ is defined as x_1 for point $(x_1, x_2, \ldots, x_n)$ and y_1 for line $[y_1, y_2, \ldots, y_n]$.

The definition of linguistic graph insures that there is a unique neighbour with the chosen colour for each vertex of the graph. Thus we define operator $u = N_a(v)$ of taking neighbour u with colour a of the vertex v of the graph. Additionally we consider operator ${}^aC(v)$ of changing colour of vertex v, which moves point $(x_1, x_2, \ldots, x_n)$ to point $(a, x_2, x_3, \ldots, x_n)$ and line $[x_1, x_2, \ldots, x_n]$ to line $[a, x_2, x_3, \ldots, x_n]$.

Let us consider a walk $v, v_1, v_2, \ldots, v_{2s}$ of even length $2s$ in the linguistic graph $I(K)$. The information on the walk is given by v and the sequence of colours $\rho(v_i)$, $i = 1, 2, \dots, 2s$. The walk will not have edge repetitions if $\rho(v_2) \neq \rho(v)$, $\rho(v_i) \neq \rho(v_{i-2})$ for $i = 3, 4, \dots, n$. Notice that v and v_{2s} are elements of the same partition set (P or L). For each vertex v of $I(K)$ we consider a variety of *walks* with jumps, i. e. totality of sequences of kind v, $v_1 = {}^{a_1}C(v)$, $v_2 = N_{a_2}(v_1)$, $v_3 = {}^{a_3}C(v_2)$, $v_4 = N_{a_4}(v_3)$, …, $v_5 = {}^{a_5}C(v_4)$, …, $v_{4s} = N_{a_{4s}}(v_{4s-1})$, $v_{4s+1} = {}^{a_{4s+1}}C(v_{4s})$. Note that for each s , $s \geq 0$ vertices v, v_1, v_{4s}, v_{4s+1} are elements of the same partition. Let $u = (a_1, a_2, \dots, a_{4s}, a_{4s+1})$ be the colours of the walk with jumps.

We introduce the following polynomial transformations of partition sets P and L. Firstly we consider the pair of linguistic graphs $I(K)$ and $I(K[x_1,$
$x_2, \dots, x_n])$. These graphs are defined by the same equations with coefficients from the commutative ring K. We look at sequences of walks with jumps of length $4s+1$ where $s \geq 0$ starting in the point $v = (x_1, x_2, \dots, x_n)$ (or line $[x_1, x_2, \dots, x_n]$) of the graph $K[x_1, x_2, \dots, x_n]$ which uses colors $a_1(x_1)$, $a_2(x_1)$, …, $a_{4s+1}(x_1)$ from $K[x_1]$. The final vertex of this walk is v_{4s+1} with coordinates $a_{4s+1}(x_1)$, $f_2(x_1, x_2)$, $f_3(x_1, x_2, x_3)$, …, $f_n(x_1, x_2, \dots, x_n)$). Let us consider the transformations ${}^uT_P$ and ${}^uT_L$ sending starting vertex to the destination point of the walk with jumps acting via the rule $x_1 \to a_{4s+1}(x_1)$, $x_2 \to f_2(x_1, x_2)$, …, $x_n \to f_n(x_1, x_2, \dots, x_n)$ on the partition sets P and L isomorphic to K^n. It is easy to see that transformations of kind ${}^uT_P$ (or ${}^uT_L$) form the semigroup $LS_P(I(K))$ ($LS_L(I(K))$ respectively). We refer to this transformation semigroup as *linguistic semigroup* of graph $I(K)$.

Let us consider an algebraic formalism for the introduction of linguistic semigroups. We take the totality of words $F(K[x])$ in the alphabet $K[x]$ and define the product of $u = (a_1(x), a_2(x), \dots, a_k(x))$ and $w = (b_1(x), b_2(x), \dots, b_s(x))$ as word $= (a_1(x)$, $a_2(x)$, …, $a_k(x)) \times (b_1(x)$, $b_2(x)$, …, $b_t(x)) = (a_1(x)$, $a_2(x)$, …, $a_{k-1}(x)$, $b_1(a_k(x))$, $b_2(a_k(x))$, …, $b_t(a(x)))$.

Obtained semigroup $F(K[x])$ is slightly modified free product of $End(K[x])$ with itself. Note that we can identify $a(x)$ from $K[x]$ with the map $x \to a(x)$ from $End(K[x])$.

Let F_K be a subsemigroup of words of length of kind $4s+1$, $s \geq 0$.

PROPOSITION 1.

Let $I(K)$ be a linguistic graph defined over commutative ring K with unity. The map ${}^{I(K)}\eta_P : F_K \to End(K[x_1, x_2, \dots, x_n])$ such that ${}^{I(K)}\eta(u) ={}^u T_P$ (or $\eta(u)_L ={}^u T_L$) is a semigroup homomorphism.

It is easy to see that ${}^{I(K)}\eta_P(F_K) = LS_P(I(K)$ and ${}^{I(K)}\eta_L(F_K) = LS_L(I(K)$.

PROPOSITION 2. (see [19] and further references)

The image of $u = (a_1(x), a_2(x), \dots, a_k(x))$ from F_K under the map ${}^I(K)\eta_P$ (or ${}^I(K)\eta_P$ is invertible element of $LS_P(I(K)$ (or $LS_L(I(K)$ if and only if the map $x \to a_k(x)$ is an element of $\mathrm{Aut}(K[x])$.

REMARK 1.

The transformations $({}^{I(K)}\eta_P(u), P)$ and $({}^{I(K)}\eta_L(u), L)$ are bijective if and only if the map $x \to b(x)$ is bijective.

ILLUSTRATIVE EXAMPLE.

Let $K = R$ (real numbers) or K be algebraically closed field of characteristic 0 and $b(x) = x^3$. The inverse map for $x \to x^3$ is birational automorphism $x \to x^{1/3}$ of $K[x]$. Thus $g_P ={}^{I(K)} \eta_P(u)$ and $g_L^{I(K)}\eta_L(u)$ do not have inverses in $End(K[x])$. They have bijective birational inverses. Noteworthy that g_P and g_L are transformations of infinite order. Degree of polynomial transformations of ${g_P}^s$ and ${g_L}^s$ are at least 3^s.

So we have an algorithm of generation bijective polynomial maps of arbitrary large degree on variety K^n.

We refer to subgroups $G_P(I(K))$ and $G_L(I(K))$ of invertible elements of $LS_P(I(K))$ and $LS_L(I(K))$ as groups of linguistic graphs $I(K)$. They are different from automorphism group of $I(K)$.

Let us consider semigroup $\tilde{F}_K$ of words of kind $u = (x, f_1, f_1, f_2, \dots, f_s, f_s)$. It is easy to see that for each linguistic graph $I(K)$ the transformations $g_P(u) = {}^I(K)\eta_P(u)$ and ${g_L}^I(K)\eta_L(u)$ are computed via consecutive usage of N_{f_i} in the linguistic graph. Thus we refer to $SW_P(I(K) = \{g_P(u) | u \in \tilde{F}_K\}$ and $SW_L(I(K) = \{g_L(u) | u \in \tilde{F}_K\}$ as semigroups of symbolic walks on partition sets of $I(K)$. We refer to $GW_P(I(K) = SW_P(I(K) \cup G_P(I(K))$ and $GW_L(I(K) = SW_L(I(K) \cap G_L(I(K))$ as groups of symbolic walks.

Finally we consider the semigroup $St(K)$ of words $u = (x+\alpha_1, x+\alpha_2, \dots, x+\alpha_k)$ where α_i are elements of K. We consider $F_K = F_K \cap St_K$ $\tilde{F}_K = \tilde{F}_K \cap St_K = \Sigma_K$ and introduce groups ${}^{I(K)}\eta_P(F_K) = \tilde{H}_P(I(K))$, ${}^{I(K)|}\eta_P(F'_K) = \tilde{H}_P(I(K))$, ${}^{I(K)|}\eta_P(\Sigma_K) = H_P(I(K))$, ${}^{I(K)|}\eta_P(\Sigma_K) = H_P(I(K))$.

We can change set P for the line set L and introduce ${}^{I(K)|}\eta_L(\Sigma_K) = H_L(I(K))$.

We refer to groups $H_P(I(K))$, $H_L(I(K))$ as groups of walks on partition sets of linguistic graph $I(K)$.

PROPOSITION 3.

If a linguistic graph $I(K)$ is connected then groups $H_P(I(K))$ and $H_L(I(K))$ are acting transitively on K^n.

THEOREM 1. (see [19])

For each commutative ring K groups $H_P(A(n,K)) = GA(n,K)$ and $H_L(A(n,K)) = {}^*GA(n,K)$ are totalities of cubical automorphisms of $K[x_1, x_2, \dots, x_n]$.

COROLLARY 1.

Let us consider element $u = (x, x+a_1, x+a_1, x+a_2, x+a_2, \dots, x+a_{k-1}, x+a_{k-1}x+a_k, x^t$ of F_K for commutative ring K with unity with finite multiplicative group of order d, $d > 2$ where $t = 2$ or $t = 3$ and $(d,t) = 1$. Then transformation ${}^{A(n,K)}\eta(u)$ is a cubical one.

THEOREM 2. (see [19]). *For each commutative ring K groups $H_P(D(n,K)) = GD(n,K)$ are totalities of cubical automorphisms of $K[x_1, x_2, \dots, x_n]$.*

COROLLARY 2. *Let us consider element $u = (x, x+a_1, x+a_1, x+a_2, x+a_2, \dots, x+a_{k-1}, x+a_{k-1}, x+a_k, x^t)$ of F_K for commutative ring K with unity with finite multi-*

plicative group of order d, $d > 2$ where $t = 2$ or $t = 3$ and $(d, t) = 1$. Then transformation ${}^{D(n,K)}\eta(u)$ is a cubical one.

V. Explicit constructions of trapdoor accelerators and their applications

EXAMPLE 1

Let us consider general commutative ring K with unity and $F_n = T_1^{A(n,K)}\eta(u)T_2$, where T_1, T_2 are elements of $AGL_n(K)$ and the tuple (x, $x+\alpha_1$, $x+\alpha_1$, $x+\alpha_2$, $x+\alpha_2$, …, $x+\alpha_2$,$\ldots$, $x+\alpha_s$, $x+\alpha_s$) such that $cn < s < n$ for some constant $c > 0$. According to Theorem 2 the transformations F_n and ${F_n}^{-1}$ are of degree 3. So $T = \{T_1, T_2, u\}$ is a trapdoor accelerator of F_n of degree 3 and level 3.

The following two constructions give families of cubic multivariate map with trapdoor accelerator of rather large level.

Let us consider the implementation of public key based on the trapdoor accelerator of Example 1.

As usually name Alice corresponds to owner of the public key and name Bob corresponds to public user of the cryptosystem. Alice has to select size of finite field and dimension of the space V of plaintexts. Assume that she takes field $F_{2^{3}2}$ and dimension $n = 256$. Additionally Alice has to identify vector space V with point set P or line set L. Assume that she select L. It means that her plaintext is the tuple [$x_{0,1}$, $x_{1,1}$, x_{12}, x_{22}, $\ldots$, $x_{127,128}$, $x_{128,128}$]. Additionally Alice has to select parameter s corresponding to length of the path in the graph $A(256, F_{2^{3}2})$. For proper selection of this parameter one can investigate cycle indicator $Cind(v)$ of the vertex v of the graph, i. e minimal length of the cycle through v and evaluate maximal value of $Cind(v)$ via all possible vertexes v (cycle indicator $A(256, F_{2^{32}})$ of the graph). Accordingly [Archive] cycle indicator of the graph $A(n, F_q)$ is at least $2n+2$. In fact $Cind(A(n, F_q)) = 2n + 2$ for infinitely many special parameters q. There are $q^{[n/2]}$ lines $[l] \in L$ such that $Cind([l]) \geq 2n + 2$. Let $[l] = [x_{01}, x_{11}, \ldots, x_{[n/2],[n/2]}]$ be one of the lines with written above property where parameter n is even integer. The trapdoor accelerator uses path $p(t_1, t_2, \ldots, t_s)$ of even length s starting in $[l]$ given by colours of vertexes x_{01}, $x_{01} + t_1$, $x_{0,1} + t_2$, …, $x_{0,1} + t_s$ where $t_2 \neq 0$, $t_i \neq t_{i-2}$, for $i = 3, 4, \ldots, s$. Let us assume that $s \leq n$ and u be the last vertex of the path. Lower bound for $Cind([l])$ insures that destination lines of $p(t_1, t_2, \ldots, t_s)$ and $p(t'_1, t'_2, \ldots, t'_s)$, $t_1 \neq t'_1$ are different. The accelerator uses destination line $[y]$ of path of $A(n, F_q[x_{01}, x_{11}, \ldots, x_{n,n}]$ with colours x_{01}, $x_{01} + t_1$, $x_{0,1} + t_2$, … $x_{0,1} + t_s$ starting in $[l]$. Assume that $[y] = [x_{01} + t_s$, g_{11}, $g_{1,2}$, $g_{2,2}$, …, $g_{n,n}]$, where g_{11} , $g_{1,2}$, …, $g_{n,n}$ are cubical or quadratic multivariate polynomials in variables x_{01}, x_{11}, …, $x_{n,n}$. The trapdoor accelerator uses cubical transformation $F(t_1, t_2, \ldots, t_s)$ of $L = {F_q}^n$ of kind $x_{01} \to x_{1,0} + t_s$,

$x_{1,1} \to g_{1,1}$,

…,

$x_{nn} \to g_{n,n}$.

It is important that the map $F(t_1, t_2, \ldots, t_s)$ differs from each of $(q-1)^s$ transformations $F(t'_1, t'_2, \ldots, t'_s)$, $t'_1 \neq t_1$ if $s \leq n$. So Alice can take $s = 256$ and select one of $q(q-1)^{255}$ sequence t_1, t_2, …, t_{256}.

To construct trapdoor accelerator Alice has to generate two bijective linear transformations ${}^1T$ and ${}^2T$ of L of kind

$x_{01} \to^i l_{01}(x_{01}, x_{11}, \ldots, x_{128,128})$

$x_{11} \to^i l_{11}(x_{01}, x_{11}, \ldots, x_{128,128})$

$x_{128,128} \to^i l_{11}(x_{01}, x_{11}, \ldots, x_{128,128})$ where $i = 1, 2$. In a spirit of LU factorisation Alice can generate each ${}^iT$ as a composition of lower triangular matrix ${}^iL$, $i = 1, 2$ with nonzero entries on diagonal and upper triangular matrices ${}^iU$ with unity elements on diagonal. For selection of the tuple t_i, $i = 1, 2, \ldots, 256$, ${}^iL$ and ${}^iU$, $i = 1, 2$ Alice can use pseudorandom generators of field elements or some methods of generating genuinely random sequences (usage of existing implementation the quantum computer, other Probabilistic modifications of Turing machine, quasi-stellar radio sources (quasars) and etc).

Alice takes tuple of variables $[x] = (x_{0,1}, x_{11}, \ldots, x_{128,128})$ and conducts the following steps.

Step 1.

She compute a product of $[x]$ and ${}^1T$. The output is a string $[{}^1l_{01}(x_{0,1}, x_{11}, \ldots,$ $x_{128,128})$, ${}^1l_{11}(x_{0,1}, x_{11}, \ldots, x_{128,128})$, $\ldots$ ${}^1l_{128,128}(x_{0,1}, x_{11}, \ldots, x_{128,128})] = [{}^1u]$. Alice treats the output as the line of graph $A(256, F_{2^{32}}[x_{01}, x_{11}, \ldots, x_{128,128}])$

Step 2.

She computes the destination line $[{}^2u]$ of path with starting line $[{}^1u]$ and colours ${}^1u_{0,1}$, ${}^1u_{0,1} + t_1$, ${}^1u_{0,1} + t_2$, …, ${}^1u_{0,1} + t_{256}$.

Step 3.

Alice takes the tuple $[{}^2u] = [{}^1u_{0,1} + t_{256}, {}^2u_{1,1}, {}^2u_{1,2}, \ldots, {}^2u_{128,128}]$ of elements $F_{2^{32}}[x_{01}, x_{11}, \ldots, x_{128,128}]$ and forms the line ${}^3u = [{}^1u_{0,1})^2$, ${}^2u_{1,1}$, $\ldots$ ${}^2u_{128,128}]$ of the vector space L.

Step 4.

She computes the composition of the tuple ${}^3u$ and the matrix of linear map ${}^2T$. So Alice has the tuple of cubic multivariate polynomials ${}^4u = (f_{01}, f_{11}, \ldots,$ $f_{128,128})$. She presents coordinates of ${}^4u$ via their standard forms, i. e sums of monomial terms taken in the lexicographical order and writes the public rule F $x_{0,1} \to f_{0,1}(x_{01}, x_{11}, \ldots, x_{128,128})$, $x_{1,1} \to f_{1,1}(x_{01}, x_{11}, \ldots, x_{128,128})$, $x_{1,2} \to f_{1,2}(x_{01}, x_{11}, \ldots, x_{128,128})$, $\ldots$ $x_{128,128} \to f_{128,128}(x_{01}, x_{11}, \ldots, x_{128,128})$.

Finally Alice announces this multivariate rule for public users. Noteworthy that for the development of this private key Alice use only operations of addition and multiplication in the commutative ring $F_{2^{32}}[x_{01}, x_{11}, x_{1,2}, \ldots, x_{128,128}]$.

ENCRYPTION PROCESS.

Public user Bob creates her message p $=$ ($p_{0,1}$, from the space $(F_{2^{32}})^m$, $m = 256$. He computes tuple $(f_{0,1}(p_{01}, p_{11}, \ldots, p_{128,128})$, $f_{1,1}(p_{01}, p_{11}, \ldots, p_{128,128})$, $f_{1,2}(p_{01}, p_{11}, \ldots, p_{128,128})$, …, $f_{128,128}(x_{01}, x_{11}, \ldots x_{128,128}))$ of the ciphertext c. Theoretical estimation of the execution time is $O(m^4)$. Let

$D(m)$ be the density of the public rule F, which is a total number of monomial terms in all multivariate polynomials f_{01}, f_{11}, f_{12}, $\ldots$. Execution time is $cD(m)$ where constant c is time of the computation of single cubic monomial term. This constant depends on the choice of the computer. The following parameters can be useful. $D(16) = 5623$, $D(32) = 62252$, $D(64) = 781087$, $D(128) = 10826616$, $D(256) = 138266164$.

We can speed up the encryption process via reduction of parameter s. If we take twice shorter of the path of the graph, i.e. select $s = m/2$ then the values of $D(m)$ would be the following. $D(32) = 5623$, $D(64) = 62252$, $D(128) = 781087$, $D(256) = 10826616$.

This numbers disclose an interesting remarkable coincidences.

We can encode each character of $F_{2^{32}}$ by four symbols of F_{2^8}. Thus we can identify plaintext and the ciphertext with the tuple of binary symbols of length 1024. So we can encrypt files with extensions .doc, .jpg, .avi, .tif, .pdf and etc.

DECRYPTION PROCEDURE.

Alice has the private key which consists of the sequence t_1, t_2, $\ldots$, t_{256} and matrices ${}^1T$ and ${}^2T$. Assume that she got a ciphertext c from Bob. She computes ${}^2T^{-1} \times c ={}^1 c$ and treats this vector as line $[{}^1l] = [c_{01}$, c_{11}, c_{12}, $\ldots$, $c_{128,128}]$. Alice computes parameter $d = c_{01}{}^{31}$. She changes the colour of $[{}^1l]$ for $d + t_{256}$ and gets the line $[l] = [d + t_{256}, c_{11}, c_{12}, \ldots, c_{128,128}]$. Alice has to form the path in the graph $A(256, F_{2^{32}})$ with the starting line $[l]$ and further elements defined by colours $d + t_{255}$, $d + t_{254}$, $d + t_{253}$, $\ldots$, $d + t_1$ and d. So she computes the destination line $[{}^1l] = [d$, $d_{1,1}$, d_{12}, $\ldots$, $d_{128,128}]$. Finally Alice computes the plaintext p as $[1^l] \times^2 T^{-1}$.

VI. Conclusions

In [31] we describe several trapdoor accelerators defined with described above approach in selected cases of finite fields and arithmetical rings Z_m, where m is a prime power. They can be used for the constructions of multivariate public keys which is able to serve as tools for the encryption or construction of digital signatures. In this paper we consider the important case of finite fields of characteristic 2. Computer simulations of several variants of implementation of this public keys are presented in [31] where time evaluation and numbers of monomial terms are given. In [31] the reader can find heuristic arguments on security of suggested public rules.

***Abstract*—Embedded systems (ES) are wide-spread in our world and responsible for many critical systems. More recently, machine learning (ML) tools have become a well-established solution for data-intensive tasks, but their application in embedded systems is still gaining traction and their real-time performance is often unclear. We provide a (non-extensive) review of the ML tools that may be suited for deployment in ES, from which we selected two representative tools – the well-established Python-based Scikit-Learn, and the interoperability-oriented ONNX Runtime – to compare their response time. Using archetypal datasets and four pre-trained ML models, we measure the prediction time for each sample, for each model, in Scikit-Learn and ONNX Runtime in a standard desktop (to compare performance of the tools in the same platform), and for ONNX Runtime in a representative ES, a Raspberry Pi v4 (to compare performance of the same tool across platforms). We report that ONNX considerably improves over Scikit-Learn, and experiences a negligible performance degradation when ported to the RPi.**

***Index Terms*—Machine Learning, Embedded Systems, Prediction Time, Scikit-Learn, ONNX Runtime**

I. Introduction

Artificial intelligence (AI) and machine learning (ML) have grown dramatically in recent years, to the point where AI & ML is becoming a core technological component in many modern systems. In turn, embedded systems (ES) are a well-established technology that has enjoyed widespread use in our world for decades now, inconspicuously ensuring the efficient execution of a plethora of everyday operations. Many applications of ES are critical and time-sensitive ones [1]; for example, the timely detection and mitigation of cyberattacks, that is crucial for the integrity and dependability of many modern-world digital systems (e.g., banking sector).

The use of ML in embedded systems has garnered substantial interest, with the topic often being referred to as *TinyML*. The challenge is that embedded systems are typically resource-constrained platforms (ranging from micro-controllers to ARM or small-scale x86 platforms) and, while there is a plethora of ML libraries, not all provide the small memory footprint and stand-alone operation (i.e., sufficiently stripped-down from external dependencies) necessary for operation in embedded systems. Furthermore, a common strategy is to carry out training at the cloud (due to the higher processing capabilities available), whereas the embedded device only performs prediction. This raises the need for interoperability, as possibly the ML tool used for training can be different than the one available at the embedded device. Finally, characterization of response time is important to design real-time systems. Reports of execution time and/or speed-up against baselines can be found (e.g., [2], [3]), but typically for single models and not considering potential response time variability.

A noteworthy category of solutions are intermediate description languages, such as *Open Neural Network Exchange* (ONNX), and associated runtime environments (RTE), notably *ONNX Runtime* and *Tensorflow Lite*. Intermediate description languages describe a (trained) ML model using a (small) set of operators that the RTE is able to execute. This reduces computational requirements as it suffices that the RTE implements that set of operators to produce predictions from a given model. Downsides are that training may not be available and that the set of models at disposal may be limited.

In this work we report the performance of two selected libraries, *Scikit-Learn* and *ONNX Runtime*, in two platforms: a standard desktop and an archetypal embedded system, a Raspberry Pi v4. We deploy four one-class ML models – Isolation Forest (iForest), Local Outlier Factor (LOF), One Class Support Vector Machine (OC-SVM) and Stochastic Gradient Descent OC-SVM (SGD-SVM) –, that were pre-trained with network traffic data sets (legitimate and malicious) to detect cyberattack-related traffic. We show that ONNX Runtime can offer a speed-up of at least ≈ 14x with respect to Scikit-Learn for most models when both are executed in the desktop, and that ONNX Runtime running in the Raspberry Pi produces speed-ups of at least ≈ 8x against Scikit-Learn running in the desktop.

The structure of this paper is as follows. Section II portrays a motivating use-case and relevant ML models. An overview on ML for ES is provided in Section III. Section IV reports response times for selected ML libraries and computing platforms. Section V draws final remarks.

II. Motivating Use-Case and Selected ML Tools

A. Cybersecurity Use-Case

Cybersecurity is a domain of notable technological and societal impact in the modern world. The exposure surface for cyberattacks, and for recruiting devices that can be commandeered to participate in those attacks, increases everyday

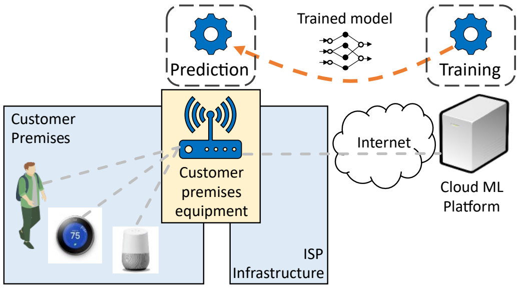

Fig. 1: Architecture of a cloud-edge system.

as the number of low-security IoT devices grows. This has been a driver for the increase of Distributed Denial of Service (DDoS) attacks, that aim at disrupting the servers of high-profile online services (e.g., Amazon, Google or Netflix) by having a very large number of infected devices (typically vulnerable IoT devices) issuing dummy requests to those servers. Internet Service Providers (ISP), that enable Internet service at customer premises through a Customer-Premises Equipment (CPE), are interested in mitigating the involvement of their customers' devices in cyberattacks through the use of Intrusion Detection Systems (IDS). The fastest response time is attained by deploying the IDS the closest possible to the targeted (or involved) nodes; for the ISP, this is the CPE.

Machine learning, whose successful application to cybersecurity is well documented [4]–[6], can help addressing this issue by learning network traffic patterns that are legitimate, and apply that knowledge to identify anomalous patterns that may concern malicious traffic. However, the CPE is often an embedded system with relatively few computational resources; while it can perform model prediction, it lacks the power to perform training, that ends up taking place in the cloud. The question arises of how to transfer models trained in the cloud, often with a state-of-the-art ML library, to the embedded system, that often will support only a limited set of ML libraries. Figure 1 presents the architecture of a cloud/edge system, and how can an ML-based IDS be deployed by leveraging the resource-rich cloud for training and transferring trained models to the resource-constrained CPE. Additional details on this use-case can be found in [7].

B. Datasets & ML Tools

To enable the presented use-case, we prepared datasets of network traffic (both legitimate and malicious) from publicly available sources, and trained four models to produce a ML mechanism that detect anomalous (potentially malicious) traffic. The details are described in [6]. We focus on One-Class (OC) models, i.e., models trained with samples of a single class to create a boundary around these, against which outliers can be detected. This semi-supervised approach allows the models to learn the regular (legitimate) traffic at a customer's network, and report anomalies that can potentially reveal themselves to be malicious traffic. All models were trained using Scikit-Learn [8], a free Python library that enjoys widespread use in the ML community.

The four selected models are reviewed next for convenience:

Isolation forest [9]: an unsupervised mechanism based on decision trees. It leverages the assumption that an anomalous sample requires less partitioning steps to be isolated. Thus, an isolation forest work by recursively generating partitions, by randomly splitting an attribute's value between the minimum and maximum values allowed for that attribute, until a target sample is contained in its own partition. Anomalies will require less partitions to be isolated.

Local Outlier Factor (LOF) [10]: LOF identifies local outliers by measuring the deviation of the density of a data point to its neighbors. The k-Nearest Neighbors is used to compute the reachability distance and local reachability density of each data point. The associated LOF score is calculated as the ratio of its local reachability density to the densities of its k-nearest neighbors. Points with high LOF scores are considered outliers. The value k (number of nearest neighbors) must be chosen carefully to avoid overfitting or underfitting.

One-Class Support Vector Machines [11]: traditional Support Vector Machines (SVM) select a decision boundary for which the margin between data points of different classes is maximized. Other interpretation is that SVMs maximize the distance between the convex hulls of points belonging to each class. One-Class SVM (OC-SVM) applies the same boundary-based mechanism for semi-supervised learning. It uses a hypervolume to encompass all of the instances; points outside the hypervolume are classified as anomalies.

Stochastic Gradient Descent [One Class] SVM (SGD-SVM) [12]: an online linear version of One-Class SVM, using a stochastic gradient descent (SDG). SDG algorithms are suited for applications where the number of data points and the problem dimensionality are both very large.

III. Overview of ML Tools for Embedded Systems

We review (not exhaustively) ML libraries targetting embedded systems and tools for interoperability and transpilation.

A. ML Libraries for Embedded Systems

TensorFlow (TF) [1] is an open-source library for AI/ML, composed of datasets and pre-trained models developed and released by the Tensorflow Community. Colaboratory (Colab) for instance, is a free Jupyter notebook environment and runs in the cloud so the user doesn't need to setup anything in his local machine. This library is supported in Haskell, C#, Julia, R, Ruby, Scala and Javascript.

Armadillo [2] is a library in C++ for linear algebra and scientific computing. It can use Open Multi-Processing (OpenMP), a free easy-to-use library for parallel computing.

mlpack [3] is a C++ ML library focused in providing fast and extensible implementations of ML models. This library is the combination of *Armadillo*, *ensmallen*, a library for numerical optimization and *cereal*, a serialization library.

[1] https://www.tensorflow.org/ (Note: all links last accessed on 2023-07-31)
[2] https://arma.sourceforge.net/
[3] https://mlpack.org/

Shogun [4] is an open-source library in C++ for machine learning development. It provides interfaces for C++, Python, Octave, R, Java, Lua, C#, Ruby and implements all the standard ML algorithms and some advanced as well. It is available for most operating systems.

SHARK [5] is an open-source machine learning library implemented in C++. It provides neural networks, kernel-based learning algorithms, linear and nonlinear optimization methods and is available for the most common operating systems.

A notable mention also goes to **CAFFE** [6], that focus on deep learning, thus supporting mostly neural networks (e.g., CNN, RCNN, LSTM).

There are also efforts focusing on deploying specific ML models in resource-scarce devices. The authors of [13] present *ProtoNN*, an algorithm that replicates k-Nearest Neighbor (k-NN) but has several orders lower storage and prediction complexity, and *ProtoNN* models can be deployed in very scarce plaforms (e.g. an Arduino UNO with 2kB RAM). The authors of [3] presents *SeeDot*, a domain-specific language to express ML inference algorithms and a compiler that compiles SeeDot programs to fixed-point code that can efficiently run on constrained IoT devices. In [2] *CMSIS-NN* is presented, which is essentially efficient kernels to maximize the performance and minimize memory footprint of neural network applications on Arm Cortex-M processors.

B. Interoperability of ML models

The following options, rather than tools, are standards to provide a common description of ML models, therefore enabling porting between libraries.

Open Neural Network Exchange (ONNX) [7] is an open specification with the following components: a definition of an extensible computation graph model; definitions of standard data types; and definitions of built-in operators. The first two make up the ONNX Intermediate Representation (or IR). In ONNX IR, each computation dataflow graph is structured as a list of nodes that form an acyclic graph. Each node is a call to an operator, and they have one or more inputs and outputs. Built-in operators are divided into a set of primitive operators and functions (the latter being, essentially, sub-graphs using primitive operators and/or other functions). Operators are implemented externally to the graph, but the set of built-in operators is portable across frameworks. Every framework supporting ONNX will provide implementations of these operators on the applicable data types. ONNX is compatible with at least 29 frameworks and converters and 30 inference runtimes.

Predictive Model Markup Language (PMML) [8] is a document format based on the Extensible Markup Language (XML) that can be used to described machine learning algorithms. It enables ML model porting between existing supporting libraries; these exist for C++, such as *cPMML* [9], and for Python, notably with the Scikit-Learn library *sklearn2pmml* [10], among others.

C. Transpilers

Transpilers translate a source code into a language different than the original one. The resulting code is described natively in the target language.

Sklearn-porter [11] is a Python library specifically developed to transpile ML models built with Scikit-Learn to other programming languages such as C, GO and JavaScript.

Model 2 Code Generator (m2cgen) [12] is a free, open-source library mainly developed in Python, that transpiles trained statistical models (trained, e.g., with Scikit-Learn or *lightning* libraries) into a native code for at least 16 different programming languages (R, Visual Basic, Haskell, C#, etc.).

D. Runtime Environments

A third dimension discussed here are tools that offer runtime environments (or simply runtime). Some of the aforementioned ML libraries leverage mechanisms for intermediate model representation that can be compiled or interpreted by a runtime environment. This solution avoids the need to deploy the entire library at the target device, thus resulting in a lightweight version of the initial library.

ONNX Runtime [13] is a cross-platform machine-learning model accelerator, used to deploy ONNX format models into production. It is meant to enable acceleration of machine learning inferencing across a variety of target hardware.

Tensorflow Lite [14] is a TF-variant tailored for resource-constrained systems that also uses a runtime. Using Tensorflow Lite, the target devices do not require the full TF library installation, but solely the *tflite_runtime* to perform inference. This tool eases the computational requirements of the target system, but its accuracy can be compromised if it uses operations not supported by the Tensorflow Lite. A recent paper reports TensorFlow Lite Micro [14], that adopts an interpreter-based approach to address ML efficiency and fragmentation in ES.

IV. Prediction Time Comparison of Selected Tools

A. Selected Tools & Experimental Setup

We have picked ONNX Runtime as the target ML tool to evaluate, and Scikit-Learn as the baseline reference. The option for Scikit-Learn was straightforward, as it is one of the most widely-used ML tools. It is also the tool used to train the models used in these measurements. As for the tools for deployment in embedded systems, we opted for ONNX Runtime based on a mix of our own requirements (that, when crossed against the available documentation, lead us to eliminate the remaining candidate tools), and impressions

TABLE I: Dataset descriptions.

Dataset	Traffic type	# samples	# Features
IOT23 [15]	IoT devices	487	26
Botnet [16]	Data theft	196	26

TABLE II: Selected platforms.

	Desktop	Raspberry Pi
Number of cores	4	4
Frequency utilized	2.00 GHz	600.00 MHz
RAM memory	9.64 GB	1.91 GB
Operating System	Ubuntu 20.04.6 LTS	Debian GNU/Linux 11
Python version	3.8.10	3.9.2
ONNX version	1.13.1	N/A
ONNXRuntime	1.14.1	1.14.1

acquired from experimenting with the other high-potential candidates. We lay down next the authors' impressions of the reviewed tools; this should not be interpreted, in any way, as a methodical and criterious analysis of these tools.

ML libraries: *Tensorflow* proved to be a collection of disperse, pre-trained models, making it hard to train new models from scratch. *Armadillo*, *mlpack*, *Shogun*, *SHARK* and *Caffe*, despite being described in C/C++, do not seem tailored for deployment in resource-constrained devices.

Interoperability: ONNX provides a clear and well document specification of how to convert models between tools, with extensive software support. PMML enables model porting between supporting libraries but, as aforementioned, we found no library to be a suitable candidate.

Transpilers: *sklearn-porter* is still under development and the range of models that can be transpiled to C is small (SVM and Decision Trees/Random Forest). Regarding *m2cgen*, even though transpiled models were able to perform closely to the original model, the tool offers very little documentation, making it hard to interpret the tool's output or even understand how the transpilation process actually occurs.

Runtimes: *ONNX Runtime* showed up as the best option. *TensorFlow Lite* was not explored, as usage of standard *TensorFlow* was also not straightforward.

Table I describes the data sets used in this performance analysis; more details in [6]. Table II presents the characteristics of the selected computing platforms. The models were converted to the ONNX specification using the *sklearn-onnx* library. A variant named *ONNX Runtime Optimized*, that optimizes the ONNX graphs describing the models, was also evaluated. Model accuracy obtained with ONNX Runtime and its Optimized variant was similar to that of Scikit-Learn.

B. Results

Figure 2 presents the average prediction time (over all input samples) of the four ML models across the three tools in the desktop equipment. Presented values are the average time of prediction for each new sample. We observe that ONNX produces an acceleration for most models, notably of ≈ 16x for Isolation Forest, ≈ 14x for OC-SVM, and ≈ 49x for SGD-SVM. In all this cases, the performance of the ONNX Runtime and its Optimized version do not differ substantially from each other. The same is not true, however, for the Local Outlier Factor (LOF), as shown in Figure 2 (top-right). We observed that ONNX underperforms in this model, taking longer than the Scikit-Learn. This leaves the door open for a more efficient implementation of LOF using the ONNX operators.

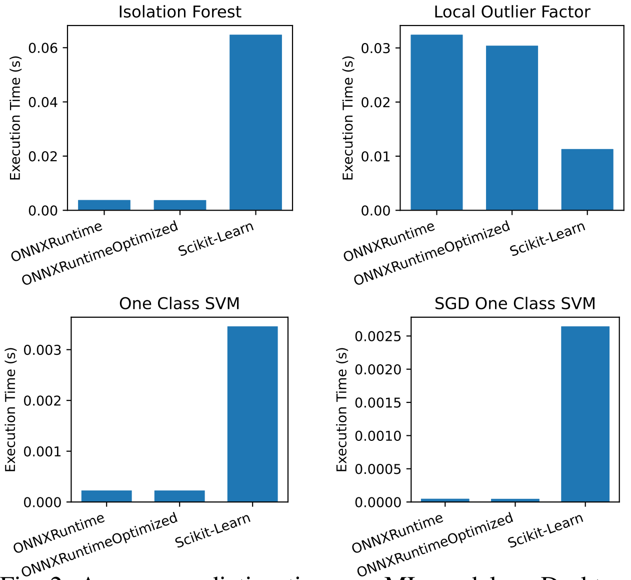

Fig. 2: Average prediction time per ML model on Desktop.

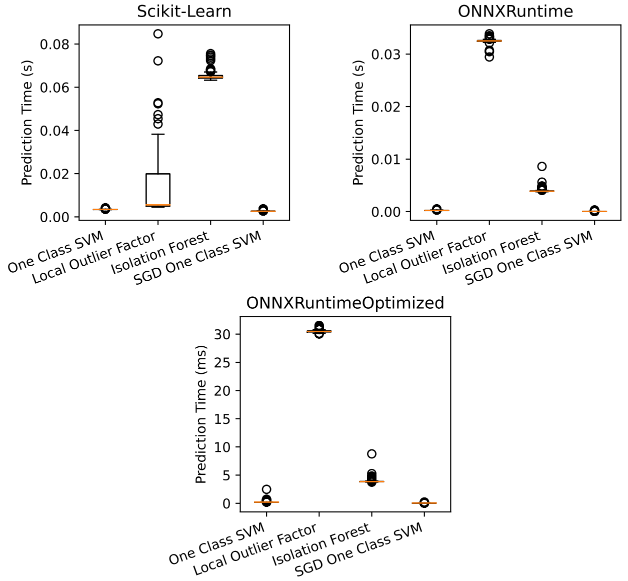

Fig. 3: Prediction time distribution per library on Desktop.

Figure 3 depicts the distribution of the prediction time of the various models per tool when executed in the Desktop. It is noteworthy for that, for ONNX Runtime (vanilla and Optimized), LOF presents the highest prediction time whereas, for Scikit-Learn, it is iForest that takes up the most time. Regarding the distribution of the samples, this is limited in the case of ONNX Runtime and Optimized to a few occasional outliers of additional time. For Scikit-Learn, LOF experiences considerable variability in prediction time. This may be a trade-off of the Scikit-Learn LOF implementation to achieve a lower average time for this concrete model.

Figure 4 exhibits the same analysis as Figure 2 for the

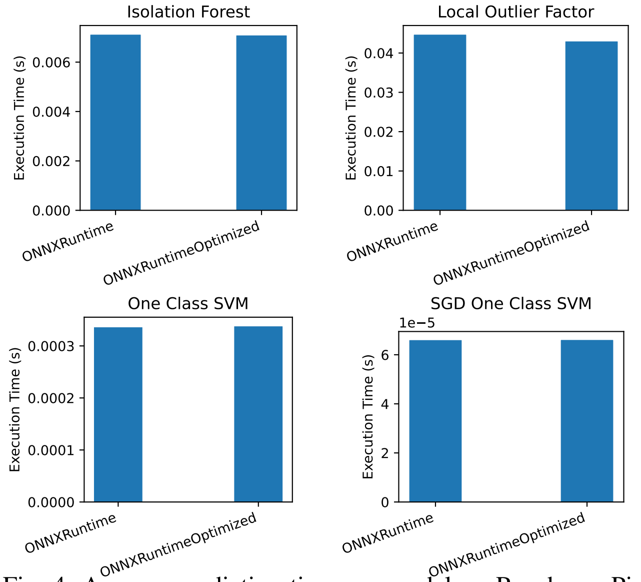

Fig. 4: Average prediction time per model on Raspberry Pi.

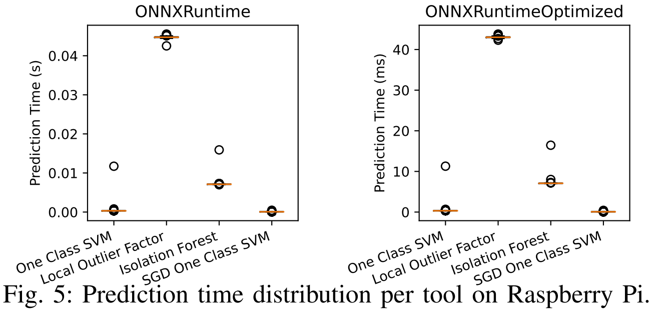

Fig. 5: Prediction time distribution per tool on Raspberry Pi.

second platform. The average of prediction time for the four ML models in the Raspberry Pi is superior to that of the Desktop response time; in detail, for Isolation Forest by $\approx 81\%$, for LOF by $\approx 37\%$; and for OC-SVM by $\approx 43\%$. However, when comparing with the Scikit-Learn running in the desktop, we obtain speedups of $\approx$ 8x for Isolation Forest, $\approx$ 9x for OC-SVM, and $\approx$ 39x for SGD-SVM. Results in Figure 5 presents little differences to Figure 3 (right and bottom) where it applies, apart from the generally higher median values in the Raspberry Pi.

V. Conclusion

We reviewed Machine Learning (ML) tools according to their potential for embedded system. We selected a particular tool, ONNX Runtime, for comparing prediction time against the well-established Python-based Scikit-Learn. ONNX Runtime is capable of running models described in the ONNX format; the models were trained in Scikit-Learn and exported to ONNX. The prediction time was measured in two platforms – a standard desktop and a target embedded system, a Raspberry Pi v4 – for four pre-trained ML models and datasets. We observe that ONNX Runtime considerably improves over the prediction time of Scikit-Learn, and experiences a negligible performance degradation when ported to the RPi. Future work will evaluate performance on more ML tools and platforms and investigate trade-offs with model target accuracy.

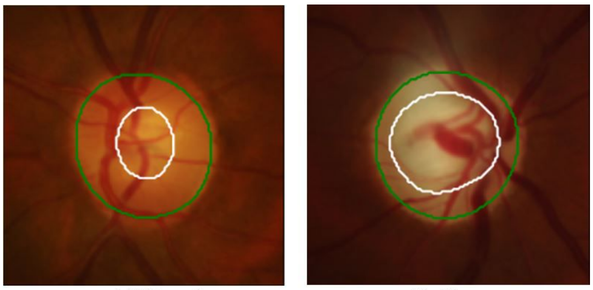
Abstract—**Glaucoma is the second eye disease causing blindness worldwide. Optic Cup-to-Disc ratio (CDR) is a commonly applied method in glaucoma detection. The CDR is calculated based on Optic Disc (OD) and Optic Cup (OC) in eye fundus image screening. Therefore, the accurate segmentation of these two parameters is very important. Lately, Deep Neural Networks have demonstrated great effort in automated Optic Disc and Optic Cup segmentation but the overlapping between regions of OC and OD cause the challenge to obtain CDR automatically with high accuracy. In this paper, we assess the performance of CDR evaluation on three modifications of the Convolutional Neural Network (CNN) U-Net, namely Attention U-Net, Residual Attention U-Net (RAUNet), and U-Net++ applied on publicly available datasets RIM-ONE, DRISHTI, and REFUGE. We calculated the ground truth CDR value of testing eye fundus images of these datasets and compared it with the CDR value obtained by trained CNNs. Our results show that Attention U-net obtains the closest CDR to the ground truth CDR value but the identification of early-stage glaucoma needs an improvement.**

I. Introduction

GLAUCOMA is a progressive eye disease caused by damage to the optic nerve which is critical to vision. Usually, there are no symptoms in its early stages, and without proper treatment, glaucoma can lead to blindness. The evaluation for glaucoma starts by evaluating the cup-to-disc ratio (CDR) which is the ratio of the vertical optic cup diameter (VCD) to the vertical optic disc diameter (VDD) of a fundus image [1]. Fig. 1. presents an example of an eye fundus image. Depending on this ratio, several stages of glaucoma are distinguished. The cup-to-disc ratio of 0.4, 0.5 – 0.7, and above 0.7 indicate early-stage glaucoma, moderate-stage glaucoma, and severe-stage glaucoma respectively. A healthy eye has a CDR of 0.3 [2]. The CDR calculation is based on the segmented optic disc and optic cup regions. OD appears as a bright oval region, and OC takes place as the brighter oval region in the center of the optic disc (Fig. 1).

Addressing the limitation of medical resources in many areas worldwide [3], deep learning methods become successful in medical image segmentation [22]. Especially convolutional neural networks (CNN) demonstrated powerful representation and generalization abilities [4][5][6]. In automated glaucoma identification, the CNNs are trained on eye fundus images having the ground truth labels of OD and OC prepared by the ophthalmologists. Therefore, precise segmentation of the optic disc and optic cup is of the essence. However, accurate calculation of cup-to-disc ratio value is still in the development stage and faces challenges [7]. Here, the complexity occurs due to overlapping in the optic disc and optic cup areas. The automated deep learning-based algorithms fail in differing the boundaries of OC in the eye fundus image. The publically available fundus image datasets have insufficient images and segmentation masks to learn CNN for OD and OC segmentation, and CDR calculation.



(a) Normal

(b) Glaucoma

Fig. 1. Eye fundus image. The Optic Disc (Green) and the Optic Cup (White).

In this research, we aim to evaluate CNN's ability to accurate segmentation of OD and OC used for further CDR calculation. As the stage of glaucoma is identified by the CDR value, our experiment seeks to verify the equivalence of the CDR calculated with the help of CNN with the CDR calculated by ophthalmologists. Therefore, the datasets consisted of eye fundus images with the ground truth of OD and OC will be used.

II. Related work

The resultant challenges in CDR estimation prompt researchers to seek the improvements in presence of deep learning-based methods and new proposals.

Zhao et al. in [7] introduced a direct CDR estimation method based on a semi-supervised learning scheme. The proposed method is directly regressing the CDR value based on

This work was not supported by any organization

TABLE I
SUMMARY OF RELATED WORKS

Work	Dataset	The task to be solved in CDR evaluation and the results
[7]	Direct-CSU and ORIGA	Regression. AUC - 0.90 on Direct-CSU, AUC - 0.88 on ORIGA
[8]	Moorfields Eye Hospital in London	Classification. Sen - 0.92, Spec - 0.88

the OD feature using a Deep learning (DL) technique, bypassing intermediate segmentation. The approach is of two stages incorporating CDR value regression by random forest regressor and unsupervised feature representation of fundus image with a CNN, named MFPPNet. Alghmdi et al. in [8] proposed an approach by utilizing linear iterative clustering (SLIC) and a feed-forward neural network classifier. The classifier was used to classify the superpixels to detect the boundaries of OD and OC. The final detection and segmentation of OD and OC were completed by applying morphological operations and an elliptical estimation. In [9] the two-stage deep learning-based approach for CDR estimation was proposed. In the initial stage of optic disc segmentation, the U-Net was adopted. At a later stage, image-processing algorithms are used to estimate the CDR. In [10] a modified U-Net model was presented to locate OD. The CDR was calculated by segmented OD and OC incorporating the adaptive thresholding.

The discussion above shows the variety of methods applied in CDR estimation and it is difficult to compare their effectiveness. The summary is provided in Table I. The metrics used in the performance evaluation of the proposed approaches are dice coefficient (Dice), Jaccard Index (IoU), sensitivity (Sen), specificity (Spec), and area under the curve (AUC). In this paper, the OD and OC segmentation task will be solved by using CNNs to calculate CDR and to compare the glaucoma stage by CDR value obtained using CNNs with the glaucoma stage provided by the experts. Therefore, the Dice measure was chosen to evaluate the obtained results.

III. Methodology

A detailed description of the applied methods is presented in four sub-sections. The sub-section *3.1.* presents the datasets. In the sub-section *3.2.* the applied image preprocessing techniques are described. The sub-section *3.3.* presents the convolutional neural networks used in our experiments. The sub-section *3.4.* provides the details of metrics used for convolutional neural networks performance evaluation and cup-to-disc ratio calculation.

A. Dataset description

The public dataset DRISHTI-GS [11] contains 101 images with ground truth divided into 50 training and 51 testing images. All the images have been marked by four eye experts. All images were taken centered on an optic disc with a Field-Of-View (FOV) of 30 degrees and saved in the PNG uncompressed image format with a resolution of 2045 x 1752. Ground truths were collected from data experts.

RIM-ONE v.3 [12] is a public dataset consisting of 159 annotated stereo eye fundus images. The images were taken by a Nidek AFC-210 camera and saved in JPEG image format with a resolution of 2144 x 1424. The OD of each image has been segmented by two experts in ophthalmology to create the ground truth.

REFUGE [13] is a public dataset containing 1200 fundus images, with ground truth and clinical glaucoma labels. The dataset is split 1:1:1 into 3 subsets equally for training, validation, and testing. The training set with a total of 400 color fundus images taken by a Zeiss Visucam 500 fundus camera of size 2124 x 2056 is provided with the corresponding glaucoma status and the unified manual pixel-wise ground truths. The testing dataset contains 800 color fundus images taken by a Canon CR-2 camera of size 1634 x 1634 and is split into 400 testing images and 400 validation images. The images of validation and testing subsets were used in this paper only.

B. Preprocessing

For the purpose of image diversity increasing, various image augmentation techniques, namely image zooming by 20%, rotation by an angle of rotation from 0° to 45°, and horizontal and vertical flipping were applied. With this approach, the number of images in each dataset was extended to 1000. The region of interest (ROI) with the double size of OD area was extracted automatically by cropping the area around the centroid of optic disc and optic cup accordingly. The ROI images were resized to a size of 512 x 512 pixels by bicubic interpolation [14].

C. Convolutional neural networks

The three CNNs, namely UNet++ [15], Attention U-Net [16], and Residual Attention U-Net (RAUNet) [17] with significant improvement in image segmentation have been chosen to be trained for optic disc and cup segmentation. During the training of these CNNs, the binary cross-entropy loss function [1] and Adam optimizer [5] have been used. The parameters such as batch size, learning rate, and dropout rate for each CNN were searched by applying the KerasTuner framework.

UNet++ [15] is a nested and dense skip connections-based method. In the encoder part, the feature maps incur a dense convolution block. Here, the pyramid level causes the number of convolution layers. Due to the nested skip pathways, the proposed network generates full-resolution feature maps at multiple semantic levels.

Attention U-Net [16] contains the encoder, decoder, and attention gate at the skip connection of each level. The pre-trained network ResNet50 takes a place as an encoder, which consists of residual blocks with skip connections overcoming the vanishing gradient problem. The decoder contains up-sampling, and concatenation. Each convolution layer is followed by a rectified linear units (ReLU) activation function and batch normalization.

Residual Attention U-Net (RAUNet) [17] is an encoder-decoder-based network, where the encoder is constructed of pre-trained ResNet34 for semantic features extraction. The decoder contains a new augmented attention module (AAM) for multi-level features fusion and global context capturing.

D. Metrics

The evaluation metrics such as the Dice coefficient (Dice) [19], [20] and the cup-to-disc ratio (CDR) [21] are used in this paper.

The cup-to-disc ratio is calculated by dividing the OC diameter by the OD diameter [10].

$$CDR \quad = \quad \frac{vertical\,cup\,diameter}{vertical\,disc\,diameter} \tag{1}$$

Dice, which describes the similarity between the two images, is applied to evaluate the performance of trained CNNs in OD and OC segmentation.

$$Dice \quad = \quad \frac{2\left|S\bigcap L\right|}{\left|S\right|+\left|L\right|} \tag{2}$$

where, S – the predicted output map by segmentation, L – the ground truth binary map.

IV. Experiment and Results

The experiment was run by training the three different CNNs, namely UNet++, Residual Attention U-Net, and Attention U-Net on a dataset consisting of combined eye fundus images and their binary labels of DRISHTI-GS, REFUGE, and RIM-ONE and named as a combined dataset. The training of convolutional neural networks was performed on a single GPU machine [18] with 1TB of RAM using Keras included in TensorFlow version 2.9.1. An early stopping technique seeking a minimum for validation loss was applied to reduce unnecessary training time. The Adam optimizer and binary cross-entropy loss function were used during the training. The KerasTuner framework was applied to search for parameters, namely the learning rate, batch size, and dropout rate of each network. The trained CNNs were tested on 50 testing images of each dataset, REFUGE, RIM-ONE, and DRISHTI-GS separately to evaluate the Dice and calculate the CDR for the predicted OD and OC by each CNN. The CDR values were grouped into ranges of (0.3-0.4], (0.4-0.7], and above 0.7 according to glaucoma stages.

Table II provides the evaluated Dice of the optic disc and cup segmentation testing the trained convolutional neural networks on REFUGE, RIM-ONE, and DRISHTI-GS test datasets. Here, comparing the performance of CNNs in OD and OC segmentation, the Attention U-Net demonstrates the highest Dice value of 0.9789, 0.9732, and 0.9770 for OD segmentation and 0.8769, 0.8742, and 0.8549 for OC segmentation on DRISHTI-GS, REFUGE, and RIM-ONE test datasets respectively. This leads to results in Table III presenting the mean and variance of ground truth CDR obtained on images

TABLE V
GROUND TRUTH CDR OF NON-GLAUCOMA EYE FUNDUS IMAGE AND CALCULATED CDR USING CNN

CDR by glaucoma stages	Test dataset	mean±variance of ground truth CDR	mean±variance of CDR calculated using CNN		
			Attention U-Net	RAUNet	UNet++
≤0.3	RIM-ONE	0.29±0.002	0.28±0.002	0.30±0.008	0.27±0.004

of each test dataset and the mean and variance of CDR calculated by Unet++, Attention U-Net, and Residual Attention U-Net on testing images of each test dataset. Assessing the mean and variance of ground truth CDR and the CDR calculated using the segmented OD and OC by CNNs, the best result was obtained by Attention U-Net.

Using the same approach, the amount of eye fundus images in each test dataset was calculated and evaluated the percentage of how many images each CNN is able to calculate the correct CDR in comparison with ground truth. The results are shown in Table IV. The obtained percentage of truth CDR and CDR calculated using segmented OD and OC by CNNs indicates that the Convolutional Neural Networks better identify moderate-stage glaucoma and severe-stage glaucoma cases but the identification of early-stage glaucoma is quite poor. For example, using Attention U-Net for REFUGE dataset images, the CDR, compared to the truth CDR, was calculated correctly for 91% of moderate-stage glaucoma images and 100% of severe-stage glaucoma images. Meanwhile, the correct CDR was calculated only for 21% of early-stage glaucoma images. The showcase examples of the optic disc and cup segmentation in the images of early-stage glaucoma by Attention U-Net and the ground truth are provided in Fig. 2. Fig. 2 (a) shows the cases when the predicted CDR by CNN is near the ground truth value of CDR. Fig. 2 (b) shows the cases when the CNN is wrong in the optic disc and cup segmentation and predicts the CDR value of moderate-stage glaucoma for early-stage glaucoma images. This can be caused by a noticeable difference in image quality. The images, for which the values of CDR were predicted correctly, are brighter and indicate more clear boundaries of OD and OC. Meanwhile, the boundaries of OD and OC in the wrongly predicted value of CDR are blurry. As the only RIM-ONE dataset has images of non-glaucoma cases, these have been tested separately and the results of the mean and variance of CDR are shown in Table V. The obtained CDR results indicate CNN's ability to segment non-glaucoma cases quite accurately. This can be influenced by clear boundaries of the optic disc and cup in images of healthy eyes.

V. Conclusion

The three Convolutional Neural Networks, namely U-Net++, Attention U-Net, and Residual Attention U-Net were applied in this paper for the evaluation of cup-to-disc ratio. The experiments show that the non-glaucoma cases were identified quite accurately by all three CNNs. However, evaluating the ability of CNNs in identifying the different glaucoma stages, it is noticed that CNNs perform better in identifying moderate-stage glaucoma and severe-stage glaucoma, but the early-stage glaucomatous cases are poorly identified. Attention U-net was able to identify 50% of early-stage glaucoma cases in RIM-ONE, and 13% and 20% early-stage glaucoma cases were identified by Residual Attention U-Net and U-Net++ respectively. In the REFUGE dataset, only 21%, 14%, and 13% of early-stage glaucoma cases were identified by Attention U-NET, U-Net ++, and Residual Attention U-net respectively. CNNs misidentify cases of early-stage glaucoma by classifying them as intermediate-stage glaucoma. Which is not so bad as such cases will be noticed by the doctors. However, further research and the refining of CNNs are needed.

***Abstract*—Social choice function or voting procedure is one of the crucial concepts in the domain of political sciences. It maps individuals' preferences over a set of candidates to some subset (possibly one-element) of the candidates who can be thought as the winners of an election procedure. The paper is aimed at applications of formal concept analysis methods to study of social choice functions. We will construct concept lattices over selected set of social choice functions characterized by possessing some properties deemed as important from the point of view of political sciences. We will discuss issues connected with reducibility of both objects and attributes, irreducibility of object concepts as well as attribute concepts and attribute implications. We will discuss also the shape of the constructed concept lattice of social choice functions which in some part is exceptionally regular from the perspective of the lattice theory.**

I. Introduction

THIS paper is aimed at some applications of formal concept analysis (FCA) methods [32], [6] in social choice theory [16], [4], [19], one of the most important research domains of political sciences. We concentrate on social choice functions or voting procedures which are concepts of a crucial importance in the theory of social choice [4], [5], [18]. Our aim is to offer a non-standard approach to studying and comparing popular social choice functions. The FCA has been used in broadly meant social choice theory (cf., e.g., [27], [27], [8] or even [6]) but not with such a specific goal as here. Also, various non-classical approaches has been proposed in this area. For example, fuzzy logic has been applied with success to model various aspects of social choice (cf., e.g.[9], [21], [10], [22], [12], [23], [11]) Another line of non-classical research in this area, which is relevant for our purposes, is based on the rough-sets theory (RST) [25], [24], [26]. In particular, the research presented in [3], [13] concentrated on the issue of reduction of voting criteria and on measuring of similarity and dissimilarity of different social choice functions, ideas and methods used in comparison of voting procedures.

Actually, rough set theory can be viewed as a similar theory to formal concept analysis in the domain of data mining and knowledge discovery [31], [30] and such view drove our attention to the idea of application of formal concept analysis methods in the area of social choice functions.

The rest of the paper is organized as follows. In Section 2 some basic concepts of theory of social choice functions are introduced and discussed including voting procedures and criteria used for comparisons of different voting procedures. In Section 3 formal context of social choice functions and its concept lattice are introduced together with an investigation of the structure of concept lattice of these social choice functions. Section 4 is devoted to analysis of information provided by concept lattice of social choice functions, including attribute independency, reduction of information and attribute implications holding in the analyzed context of voting procedures. Section 4 is followed by Conclusions discussing results and presenting directions for further research.

II. Social choice functions

We consider social choice problem in a general setting which may be characterized as follows. There is a set of experts $E = \{e_j\}_{j \in J}$ and a set of options (alternatives) $O = \{o_i\}_{i \in I}$. Each expert e_j is assumed to represent his or her testimonies over the set of options O in the form of a binary preference relation $R_j \subset O \times O$ where $R_j(o_{i_1}, o_{i_2})$ is meant to represent preference of the expert e_j for the option o_{i_1} over the option o_{i_2}, i.e., that in his or her opinion option o_{i_1} is better than the option o_{i_2}. Preference relations R_j may be assumed to exhibit various properties. Often, the transitivity ($R_j(o_{i_1}, o_{i_2}) \wedge R_j(o_{i_2}, o_{i_3})$ implies $R_j(o_{i_1}, o_{i_3})$), completeness ($\forall i_1, i_2 \in I$ either $R_j(o_1, o_2)$ or $R_j(o_2, o_1)$ holds), and some form of anti-symmetry (e.g., $R_j(o_1, o_2) \implies \neg R_j(o_2, o_1)$), is assumed.

In such a setting, the *social choice function* F may be defined as follows:

$$F(X, \{R_j\}) = Y \tag{1}$$

where $X, Y \subseteq O$ are sets of options such that $Y \subseteq X$, and $\{R_j\}$ is a set of preference relations on O.

Thus, a social choice function determines which options Y are to be selected from a set of options X in view of the preference relations $\{R_j\}$ of a group of experts.

Voting procedures used in the *elections* may be interpreted as social choice functions. Often, the voting procedure is required to indicate as Y exactly one element subset of X (cf. (1)), i.e., $Y = \{o_i\}$ and the option (candidate) o_i is then called the *winner* of the election. In case of voting procedures we will usually refer to experts and options as voters and candidates, respectively.

Particular voting procedures differ in that how the winner is selected. For example, some arrive at the decision in an iterative way and the voters are requested to express their preferences several times, often with respect to a changing set of candidates. Often, the *agenda* is established which determines in which order the candidates are voted for. Most of voting procedures do not require voters to express their whole preference relations, at least not at the very beginning, but assuming existence of such a complete preference relation (*ranking* of the candidates) makes it possible to derive the winner of the election (assuming they always vote in accordance with their complete preference relation).

There are many postulated properties which are desired to be met by a fair voting procedure properly reflecting the preferences of the voters. However, it turns out that it is impossible to find one possessing all desired properties. Thus, satisfaction of such desired properties may be treated as criteria in evaluation of particular voting procedures.

In our approach, based on our previous work [3], [11], [13], [23], our point of departure is the following list of desired properties (criteria) of voting procedures:

A - Condorcet winner If each time a candidate is preferred by the majority of voters when compared to any other candidate then it has to be the winner.

B - Condorcet loser If all other candidates are preferred by the majority of voters when compared to a given candidate then the latter candidate cannot be the winner.

C - majority winner if a candidate is top-ranked in the rankings of the majority (more than 50%) of voters then this candidate have to be the winner.

D - monotonicity If a candidate is the winner then if it is ranked higher by a voter then it has still to be the winner and if a candidate is not the winner then if ranked lower by a voter cannot become the winner.

E - weak Pareto winner If for a given candidate o_1 there exists another candidate o_2 which is ranked higher than o_1 by all voters then o_1 cannot be the winner.

F - consistency If the set of voters E is divided in two groups ($E = E_1 \cup E_2$), in any possible way, and a candidate is the winner both for E_1 and E_2 then it has to be the winner for E.

G - heritage If a candidate $o_i \in O$ is the winner then it has to be the winner also when any subset of candidates $O_1 \subseteq O$ is considered such that $o_i \in O_1$

In the paper we will consider some popular voting procedures which are briefly characterized below.

Amendment Candidates are voted individually, in some order, and if a candidate gets the majority of votes it becomes the winner; otherwise the next candidate is voted.

Copeland the winner is a candidate for which the highest is the difference between the numbers of pairwise comparisons with other candidates in which it is voted by majority, respectively, as better and as worse.

Dodgson the winner is the candidate for which the minimum number of changes in voters rankings is needed to make it a Condorcet winner.

Schwartz if there is a Condorcet winner it is the winner; otherwise the set $O_S \subseteq O$ of all candidates who are voted as better by majority of voters in pairwise comparison with all candidates belonging to the set $O \setminus O_S$ are the winners.

Max-min/Egalitarian The winner is the candidate whose worst position over the rankings of all voters is the highest.

Plurality Only top-ranked candidates for each voter are taken into account and the winner is the one which is most often among them.

Borda Each position in the ranking is assigned a score, highest for the top position and lowest for the last one and the winner is a candidate for which the sum of scores of the positions it takes in rankings of particular voters (the Borda count) is the highest.

Approval Each voter points out a subset of preferred candidates and the winner is the option which is present in the highest numer of these subsets.

Black The winner is the Condorcet winner, if it exists; otherwise the Borda voting procedure is used.

Runoff Works like Plurality but two best candidates are selected and then Plurality voting is repeated for just two of them.

Nanson The Borda voting procedure is iteratively repeated and in each iteration a candidate with the lowest Borda count is excluded from the voting in the following iteration.

Hare The Plurality voting procedure is iteratively repeated and in each iteration candidates with the lowest number of top positions in the rankings are excluded from the voting in the following iteration.

Coombs The winner is a candidate which is top-ranked by the majority of voters, if it exists. Otherwise, the procedure is iteratively repeated but in each iteration the candidate which is most often ranked as the last one is eliminated.

III. Formal Concept Analysis

Formal concept analysis (FCA) was introduced by Wille in [32]. FCA is founded on lattice theory and aimed at data analysis and representation. FCA uses tabular-type data representations called *formal contexts* where objects are characterized by mono-valued attributes[1]. In FCA data are represented and analyzed by concept lattices using algebraic, order and logical methods based on concept lattices. A construction of concept lattices is based on Galois connections determined by formal contexts. Here we present basic notions of FCA. For a detailed

[1] In the process of development, FCA was broadened also for multi-valued attributes by means of conceptual scaling [6].

presentation of formal concept analysis see the first monograph on FCA by Ganter and Wille [6] and for elements of lattice theory see an excellent textbook freely available on-line by Burris and Sankappanavar [2].

A *formal context* is defined as a triple of the form (G, M, I), where G and M are sets, while I is a binary relation $I \subseteq G \times M$. Elements of set G and M are called *objects* and *attributes* respectively as well as *an extent* and *an intent*, respectively, of the context (G, M, I). The fact that $a \in G$ and $m \in M$ are in relation I will be denoted as $a\ I\ m$, and will be described as that *object a possesses attribute m*, or that *attribute m is possessed by object a*.

For context (G, M, I) two different operators between power sets $\wp(G)$ and $\wp(M)$ are defined:

$$X \mapsto X^i = \{m \in M : a\ I\ m,\ \forall\ a \in X\},$$

$$Y \mapsto Y^e = \{a \in G : a\ I\ m,\ \forall\ m \in Y\},$$

for each $X \subseteq G$, $Y \subseteq M$. Operator $\cdot^i$ is called *an intension operator* and operator $\cdot^e$ is called *an extension operator*. One can note that operators $\cdot^i$ and $\cdot^e$ are perfectly dual in the sense of order theory, thus in FCA there is commonly used practice to denote these operators by the same prime symbol $\cdot'$ [6]. This practice is justified by the formal properties of extension and intension operators presented in Table I and makes calculation easier. It also does not lead into confusion: in Table I for example, since $Y \subseteq M$, then formula (3b) $Y' = Y'''$ can be rewritten as $Y^e = Y^{eie}$.

TABLE I
BASIC PROPERTIES OF INTENSION AND EXTENSION OPERATORS FOR FORMAL CONTEXT (G, M, I) AND SETS $X, X_1, X_2 \subseteq G$ AND $Y, Y_1, Y_2 \subseteq M$ [6].

(1a) $X_1 \subseteq X_2 \Rightarrow X_2' \subseteq X_1'$	(1b) $Y_1 \subseteq Y_2 \Rightarrow Y_2' \subseteq Y_1'$
(2a) $X \subseteq X''$	(2b) $Y \subseteq Y''$
(3a) $X' = X'''$	(3b) $Y' = Y'''$
(4a) $(X_1 \cup X_2)' = X_1' \cap X_2'$	(4b) $(Y_1 \cup Y_2)' = Y_1' \cap Y_2'$

A *formal concept* of context (G, M, I) is pair (A, B) with $A \subseteq G$, $B \subseteq M$, such that $A = B'$ and $B = A'$. A and B are called *the extent* and *the intent* of the concept (A, B) respectively. The family of all formal concepts of context (G, M, I) is denoted by $\mathfrak{B}(G, M, I)$. If $(A, B) \in \mathfrak{B}(G, M, I)$ and $g \in A$, then g is *an object from the concept* (A, B). Using properties form Table I one can show that for any object $g \in G$ and any attribute $m \in M$, the following equations hold: $(\{g\}'', \{g\}'), (\{m\}', \{m\}'') \in \mathfrak{B}(G, M, I)$. Concept $(\{g\}'', \{g\}')$ is called *an object concept of object g* whereas concept $(\{m\}', \{m\}'')$ is *an attribute concept of attribute m*. The object concept of any object $g \in G$ we denote by $\tilde{\gamma}(g)$ and the attribute concept of any attribute $m \in M$ we denote by $\tilde{\mu}(m)$. If $(A, B) = (\{g\}'', \{g\}')$, then object g is called *an own object* of concept (A, B), i.e. g posses only those attributes which are contained in B. Analogically, If $(A, B) = (\{m\}', \{m\}'')$, then attribute m is called *an own attribute of concept* (A, B), i.e. m is possessed only by those objects which are contained in A.

Let (G, M, I) be a formal context. On family $\mathfrak{B}(G, M, I)$ we define relation $\preccurlyeq$ in the following way:

$$(A_1, B_1) \preccurlyeq (A_2, B_2) \Leftrightarrow A_1 \subseteq A_2 (:\Leftrightarrow B_2 \subseteq B_1).$$

where $(A_1, B_1), (A_2, B_2) \in \mathfrak{B}(G, M, I)$. In this case (A_1, B_1) is called *a subconcept* of (A_2, B_2) and (A_2, B_2) is called *a superconcept* of (A_1, B_1). The relation $\preccurlyeq$ is a partial order on the family $\mathfrak{B}(G, M, I)$ and it is called *the hierarchical order* (or simply *order*). One can show that the family $\mathfrak{B}(G, M, I)$ ordered by the relation $\preccurlyeq$ is a complete lattice called the *concept lattice* of the context (G, M, I). We denote that lattice by $\underline{\mathfrak{B}}(G, M, I)$.

Having the relation $\preccurlyeq$ defined for the concept lattice one can equivalently consider two binary operations denoted as $\wedge$ and $\vee$ which can be expressed in terms, respectively, of the *infimum* and *supremum* with respect to relation $\preccurlyeq$. Namely, $a \wedge b = \inf\{a, b\}$ and $a \vee b = \sup\{a, b\}$. Thanks to the semantics of the infimum and supremum, these operations may be easily extended for arbitrary sets of arguments. The Basic Theorem on Concept Lattices [32], [6] shows that in the case of the concept lattice $\underline{\mathfrak{B}}(G, M, I)$ these operations and their generalizations for arbitrary sets of concepts are given by the following equations respectively:

$$\bigwedge_{i \in I}(A_i, B_i) = (\bigcap_{i \in I} A_i, (\bigcup_{i \in I} B_i)''),$$

$$\bigvee_{i \in I}(A_i, B_i) = ((\bigcup_{i \in I} A_i)'', \bigcap_{i \in I} B_i).$$

Therefore concept lattices can be viewed as hierarchical conceptual structures equipped with some operations on concepts and representing data stored in formal contexts. When the number of objects or the number of attributes in formal contexts are relatively small, then concept lattices can be used also for visualization of information stored in their formal contexts. In the next section we present a relatively small concept lattice representing a selection of social choice functions characterized by selected voting criteria, briefly introduced in section II.

IV. CONCEPT LATTICE OF SOCIAL CHOICE FUNCTIONS

This section is devoted to construction and structural analysis of proposed lattice of social choice functions. We start with definition of formal context of social choice functions on the basis of consideration conducted in the previous section. Let

$$\mathbb{SCF} := (\mathrm{G}_{\mathbb{SCF}}, \mathrm{M}_{\mathbb{SCF}}, \mathrm{I}_{\mathbb{SCF}})$$

be a formal context where set $\mathrm{G}_{\mathbb{SCF}}$ comprises all voting procedures presented in Section II, set $\mathrm{M}_{\mathbb{SCF}}$ consists of selected criteria denoted by letters $A, ..., G$ in Section II, while set of pairs $\mathrm{I}_{\mathbb{SCF}}$ is the incidence relation presented in Table II.

Now, on the basis of formal context $\mathbb{SCF}$ we construct the concept lattice of social choice functions $\underline{\mathfrak{B}}(\mathrm{G}_{\mathbb{SCF}}, \mathrm{M}_{\mathbb{SCF}}, \mathrm{I}_{\mathbb{SCF}})$ (Fig. 1) and study its properties[2].

[2] Diagrams of concept lattices are generated with usage of ConExp software by Serhiy A. Yevtushenko.

TABLE II
A FORMAL CONTEXT OF SELECTED SOCIAL CHOICE FUNCTIONS. ROWS CORRESPOND TO FORMAL OBJECTS WHICH ARE SOCIAL CHOICE FUNCTIONS AND COLUMNS CORRESPOND TO FORMAL ATTRIBUTES WHICH ARE SOME CRITERIA INTRODUCED IN SECTION II.

Voting procedures	Criteria						
	A	B	C	D	E	F	G
Amendment	×	×	×	×			
Copeland	×	×	×	×	×		
Dodgson	×		×		×		
Schwartz	×	×	×	×			
Max-min	×		×	×	×		
Plurality			×	×	×	×	
Borda		×		×	×	×	
Approval				×		×	×
Black	×	×	×	×	×		
Runoff		×	×		×		
Nanson	×	×	×		×		
Hare		×	×		×		
Coombs		×	×		×		

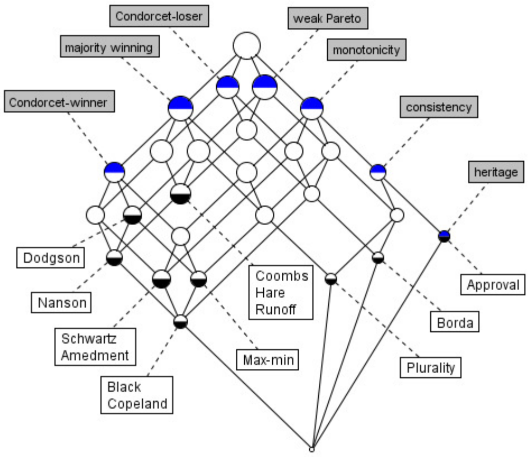

Fig. 1. Concept lattice of social choice functions $\underline{\mathfrak{B}}(\mathrm{G}_{\mathbb{SCF}}, \mathrm{M}_{\mathbb{SCF}}, \mathrm{I}_{\mathbb{SCF}})$. Half-black nodes represent object concepts while half-blue nodes represent attribute concepts .

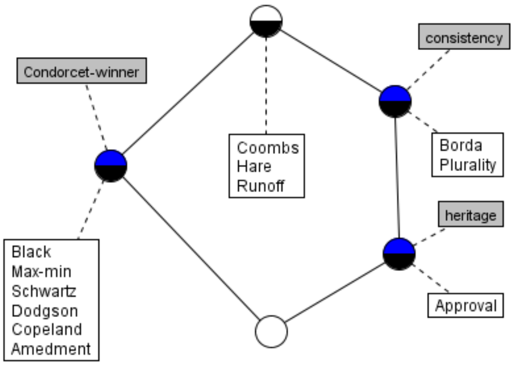

Fig. 2. Concept lattice $\underline{\mathfrak{B}}(\mathrm{G}_1, \mathrm{M}_1, \mathrm{I}_1)$.

Fact 1: Concept lattice of social choice functions $\underline{\mathfrak{B}}(\mathrm{G}_{\mathbb{SCF}}, \mathrm{M}_{\mathbb{SCF}}, \mathrm{I}_{\mathbb{SCF}})$ is nondistributive, i.e., it is not the case that $\forall C_1, C_2, C_3 \in \mathfrak{B}(\mathrm{G}_{\mathbb{SCF}}, \mathrm{M}_{\mathbb{SCF}}, \mathrm{I}_{\mathbb{SCF}})$ $C_1 \wedge (C_2 \vee C_3) = (C_1 \wedge C_2) \vee (C_1 \wedge C_3)$ nor $C_1 \vee (C_2 \wedge C_3) = (C_1 \vee C_2) \wedge (C_1 \vee C_3)$.

In order to show this one can consider the following formal context:

$$\mathbb{K}_1 := (\mathrm{G}_1, \mathrm{M}_1, \mathrm{I}_1),$$

where $\mathrm{G}_1 := \mathrm{G}_{\mathbb{SCF}}$, $\mathrm{M}_1 := \{Condorcet-winner, \; consistency, \; heritage\}$, and $\mathrm{I}_1 := \mathrm{I}_{\mathbb{SCF}} \; \cap (G_1 \times M_1)$. Now one can note that its concept lattice $\underline{\mathfrak{B}}(\mathrm{G}_1, \mathrm{M}_1, \mathrm{I}_1)$, which is presented in Fig. 2, is a famous N5 lattice [2] and can be embedded into concept lattice of social choice functions $\underline{\mathfrak{B}}(\mathrm{G}_{\mathbb{SCF}}, \mathrm{M}_{\mathbb{SCF}}, \mathrm{I}_{\mathbb{SCF}})$. This by famous theorems by Dedekind and by Birkhoff implies that concept lattice of social choice functions $\underline{\mathfrak{B}}(\mathrm{G}_{\mathbb{SCF}}, \mathrm{M}_{\mathbb{SCF}}, \mathrm{I}_{\mathbb{SCF}})$ is neither modular nor distributive (see e.g. [2]).

The fact that concept lattice $\underline{\mathfrak{B}}(\mathrm{G}_{\mathbb{SCF}}, \mathrm{M}_{\mathbb{SCF}}, \mathrm{I}_{\mathbb{SCF}})$ lacks such regular property as distibutivity is not surprising. In fact it is quite rare phenomenon that real, non-manipulated data generate concept lattice possessing some regular properties. For example, one can consult concept lattice presented in [17] and generated from Threats Matrix (in German *Gefahrenmatrix*) used in commanding of tactical actions by German Fire Service [1], [7]. However, looking at the concept lattice presented in Fig. 1 one can note that the left part of this lattice diagram reveals some regularity. Namely, the concept lattice of social choice functions $\underline{\mathfrak{B}}(\mathrm{G}_1, \mathrm{M}_1, \mathrm{I}_1)$ contains as sublattices some distributive lattices or some Boolean algebras. Moreover, some subcontexts generated from context $\mathbb{SCF}$ of social choice functions generate lattices possessing some regularity.

Let

$$\mathbb{K}_2 := (\mathrm{G}_2, \mathrm{M}_2, \mathrm{I}_2),$$

be a formal context, where $\mathrm{G}_2 := \mathrm{G}_{\mathbb{SCF}}$, $\mathrm{M}_2 := \{Condorcet-winner, majority\ winning, \; weak\ Pareto, \; monotonicity\}$, and $\mathrm{I}_2 := \mathrm{I}_{\mathbb{SCF}} \; \cap (G_2 \times M_2)$, thus $\mathbb{K}_2$ is subcontext of social choice functions context $\mathbb{SCF}$. Then concept lattice $\underline{\mathfrak{B}}(\mathrm{G}_2, \mathrm{M}_2, \mathrm{I}_2)$ is presented in Figure 3. One can note that concept lattice $\underline{\mathfrak{B}}(\mathbb{K}_2)$ is distributive.

For another example let us consider the following subcontext of social choice functions context $\mathbb{SCF}$:

$$\mathbb{K}_3 := (\mathrm{G}_3, \mathrm{M}_3, \mathrm{I}_3),$$

where $\mathrm{G}_3 := \mathrm{G}_{\mathbb{SCF}}$, $\mathrm{M}_3 := \{Condorcet-loser, \; majority\ winning, \; weak\ Pareto, monotonicity\}$, and $\mathrm{I}_3 := \mathrm{I}_{\mathbb{SCF}} \cap (G_3 \times M_3)$. One can note that concept lattice $\underline{\mathfrak{B}}(\mathbb{K}_3)$ presented in Figure 4 is Boolean lattice isomorphic to the power set algebra of a four-element set.

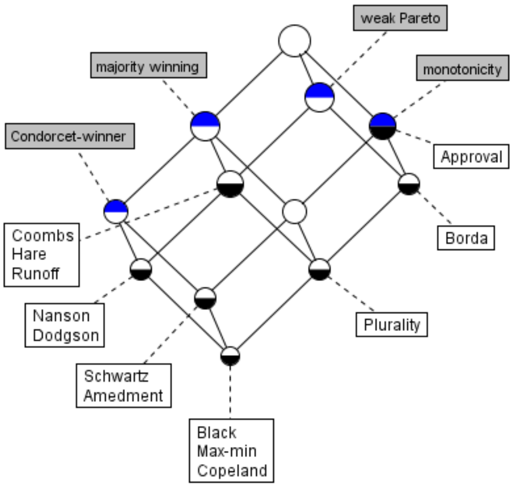

Fig. 3. Distributive concept lattice $\underline{\mathfrak{B}}(\mathrm{G}_2, \mathrm{M}_2, \mathrm{I}_2)$.

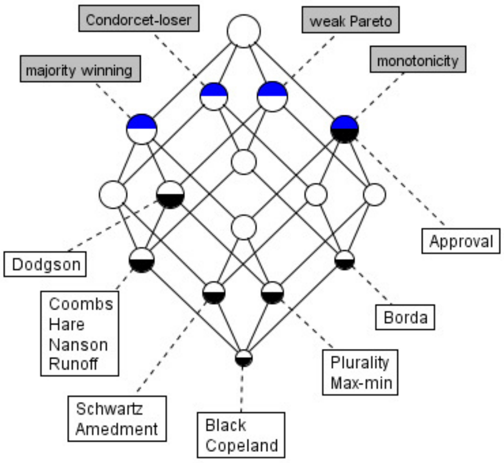

Fig. 4. Boolean concept lattice $\underline{\mathfrak{B}}(\mathrm{G}_3, \mathrm{M}_3, \mathrm{I}_3)$.

V. Information Provided by Lattice of Social Choice Functions

This section is devoted to the analysis of social choice functions listed in Section II by means of the FCA. We will concentrate on issues of attribute independency, reduction of information and on attribute implications derived from proposed formal context of social choice functions by means of FCA.

A. Attribute Independency

Let us start our consideration with the independency of attributes in the formal context $\mathbb{SCF}$ of social choice functions (voting procedures). Let (G, M, I) be the formal context. Attributes in $X \subseteq M$ are independent if there are no trivial dependencies between them i.e. functional (or ordinal) dependencies where set of attributes Y is functionally (ordinally) dependent on set of attributes X and $Y \subseteq X$. Following [29] we recall:

Lemma 1: Attributes are independent if they span a hypercube in a concept lattice.

For example concept lattice of social choice functions has four coatoms and these formal concepts as coatoms are also attribute concepts, namely these are $\tilde{\mu}(majority\ winning)$, $\tilde{\mu}(Condorcet - loser)$, $\tilde{\mu}(weak\ Paretto)$ and $\tilde{\mu}(monotonicity)$. These attributes are independent since every three attributes from this set (by their attribute concepts) span a hypercube in the concept lattice $\underline{\mathfrak{B}}(\mathrm{G}_{\mathbb{SCF}}, \mathrm{M}_{\mathbb{SCF}}, \mathrm{I}_{\mathbb{SCF}})$. In fact, in concept lattice $\underline{\mathfrak{B}}(\mathrm{G}_{\mathbb{SCF}}, \mathrm{M}_{\mathbb{SCF}}, \mathrm{I}_{\mathbb{SCF}})$ it is easier to characterize sets of attributes which are not independent: in concept lattice $\underline{\mathfrak{B}}(\mathbb{SCF})$ there are four two-element chains of attribute concepts, namely:

- $\{\tilde{\mu}(Condorcet - winner), \tilde{\mu}(majority\ winning)\}$,
- $\{\tilde{\mu}(heritage),\ \tilde{\mu}(consistency)\}$,
- $\{\tilde{\mu}(heritage),\ \tilde{\mu}(monotonicity)\}$,
- $\{\tilde{\mu}(consistency),\ \tilde{\mu}(monotonicity)\}$.

Sets of attributes which are not independent are exactly sets of attributes containing at least one pair of attributes such that their attribute concepts are contained in one of the above two-element chains.

B. Reducibility of Information

Reduction of information is one of the main advantages of formal concept analysis. Here we describe reduction of information within concept lattice of social choice functions.

Let us recall that context (G, M, I) is called *clarified* if for any objects $g, h \in G$, $g' = h'$ implies $g = h$ and for any attributes $m, n \in M$, $m' = n'$ implies $m = n$. Now let us note the following facts:

Fact 2: Context $\mathbb{SCF}$ is not clarified.
It is so since, e.g., $\{Coombs\}' = \{Runoff\}'$ but obviously $Coombs \neq Runoff$. However, for the set of all attributes of context $\mathbb{SCF}$ (denoted by $\mathrm{M}_{\mathbb{SCF}}$) one of the necessary conditions for a clarified context holds, i.e.:

Fact 3: For all attributes (criteria) $m, n \in \mathrm{M}_{\mathbb{SCF}}$ the following implication holds:

$$\{m\}' = \{n\}' \Rightarrow m = n.$$

It is easily seen in Fig. 1 where there are no two criteria determining the same attribute concept.

Let us recall that for any formal context (G, M, I), object $g \in G$ is *reducible* if its object concept $\tilde{\gamma}(g)$is *supremum-reducible*, i.e., can be represented as the supremum of strictly smaller concepts what implies that concept $\tilde{\gamma}(g)$ has no unique lower neighbour in concept lattice $\underline{\mathfrak{B}}(G, M, I)$. Analogously, for any context (G, M, I), attribute $m \in M$ is *reducible* if its attribute concept $\tilde{\mu}(m)$ is *infimum-reducible*, i.e., can be represented as infimum of strictly greater concepts, i.e. concept $\tilde{\gamma}(m)$ has no unique upper neighbour in concept lattice $\underline{\mathfrak{B}}(G, M, I)$. Now one can note that:

Fact 4: The social choice function Dodgson (more formally: the object representing this social function in the lattice) is reducible. The rest of social choice functions from the context $\mathbb{SCF}$ are irreducible.

One can note that social choice function $Dodgson$ as a formal object is reducible since its object concept is a supremum of two different concepts:

$$\tilde{\gamma}(Dodgson) = \tilde{\gamma}(Nanson) \vee \tilde{\gamma}(Max - min),$$

in $\underline{\mathfrak{B}}(G, M, I)$, the concept lattice of social choice functions. Namely the object concept $\tilde{\gamma}(Dodgson)$ is the lattice union of the object concepts determined by voting procedures Nanson and the object concept determined by the voting procedure Max-min. This observation may be expressed in a different way by saying that the Dodgson social choice function is Pareto-dominated by the Nanson and Max-min functions. Such a statement is justified as the attributes of the functions express their desired properties and thus the aforementioned dominance is here well-defined.

Concerning the rest of voting procedures from the social choice functions context $\mathbb{SCF}$, their object concepts have exactly one lower neighbour in the concept lattice of social choice functions, thus by Proposition 2 of [6] these object concepts are irreducible.

Fact 5: All attributes are irreducible.

One can note that every attribute concept determined by a criterion from the context $\mathbb{SCF}$ has exactly one upper neighbour what in the light of Proposition 2 of [6] shows that all attribute concepts in the social choice context $\mathbb{SCF}$ are infimum-irreducible.

Fact 6: In the formal context $\mathbb{SCF}$ of social choice functions there is only one concept which is both object concept and attribute concept.

In order to show this one can note that:

$$\tilde{\gamma}(Approval) = \tilde{\mu}(heritage),$$

i.e. social choice function (voting procedure)$Approval$ and voting criterion $heritage$ determine the same concept in the concept lattice of social choice functions. It stems from the fact, that the property (attribute) $heritage$ distinguishes the voting procedure $Approval$ from the other procedures and, at the same time, property $heritage$ is satisfied only by $Approval$.

C. Implications holding in the Context of Social Choice Functions

The FCA based analysis of voting procedures brings in another potentially interesting insight into their functioning. Namely, *implications* holding in the context of social choice functions may provide social choice theorists with valuable information. Those implications are not laws derived by theoretical considerations directly from knowledge gathered in the framework of the social choice theory but they are derived from the description of the voting procedures created by politicians and social choice theorist and expressed in terms of different properties postulated by social choice theorists.

Let us recall the notion of attribute implication. Informally, implications between attributes are the statements of the following form "Every object with the attributes a, b, c, ... also has the attributes x, y, z, ... " [6]. Formally speaking, an implication between attributes in context (G, M, I) is a pair of subsets of the attribute set M. If $A, B \subseteq M$, then implication between A and B is denoted by $A \rightarrow B$. An implication between attributes may or may not hold in a given formal context. Instead of formal definition of implication which holds in a given formal context we recall a transparent characterization of this notion given in Proposition 19 in [6]: an implication $A \rightarrow B$ holds in (G, M, I) if and only if $B \subseteq A''$.

Looking at concept lattice of social choice functions presented in Fig. 1 one can note relatively large number of nontrivial implications between singular attributes which are enlisted below:

- $\{Condorcet - winner\} \rightarrow \{majority\ winning\}$
- $\{heritage\} \rightarrow \{consistency\}$
- $\{consistency\} \rightarrow \{monotonicity\}$

One of the formal reasons for that is the fact that five of seven attribute concepts are involved into two chains maximal with respect to the property that they consist only of attribute concepts, namely the following two chains:

- $\{\tilde{\mu}(Condorcet - winner), \tilde{\mu}(majority\ winning)\}$
- $\{\tilde{\mu}(heritage),\ \tilde{\mu}(consistency),\ \tilde{\mu}(monotonicity)\}$.

Finally, one can note that maximal antichains consisting only of attribute concepts have four elements which seems to be a relatively high number compared to the fact that maximal antichains in concept lattice of social choice functions analyzed within this paper have seven elements, i.e. the width of the concept lattice of social choice functions is 6.

VI. Conclusions

The concept lattice of social choice functions constructed and analyzed within this paper has an interesting and pretty regular structure. Despite the fact that itself it is nondistributive lattice it contains quite a few regular sublattices, including Boolean, distributive and modular lattices of a quite large size compared to the size of the whole lattice.

From the perspective of social choice theory interesting is a comparison of the applicability of formal concept analysis methods and rough sets theory methods. The latter has been already reported in the literature [3], [13]. One of particular dimensions of such comparison will be the issue of information reduction in both approaches.

And last but not least, an interesting issue worth of further research from the perspective of FCA is to find out whether observations reported in the paper can be interpreted in a deeper way in the language of the social choice theory. Thus, the further research in this direction can be focused on one task: to understand the observed phenomena presented in this paper in terms of social choice theory.

***Abstract*—We introduce a novel approach to postquantum symmetric encryption that allows us to modify and continue to use any encryption scheme. By composing the encryption and decryption functions with the evaluation of arbitrarily wide neural networks we are able to verify that anyone performing these functions has access to at least a certain amount of memory. Since the number of qubits in quantum computers has been relatively slow-growing, this provides us security from the Grover's search attack, and any attack utilizing a similar oracle circuit.**

***Index Terms*—post-quantum cryptography, symmetric key cryptography, encryption, neural networks**

I. Introduction

THE development of quantum computers is likely to lead to major breakthroughs in many areas of science and engineering. Cryptography is one area where this breakthrough is already evident. Although we do not yet have a quantum computer capable of cracking the 2048-bit RSA key, the world is preparing for that moment. In 2016, the US NIST announced a competition for a post-quantum public key algorithm. In June 2022, after three rounds of review, four algorithms implementing key encapsulation (Crystals-Kyber) and digital signature functionality (Crystals-Dilithium, Falcon, Sphincs+) were selected.

Secret key cryptography is much less threatened by quantum computers. The Grover algorithm is only able to halve the security strength of the AES algorithm. This means that AES with a 256-bit key will be as secure as AES with a 128-bit key is today.

This is still enough of a security margin not to change the cipher, which is the "workhorse" of the Internet, too quickly.

However, it is worth considering all possible directions for post-quantum secret key cryptography. Here, we present an idea of making Grover's search attack more challenging in terms of qubits of memory needed on a quantum computer.

II. State-of-the-art

Currently, the most widely used symmetric cipher is AES [1], which is susceptible to the Grover's search attack. AES exists in three variants: AES-128, AES-196, and AES-256 named after the length of the binary key string. The key spaces are then of size 2^{128}, 2^{196}, and 2^{256} respectively. Since Grover's search attack effectively halves the exponent of the key space size, AES-256 would be reduced to the security level of AES-128 and the remaining two variants would become insecure by the previous standard. Since AES-128 is currently considered secure, switching to AES-256 is the solution provided in [2] and [3]. Additionally, for purposes requiring AES-256 level security, [3] extends AES to include a 512 key length variant.

It is first worth noting that there already exist solutions that are secure against the Grover's search attack, in particular AES-QPP, which is a variant of AES in which the SubBytes and AddRoundKey are replaced by a Quantum Permutation Pad operation, granting quantum safety [4], or Saturnin, which is a block cipher that has been specifically designed for the purpose of being quantum-safe while also maintaining lightweight properties making it more suitable for IoT applications [5]. In comparison to them, however, AES has the benefit of having been exposed to extensive analysis by the public.

Using neural networks cryptographic solution, at least academically, is not a novel concept either. In [6] the authors utilize recurrent neural networks of a specific shape to define a symmetric cipher. In [7] a cryptographic hash function is defined based on the evaluation of a neural network with randomized matrices.

III. Preliminaries and Definitions

In this section, we introduce the terms and notation we will use throughout this article. Since this work exist at the intersection of a few different subfields within computer science, we divide it into subsections

A. Algebraic notation

For the sake of simplicity of notations in this subsection, we will introduce some shorthands that we will use throughout this article.

Let $v \in \mathcal{F}^n$ be an n-dimensional vector over some field $\mathcal{F}$, by $v[i]$ for $0 \leq i < n$ we will denote the i-th element of the vector.

A **Galois field** is synonymous to a finite field and we use the notation $GF(q)$ to denote a Galois field of size q. By a well-known algebraic theorem when q is of the form $q = p^n$ for some prime p and some $n \in \mathbb{N}_+$ then $GF(q)$ exists and is unique in the sense of isomorphisms. For any other size a finite field does not exist, thus $GF(q)$ is well-defined only for powers of a prime number.

B. Cryptography

Here we attempt to formalize some notions present in cryptography. Note that it is particularly difficult to reflect the practical nature of this field. We nonetheless make the attempt in order to provide a mathematical argument for the correctness of our claims.

Definition 1. *A **symmetric cipher** is a tuple $(e, d, \mathcal{P}, \mathcal{C}, \mathcal{K})$ such that:*

- *$\mathcal{P}$ is a set of plaintexts,*
- *$\mathcal{C}$ is a set of ciphertexts,*
- *$\mathcal{K}$ is a key space,*
- *$e : \mathcal{P} \times \mathcal{K} \to \mathcal{C}$,*
- *$d : \mathcal{C} \times \mathcal{K} \to \mathcal{P}$,*
- *for any $p \in \mathcal{P}$, $k \in \mathcal{K}$: $d(e(p, k), k) = p$.*

A cipher $\sigma = (e, d, \mathcal{P}, \mathcal{C}, \mathcal{K})$ is going to be **secure** if the following conditions are met:

1) Given only the value of $e(p, k)$ it is impossible to reliably compute p faster than the naive approach of iterating through all of the key space.
2) Given only the values of $e(p, k)$ and p it is impossible to reliably compute k faster than the naive approach of iterating through all of the key space.

Any algorithm or process that proves a cipher to be insecure is called an attack. Note that this is one place where there is a discrepancy between this formal definition and the practical notion of security — many ciphers are still considered practically secure despite existing attacks because those attacks are proved to be impractical.

An attack that violates the first property will be called a **ciphertext-only attack** and an attack that violates the second (but not the first) will be called a **known-plaintext attack**.

C. Neural networks

Since the main result of this work is heavily inspired by neural networks, we feel the need to define some notions from that field of study. Let us start with defining, arguably, the simplest type of neural network — the multilayer perceptron. This will be the only type of neural network we will refer to in this work, so we will sometimes use the term neural network as a synonym for a multilayer perceptron, but we note that in the wider topic such equivalence would be false.

Definition 2. *A **multilayer perceptron** over the field $\mathcal{F}$ is a function $f : \mathcal{F}^{n_1} \to \mathcal{F}^{n_{d+1}}$ of form $f = l_1 \circ l_2 \circ \cdots \circ l_d$, where $d \in \mathbb{N}_+$ is the **depth** of the neural network. Each function $l_i : \mathcal{F}^{n_i} \to \mathcal{F}^{n_{i+1}}$ for $1 \le i \le d$ (which we will call a **layer**) must be in the form $l_i = m_i \circ a_i$ where:*

- *$m_i : \mathcal{F}^{n_i} \to \mathcal{F}^{n_{i+1}}$ is a linear transformation using the matrix $M_i \in \mathcal{F}^{n_i \times n_{i+1}}$,*
- *$a_i : \mathcal{F}^{n_{i+1}} \to \mathcal{F}^{n_{i+1}}$ is a non-linear transformation (we will sometimes call a_i the **activation** function).*

Note that the typical definition is usually constrained to $\mathcal{F} = \mathbb{R}$ and also requires the activation function to be differentiable and monotonic on each element. This is a conscious choice on our part, since we need to generalize this concept to other fields, because of the impracticality of representing real numbers on computers.

D. Quantum computing

A **qubit** is the most fundamental unit of quantum information. The state of a qubit is any vector $\psi \in \mathbb{C}^2$ with its norm equal to 1. We traditionally denote the state of a qubit as a ket in bra-ket notation (also called Dirac notation), like so $|\psi\rangle$. Two special states, forming an orthogonal basis, are usually distinguished:

$$|0\rangle = \begin{pmatrix} 1 \\ 0 \end{pmatrix},\ |1\rangle = \begin{pmatrix} 0 \\ 1 \end{pmatrix}.$$

If more than one qubit exists, the state of such a system is the Hadamard product of the states of each qubit. In bra-ket donation, the Hadamard product of two states $|\psi\rangle$ and $|\phi\rangle$ is denoted by $|\psi\rangle |\phi\rangle$, or sometimes $|\psi\phi\rangle$. For an n-qubit system we also define the orthogonal basis $\{|0\rangle_n, |1\rangle_n, \cdots, |2^n - 1\rangle_n\}$ where $|i\rangle_n$ is a vector such that $|i\rangle_n [i] = 1$.

A quantum gate O, acting on an n-qubit state, is any invertible, unitary $2^n \times 2^n$ matrix over complex numbers. The application of O on the state $|\phi\rangle$ is the product of the matrix and vector, and is denoted as $O |\psi\rangle$.

Notice that because of the definition of a quantum gate, to uniquely identify a quantum gate, it suffices to define the results of applying it to some basis. Below we use this fact to define some gates that will be referenced throughout this article.

The NOT gate, or the X gate is a quantum gate acting on a single qubit, and is defined as follows:

- $X |0\rangle = |1\rangle$,
- $X |1\rangle = |0\rangle$.

The Toffoli or the CCX gate is a quantum gate acting on a 3-qubit state. The Toffoli gate acts according to the following rules:

- $CCX |11a\rangle = |11\rangle (X |a\rangle)$,
- $CCX |abc\rangle = |abc\rangle$, if $|ab\rangle \neq |11\rangle$.

IV. Cryptanalysis with quantum computers

The development of quantum computing technology poses a threat to our existing, widely used, ciphers. In the field of public-key cryptography, there is, for example, the famous Shor's algorithm, the usage of which can break RSA (Diffie-Hellman, ElGamal and elliptic curve cryptography too) in polynomial time. For private-key encryption the known quantum attacks are much less spectacular, nonetheless, they do exist and are worth investigating.

Grover's search algorithm is a quantum computing algorithm that, given an oracle circuit Q, over $n + 1$ qubits, with the property that for any $x \in \{0, 1, \cdots, N-1\}$, and for any $a \in \{0, 1\}$

$$Q|x\rangle|a\rangle = \begin{cases} |x\rangle X|a\rangle, \text{ iff } x = a \\ |x\rangle|a\rangle, \text{ otherwise} \end{cases}$$

is able to find a with only $O(\sqrt{N})$ invocations of Q. This is an obvious improvement over an analogous situation in classical computing where the fastest such algorithm needs $O(N)$ invocations.

For any symmetric cipher $\sigma = (e, d, \mathcal{P}, \mathcal{C}, \mathcal{K})$ we may then define the following known plaintext attack:

1) Define an oracle Q that given k_1 as input, returns $e(p, k) = e(p, k_1)$.
2) Use Grover's search algorithm to compute k.

This takes $O(\sqrt{|\mathcal{K}|})$ invocations of Q, making it an attack on σ. Note that this attack is only possible if the attacker is able to execute the oracle circuit — which is what we make use of in this work.

V. The Proposed Solution

We introduce a novel approach that allows one to secure any private key cipher against a Grover attack, provided that both communicating sides have more memory bits on their machines than an attacker might have on their quantum computer. The algorithm works by modifying a scheme σ to form a scheme σ', such that the decryption function σ' requires at least a set number of bits of memory to compute — thus preventing the formation of the Grover oracle. In this section, we will detail how we achieve this.

Let's start with an arbitrary encryption scheme $\sigma := (e, d, \mathcal{P}, \mathcal{C}, \mathcal{K})$ and a bijection $f : \mathcal{C}^n \to \mathcal{P}^n$, for some n, the details of which we outline in Section VI. The scheme $\sigma' := (e', d', \mathcal{P}^n, \mathcal{C}^n, \mathcal{K})$ is then defined such that for a key $k \in \mathcal{K}$:

- $e'((p_1, p_2, \cdots, p_n), k) := (e(f(e(p_1, k)), k), \cdots, e(f(e(p_n, k)), k))$,
- $d'((c_1, c_2, \cdots, c_n), k) := (d(f^{-1}(d(c_1, k)), k), \cdots, d(f^{-1}(d(c_n, k)), k))$.

In other words, to encrypt a message, we concatenate n messages encrypted with σ, pass the output through f, split it back into n messages, and encrypt them again. To decrypt a message we then: decrypt the ciphertexts using σ, concatenate them, pass the output through f^{-1}, split them, and decrypt them using σ.

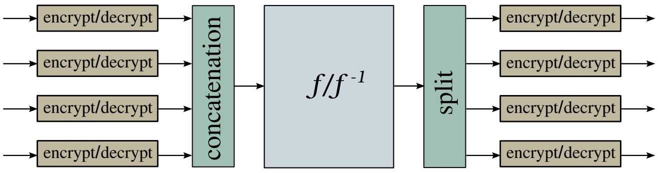

Figure 1: The proposed solution: securing cipher against Grover's attack with nonlinear bijective function f

Let us define a k-mixing function:

Definition 3. *A function $g : GF(2)^n \to GF(2)^n$ is k-**mixing** if, it is impossible to compute values for any subset of output bits, given only k of input bit values.*

Let us then state the following observation

Observation 1. *The proposed above solution produces a scheme that is secure against the Grover attack on machines with at most k qubits if the function f is k-mixing.*

Proof. Since the Grover attack requires the attacker to formulate an oracle circuit, and the attacker has at most k qubits available, this oracle function would have to compute values of some output bits given only k of the input bits, since that is all the attacker could store in memory. □

All that is now needed is to propose a family of bijective functions that will contain k-mixing functions for arbitrarily large k-s. At first glance, traditional multilayer perceptrons could be utilized. Indeed, a sigmoid activation function and invertible weight matrices would guarantee bijectivity, and the expressive power of neural networks should, at least intuitively, correlate to the mixing property, if random weights were used. However, with this approach, a practical issue arises - the naive implementation of such a function utilizing floating point arithmetic, would almost certainly not be able to produce an exact mathematical inverse. Instead, in the following section, we introduce a structure that operates on the finite field $GF(2)$ in a similar way that traditional multilayer perceptrons operate on $\mathbb{R}$, which we then may use instead.

VI. Definition of the f Function

Let us define a Galois neural network:

Definition 4. *A **Galois neural network** is a multilayer perceptron over a Galois field.*

Let's observe that such a Galois network may serve as our f function, as long as we design it to be a bijection. To do so, it suffices to design a layer that is bijective. For the linear part of each layer, since we have total control of the values of the matrices, it suffices to find an invertible matrix M. For the activation function, this is less trivial, partially since, unlike traditional neural networks, all bijections over the field $GF(2)$ are linear, and so this activation function must in some way require interaction between elements of a vector. Below, we detail the design of the family of functions that fit these requirements.

We define a family of functions that work analogously to the iterative application of the Toffoli gate in quantum computers.

Definition 5. *A function $t_{m,k,l} : GF(2)^n \to GF(2)^n$ will be called a **Toffoli function** acting on bit m with control bits k, l (where m, k, l are pairwise different and $k < l$) if for all $v \in GF(2)^n$:*

1) $\forall_{i \neq m} t_{m,k,l}(v)[i] = v[i]$,
2) $(t_{m,k,l}(v)[m] \neq v[m]) \iff (v[k] = v[l] = 1)$.

The following lemma is then true:

Lemma 1. *Let $f : GF(2)^n \to GF(2)^n$ be a composition of at least one Toffoli function $f = t_{m_1,k_1,l_1} \circ t_{m_2,k_2,l_2} \circ \cdots \circ t_{m_i,k_i,l_i}$, such that for any $1 \leq \alpha, \beta \leq i$ where $\alpha \neq \beta$, at least one of the following is true:*

1) $m_\alpha \neq m_\beta$,
2) $k_\alpha \neq k_\beta$ *or* $l_\alpha \neq l_\beta$.

Then f is

1) *bijective,*
2) *nonlinear.*

Proof. The function is trivially bijective since $t_{m_1,k_1,l_1} = t^{-1}_{m_1,k_1,l_1}$.

Let us then prove nonlinearity, and suppose, by contradiction f is linear. There have to then exist $A \in GF(2)^{n \times n}, b \in GF(2)^n$ such that $f(v) = Av + b$ for any $v \in GF(2)^n$. Take t_{m_1,k_1,l_1} and consider a vector v_0, that is defined as follows:

- $v_0[i] = 0$ for all $i \notin \{k_1, l_1\}$,
- $v_0[i] = 1$ for all $i \in \{k_1, l_1\}$.

We know, from the definition of f that $v_0[m_1] = 1$, on the other hand $v_0[m_1] = (Av_0 + b)[m_1] = A[m_1]v_0 + b[m_1] = A[m_1][k_1] + A[m_1][l_1] + b[m_1]$. Notice that $b[m_1]$ must equal 0 since $f(0) = 0$, by definition of a Toffoli function. That means exactly one of $A[m_1][k_1], A[m_1][l_1]$ must equal one. Suppose, without loss of generality it is $A[m_1][k_1]$. Consider then a vector v_1, that only has a one as its k_1-th element. By definition of a Toffoli function, $f(v_1) = v_1$, but since $A[m_1][k_1] = 1$ and $b[k_1] = 0$, $f(v_1)[m_1] = 1 \neq v_1[m_1]$, thus we have a contradiction. □

Notice how Lemma 1 guarantees exactly the requirements for an activation function for a bijective Galois neural network.

We now formulate a conjecture which, if true, would guarantee security by Observation 1.

Conjecture 1. *For each $w \in \mathbb{N}_+$ there exists a w-mixing Galois neural network.*

We will try to argue for the validity of this conjecture by applying some statistical tests to randomly generated Galois neural networks in Section VIII.

VII. Performance Test

In this section, we evaluate the applicability of this approach through performance test results. We note, however, that the implementation used for these tests has likely yet to be fully optimized, one can expect enhancement in that regard with further development.

The Galois neural networks have been implemented using bitwise logical operations in Numpy [8] and the correctness of this approach was validated against the Galois package [9] for Python.

We will contain ourselves to single-layer NNs for the purposes of this evaluation, since increasing the number of layers since increasing the number of layers results in almost exactly linear growth of computation time.

To establish a frame of reference, we will contrast these results with the AES-256 implementation found in the PyCryptodome [10] package, note however that while we choose to compare to AES, because of its popularity, our solution is designed to work with any cipher, in particular less performant ones, where the performance gap might be less noticeable.

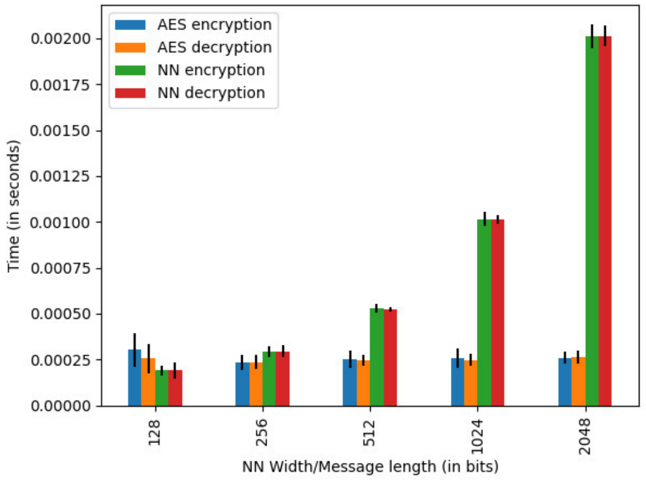

Figure 2: Results of performance tests. Encryption/decryption time contrasted with that of AES.

We compare the performance of a Galois neural network of a certain width on a single input with the performance of AES on that same input. For each of the lengths 128, 256, 512, 1024, and 2048 we ran 20 randomized messages, encrypted and decrypted them, and recorded the means and standard deviation. The tests were run on a mid-range laptop.

The results of these tests can be seen in Figure 2. Unsurprisingly, as Galois neural network evaluation has cubic complexity with respect to the width, the neural network execution time quickly trumps that of AES. However, this level of increased execution time might still be acceptable for applications where speed is not of high priority. Nonetheless, for most usecases, this data indicates a need for optimization, especially past the 512 mark.

Note that the results for AES do not seem to increase as the length of the messages increases. This is likely due to some kind of parallel execution.

VIII. Statistical Tests

To investigate the validity of Conjecture 1 we performed a suite of tests to examine some properties of Galois neural networks with randomized but constant weights.

A. *Uniform distribution test*

First, we propose the following test. Let w be the (even) width of a Galois neural network, randomly select the first $w/2$ bits of the input. Then repeatedly randomly select the remaining $w/2$ bits, concatenate all w bits together, compute the output of the network, and record the first few bits of the output. For a $w/2$-mixing function, we would expect a roughly uniform distribution of output values.

We performed this test, recording the counts for each output value, we then used the chi-squared test to assess how alike

		chi on 2 bits (3 degrees of freedom)	chi on 3 bits (7 degrees of freedom)	chi on 4 bits (15 degrees of freedom)	chi on 5 bits (31 degrees of freedom)
size	depth				
128	1	2.289062	6.421875	16.93750	36.2500
	2	1.929688	2.468750	16.56250	51.8125
	3	1.906250	7.984375	30.34375	33.5625
	4	3.375000	9.593750	6.28125	30.7500
256	1	2.781250	7.125000	7.18750	29.0625
	2	3.398438	15.875000	16.93750	25.5625
	3	1.117188	5.406250	7.93750	31.7500
	4	5.164062	4.843750	11.78125	19.7500
512	1	2.953125	3.125000	7.43750	25.7500
	2	2.843750	4.078125	18.71875	44.3125
	3	0.101562	6.562500	21.43750	24.4375
	4	4.507812	3.218750	9.06250	23.3125
1024	1	2.210938	8.859375	17.65625	30.2500
	2	1.890625	7.921875	10.18750	38.1875
	3	9.242188	9.468750	13.78125	38.2500
	4	3.226562	5.046875	14.56250	31.2500
2048	1	6.390625	6.343750	17.71875	39.0625
	2	2.039062	4.781250	20.90625	51.7500
	3	1.742188	9.062500	9.00000	26.7500
	4	1.882812	4.796875	18.68750	51.3125

Figure 3: χ^2 values from 1024 iterations of the uniform distribution tests.

these outputs are to those from a uniform distribution. The results values of those tests can be viewed in figure 3. The critical values for significance level 0.01 and the given degrees of freedom are (approx.) 11.345, 18.475, 30.578, 52.191 respectively. Thus all those tests failed to reject the null-hypothesis with a significance level of at least 0.01.

B. The bit flip test

Another property a mixing function should have, is that a small change in the input should have a large impact on the output. In [11] this property is tested in the following way:

- Consider x a random input to the function, record $f(x)$.
- Change a random bit of x, call it x', record $f(x')$.
- Compute the number of bits that are different between $f(x)$ and $f(x')$.

If f were a random permutation, we would expect the number of differing bits to follow a binomial distribution. Since we expect f to behave like a random permutation, we may use the Student's t-test to check if that is the case.

We performed 1000 samples of this test for every combination of $1, 2, 3$, and 4 deep and 128, 256, 512, 1024, and 2048 wide Galois neural networks. We then computed the Student's t test z statistic for each of those combinations and found the highest of these values to be less than 0.002, since for significance level 0.01 and 999 degrees of freedom, the passing z value is around 2.58, this indicates passing of the Student's t test.

C. Nonlinearity measurement

One of the fundamental properties of neural networks is their lack of linearity, in traditional applications this is useful because it lets them express and approximate nonlinear functions. Here, we would also benefit from a similar property, as if our function f were to be linear, it would be easily recognizable from a random permutation. We had already proven in Lemma 1 that, at least a single layer, Galois neural network would be nonlinear. In this section, we investigate the extent of nonlinearity, as depth increases.

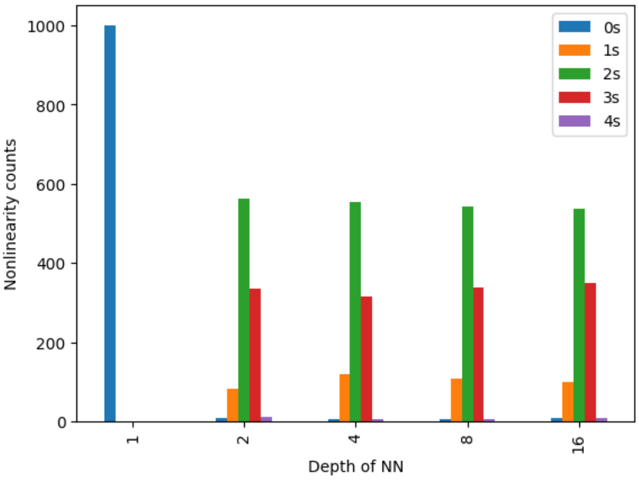

Figure 4: The distribution of nonlinearity for $w = 128$, $t = 5$, exponentially growing GNN depth. 1000 samples.

In [12] the nonlinearity of a function $f : \mathcal{F}^n \rightarrow \mathcal{F}^m$ where $m, n \in \mathbb{N}_+$, and $\mathcal{F}$ is a finite field, is defined in the following fashion.

Definition 6. *The **nonlinearity** $\mathcal{N}$ of a function $f : \mathcal{F}^n \rightarrow \mathcal{F}^m$ is given as:*

$$\mathcal{N}(f) = \min_{(u,w,v) \in \mathcal{F}^n \times \mathcal{F}^m \times \mathcal{F}} \#\{x \in \mathcal{F}^n | w^t f(x) \neq u^t x + v\}$$

In other words, we look at how closely we may approximate a projection of the output to a scalar, with an affine transformation of the input. We may use this definition to apply a measure to the notion of nonlinearity and express how nonlinear each depth of a neural network is.

Unfortunately, the naive computation of $\mathcal{N}(g)$, where $g : GF(2)^n \rightarrow GF(2)^m$ requires $\mathcal{O}(2^{n+m})$ time complexity, and $\mathcal{O}(2^n)$ invocations of g. This is too steep to compute for a wide Galois neural network. Instead, we may propose the following experiment:

1) Define a Galois neural network of width w, let $f : GF(2)^n \rightarrow GF(2)^n$ signify its computation.
2) Take a small number t.
3) Randomize the last $w - t$ bits and call them v_s.
4) Consider a function $f_t : GF(2)^t \rightarrow GF(2)^t$ that for input v_p is equal to $f(c(v_p, v_s))$ constrained to the first t bits, where c is a function that concatenates two vectors.
5) Compute the nonlinearity of f_t.

Such an experiment may help us derive some insights into the function f, and the efficiency of the activation function. Note that unlike measuring the nonlinearity of f, this is a random process so we will have to repeat it to gather reliable data.

In figures 4 and 5 we can see the results of such experiments. We may notice that for only one layer, and therefore only one activation function the nonlinearity values seem low and constant. This might be the result of the exact

depth	0	13	14	15	16	17	18	19	20
1	100	0	0	0	0	0	0	0	0
2	0	1	2	6	13	42	31	4	1

8	0	2	0	4	2	9	8	18	15	23	13	5	1
16	0	1	1	2	2	8	14	21	14	17	18	2	0

(c) $t = 8$

Figure 5: The distribution of nonlinearity values for larger t-s, $w = 128$, exponentially growing GNN depth. 100 samples for each.

implementation of the activation function, but nonetheless, this seems like a strong argument not to use such a low-depth GNN.

It is also noteworthy, that, with the exception of depth equal to 1, while the GNN depth increases exponentially it fails to have a significant impact on the magnitude of nonlinearity (at least in these experiments). However, the results for depth 2 still show some non-random behavior, like the results for t equal to 7 and 8 seemingly avoiding odd values. While a depth of 2 seems to be enough for the purposes of nonlinearity, practically it may be wise to air on the side of caution and recommend larger values.

IX. Future Work

It seems that the biggest area for improvement with this algorithm is performance. In the current form, it seems unlikely that the algorithm would see widespread use.

One idea to deal with that limitation would be to see if sparse matrices could be utilized to improve performance without loss of the statistical properties. One could also propose a different architecture for the underlying Galois neural network.

A different approach would be to seek improvements in the technical implementation of the algorithm, and either find improvements on the side of the algorithm or try to achieve better hardware support.

The second area for potential further work is trying to further verify and work towards proving Conjecture 1. One could for example try to replicate existing and to design new statistical tests perhaps on a bigger scale in order to show the guarantees required for widespread usage.

***Abstract*—Biomedical event detection is an essential subtask of event extraction that identifies and classifies event triggers, indicating the possible construction of events. In this work we propose the comparison of BERT and four of its variants for the detection of biomedical events to evaluate and analyze the differences in their performance. The models are learned using seven manually annotated corpora in different biomedical subdomains and fine-tuned by adding a linear layer and a Bi-LSTM layer on top of the models. The evaluation is done by comparing the behavior of the original models and by adding a lexical and a syntactic features. SciBERT emerged as the highest performing model when the fine-tuning is done using a Bi-LSTM layer, without need of extra features. This result suggests that the use of a transformer model that is pretrained from scratch and uses biomedical and general data for its pretraining, allows to detect event triggers in the biomedical domain covering different subdomains.**

***Index Terms*—Biomedical Event Extraction, Event Detection, Transformer Language Models, Named Entity Recognition**

I. Introduction

BIOMEDICAL event extraction is a complex information extraction task that identifies key information from large sets of textual data for further applications, such as the study of biomolecular mechanisms or epigenetic changes. A biomedical event is constructed from an event trigger and one or more arguments that orbit around the trigger. Event triggers generally refer to nouns or verbs that express an action, circumstance or eventuality, while the arguments refer either to biomedical entities or to other events, called nested events. Fig. 1 shows the example of a sentence annotated with two biomedical events, '-Reg' (which stands for 'Negative regulation') and 'Locl' (which stands for 'Localization'). The event 'Locl' (the event is given the same type as the trigger) that is constructed from the trigger word 'excretion' presents as argument the biomedical entity of the type 'D/C' (which stands for 'Drug or compound'), who plays the role 'Th' (which stands for 'Theme'). This role allows answering the question 'What is excreted?'. While the event '-Reg', constructed from the trigger word 'reduces', presents two arguments. The first argument is a biomedical entity of the type 'Drug or compound', who plays the role 'Cause'. This role allows answering the question 'What causes the reduction?'. The second argument is the nested event 'Locl' described before, who plays the role 'Theme', answering the question 'What is reduced?'.

Fig. 1. Example of event extraction; the '-Reg' (negative regulation) event has the 'Locl' (localization) nested event as argument.

Event extraction is usually divided into three main sub-tasks, event detection, argument identification and event construction. Event detection identifies and classifies the trigger words into a set of predefined types of event triggers, while argument identification identifies and classifies the corresponding event arguments and their respective roles [1]. Event construction refers to the merging of the relations that correspond to the same event. This work focuses on event detection, which has a fundamental role in the construction of events, since the triggers are the targets that allow to know that an event may exist [2]. Difficulty for trigger detection comes from the sensitivity to the domain or subdomain (text can present specialized language), linguistic forms (triggers can be single words, multi-words, discontinuous markers) and ambiguity on the trigger class (a trigger word can be given different trigger classes) [3]. According to different works, such as in [1], solutions to address these issues may include additional features to provide lexical, syntactic and semantic information about text, which have proven to be useful for detecting event triggers. Transformers models have been adopted for event detection due to their positive achievements in performance for solving different Natural Language Processing (NLP) tasks [4], [5]. BERT [6], which stands for Bidirectional Encoder Representations from Transformers, is pretrained to generate bidirectional representations of the words, taking into account the semantics by considering both left and right directions of the text. From this pretraining, BERT can be fine-tuned by including additional layers on top of the model to solve new specific tasks. Furthermore, a series of variants from BERT have been developed for specific domains by being trained on large corpus with the same context, such as the biomedical domain.

In this work we compare BERT and four of its variants pretrained in the biomedical domain for the detection of biomedical event triggers to analyze their performance and identify which model is the most appropriate to address this task. For this purpose, BERT, BioBERT, SciBERT, Pub-

MedBERT, and BioMedRoBERTa are fine-tuned using two different classifiers, a linear layer and a Bidirectional Long Short Term Memory (Bi-LSTM) layer, to detect biomedical event triggers. These BERT variants have been chosen for comparison because they share the same BERT architecture but have previously been pretrained using different data in the biomedical and/or general domain [7]–[9]. The models are learned using seven manually annotated data sets merged together. These corpora were originally developed for the event extraction task in different biomedical subdomains. In addition to these data, two features are included as lexical and syntactical extra-information to the models, the stems and the parts-of-speech (POS) tags, respectively. SciBERT presented the highest performance when the fine-tuning is done using a Bi-LSTM classifier without adding any extra-features. This result suggests that using a transformer model that is pretrained from scratch using biomedical and general domain data, allows to detect biomedical event triggers addressing different biomedical subdomains.

Our main contributions refer to the (1) comparison of the capability of different pretrained transformer models to detect biomedical events, (2) evaluation of the performance of two different classifiers for the fine-tuning of event detection, (3) analysis of the impact of manually annotated corpora on different biomedical subdomains to detect event triggers, and (4) assessment of whether adding lexical and syntactic information improves biomedical event detection.

II. Related Work

Current SOTA systems for event detection use neural network models due to their robust event extraction capabilities.

P. V. Rahul et al. [10] used Recurrent Neural Networks (RNN) to extract higher level features through the hidden state of the network to identify biomedical event triggers. They also used the word and the entity type embeddings as features, demonstrating positive results in the MLEE [11] corpus. S. Duan et al. [12] and Y. Zhao et al. [13] explored an augmentation of the semantic information by integrating the full document representation. Both proposed the use of RNNs to extract cross-sentence features without the use of external resources. T. H. Nguyen and R. Grishman [14] presented a Graph Convolution Network (GCN) model to exploit syntactic dependency relations. They used dependency trees to link words to their informative context for event detection. H. Yan et al. [15] also proposed a GCN model, integrating aggregative attention to model and aggregate multi-order syntactic representations of the sentences, while in the case of S. Cui et al. [2], they extended the GCN by adding the relation aware concept, which exploits the syntactic relation labels and models the relation between words. DeepEventMine [16] is an end-to-end system for event extraction that consists on four main modules; BERT model, trigger and entity detection and classification, relation extraction and event identification. For each of the modules, BERT is used as base model and a linear layer is added. One of the main objectives of this system is improving the extraction of nested events, where it has achieved the new SOTA performance on seven biomedical nested event extraction tasks. B. Portelli et al. [17] compared BERT and five of its variants for the identification of Adverse Drugs and Events (ADEs). They showed that span-based pretraining, from spanBERT, provides an improvement in the recognition of ADEs, and that the pretraining of the models in the specific domain is particularly useful in comparison to train the models from scratch. A. Ramponi et al. [18] developed BEESL, a neural network model based on a sequence labeling system for the extraction of events. The system converts the event structures into a format of sequence labeling, and uses BERT as language model. Y. Chen [19] proposed the Multi-Source Transfer Learning-based Trigger Recognizer system, which is an extension on transfer learning using multiple source domains. All the datasets from the different domains are used for jointly train the neural network, achieving a higher recognition performance on the biomedical domain, having a wide coverage of events.

According to these works, transformer architectures have achieved positive results for detecting event triggers, and the use of pretrained language models has shown an improvement in the performance of this task. However, these works have been developed in a specific biomedical subdomain or in the general domain, not allowing a generalization to different biomedical subdomains. This may present a limitation in the detection of biomedical triggers because the language in biomedical texts is usually specialized and very specific. In addition, an analysis on how the pretrained language models used were selected over the other existing models is not described. Besides, according to A. Ramponi et al. [18], the detection of triggers continues to be the most important source of errors in event extraction, where around 31 % of the errors correspond to non-detection of triggers and 28 % to over-detection of triggers.

III. Materials and Methods

Fig. 2 shows the approach followed in this work. The annotated data is given as input to the pretrained transformer models to calculate the embeddings. The models used are BERT and four of its variants, who have achieved state-of-the-art performance in different NLP tasks without requiring major architectural modifications according to the specific tasks. In addition, the embeddings of a lexical and a syntactic features are also calculated. Then, a classification layer is added on top of the models for fine-tuning to detect event triggers.

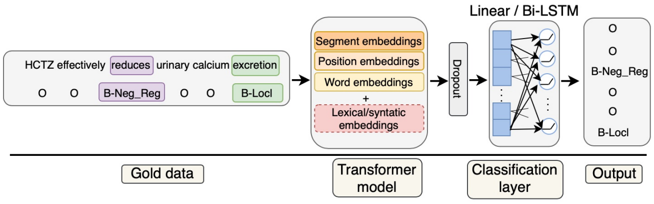

Fig. 2. Overview of the approach proposed to detect event triggers.

A. Transformer Model: BERT

BERT [6] is a contextualized word representation model based on a masked language model pretrained with bidirectional transformers [7]. In BERT, the sequence of input tokens (words or sub-words) is constituted with initial vectors that are the combination of the token embeddings, the (token) position embeddings and the segment embeddings (text segment to which the token corresponds) through element-wise summation. The embeddings of extra features can be computed and included in this summation, such as the POS embeddings (token function in meaning and grammar within the sentence), which has demonstrated to be helpful in detecting event triggers [1]. The embeddings are then passed to a set of layers of transformer modules. Each transformer layer generates a contextual representation of every token by summing the non-linear transformation of the tokens' representations from the previous layer. This representation is weighted by the attentions calculated using the representations of the previous layer as query. The last layer generates the contextual representations for all the tokens, where the information of the whole text span is combined [20]. Following the BERT principle, other transformer models have been developed being pretrained with data from specific domains, e.g. biomedical data, presenting better adaptation for solving in-domain tasks. BioBERT [7] and BioMedRoBERTa [21] are some examples of BERT variants pretrained in the biomedical domain.

B. Fine-Tuning Transformer Models for Event Detection

Various downstream text mining tasks can be performed by making minimal modifications to the BERT architecture through a process of fine-tuning. Here, the transformer models are fine-tuned following the Named Entity Recognition (NER) task. NER is one of the main tasks of biomedical text mining, which aims to recognize domain-specific nouns in a biomedical corpus by giving each word s_i in a sentence $S = s_1, s_2, ..., s_n$ (n refers to the number of words in the sentence) a predefined class $l \in L$ (where L refers to the predefined collection of entity types including the no-entity class). In this work, NER is adapted to identify triggers, which implies not only identifying nouns, but also verbs and in some cases adjectives. Two different classification layers, a linear layer and a Bi-LSTM layer, are used separately for comparison. The output labels are obtained following the IOB (Inside-Outside-Beginning) tagging to identify and classify the triggers into the predefined trigger categories (in the case of the I and B tags).

IV. Experimental Settings

A. Corpus

Table I presents the seven datasets [1] (all publicly available) used for fine-tuning the transformer models. These corpora were manually or semi-manually annotated by experts and released to be used in the development and improvement of event extraction models.

TABLE I
STATISTICS OF THE CORPUS USED

Dataset	No. Triggers	Trig Classes	Documents	Train/Dev/Test
CG 2013	9,790	35	PubMed abstracts	300/100/200
EPI 2011	2,035	14	PubMed abstracts	600/200/400
GENIA 2011	10,210	10	MEDLINE abstracts	1,000 (total)
GENIA 2013	4,676	12	PMC full-text	34 (total)
ID 2011	2,155	10	PMC full-text	15/5/10
PC 2013	6,220	22	PubMed abstracts	260/90/175
MLEE	5,554	15	PubMed abstracts	131/44/87

For the development of the experiments, the training and development datasets of all the corpora are initially merged into one single dataset and split into sentences, obtaining a total of 24,819 sentences. The original test sets are not used since the annotation are not released. Then, a random data partition into 80/20 is applied to obtain the training and testing sets, containing 19,855 and 4,964 sentences, respectively. Each sentence is further split into words by spaces and then, each word into sub-words or tokens following the setting of the BERT tokenization. These tokens are then given as input to the transformer model. All the trigger classes from each corpus are considered for the final trigger classification, presenting a final set of 58 classes (some classes overlap among the different corpora).

B. Pretrained Transformer Models

The transformer model, BERT [6], and four BERT variants pretrained in the biomedical domain, BioBERT [7], SciBERT [8], PubMedBERT [20], and BioMedRoBERTa [21], are used and compared for the detection of event triggers. These models differ from each other by the corpora in which they were pretrained (all in English), the type of pretraining and the size of the vocabulary. SciBERT and PubMedBERT, were pretrained from scratch, meaning that they use a unique vocabulary on the pretraining corpus and include embeddings that are specific for in-domain words. BioBERT and BioMedRoBERTa were pretrained starting from the BERT checkpoints, which means that the vocabularies are built with general-domain texts (similar to BERT) as well as the initialization of the embeddings.

C. Lexical and Syntactic features

The embeddings of stems and POS tags are also computed and added as extra-features. Stems provide lexical information that correspond to the words reduced to their word roots, without needing to be an existing word in the dictionary. Stems are obtained by applying a set of rules to remove attached suffixes and prefixes (affixes) from terms without considering the POS or the context of the word occurrence [27]. POS tags represent syntactic information that provides the categorical differences of the words according to their functions in meaning and grammatically within the sentence. POS tagging consists on automatically obtaining the POS tag of each word among the different POS categories corresponding to their

[1] Cancer Genetics (CG) 2013 [22], Epigenetics and Post-translational Modifications (EPI) 2011 [23], GENIA 2011 [24], GENIA 2013 [25], Infectious Diseases (ID) 2011 [26], Pathway Curation (PC) 2013 [22], Multi-Level Event Extraction (MLEE) [11]

syntactical role [28]. For this work, the stems of the words are obtained using the 'Snowball Stemmer' module from NLTK-3.4.5 [2], while the POS were obtained using spaCy-3.0.0 [3], using 'en_core_web_sm', a pipeline developed for biomedical data. The embeddings of the stems and POS tags are summed to the rest of the embeddings (token, position and segment) calculated by the transformer models.

D. Parameters Settings

All the experiments are done with PyTorch, using the Transformers [4] library and the models were taken from Hugging Face [5]. The transformer models are trained using the original parameters from BERT, presenting a dropout probability for the attention heads and hidden layers of 0.1, a hidden size of 768, an initializer range of 0.02, a max position embeddings of 512 and an intermediate size of 3,072. The number of attention heads and hidden layers was 12 for both. 'Adam' was used as optimizer and 'gelu' as activation function. The training parameters of the classification layers, both linear and Bi-LSTM, were set as follows; batch size of training and testing sets of 16, learning rate of 1e-05 and max gradient norm of 10, since gradient clipping was included. The maximum length of the sentences was set to 256. All the models were trained during 100 epochs on the training set without applying early stopping, and evaluated by measuring the precision (P), recall (R) and F1-score.

V. Results and Discussion

The evaluation results of the fine-tuning of the models for event detection are shown in Table II. The approximate time in hours for the fine-tuning of each model is presented in the last column of the table. The highest results obtained in epochs 10, 30 and 100 are presented in bold, and the highest overall results of all epochs are presented in bold and underlined. First, we observe that SciBERT, which was pretrained from scratch using biomedical and general data, obtained the best results for each number of epochs and overall, in P, R and F1. It presented higher values when Bi-LSTM was used as classifier, especially when extra features were not added or when the lexical feature is added in the case of the training for 10 epochs. When the training was done for more than 10 epochs, the performance between SciBERT+POS (syntactic feature) and SciBERT+stem (lexical feature) was very similar. When the fine tuning was done using a linear classifier, SciBERT+POS achieved the best results, having a difference of around 10 % to when the lexical feature (SciBERT+stem) is added. PubMedBERT, a model pretrained from scratch using biomedical data, achieved the second best performance, being below SciBERT by 4 % when the training is done for 30 epochs, using Bi-LSTM as classifier and no adding extra-features (which was the best overall result of SciBERT). When PubMedBERT used Bi-LSTM as classifier, the results were very similar between adding the syntactic or lexical features and not adding them. These results were also similar to when a linear classifier was used and the extra features are added, noticing that the result was worse when no features were added. In the case of BERT, which was trained from scratch using data from the general domain, it presented lower results than PubMedBERT by around 5 %. The best results of BERT were obtained using a linear classifier and not adding extra features, noticing that the results of BERT+POS and BERT+stem were slightly lower and very similar between each other. This same behavior can be noticed when Bi-LSTM was used as classifier. These three last transformer models, SciBERT, PubMedBERT and BERT, presented some similarities in that they were trained from scratch, used very comparable text sizes for their pretraining and had similar vocabulary sizes. The two models that presented the lowest performance are BioBERT and BioMedRoBERTa, both pretrained from the BERT weights, using biomedical and, biomedical and general data, respectively, presenting the largest text sizes of all the models. BioBERT used the smallest vocabulary for its pretraining, while BioMedRoBERTa used the largest in comparison to the rest of the models. In both models it was observed that there was not significant change when adding the extra features, although there was an improvement of around 7 % when using a Bi-LSTM classifier compared to a linear classifier. In general, what can be noticed in all the models is that adding the syntactic and lexical features does not improve the performance for detecting biomedical events.

Fig. 3 shows the performance of fine-tuning SciBERT during 30 epochs using a Bi-LSTM classifier on the seven datasets separately. The F1-scores obtained using EPI, CG, ID, GE'13 and PC were similar between each other, obtaining values between 0.70 and 0.80. When GE'11 was used, the F1-score reached a value of around 0.65 and when MLEE was used, the model completely failed the detection of triggers. In Fig. 4 it is observed the effect of fine-tuning SciBERT over 30 epochs using a Bi-LSTM classifier without adding extra-features by cumulatively adding each corpus one by one. Below each corpus is shown the total number of classes by adding each corpus. Recall was improved when CG and EPI were used together, and then reduced as the rest of the corpora were added. Precision was affected when EPI and GE'11 were added. The behavior of recall and precision varied differently depending on the added corpus, although when GE'13 was added both values were comparable, and as might be expected according to the observed on Fig. 3, when MLEE was added the values were negatively affected. This behavior may be due to the fact that when adding a new corpus for the fine-tuning of the models, some classes may overlap between the corpora while other classes do not, causing to probably have less samples in the new classes and, therefore, affecting the balance of the data. In addition, the context of the different biomedical subdomains may also affect the performance, since BERT and its variants compute embeddings considering the semantics.

VI. Conclusions and Limitations

In this work, we analyze BERT and four of its variants for biomedical event detection using corpora of different biomedical subdomains. By comparing the performance of the models and by adding a lexical and syntactic features, we found that fine-tuning SciBERT during 30 epochs using a Bi-LSTM classifier is the best strategy to detect biomedical events, especially if the additional features are not included. Furthermore, it is shown that fine-tuning the models for 10 to 30 epochs achieves most of the model learning, while training for more epochs can only achieve a slightly better result. One of the limitations of this work is the imbalance of the data. Since some classes of the different corpora overlap, the samples for those classes are increased, while the unique classes for each corpora present fewer samples. This can negatively affect the behavior of the models between the different subdomains. Also, using external tools to get POS tags and stems can lead to errors that are learned by the models and may be one of the reasons why performance without additional features achieves better results.

Abstract—**The main purpose of this article is to compare the sensitivity of the weights of individual criteria in the assessment of the most popular banks' websites and the impact of the MCDA methods applied on the results of these assessments. The analysis was carried out for three selected, the most popular and different assessment methods: TOPSIS, VIKOR and PROMETHEE II. The evaluation of the websites was made on a sample of 350 bank customers, whose opinions were obtained using the CAWI method using a survey form. The survey made it possible to distinguish the 16 most popular banking services in this group, and only these banks were then evaluated. The survey questionnaire was obtained after verification of the pilot version created on the basis of previous research. The websites most known to the respondents were tested using three MDCA methods: TOPSIS, VIKOR, PROMETHEE II. The sensitivity of the results in each of the banks to the development of weights for 18 attributes (service evaluation criteria) was examined. The obtained results indicate the possibility of interchangeable use of the distinguished assessment methods, which may be helpful for business practitioners when analyzing and designing banking services.**

I. Introduction

TO PREPAREhe main purpose of this article is to determine the sensitivity of the position of the websites of the rated banks (C1, ..., C16) in the respondents' rankings depending on the weights of the distinguished assessment attributes (A1, ..., A18). Evaluations of websites, [1] assessed by respondents at the end of 2022, allowed for the construction of a common data set. Based on this set, three experiments were performed:

- comparison of the results obtained from the simple point method with the new, original MDCA method [2], [3] - the Conversion method [4],
- banking services were assessed and the five most popular MDCA [5], [6], [7] methods: TOPSIS [7], COMET [8], VIKOR [9], PROSA-C and PROMETHE II [10] were compared, in terms of convergence of results, to see if the situation observed in the first experiment also occurs among the methods already widely known and recognized . The obtained results indicate significant deviations of the applied VIKOR [11] method from other methods. Thus, the discrepancies in the results of the Conversion method in this light did not seem to be something exceptional after this study,
- the most important factor determining the assessment, and thus the position of individual banking services in the ranking, are their attributes, a priori determined at the beginning of the study. Therefore, the sensitivity of the position in the ranking of banking services depending on the change in the weights of these attributes was examined.

This article presents the results of a recent experiment. It is a continuation of research undertaken on the application of multi-criteria methods [12], [13] for evaluating the latest IT solutions in the economy [14]. These studies are both methodical and practical. Because, as it turned out, there is no single, universal method of assessing usability [15]. The results depend primarily on the selection of parameters (attributes) - evaluating the studied phenomenon. These parameters vary depending on the studied phenomenon, industry, end user, purpose of the results, etc. [16].

This study uses a constantly modified set of criteria agreed in 2008 with the best specialists in Poland dealing with research in the banking industry. During subsequent crises, it was modified arbitrarily by the authors (external factors - high inflation, pandemic) and by end users (bank customers) for reasons of comprehensibility and preferences. External factors extended the list of attributes, which in turn, after verification by a pilot group of users, was reduced to the most understandable attributes (after possible corrections) and important from the client's point of view [17].

The problem directly resulting from the selection of attributes are the significance weights assigned to them, which in a sense reduce the subjectivity of the final methods [18]. The simplest method to solve this problem is, of course, to ask end users about the level of significance of a given criterion,

This work was not supported by any organization

and to take the average of their answers.

However, a different approach is often used that simulates the results depending on the level of weights assigned to them. Sometimes it is assigning weights to specific types of attributes (in the case of banking services: economic, technical and anti-crisis), and sometimes to each assigned attribute and observing the results [19]. The simplest method to solve this problem is, of course, to ask end users about the level of significance of a given criterion, and to take the average of their answers.

However, a different approach is often used that simulates the results depending on the level of weights assigned to them. Sometimes it is assigning weights to specific types of attributes (in the case of banking services: economic, technical and anti-crisis), and sometimes to each assigned attribute and observing the results.

II. Preliminaries

A. Research procedure

The research procedure in this case included the following steps:

- bibliographic analysis of website evaluation using MCDA methods,
- construction of a pilot version of the survey questionnaire,
- verification of the survey form and preparation of its final version,
- random selection of groups of respondents and inviting them to complete a questionnaire using the CAWI (Computer Associated Web Interview) method,
- obtaining data and initial verification of their correctness,
- selection and justification of methods for evaluating banking services in order to make calculations and obtain results as well as to make comparisons between them,
- analysis, discussion and comparison of results
- drawing conclusions, defining limitations and further directions of research.

Due to the research conducted earlier and the popularity of the analyzed methods, two of them were initially selected in the first experiment: the simple point method and the Conversion method [20]. Interpretation and comparison of the results obtained with these methods and their differentiation by means of the Euclidean distance were performed. Then, for five consecutive MDCA [14], [21], [22] methods: TOPSIS [23], COMET [24], VIKOR [25], PROSA-C [26] and PROMETHE II [27], calculations were made, ranking lists were prepared and the results were compared. In the analysis of the results, the calculated values of the preference function for subjective weights were taken into account. Then, the correlations between the rankings obtained with different methods and the Euclidean distances were calculated in order to examine the level of differentiation of the results obtained between the individual pairs of the methods used. The above analyzes were the content of the previous two articles.

However, this paper presents a sensitivity simulation. It consisted in the fact that for each method (TOPSIS, VIKOR, PROMETHEE II) [28], [29], [30] the values of the weights of individual evaluation criteria (A1,. . . , A18) of the existing selection variants (C1 - C16) were successively modified. The value of the weights was changed successively, and the weights of the remaining criteria were adjusted - in equal proportions, so that the weights of all the criteria add up to 1.

B. Sample characteristic

The rankings of websites were based on data collected using the CAWI method in autumn 2022. They covered 356 people, with over 48% survey response. A five-point, simplified, standardized Likert [31] scale was adopted to assess individual criteria:

- 1.0 - fully meets the requirements of the criterion,
- 0.75 - almost completely meets the requirements of the criterion,
- 0.50 - meets the requirements of the criterion on average,
- 0.25 - meets the requirements of the criterion at least,
- 0.00 - does not meet the requirements of the criterion.

The original form of the questionnaire was verified on a pilot sample of 50 people, conducted in an academic environment. Individual criteria - attributes of banking services - were examined in terms of their comprehensibility and importance for an average website user. After verification, corrections and removal of the least important criteria, 18 attributes were taken into account for the assessment of each website, divided into the following three groups: economic, technological and anti-crisis. A detailed list of attributes is included in Table 1.

The evaluation was conditional upon evaluating the websites of a well-known electronic bank in comparison with the website of another banking website. This condition resulted from the desire to obtain answers from experienced respondents dealing with various electronic banking services. Thus, a total of 712 full banking service ratings were received, as some respondents rated two or three banks.

Respondents rated the sixteen (A1, A2, . . . , A16) the most frequently used banking websites. They can be found in Table 2. All banking services that received less than five ratings are not included in this list - the ratings of 16 banks were rejected.

The research sample was selected in a diversified way: on purpose - the research was carried out in the academic environment in randomly selected didactic groups and using a link to the online survey [32].

The survey was mainly aimed at young people. The age range therefore ranged from 19 to 35 years). This choice could have influenced the results of the survey (41 million people in Poland are potential customers of online and mobile banking, over 54% of registered customers are active users of online banking and 44% of active users of mobile banking). The surveyed age group constitutes over 65% of users) . Among the surveyed respondents there were over 70% women and nearly 30% men. 19% had bachelor's and incomplete higher education, and 80% had secondary education. The largest group of people came from large cities (over 200,000 inhabitants), and 19% from rural areas. One fourth came from small, medium and large towns - up to 200,000. inhabitants.

C11	**mBank SA**
C12	**Nest Bank SA**
C13	**PKO Bank Polski SA**
C14	**Santander Bank Polska SA**
C15	**Santander Consumer Bank SA**
C16	**TOYOTA Bank Polska SA**

Among the respondents, there were 52% of students, 31% of people working under a contract for specific work, mandate or running their own business and 17% working under an employment contract. The most frequently performed occupations are: office workers (63%), service workers (16%), specialists (8%) and workers employed for simple technical work (7%). Most of them describe their financial situation as good (61%), very good (22%), average (16%) and sufficient (2%).

Data on the assessment of banking services are generally relatively homogeneous and consistent. After obtaining them, a reliability test in the form of Cronbach's alpha coefficient was applied. For all attributes, the Cronbach's alpha coefficient indicating the internal consistency and reliability of the sample [68] was greater than 0.75. The measure of internal consistency of the 16 dependent variables, based on Cronbach's alpha coefficient, was 0.85 (0.94 for Cronbach's alpha calculated on the basis of standardized items), for 18 items in total.

III. ANALYSIS OF RESULTS AND DISCUSSION

Sensitivity analysis is a technique that studies the effect of changes in one of the independent variables that make it up on the dependent variable of any model. In order to study in detail how the changes in weights affect the final ranking, a sensitivity analysis was performed. For each criterion, nine evaluations were performed, where the criterion in question was given weight 0.1, 0.2, ..., 0.9 while all other criteria were set to 0.5. This allowed to study the effect of each particular criterion on the overall ranking. A total of 162 evaluations was therefore performed. The results of these evaluations were then plotted and are presented on `figure1` and `figure2`. Here are shown results of the sensitivity test to changes in the weights for individual attributes (A1, A2, ..., A18) successively, for all sixteen analyzed banking services (C1, C2, ..., C16). Place - position in the ranking (on the y-axis) 1 - is the best, 18 - is the worst. On the x-axis, there are weights of the selected criterion (its symbol is in the chart title). The weight values in all cases changed every 0.1. Examination of the figure below shows that although sometimes very minor,

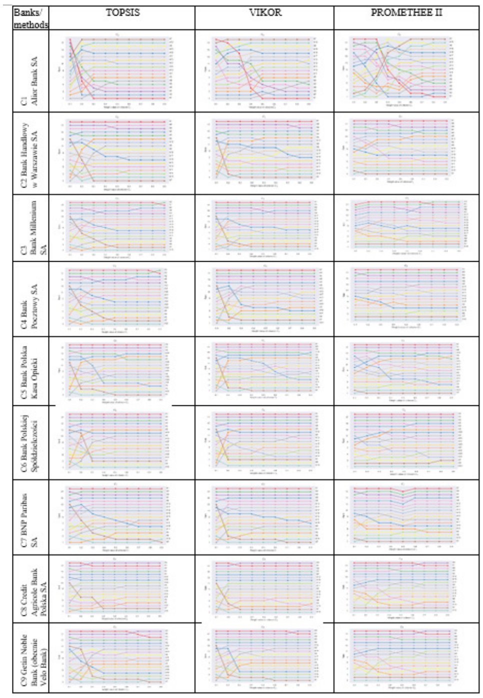

Fig. 1. Sensitivity to simulated changes in the weights of individual attributes in the analyzed banks, banks C1-C9; Source: own study

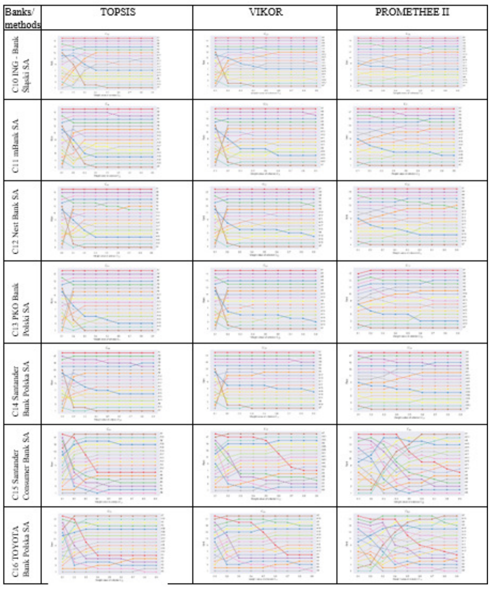

Fig. 2. Sensitivity to simulated changes in the weights of individual attributes in the analyzed banks, banks C10-C16; Source: own study

there are some changes in ranking positions if the weights are manipulated in procedurę of simulation. Sensitivity analysis was carried out for three popular MDPI methods: TOPSIS, VIKOR and PROMETHEE II in order to compare how the positions in the ranking of the analyzed banks react to changes in the weights of individual attributes (based on the same data and the same attributes).

The analysis of the sensitivity of the position in the ranking of individual banks to changes in attributes leads to the following assessments. For C1, the key attribute in the TOPSIS method is A7, which, when raised to the value of 0.3, shifts the significance of this parameter to the first position. It reacts similarly to changes in parameters A2, A3 and A8. Similar behavior can be observed in the VIKOR method, but it requires a value of 0.5. However, the ranking positions for C1 behave separately and completely chaotically. For C2 - the key attribute is A7, a slight increase in its value moves its position from 13th to 1st in the TOPSIS and VIKOR methods. In the PROMETHEE II method, this change, as in the case of other parameters, increased the position by only one position. For the C3 bank - the most important feature is A10, after raising the weight to the value of 0.2-0.3, it moves to the first position after using the TOPSIS and VIKOR methods, in the PROMETHEE II method, the A10 attribute remains firmly in the first place. For the A4 bank, such a key attribute is also A10, after increasing the weight of this parameter (using the TOPSIS method), it moves to the first place in the ranking, the attribute A9, which previously occupied it, moves to the thirteenth place. It is similar in the other two methods, in PROMETHEE II, it is still the most important attribute, regardless of the weight assigned to it.

The situation is slightly different for the C5 bank. Here, the most important parameter is A7, which with the increase of the weight value moves from the twelfth position first to the third, and then with the weight equal to 0.5 - to the first place. A similar "jump" can be observed in the VIKOR method, while in the PROMETHEE II method this process is more stable. For the C6 bank, the most important attribute is A10, while the most sensitive to weight change is A7, which was moved from thirteenth to third position in the TOPSIS method. Such a tendency is shown by the attributes A10 and A7 in the VIKOR method, while in the PROMETHEE II method they always stop at the first and third position, regardless of the values of the adopted weights. A similar situation occurs for the C7 bank, where A7 moves from the twelfth to the first position in the ranking, with weight=0.9, dealing with the A10 parameter (TOPSIS method). When using the VIKOR method, this scheme is almost duplicated, the application of the PROMETHEE II method shows a low sensitivity of these attributes to the change of weights and leaves them respectively on A7 in the first position, A10 in the second position. For banks C8-C14, the situation almost repeats itself, as the weight increases, the attribute A7 from the further position is moved to the first position, replacing the parameter A10 (except for C9, where A10 remains in the first position all the time as the weight increases). For all the cases mentioned so far, the attributes A1-A4 and A8 are relatively stable and independent of the weights and the assessment method adopted, sometimes only changing places in the ranking. That is, for these banks the most important attributes are: security and the amount of the bank card fee (if any), and the least important: nominal annual interest rate on personal accounts, keeping an account in PLN/month, fee for transfer to the parent bank, and fee for transfer to another bank and additional services.

The situation is completely different for the C15 bank. In the TOPSIS method, A8 moves from position 15 to the first position and A2 from the twelfth position to the second position. As the weights increase, parameters A9 and A5 are lost. Finally placing respectively in: fifth and sixth position. This phenomenon is repeated for the VIKOR and PROMETHEE II methods, where there is also the strongest so far "shaking" of the attributes' positions due to the height of the simulated weights (all of them change their place in the ranking). The sensitivity of the attributes to the change of weights for the C16 bank is also different. The first two positions A8 and A9 are relatively stable, regardless of the calculation method. In the TOPSIS and VIKOR methods, the remaining attributes undergo significant changes in the ranking position. In the PROMETHEE II method, the remaining attributes undergo far-reaching changes in position. An interesting phenomenon is the fact that the parameters A7 and A10 for the last two analyzed cases are moved to the last positions in the ranking as the weights increase. The analysis shows that for the customers of these two banks the most important features may be: additional services and account access channels, and much less important attributes related to fees. Technical parameters turned out to be the least sensitive to weight changes in all cases.

IV. Conclusions

This work was aimed at comparing:

- sensitivity of the results of the multi-criteria evaluation of websites of the most popular banks in Poland to changes in the weights of the attributes used for this evaluation,
- the results of changes in attribute weights in three selected MDCA methods: TOPSIS, VIKOR and PROMETHEE II.

The results obtained as a result of three experiments allow us to conclude that for the proper evaluation of a multi-criteria problem, certain conditions must be met:

- firstly, it is necessary to select the evaluation criteria (attributes) characterizing the most important features of the analyzed issue from the user's point of view,
- secondly - the selection of a method that will guarantee that the collected data will be properly used,
- thirdly - the method of comparing the results obtained,
- fourthly - it is also recommended to select the appropriate criteria weights, the structure of which may reflect the preferences of the decision maker or the client.

The current research shows that the most comparable rankings were obtained using the TOPSIS and COMET methods, while the greatest differences in relation to the results obtained from other methods were observed using the VIKOR method. On the other hand, the results obtained using the VIKOR method were closest to the results obtained using the TOPSIS method.

When testing the sensitivity of the results to changes in the criteria weights during the experiments, the results obtained with the TOPSIS and VIKOR methods behaved similarly. Separate results were obtained for the results obtained using the PROMETHEE II method.

It seems that it is difficult to judge the optimality of the methods used or their objectivity even after this series of experiments. However, it cannot be ruled out that the combination of several methods, e.g. simple methods for preliminary analyzes and complex methods such as VIKOR or PROMEYHEE II for more comprehensive results, would give positive results.

The main barriers of this work were the limitation of obtaining data to academic representatives of generation Z, which on the one hand indicates the main, future users of banking services, but on the other hand makes it difficult to generalize conclusions and use a limited number of the five most popular MCDA complex methods.

Nevertheless, the results of the conducted experiments encourage to continue research in order to expand the set of MCDA methods enabling the pursuit of convergence of results and thus the objectification of assessments in the analyzed area. Also, due to the importance of the banking sphere and the importance of the tool of communication with the user, which is the website, this direction will dominate in future research.

Abstract—**Regarding the parameter estimation task, besides the time effectiveness of the simulation, parameter estimates are required to be precise enough. Usually, the estimates are Monte Carlo-simulated using a prior estimated variability within a small sample. However, the problem with pre-estimated variability is that it can be estimated imprecisely or, even worse, underestimated, resulting in estimation bias. In this work, we address the abovementioned issue and suggest estimating all parameters as probabilities. Since the probability is not only finite but has its theoretical maximum as 1, using outcomes of Bernoulli and binomial distribution's upper-bounded variance and Chebyshev's inequality, the estimator's variability is theoretically upper-bounded within the Monte Carlo simulation and estimation process. It cannot be underestimated or estimated inaccurately; thus, its precision is ensured till a given decimal digit, with very high probability. If there is a known process that treats the parameter of interest in terms of probability, we can estimate how many iterations of the Monte Carlo simulation are needed to ensure parameter estimate on a given level of precision. Also, we analyze the asymptotic time complexity of the proposed estimation strategy and illustrate the approach on a short case study of π constant estimation.**

I. Introduction

In THIS work, we focus on the estimation of parameters that are of a non-probabilistic fashion, e.g., simulated estimates of claim amounts in actuaries [1] or simulated numbers of patients at risk of disease recurrence [2]. Typically, these parameters are hardly analytically derivable, thus estimated using Monte Carlo simulation and the following logic [3]. Firstly, within an initial Monte Carlo simulation, a number of iterations (100, 1000, and so) generating the parameter estimate is run, and the parameter estimates from individual iterations are averaged, and their standard deviation is calculated. Then, applying the central limit theorem, a confidence interval for the parameter is constructed, and the Monte Carlo simulation is repeated so many times that the interval is no wider than a given precision. A problem of the abovementioned approach is in the parameter's variability estimation within the initial Monte Carlo simulation. If the variability is underestimated, the confidence interval is falsely narrower than it should be, and the precision is, in fact, lower than expected. To overcome this issue, we rather refine the simulation logic – firstly, we find a function of the parameter equal to some probability, which is then simulated using Monte Carlo simulation. Since the probability has a theoretically-based upper bound, its variability is upper-bounded. Then, we use the properties of the Bernoulli distribution to estimate the largest possible variability of the parameter as a probability and Chebyshev's inequality to enumerate the number of iterations keeping the parameter estimate's precision. Due to Chebyshev's inequality, we do not need the assumption of the parameter estimate's normality, which makes the proposed approach more robust.

II. A traditional approach to Monte Carlo simulation and estimation of parameters of non-probabilistic fashion

Let us assume a parameter θ of a non-probabilistic fashion that can be estimated n times using point estimates $\hat{\theta}_1, \hat{\theta}_2, \dots, \hat{\theta}_n$. Then, calculation of the estimates' average and standard deviation, i.e.,

$$\bar{\theta} = \frac{1}{n}\sum_{i=1}^{n}\hat{\theta}_i \qquad \text{and} \qquad \sigma_\theta = \sqrt{\frac{1}{n-1}\sum_{i=1}^{n}(\hat{\theta}_i - \bar{\theta})^2},$$

is feasible. To estimate parameter θ using Monte Carlo simulation on a given level of precision $1-\varepsilon$, where $\varepsilon \gtrsim 0$, reached with probability $1-\alpha$, one needs to know a number of iterations n of the simulation [3].

A. Principles of the traditional approach to Monte Carlo simulation and estimation of parameters of non-probabilistic fashion

Adopting the mathematical notation from the previous section, typical values of ε and α are, e.g., $\varepsilon = 0.001$ and $\alpha = 0.05$, respectively. A traditional approach to parameter θ estimation follows.

Thematic track: Computer Aspects of Numerical Algorithms

(i) Choose n_0 for initial Monte Carlo simulation that would pre-estimate parameter θ using individual estimates $\hat{\theta}_{0,1}, \hat{\theta}_{0,2}, \ldots, \hat{\theta}_{0,n_0}$. Typically, n_0 is chosen as $n_0 = 100$ or $n_0 = 1000$ or similar.

(ii) Calculate an average and a standard deviation of the pre-estimated parameter as

$$\bar{\theta}_0 = \frac{1}{n_0}\sum_{i=1}^{n_0} \hat{\theta}_{0,i} \text{ and } \sigma_{0,\theta} = \sqrt{\frac{1}{n_0 - 1}\sum_{i=1}^{n_0} (\hat{\theta}_{0,i} - \bar{\theta}_0)^2}.$$

(iii) Applying Ljapunov's central limit theorem [4], parameter θ should lie in an interval of

$$\left\langle \bar{\theta}_0 - u_{1-\alpha/2}\frac{\sigma_{0,\theta}}{\sqrt{n}},\ \bar{\theta}_0 + u_{1-\alpha/2}\frac{\sigma_{0,\theta}}{\sqrt{n}} \right\rangle \quad (1)$$

in $(1-\alpha)n$ cases of n total cases, thus, approximately with a probability $1-\alpha$, where $u_{1-\alpha/2}$ is the $(1-\alpha/2)$-th quantile of the standard normal distribution.

(iv) Number of iterations n of the main Monte Carlo simulation, outputting parameter estimates $\hat{\theta}_1, \hat{\theta}_2, \ldots, \hat{\theta}_n$, is chosen to keep precision $1-\varepsilon$ with probability $1-\alpha$, so the confidence interval's half length from formula (1) should be less than or equal to ε, thus

$$u_{1-\alpha/2}\frac{\sigma_{0,\theta}}{\sqrt{n}} \leq \varepsilon, \quad (2)$$

and, equivalently, the number of needed iterations is

$$n \geq \left(\frac{u_{1-\alpha/2} \cdot \sigma_{0,\theta}}{\varepsilon}\right)^2. \quad (3)$$

(v) Finally, parameter θ is estimated using $\bar{\theta} = \frac{1}{n}\sum_{i=1}^{n} \hat{\theta}_i$, believed to keep precision $1-\varepsilon$ with probability $1-\alpha$.

B. Limitations of the traditional approach to Monte Carlo simulation and estimation of parameters of non-probabilistic fashion

Although the abovementioned approach works in general and is commonly applied, it can suffer from not meeting the asymptotic properties assumed by Ljapunov's central limit theorem when the confidence interval from formula (1) is constructed. This might happen particularly for low values of n or very high demands on precision, e.g., when $\varepsilon < 10^{-6}$. On a more practical note, inspecting formula (3), if the parameter's standard deviation σ_θ is underestimated by $\sigma_{0,\theta}$, i.e., when $\sigma_{0,\theta} < \sigma_\theta$, then also number n of iterations needed to keep imprecision $\leq \varepsilon$ is underestimated, which may result into imprecise, i.e., wrong (!) decimal digits staring the i-th digit behind (or before) the decimal point, where $i = \lfloor |\log_{10}(\varepsilon)| \rfloor$, if $\varepsilon < 1$ (or $\varepsilon > 1$, respectively).

C. The asymptotic time complexity of the traditional approach to Monte Carlo simulation and estimation of parameters of non-probabilistic fashion

Obviously, if one iteration of the Monte Carlo simulation takes τ units of time, then, since the simulation is repeated two times, firstly with n_0 iterations and secondly with $n \geq \left(\frac{u_{1-\alpha/2} \cdot \sigma_{0,\theta}}{\varepsilon}\right)^2$ iterations as comes from formula (4), the total asymptotic time complexity of the procedure, $\Theta(\dagger)$, is

$$\begin{aligned} \Theta(\dagger) &= \Theta\left((n_0 + n)\tau\right) \geq \\ &\geq \Theta\left(\left(n_0 + \left(\frac{u_{1-\alpha/2} \cdot \sigma_{0,\theta}}{\varepsilon}\right)^2\right)\tau\right), \end{aligned} \quad (4)$$

so, while $\Theta(\dagger)$ is linear in n_0 and n terms, it is quadratic in $\sigma_{0,\theta}$ and $\frac{1}{\varepsilon}$ terms.

III. A proposed approach to Monte Carlo simulation and estimation of parameters of (non-)probabilistic fashion

Let us suppose a parameter θ of non-probabilistic fashion. Besides the traditional approach for θ estimation as introduced above, we may assume a link function $f(\bullet)$ so that $f(\theta)$ has got a dimension of probability, so,

$$f(\theta) = P(\mathcal{T}), \quad (5)$$

where $P(\bullet)$ is a probability function as comes from σ-algebra, and $\mathcal{T}$ is a random event or a proposition consisting of random events. If occasionally θ would be apriori a probability, then the link function $f(\bullet)$ is an identity, i.e., $f(\theta) = \theta$, and the approach below still works. That is why we bound the prefix *non-* into brackets in the section title.

Thus, to estimate parameter θ of the (non-)probabilistic fashion, keeping precision $1-\varepsilon$ with probability $1-\alpha$, let us first assume a random variable X following Bernoulli distribution with an argument $P(\mathcal{T})$, i.e., $f(\theta)$ (probability of success). A sum of n independent Bernoulli trials follows the binomial distribution with arguments n (number of trials) and $f(\theta)$ (probability of success in each trial). After collecting n estimates $\hat{X}_i$ coming from the above mentioned Bernoulli distribution, we calculate $\frac{1}{n}\sum_{i=1}^{n}\hat{X}_i$ to estimate parameter $f(\theta)$. The number of trials n, i.e., a number of iterations of Monte Carlo simulation, is prior estimated using Chebyshev's inequality, also considering the terms of precision, $1-\varepsilon$, and confidence probability, $1-\alpha$.

A. Mathematical and statistical preliminaries of the proposed approach to Monte Carlo simulation and estimation

As we have seen, we need to revisit Bernoulli and binomial distribution and Chebyshev's inequality and their statistical properties. So let's start with Bernoulli and binomial distributions.

Definition 1 (Bernoulli distribution)**.** *A random variable X follows Bernoulli distribution with an argument $0 \leq p \leq 1$ (probability of success), if*

$$X = \begin{cases} 1, & \textit{with probability } p \\ 0, & \textit{with probability } 1-p. \end{cases}$$

Formally, we write $X \sim$ Bernoulli(p).

Lemma 1 (Bernoulli distribution's expected value and variance)**.** *Let random variable X follow Bernoulli distribution with an argument p. Then expected value of X is $\mathbb{E}(X) = p$ and variance of X is $\operatorname{var}(X) = p(1-p)$.*

Proof. According to definition 1, it is $\mathbb{E}(X) = \sum_{i \in \{0,1\}} i \cdot P(X = i) = 0 \cdot (1-p) + 1 \cdot p = p$, and $\mathbb{E}\left(X^2\right) = \sum_{i \in \{0,1\}} i^2 \cdot P(X = i) = 0^2 \cdot (1-p) + 1^2 \cdot p = p$. Since routinely is $\operatorname{var}(X) = \mathbb{E}\left(X^2\right) - (\mathbb{E}(X))^2$, we get $\operatorname{var}(X) = \mathbb{E}\left(X^2\right) - (\mathbb{E}(X))^2 = p - p^2 = p(1-p)$.

□

Definition 2 (Binomial distribution)**.** *A random variable X follows binomial distribution with arguments $n \in \mathbb{N}$ and $0 \leq p \leq 1$, if X is sum of n independent variables following Bernoulli distribution with an argument $0 \leq p \leq 1$ (i.i.d.). Formally, we write $X \sim \text{binomial}(n, p)$.*

Lemma 2 (Binomial distribution's expected value and variance)**.** *Let random variable X follow binomial distribution with arguments n and p. Then expected value of X is $\mathbb{E}(X) = np$ and variance of X is $\operatorname{var}(X) = np(1-p)$.*

Proof. According to definition 2, if $X \sim \text{binomial}(n, p)$, it is $X = Y_1 + Y_2 + \cdots + Y_n = \sum_{i=1}^{n} Y_i$, where $Y_i \sim \text{Bernoulli}(p)$ for $\forall i \in \{1, 2, \ldots, n\}$. So, $\mathbb{E}\left(Y_i\right) = p$ (†) and $\operatorname{var}\left(Y_i\right) = p(1-p)$ (‡). Thus,

$$\mathbb{E}(X) = \mathbb{E}\left(\sum_{i=1}^{n} Y_i\right) \overset{\text{i.i.d.}}{=} \sum_{i=1}^{n} \mathbb{E}\left(Y_i\right) \overset{(\dagger)}{=} \sum_{i=1}^{n} p = np, \tag{6}$$

and also

$$\begin{aligned} \operatorname{var}(X) = \operatorname{var}\left(\sum_{i=1}^{n} Y_i\right) \overset{\text{i.i.d.}}{=} \sum_{i=1}^{n} \operatorname{var}\left(Y_i\right) \overset{(\ddagger)}{=} \sum_{i=1}^{n} p(1-p) = \\ = np(1-p). \end{aligned} \tag{7}$$

□

Lemma 3 (Binomial distribution's maximum variance)**.** *Let random variable X follow binomial distribution with arguments n and p. Then maximum possible variance of X is $\operatorname{var}(X) = \frac{n}{4}$.*

Proof. According to lemma 2 and formula (7), if $X \sim \text{binomial}(n, p)$, it is $\operatorname{var}(X) = np(1-p)$. Let mark $p \equiv \frac{1}{2} + \delta$, where $\delta \in \left\langle -\frac{1}{2}, \frac{1}{2} \right\rangle$. Then, obviously,

$$\begin{aligned} \operatorname{var}(X) = np(1-p) = n\left(\frac{1}{2} + \delta\right)\left(1 - \left(\frac{1}{2} + \delta\right)\right) = \\ = n\left(\frac{1}{2} + \delta\right)\left(\frac{1}{2} - \delta\right) = n\left(\frac{1}{4} - \delta^2\right) \leq \frac{n}{4}. \end{aligned} \tag{8}$$

Thus, generally $\operatorname{var}(X) \leq \frac{n}{4}$, and $\operatorname{var}(X) = \frac{n}{4} = n\left(\frac{1}{4} - 0^2\right)$ for $\delta = 0$, so if and only if $p = \frac{1}{2} + \delta = \frac{1}{2} + 0 = \frac{1}{2}$. □

Finally, let's revisit Markov's and Chebyshev's inequalities [5], that enables us to derive the number of needed iterations of Monte Carlo simulation.

Theorem 1 (Markov's inequality)**.** *Let X be a non-negative random variable with expected value $\mathbb{E}(X)$. For $a > 0$ is*

$$P(X \geq a) \leq \frac{\mathbb{E}(X)}{a}. \tag{9}$$

Proof. Surely, since $a > 0$ and $X \geq 0$, it is $\mathbb{E}(X \mid X < a) \geq 0$ and $\mathbb{E}(X \mid X \geq a) \geq a$ (†). Because $\mathbb{E}(X \mid X < a) \geq 0$ and $P(X < a) \geq 0$, it is also $\mathbb{E}(X \mid X < a)P(X < a) \geq 0$. So, $\mathbb{E}(X) \geq \mathbb{E}(X) - \mathbb{E}(X \mid X < a)P(X < a)$. Also, due to the total expectations theorem, it is $\mathbb{E}(X) = \mathbb{E}(X \mid X < a)P(X < a) + \mathbb{E}(X \mid X \geq a)P(X \geq a)$, and $\mathbb{E}(X) - \mathbb{E}(X \mid X < a)P(X < a) = \mathbb{E}(X \mid X \geq a)P(X \geq a)$. Thus,

$$\begin{aligned} \mathbb{E}(X) \geq \mathbb{E}(X) - \mathbb{E}(X \mid X < a)P(X < a) = \\ = \mathbb{E}(X \mid X \geq a)P(X \geq a) \overset{(\dagger)}{\geq} a \cdot P(X \geq a), \end{aligned}$$

and, finally,

$$P(X \geq a) \leq \frac{\mathbb{E}(X)}{a}.$$

□

Theorem 2 (Chebyshev's inequality)**.** *Let X be a random variable with expected value $\mathbb{E}(X)$, and non-zero and finite variance $0 < \operatorname{var}(X) < \infty$. For $b > 0$ is*

$$P(|X - \mathbb{E}(X)| \geq b) \leq \frac{\operatorname{var}(X)}{b^2}. \tag{10}$$

Proof. If we realize that $\operatorname{var}(X) = \mathbb{E}\left((X - \mathbb{E}(X))^2\right)$ (†) and formally put $X \equiv (X - \mathbb{E}(X))^2$ and $a \equiv b^2$ into formula (9) of Markov's inequality, we directly get Chebyshev's inequality,

$$\begin{aligned} P(X \geq a) &\leq \frac{\mathbb{E}(X)}{a} \\ P\left((X - \mathbb{E}(X))^2 \geq b^2\right) &\leq \frac{\mathbb{E}\left((X - \mathbb{E}(X))^2\right)}{b^2} \\ P\left(|X - \mathbb{E}(X)| \geq b\right) &\overset{(\dagger)}{\leq} \frac{\operatorname{var}(X)}{b^2}. \end{aligned}$$

□

B. Number of needed iterations of Monte Carlo simulation for parameter estimation keeping the estimate's given precision

Let's assume a random variable X following Bernoulli distribution with an argument $P(\mathcal{T})$, i.e., $X \sim \text{Bernoulli}(P(\mathcal{T}))$. Thus, probability of a success in each Bernoulli trial is $P(\mathcal{T}) = f(\theta)$. If we repeat Bernoulli trials n times, based on definition 1, we can get a random variable $\sum_{i=1}^{n} X_i$, where $X_i \sim \text{Bernoulli}(P(\mathcal{T}))$ for $i \in \{1, 2, \ldots, n\}$. Since lemma 2, it is $\mathbb{E}\left(\sum_{i=1}^{n} X_i\right) = nP(\mathcal{T}) = nf(\theta)$ and $\operatorname{var}\left(\sum_{i=1}^{n} X_i\right) = nP(\mathcal{T})(1 - P(\mathcal{T})) = nf(\theta)(1 - f(\theta))$ (†). Using Chebyshev's inequality from formula (10), we get

$$P\left(\left|\sum_{i=1}^{n} X_i - \mathbb{E}\left(\sum_{i=1}^{n} X_i\right)\right| \geq b\right) \leq \frac{\operatorname{var}\left(\sum_{i=1}^{n} X_i\right)}{b^2}$$
$$P\left(\left|\sum_{i=1}^{n} X_i - nf(\theta)\right| \geq b\right) \overset{(\dagger)}{\leq} \frac{nf(\theta)(1-f(\theta))}{b^2}$$

We can simplify the right-hand side using lemma 3, i.e., $\operatorname{var}\left(\sum_{i=1}^{n} X_i\right) \leq \frac{n}{4}$, so

$$P\left(\left|\sum_{i=1}^{n} X_i - nf(\theta)\right| \geq b\right) \leq \frac{nf(\theta)(1-f(\theta))}{b^2} \overset{(8)}{\leq} \frac{n}{4b^2}$$
$$P\left(\left|\frac{1}{n}\sum_{i=1}^{n} X_i - \frac{nf(\theta)}{n}\right| \geq \frac{b}{n}\right) \leq \frac{n}{4b^2}$$
$$P\left(\left|\bar{X} - f(\theta)\right| \geq \frac{b}{n}\right) \leq \frac{n}{4b^2},$$

let's set $b \equiv n\varepsilon$, then we get

$$P\left(\left|\bar{X} - f(\theta)\right| \geq \frac{n\varepsilon}{n}\right) \leq \frac{n}{4(n\varepsilon)^2}$$
$$P\left(\left|\bar{X} - f(\theta)\right| \geq \varepsilon\right) \leq \frac{1}{4n\varepsilon^2},$$

and by setting the probability's uncertainty as $\frac{1}{4n\varepsilon^2} \leq \alpha$ is

$$P\left(\left|\bar{X} - f(\theta)\right| \geq \varepsilon\right) \leq \frac{1}{4n\varepsilon^2} \leq \alpha. \tag{11}$$

Formula (11) tells us that a probability of getting a distance between the parameter $f(\theta)$ and its estimate $\bar{X}$ greater than ε, is lower than α. Thus, to keep imprecision $\leq \epsilon$, i.e., to keep $\frac{1}{4n\varepsilon^2} \leq \alpha$, we need n iterations of the Monte Carlo simulation,

$$n \geq \frac{1}{4\alpha\varepsilon^2}, \tag{12}$$

and unlike (3), formula (12) does not include a stochastic term.

C. A scheme of the proposed approach to Monte Carlo simulation and estimation of parameters

The previous paragraphs and particularly formulas (11) and (12) suggest Monte Carlo simulation for not only probabilistic-like parameters, keeping non-underestimated precision, that consists of the following steps.

(i) Setting the tuning parameters of the simulation – precision $1-\varepsilon$ and probability $1-\alpha$.

(ii) Assuming formula (5), constructing a generative Bernoulli process $X \sim \text{Bernoulli}(P(\mathcal{T}))$. We want to estimate parameter θ's value since we don't know it using link function f and a different random process, known from theory, with outcome $P(\mathcal{T})$ where $P(\mathcal{T}) = f(\theta)$.

(iii) Repeating Bernoulli process n times, where $n \geq \frac{1}{4\alpha\varepsilon^2}$, and collecting the outcomes $\hat{X}_1, \hat{X}_2, \ldots, \hat{X}_n$.

(iv) Finally, averaging the outcomes, $\bar{X} = \frac{1}{n}\sum_{i=1}^{n}\hat{X}_i$, by getting estimate $f(\theta)$ on precision level $1-\varepsilon$ with probability $1-\alpha$.

(v) Parameter θ's estimate is $f^{-1}(f(\theta)) = f^{-1}\left(\bar{X}\right)$. While parameter $f(\theta)$ is estimated with imprecision ε, parameter $\theta = f^{-1}\left(\bar{X}\right)$ is estimated with imprecision $f^{-1}(\varepsilon)$.

An algorithm for the proposed Monte Carlo simulation is in Algorithm 1.

Algorithm 1: The proposed approach to Monte Carlo simulation and estimation of parameters of not only probabilistic fashion

```
Data: generative Bernoulli process with probability of
      success $P(\mathcal{T})$, link function $f$ ensuring that
      $P(\mathcal{T}) = f(\theta)$, precision $1-\varepsilon$, probability $1-\alpha$
Result: parameter $\theta$'s estimate
$\boldsymbol{X} = \{\emptyset\}$                // a vector for;
                                 // estimates saving;
$n_{\min} = \frac{1}{4\alpha\varepsilon^2}$            // # of iterations;
for $i = 1 : n_{\min}$ do
    generate outcome $\hat{X}_i$ from $X \sim \text{Bernoulli}(P(\mathcal{T}))$;
    $\boldsymbol{X} = \{\boldsymbol{X}, \hat{X}_i\}$     // update the vector;
end
estimate $\theta$ as $\theta = f^{-1}\left(\bar{\boldsymbol{X}}\right) = f^{-1}\left(\frac{1}{n}\sum_{i=1}^{n}\hat{X}_i\right)$;
```

D. The asymptotic time complexity of the proposed approach to Monte Carlo simulation and estimation of parameters

The simulation is repeated n times where $n \geq \frac{1}{4\alpha\varepsilon^2}$, as comes from formula (12). Assuming one iteration of the Monte Carlo simulation takes τ time units, the total asymptotic time complexity of the procedure, $\Theta(\ddagger)$, is

$$\Theta(\ddagger) = \Theta(n\tau) \geq \Theta\left(\frac{1}{4\alpha\varepsilon^2}\tau\right), \tag{13}$$

so, while $\Theta(\ddagger)$ is linear in n and $\frac{1}{\alpha}$ terms, it is quadratic in $\frac{1}{\varepsilon}$ term. To compare asymptotic time complexity $\Theta(\dagger)$ from formula (4) for the traditional estimation procedure and $\Theta(\ddagger)$ from formula (13) for the proposed one, assuming that $n_0 \ll n$, it is $\Theta(\ddagger) > \Theta(\dagger)$, since, in general, is $\frac{1}{\alpha} > u_{1-\alpha/2}$. Both functions $\frac{1}{\alpha}$ and $u_{1-\alpha/2}$ are monotonous and decreasing while α increases, but for $\alpha \leq 0.05$ is $u_{1-\alpha/2} \gtrsim 2$ while $\frac{1}{\alpha} \geq 20$. So, while the traditional approach is "faster" in terms of time complexity, it may suffer from false underestimating of the parameter estimate's variability.

E. Keeping the first k decimal digits precise in the proposed approach to Monte Carlo simulation and estimation

Due to avoiding the issue of variability coming from lemma 3 and Chebyshev's inequality (10), an appropriate setting of precision level $1-\varepsilon$ can ensure the first k decimal digits are correctly estimated within the proposed simulation and estimation approach. Inspecting formula (11), we can realize that $\bar{X} - \varepsilon \leq f(\theta) \leq \bar{X} + \varepsilon$ with probability $1-\alpha$. On a given probability level $1-\alpha$, to avoid rounding error up to k-th decimal digit, we should set ε as

$$\varepsilon < 0.5 \cdot 10^{-k}. \tag{14}$$

Moreover, if the inversion function to link function f is of an additive (linear) form, i.e., $\forall \xi, \eta \in \mathbb{R}$ is $f^{-1}(\xi+\eta) = f^{-1}(\xi) + f^{-1}(\eta)$, it is also $f^{-1}(\bar{X}-\varepsilon) \leq f^{-1}(f(\theta)) \leq f^{-1}(\bar{X}+\varepsilon)$, so, $f^{-1}(\bar{X}) - f^{-1}(\varepsilon) \leq \theta \leq f^{-1}(\bar{X}) + f^{-1}(\varepsilon)$, and we can estimate also the *real* imprecision level ε_θ for parameter θ, i.e., not only $f(\theta)$, as

$$f^{-1}(\varepsilon_\theta) < 0.5 \cdot 10^{-k}, \quad \text{or,} \quad \varepsilon_\theta < f(0.5 \cdot 10^{-k}). \tag{15}$$

IV. The proposed approach to Monte Carlo simulation and estimation applied: π estimation

Revisiting the well-known example of π constant estimation using Monte Carlo simulation, let us assume a quarter circle with a radius of 1 as in Fig. 1. For a random point $A = [x, y]$ in the unit square around the quarter circle, where $[x, y] \in \langle 0, 1\rangle^2$, the generative Bernoulli process $X \sim \text{Bernoulli}(P(\mathcal{T}))$ here returns number 1 if A lies in the quarter circle (in gray color in Fig. 1), otherwise it returns 0. Thus, the random event is $\mathcal{T} = \{A \in \text{quarter circle} \mid A \in \text{unit square}\}$ and $P(\mathcal{T}) = \frac{S_{\text{quarter circle}}}{S_{\text{unit square}}} = \frac{\pi \cdot 1^2}{4}/1 = \frac{\pi}{4}$. So, the Bernoulli process enables us to estimate $f(\theta) = \frac{\pi}{4}$, which implies the link function f as $f(\eta) = \frac{\eta}{4}$.

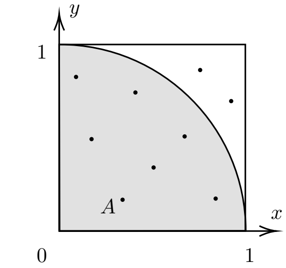

Fig. 1. A quarter circle in a unit square enabling estimation of $\frac{\pi}{4}$ parameter using Monte Carlo simulation of many points such as $A = [x, y] \in \langle 0, 1\rangle^2$.

Both for traditional and the proposed approach, we repeated Monte Carlo simulation $m = 100$ times to evaluate how likely the k-th decimal digit is not correct, with $k \in \{1, 2, 3\}$. We set probability level $\alpha = 0.05$ and real imprecision $\varepsilon_\theta = f(0.4 \cdot 10^{-k}) = \frac{0.4 \cdot 10^{-k}}{4} = 0.1 \cdot 10^{-k}$ using formula (15). The number of simulation iterations was estimated using formulas (3) and (12). The initial number of iterations for the traditional approach needed for pre-estimating the estimate's standard deviation $\sigma_{0,\theta}$, was $n_0 = 100$. We used R programming language and environment [6] for the Monte-Carlo simulations. There are more numerical applications of R language to various fields in [7]–[9].

Results are in Table I. While the traditional approach did not always ensure the precise k-th digit, particularly (but rarely, in $\leq \alpha = 0.05 = 5$ % of all cases) for $k = 2$ and $k = 3$, the proposed approach kept the k-th digit's precision every time. Unlike the proposed method not considering a stochastic term (see formula (12)), the traditional one may suffer from a possible underestimate of initial estimate's variability $\sigma_{0,\theta}$ and needed number n of Monte Carlo iterations (see formula (3)).

TABLE I
Proportions of cases when the k-th digit was incorrect out of $m = 100$ repetitions (marked as r) of Monte Carlo simulation.

		traditional approach		proposed approach	
k	ε_θ	$n_{\min}$	r	$n_{\min}$	r
1	0.01	1,028	0.00	50,000	0.00
2	0.001	102,765	0.01	5,000,000	0.00
3	0.0001	10,276,423	0.01	500,000,000	0.00

V. Conclusions remarks

We introduced an alternative approach to Monte Carlo estimation, using refining all estimated parameters as probabilities. That enables us to apply Bernoulli trials with upper-bounded variability of the estimate and Chebyshev's inequality for a robust estimate of the number of iterations needed to ensure the estimate's precision on a given probability level.

***Abstract*—Assuming a bounded polygon and a point inside the polygon or on its boundary, the visibility polygon, also called the visibility region, is a polygon reachable, i.e., visible by straight lines from the point without hitting the polygon's edges or vertices. If the polygon is bounded, then the visibility polygon is bounded, and the proportion of the visibility polygon's surface area to the given polygon's surface area could be enumerated. Many papers investigate applications of the visibility polygons in robotics and computer graphics or focus on computationally effective finding the visibility region for a given polygon. However, surprisingly, there seems to be no work estimating the proportion of a visibility polygon's surface to an entire polygon's surface or its bounds. Thus, in this paper, we search for a lower bound of the surface proportion of a visibility polygon to a given one. Assuming n-sided simple polygon, i.e., a polygon without holes and edge intersections, we apply the well-known art gallery problem and derive there is always a point inside the polygon or on its boundary that guarantees the proportion of the visibility polygon's surface to the entire polygon's surface is at least $\frac{1}{\lfloor n/3 \rfloor}$. We also show that there are n-sided polygons for which the proportion of the visibility polygon's surface to the entire polygon's surface is asymptotically not greater than $\frac{1}{\lfloor n/3 \rfloor}$ for any point inside the polygon or on its boundary. So, the lower bound of the proportion of the visibility polygon's surface to the entire polygon's surface, $\frac{1}{\lfloor n/3 \rfloor}$, cannot be improved in general.**

I. Introduction

THE visibility region of a polygon related to a given polygon's point, i.e., the largest part of the polygon, so that each point of such a polygon's part is directly visible from the given point, has multiple applications in robotics, operational research, and logistics, security, video game creation, and other situations, mainly of optimization character.

In robotics, visibility regions (polygons) are typically important for robotic agents to enable appropriate movement-making and planning [1]. There is a well-known problem called facility location problem where a number of facilities are to be optimally placed to minimize any transportation costs [2]. Besides other approaches, such as clustering, the visibility polygons could help to find the optimal facility setting [3], [4]. Similarly, in security applications, areas of various geometric shapes are often required to be guarded – then, a number and placement of guards watching the area could be researched using visibility polygons [5].

Since most problems are based on specific n-sided polygons, many papers search for an algorithm for building the visibility polygon in the shortest possible asymptotic time complexity. The naive approach takes quadratic time in terms of n – each pair of every two vertices is inspected to determine whether they are visible from a given point. While Asano published a faster sweeping algorithm for the visibility polygon construction, taking $n \log n$ asymptotic time [6], Lee developed the algorithm in linear time [7] by tricky stacking. Afterward, Joe and Simpson made Lee's algorithm even more robust, keeping it still in linear time [8].

In this paper, we go deeper rather into an estimate of a proportion of the visibility region's surface to the polygon's surface, assuming a point inside the polygon or on its boundary. In general, publications on this topic are missing. A guaranteed lower bound of the proportion, if this would be sufficiently high for at least one polygon's point, could, for instance, help in various tasks to decide whether one point with its visibility region is enough to satisfy the task conditions. On the other hand, cases of polygons that would show the lower bound of the proportion could not be greater than, e.g., some constant, might also imply that there is, for example, no optimal solution of the given task using only one chosen point. We research both situations more in detail and apply the outcomes on the *garden-watering problem*.

II. Preliminaries

Firstly, let us define the visibility region and the proportion of a visibility polygon's surface to an entire polygon's surface. In general, we do not assume convexity of polygons.

Definition 1 (The visibility polygon, visibility region)**.** *Let us assume a simple non-empty n-sided polygon $\mathcal{P}$, i.e., a polygon that does not intersect itself and has no holes, with $n \in \mathbb{N}$ and $n \geq 3$. Let A be a point inside polygon $\mathcal{P}$ or on its boundary, i.e., $A \in \mathcal{P}$. A visibility polygon (region) for point A in polygon $\mathcal{P}$ is polygon $\mathcal{V}_{A,\mathcal{P}}$ created by a set of all points $B \in \mathcal{P}$ so that each segment AB lies completely in $\mathcal{P}$, i.e., $AB \in \mathcal{P}$.*

As an example, the visibility polygon (region) of the polygon in Fig. 1 is colored in gray.

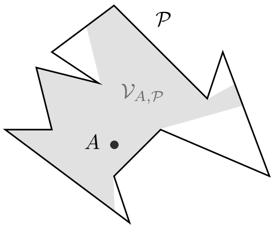

Fig. 1. An example of n-sided polygon $\mathcal{P}$ with $n = 12$. The visibility polygon $\mathcal{V}_{A,\mathcal{P}}$ for point A in polygon $\mathcal{P}$ is in gray color.

Definition 2 (A proportion of a visibility polygon's surface to an entire polygon's surface)**.** *Following definition 1, let us assume $n \in \mathbb{N}$ so that $n \geq 3$, a simple non-empty n-sided polygon $\mathcal{P}$ and a point $A \in \mathcal{P}$. Let $S\left(\mathcal{V}_{A,\mathcal{P}}\right)$ be a surface of the visibility polygon for point A and $S(\mathcal{P})$ be a surface of polygon $\mathcal{P}$. Then, the proportion of the visibility polygon's surface $S\left(\mathcal{V}_{A,\mathcal{P}}\right)$ to the entire polygon's surface $S(\mathcal{P})$ is marked ν and is equal to*

$$\nu = \frac{S\left(\mathcal{V}_{A,\mathcal{P}}\right)}{S(\mathcal{P})}.$$

While trivial upper and lower bounds of the proportion of a visibility polygon's surface to an entire polygon's surface are apparent, as shown in the following lemma, more efficient estimates of the proportion bounds might be tricky, though.

Lemma 1. *Assuming definition 2, the proportion of a visibility polygon's surface $S\left(\mathcal{V}_{A,\mathcal{P}}\right)$ to an entire polygon's surface $S(\mathcal{P})$ is always*

$$0 \leq \nu = \frac{S\left(\mathcal{V}_{A,\mathcal{P}}\right)}{S(\mathcal{P})} \leq 1.$$

Proof. The n-sided polygon $\mathcal{P}$ is non-empty, so $S(\mathcal{P}) > 0$. Since surely $S\left(\mathcal{V}_{A,\mathcal{P}}\right) \geq 0$, it is $\nu = \frac{S(\mathcal{V}_{A,\mathcal{P}})}{S(\mathcal{P})} \geq 0$. The visibility polygon $\mathcal{V}_{A,\mathcal{P}}$ is created by points $B \in \mathcal{P}$, thus $S\left(\mathcal{V}_{A,\mathcal{P}}\right) \leq S(\mathcal{P})$ and $\nu = \frac{S(\mathcal{V}_{A,\mathcal{P}})}{S(\mathcal{P})} \leq 1$. □

Due to the optimization fashion of the tasks using the visibility polygon, it is much more useful to investigate a lower bound of the proportion of a visibility polygon's surface to an entire polygon's surface, which may ensure that for a smart choice of the polygon's point, its visibility region is guaranteed to be sufficiently high. The proportion's upper bound equaled to 1, as shown in lemma 1, is often satisfied, e.g., for convex polygons, as proved below.

Lemma 2. *Assuming definition 2, the proportion of a visibility polygon's surface $S\left(\mathcal{V}_{A,\mathcal{P}}\right)$ to an entire polygon's surface $S(\mathcal{P})$ is equal to 1 if polygon $\mathcal{P}$ is convex.*

Proof. Let us proof that if polygon $\mathcal{P}$ is convex, then for any point $A \in \mathcal{P}$ is $\mathcal{V}_{A,\mathcal{P}} = \mathcal{P}$. Polygon $\mathcal{P}$ is convex, so, for each points $C \in \mathcal{P}$ and $D \in \mathcal{P}$ holds that $CD \in \mathcal{P}$ (†). By contradiction, let's assume there is point $X \in \mathcal{P}$ so that $X \notin \mathcal{V}_{A,\mathcal{P}}$. From definition 1, since the visibility polygon $\mathcal{V}_{A,\mathcal{P}}$ is created by points $B \in \mathcal{P}$, it is surely $\mathcal{V}_{A,\mathcal{P}} \subseteq \mathcal{P}$. If $X \notin \mathcal{V}_{A,\mathcal{P}}$, then $AX \notin \mathcal{P}$, otherwise, due to definition 1, necessarily would be $X \in \mathcal{V}_{A,\mathcal{P}}$. But, if $AX \notin \mathcal{P}$ and both $A \in \mathcal{P}$ and $X \in \mathcal{P}$, this is contrary to (†). Thus, if polygon $\mathcal{P}$ is convex, then for any point $A \in \mathcal{P}$ is $\mathcal{V}_{A,\mathcal{P}} = \mathcal{P}$, so $S\left(\mathcal{V}_{A,\mathcal{P}}\right) = S(\mathcal{P}) > 0$ and $\nu = \frac{S(\mathcal{V}_{A,\mathcal{P}})}{S(\mathcal{P})} = 1$. □

If one could ensure that there always exists a point in a polygon so that the proportion of the surface of the visibility polygon for the point and surface of the entire polygon is greater than or equal to a constant, derivable from the polygon's characteristics, many of the optimization tasks, e.g., in security or logistics could have a plausible solution using only one point (or agent). In another way, there is a class of polygons for which the proportion of a visibility polygon's surface to an entire polygon's surface is not much greater than the constant from the previous case, regardless of the polygon's point choice; it is additional information for the task solution, too – there likely does not exist a satisfying solution using only one point (agent).

III. More on a lower bound of the proportion of a visibility polygon's surface to an entire polygon's surface

In the following sections, we investigate the existence of a simple n-sided polygon's point, i.e., a point in the polygon or on its boundary, so that a proportion of the surface of the visibility polygon for the point and the surface of the entire polygon is always greater than or equal to a constant, related to n. Also, we demonstrate there are n-sided polygons so that each visibility polygon is not much greater than the constant, regardless of the polygon's point selection. Thus, we show the surface proportion that is always greater than or equal to a constant for at least one point in the polygon could not be much more effective.

A. The existence of a polygon's point guaranteeing that the proportion of a visibility polygon's surface to an entire polygon's surface is not lower than a polygon-related constant

Using the popular art gallery problem [9], we prove that, assuming a simple non-empty n-sided polygon, there always exists a point in the polygon so that the proportion of the surface of the visibility polygon for the point, and the surface of the entire n-sided polygon is greater than or equal to $\frac{1}{\lfloor n/3 \rfloor}$.

Let us start with the art gallery problem, first introduced by Chvátal in [9].

Theorem 1 (The art gallery problem)**.** *Assume $n \in \mathbb{N}$ so that $n \geq 3$ and an art gallery of a shape following a simple non-empty n-sided polygon $\mathcal{P}$. Then, $\lfloor n/3 \rfloor$ guards are enough to watch the entire area of the art gallery, i.e., each point in the art gallery's polygon is visible by at least one of the $\lfloor n/3 \rfloor$ guards.*

Proof. The first proof of the classical art gallery problem was published in [9], and the short and elegant one came from [10]. □

In Fig. 2, there is an illustration of the art gallery problem for an art gallery following a shape of n-sided polygon $\mathcal{P}$ with $n = 8$.

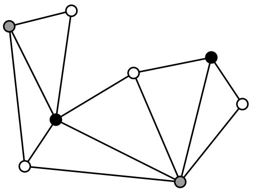

Fig. 2. An example of an art gallery following a shape of n-sided polygon $\mathcal{P}$ with $n = 8$. The n-sided polygon is triangulated, and white, gray, and black colors color the vertices of each triangle. As in theorem 1, $\lfloor n/3 \rfloor = \lfloor 8/3 \rfloor = 2$ guards, placed in vertices of black or gray color, is enough to ensure each point of the polygon is visible by at least one of them. (However, still, in fact, one guard, placed in the left bottom white vertex, is enough to watch the gallery.)

Working out some of the consequences of the art gallery problem, we get the following.

Theorem 2 (Surface of a visibility polygon of a guard in the art gallery)**.** *Let us assume $n \in \mathbb{N}$ and $n \geq 3$, and an art gallery following a simple non-empty n-sided polygon $\mathcal{P}$ with surface $S(\mathcal{P})$. Also, let us assume there are $\lfloor n/3 \rfloor$ guards, placed in vertices of the polygon. There exists a guard, i.e., a point in the polygon or on its boundary, so that a surface of their visibility polygon is greater than or equal to $\frac{S(\mathcal{P})}{\lfloor n/3 \rfloor}$.*

Proof. Let us prove the theorem by contradiction. For $\forall i \in \{1, 2, \ldots, \lfloor n/3 \rfloor\}$, let $\mathcal{V}_{G_i,\mathcal{P}}$ be a visibility polygon of guard G_i and also let us assume that $S(\mathcal{V}_{G_i,\mathcal{P}}) < \frac{S(\mathcal{P})}{\lfloor n/3 \rfloor}$ (†). Due to theorem 1, $\lfloor n/3 \rfloor$ guards are enough to ensure that each point of the polygon is visible for one or more of them. Thus, the polygon created by union of all $\lfloor n/3 \rfloor$ guards' visibility polygons should be of a surface that covers the surface $S(\mathcal{P})$ of polygon $\mathcal{P}$. However, under (†), a surface of the union of all guards' visibility polygons is

$$\begin{aligned} S\left(\bigcup_{i=1}^{\lfloor n/3 \rfloor} \mathcal{V}_{G_i,\mathcal{P}}\right) &\leq \sum_{i=1}^{\lfloor n/3 \rfloor} S(\mathcal{V}_{G_i,\mathcal{P}}) \overset{(\dagger)}{<} \\ &\overset{(\dagger)}{<} \lfloor n/3 \rfloor \cdot \frac{S(\mathcal{P})}{\lfloor n/3 \rfloor} = \\ &= S(\mathcal{P}), \end{aligned}$$

which is contrary to theorem 1's output that $\lfloor n/3 \rfloor$ guards sufficiently secure the polygon. So, (†) cannot be true and the surface of each guard's visibility polygon cannot be lower than $\frac{S(\mathcal{P})}{\lfloor n/3 \rfloor}$. Thus, there must exist at least one guard, i.e., a point in the polygon or on its boundary, with the visibility polygon of surface greater than or equal to $\frac{S(\mathcal{P})}{\lfloor n/3 \rfloor}$. □

Finally, now we can prove the main idea of the section.

Theorem 3. *Let us assume $n \in \mathbb{N}$ and $n \geq 3$, and a simple non-empty n-sided polygon $\mathcal{P}$ with surface $S(\mathcal{P})$. There always exists a point A in polygon $\mathcal{P}$ or on its boundary, so that the proportion of surface $S(\mathcal{V}_{A,\mathcal{P}})$ of visibility polygon $\mathcal{V}_{A,\mathcal{P}}$ for the point A, and surface $S(\mathcal{P})$ of polygon $\mathcal{P}$ is greater than or equal to $\frac{1}{\lfloor n/3 \rfloor}$, i.e.,*

$$\nu = \frac{S(\mathcal{V}_{A,\mathcal{P}})}{S(\mathcal{P})} \geq \frac{1}{\lfloor n/3 \rfloor}.$$

Proof. Revisiting theorem 2, the point A is identical to the guard with a visibility polygon of surface at least $\frac{S(\mathcal{P})}{\lfloor n/3 \rfloor}$. The existence of such a guard is proved by theorem 1 and 2. Since the polygon is non-empty, i.e., $S(\mathcal{P}) > 0$ (‡), and surface of their visibility polygon is greater than or equal to $\frac{S(\mathcal{P})}{\lfloor n/3 \rfloor}$, it is $S(\mathcal{V}_{A,\mathcal{P}}) \geq \frac{S(\mathcal{P})}{\lfloor n/3 \rfloor}$ and

$$\nu = \frac{S(\mathcal{V}_{A,\mathcal{P}})}{S(\mathcal{P})} \geq \frac{\frac{S(\mathcal{P})}{\lfloor n/3 \rfloor}}{S(\mathcal{P})} \overset{(\ddagger)}{=} \frac{1}{\lfloor n/3 \rfloor}. \tag{1}$$

□

So, we demonstrated that there is always a point in a given simple n-sided polygon (convex or concave) that ensures that a proportion of its visibility polygon's surface and the entire polygon's surface is at least $\frac{1}{\lfloor n/3 \rfloor}$. Such knowledge could be handy in a class of tasks using the visibility polygon based on not necessarily coverage of a given polygon by the visibility polygon.

B. The polygons for which the proportion of a visibility polygon's surface to an entire polygon's surface is asymptotically not greater than a polygon-related constant

Although we showed that there must be a point in a simple n-sided polygon or on its boundary for which a proportion of its visibility polygon's surface and the entire polygon's surface is at least $\frac{1}{\lfloor n/3 \rfloor}$, for each $n \in \mathbb{N}$ where $n \geq 6$, there are polygons that regardless of the point choice, the surface proportion is asymptotically not greater than $\frac{1}{\lfloor n/3 \rfloor}$. Firstly, let's define such polygons and estimate the total surface of their visibility polygons.

Definition 3 (The saw-like polygons)**.** *Let $n \in \mathbb{N}$ so that $n \geq 6$. A saw-like n-sided polygon is a concave polygon consisting of $k = \lfloor n/3 \rfloor$ periodically repeating triple structures: each structure includes a triangle part, a base part and a connection part. While the triangle part is an isosceles triangle with a base of length $a > 0$, the base and connection parts are rectangles with edges of length $a > 0$ and $\varepsilon > 0$, where $a \gg \varepsilon \gtrsim 0$. Thus, the triangle part's surface is much greater than the base or connection part's surface. If $n = 3k$ for $k \in \mathbb{N}$, then the rightmost connection part is missing, and* *if $n = 3k + 1$, then the rightmost connection part is halved into a triangle shape; see Fig. 3 for details and illustration.*

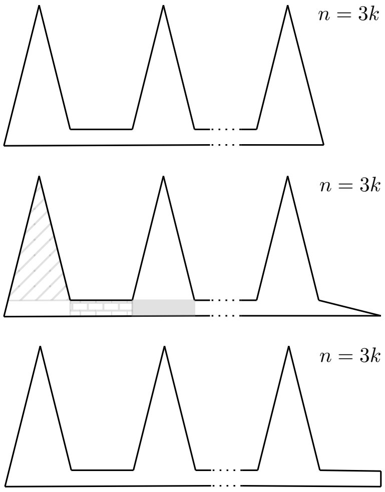

Fig. 3. Examples and patterns of the saw-like n-sided polygons. The triangle part is in a line hatch pattern, the base part is in gray, and the connection part is in a brick hatch pattern. Assuming $k \in \mathbb{N}$, then if $n = 3k$ for $k \in \mathbb{N}$, then the rightmost connection part is missing (top subfigure), if $n = 3k + 1$, the rightmost connection part is halved into a triangle shape (middle subfigure), if $n = 3k + 2$, the rightmost connection part is a rectangle as expected (bottom subfigure).

Lemma 3. *For each $n \in \mathbb{N}$ so that $n \geq 6$, i.e., $n = 3k$, or $n = 3k + 1$, or $n = 3k + 2$, where $k \in \mathbb{N}$, is $k = \lfloor n/3 \rfloor$.*

Proof. If $n = 3k$, then $k = \lfloor n/3 \rfloor = \left\lfloor \frac{3k}{3} \right\rfloor = \lfloor k \rfloor = k$. Else if $n = 3k + 1$, then $k = \lfloor n/3 \rfloor = \left\lfloor \frac{3k+1}{3} \right\rfloor = \left\lfloor k + \frac{1}{3} \right\rfloor = k$. Finally, if $n = 3k + 2$, then $k = \lfloor n/3 \rfloor = \left\lfloor \frac{3k+2}{3} \right\rfloor = \left\lfloor k + \frac{2}{3} \right\rfloor = k$. □

Theorem 4. *Let us assume a saw-like n-sided polygon $\mathcal{P}$ with $n \geq 6$ according to definition 3. For any point $A \in \mathcal{P}$, the proportion of its visibility polygon's surface $S\left(\mathcal{V}_{A,\mathcal{P}}\right)$ to an entire polygon's surface $S\left(\mathcal{P}\right)$ is asymptotically not greater than $\frac{1}{\lfloor n/3 \rfloor}$, i.e.,*

$$\nu = \frac{S\left(\mathcal{V}_{A,\mathcal{P}}\right)}{S(\mathcal{P})} \lesssim \frac{1}{\lfloor n/3 \rfloor}.$$

Proof. Mark $S(\mathcal{T})$ a surface of the triangle part, $S(\mathcal{B})$ a surface of the base part, and $S(\mathcal{C})$ a surface of the connection part. Applying definition 3, obviously, it is $S(\mathcal{B}) = S(\mathcal{C}) = a\varepsilon$ (†). Since lemma 3, polygon $\mathcal{P}$ contains exactly $k = \lfloor n/3 \rfloor$ structures (•) consisting of one triangle, base and connection part (with exception for the rightmost connection part[1], see Fig. 3), the surface of polygon $\mathcal{P}$ is

$$S(\mathcal{P}) \geq k \cdot (S(\mathcal{T}) + S(\mathcal{B}) + S(\mathcal{C})) - S(\mathcal{C}). \qquad (2)$$

For any point $A \in \mathcal{P}$ in any triangle part of polygon $\mathcal{P}$, the visibility polygon $\mathcal{V}_{A,\mathcal{P}}$ includes the triangle part and, at maximum, all base and connection parts; thus, its surface is

$$S\left(\mathcal{V}_{A,\mathcal{P}}\right) \leq S\left(\mathcal{V}_{A,\mathcal{P}}\right)_{\mathcal{T}} = S(\mathcal{T}) + k \cdot S(\mathcal{B}) + k \cdot S(\mathcal{C}), \quad (3)$$

see Fig. 4 for details. Also, for any point $A \in \mathcal{P}$ in any base part of polygon $\mathcal{P}$, the visibility polygon $\mathcal{V}_{A,\mathcal{P}}$ includes the appropriate triangle part and, at maximum, all base and connection parts multiplied by a multiplier ℓ that reflects some fractions of other triangle parts could be partly visible; thus, its surface is

$$S\left(\mathcal{V}_{A,\mathcal{P}}\right) \leq S\left(\mathcal{V}_{A,\mathcal{P}}\right)_{\mathcal{B}} = S(\mathcal{T}) + \ell k \cdot S(\mathcal{B}) + \ell k \cdot S(\mathcal{C}). \quad (4)$$

Finally, for any point $A \in \mathcal{P}$ in any connection part of polygon $\mathcal{P}$, the visibility polygon $\mathcal{V}_{A,\mathcal{P}}$ includes, at maximum, all base and connection parts multiplied by a multiplier ℓ that reflects some fractions of triangle parts could be partly visible; thus, its surface is

$$S\left(\mathcal{V}_{A,\mathcal{P}}\right) \leq S\left(\mathcal{V}_{A,\mathcal{P}}\right)_{\mathcal{C}} = \ell k \cdot S(\mathcal{B}) + \ell k \cdot S(\mathcal{C}). \qquad (5)$$

Putting formulas (3, 4, 5) together, we get

$$\begin{aligned} S\left(\mathcal{V}_{A,\mathcal{P}}\right) &\leq \max\left\{S\left(\mathcal{V}_{A,\mathcal{P}}\right)_{\mathcal{T}}, S\left(\mathcal{V}_{A,\mathcal{P}}\right)_{\mathcal{B}}, S\left(\mathcal{V}_{A,\mathcal{P}}\right)_{\mathcal{C}}\right\} = \\ &= S(\mathcal{T}) + \ell k \cdot S(\mathcal{B}) + \ell k \cdot S(\mathcal{C}). \qquad (6) \end{aligned}$$

Finally, since it is $a \gg \varepsilon \gtrsim 0$, it is also $S(\mathcal{T}) \propto a^2 \gg a\varepsilon = S(\mathcal{B}) = S(\mathcal{C}) \gtrsim 0$ and $1 \gg \frac{a\varepsilon}{S(\mathcal{T})} \gtrsim 0$ (∗). Also, we may expect, that $\ell \approx k$, or, moreover, we may set $\varepsilon \gtrsim 0$ so that $\ell k \cdot \frac{a\varepsilon}{S(\mathcal{T})} \gtrsim 0$ (‡). We get

$$\begin{aligned} \nu = \frac{S\left(\mathcal{V}_{A,\mathcal{P}}\right)}{S(\mathcal{P})} &\overset{(2,6)}{\leq} \frac{S(\mathcal{T}) + \ell k \cdot S(\mathcal{B}) + \ell k \cdot S(\mathcal{C})}{k \cdot (S(\mathcal{T}) + S(\mathcal{B}) + S(\mathcal{C})) - S(\mathcal{C})} \overset{(\dagger)}{=} \\ &\overset{(\dagger)}{=} \frac{S(\mathcal{T}) + \ell k \cdot a\varepsilon + \ell k \cdot a\varepsilon}{k \cdot (S(\mathcal{T}) + a\varepsilon + a\varepsilon) - a\varepsilon} = \\ &= \frac{S(\mathcal{T}) + 2\ell k \cdot a\varepsilon}{kS(\mathcal{T}) + (2k-1) \cdot a\varepsilon} = \\ &= \frac{1 + 2\ell k \cdot \frac{a\varepsilon}{S(\mathcal{T})}}{k + (2k-1) \cdot \frac{a\varepsilon}{S(\mathcal{T})}} \overset{(*)}{=} \\ &\overset{(*)}{=} \lim_{\frac{a\varepsilon}{S(\mathcal{T})} \to 0} \frac{1 + 2\ell k \cdot \frac{a\varepsilon}{S(\mathcal{T})}}{k + (2k-1) \cdot \frac{a\varepsilon}{S(\mathcal{T})}} \overset{(\ddagger)}{=} \\ &\overset{(\ddagger)}{=} \frac{1+0}{k+0} = \frac{1}{k} \overset{(\bullet)}{=} \\ &\overset{(\bullet)}{=} \frac{1}{\lfloor n/3 \rfloor}. \qquad (7) \end{aligned}$$

Thus, we showed that for any point in an n-sided saw-like polygon or on its boundary is the proportion ν of its visibility polygon's surface to an entire polygon's surface asymptotically not greater than $\frac{1}{\lfloor n/3 \rfloor}$, i.e., $\nu \lesssim \frac{1}{\lfloor n/3 \rfloor}$.

□

So, for each simple n-sided polygon, there indeed exists a point in the polygon or on its boundary so that the proportion ν of its visibility polygon's surface to an entire polygon's

[1] Formula (2) could be precised according to whether $n = 3k$, $n = 3k + 1$ or $n = 3k + 2$; however, it has only a low significance for the proof.

surface is $\nu \geq \frac{1}{\lfloor n/3 \rfloor}$. However, the saw-like polygons are examples of n-sided polygons where the proportion ν is upper-bounded, so it is $\nu \lesssim \frac{1}{\lfloor n/3 \rfloor}$, and, finally, $\frac{1}{\lfloor n/3 \rfloor} \leq \nu \lesssim \frac{1}{\lfloor n/3 \rfloor}$, i.e., $\nu \approx \frac{1}{\lfloor n/3 \rfloor}$ for any point in this kind of polygon or on its boundary. So, the lower bound estimate for the surface proportion ν cannot be in general greatly improved.

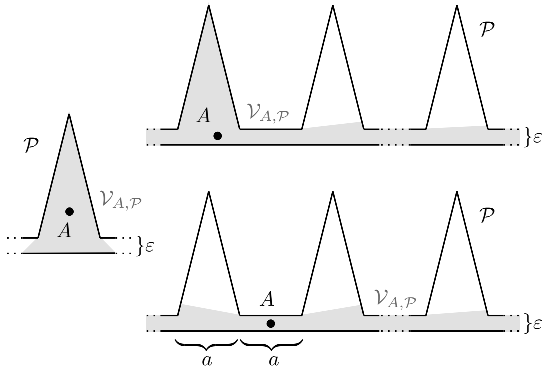

Fig. 4. Visibility polygons (in gray color) for point A in polygon $\mathcal{P}$. For any point $A \in \mathcal{P}$ the visibility polygon $\mathcal{V}_{A,\mathcal{P}}$ includes (i) the triangle part and, at maximum (!), all base and connection parts (left middle subfigure), if $A \in \mathcal{P}$ is in any triangle part of $\mathcal{P}$; (ii) the appropriate triangle part and, at maximum (!), all base and connection parts multiplied by a multiplier ℓ that reflects some fractions of other triangle parts could be partly visible, if $A \in \mathcal{P}$ is in any base part of $\mathcal{P}$ (right top subfigure); (iii) at maximum (!), all base and connection parts multiplied by a multiplier ℓ that reflects some fractions of triangle parts could be partly visible, if $A \in \mathcal{P}$ is in any connection part of $\mathcal{P}$ (right bottom subfigure).

IV. An application of the lower bound of the proportion of a visibility polygon’s surface to an entire polygon’s surface: garden-watering problem

Let us have a garden patch following a shape of a simple n-sided polygon, $n \geq 3$, that needs to be watered using a rotary sprinkler placed in the polygon or on its boundary. Due to the patch’s loose soil and water diffusion, it is enough to water only any η-proportion of the patch’s surface to hydrate the entire patch, where $0 \leq \eta \leq 1$. The sprinkler can water any point of the patch at any distance, but its water stream cannot cross the patch’s boundary. Is it possible to water the patch using only one sprinkler?

Solution. Applying theorem 3, one sprinkler can surely water ν-proportion of the entire patch, where $\nu \geq \frac{1}{\lfloor n/3 \rfloor}$. Thus, if $\frac{1}{\lfloor n/3 \rfloor} \geq \eta$, one sprinkler is sufficient. Moreover, using lemma 2, very likely one sprinkler could water an even greater proportion of the patch, up to $\nu = 1$ if the patch is, e.g., convex. However, if the patch follows a shape of the saw-like polygon as introduced in definition 3 for $n \geq 6$, one sprinkler can water no more than only ν-proportion of the patch, where $\nu \lesssim \frac{1}{\lfloor n/3 \rfloor}$, as proved in theorem 4. As a footnote, the solution is non-constructive, given the garden patch follows a simple n-sided polygon’s shape. So, a sprinkler of the properties mentioned above exists in the polygon or on its boundary. However, the introduced solution does not offer a way to find the exact position of the sprinkler in the polygon or on its boundary, satisfying the demanded properties. Searching for such a sprinkler position could be of high computational complexity. □

V. Conclusion remarks

Having an n-sided polygon without holes and edge intersections for $n \geq 3$, there is always a point inside the polygon or on its boundary that ensures a proportion of the visibility polygon’s surface for the point to the entire polygon’s surface is at least $\frac{1}{\lfloor n/3 \rfloor}$, as derived using the art gallery problem. Also, there are n-sided polygons, e.g., the saw-like ones for $n \geq 6$, so that for any point in the polygon or on its boundary is the proportion of the visibility polygon’s surface for such a point to the entire polygon’s surface not greater than $\frac{1}{\lfloor n/3 \rfloor}$. Thus, the lower bound of the proportion of the visibility polygon’s surface to the entire polygon’s surface, $\frac{1}{\lfloor n/3 \rfloor}$, cannot be generally improved.

***Abstract*—Many cities around the world are aspiring to become *smart*. However, smart initiatives often give little weight to the opinions of average citizens.**

Social media are one of the most important sources of citizen opinions. This paper presents a prototype of a framework for processing social media posts with municipal decision-making in mind. The framework consists of a sequence of three steps: (1) determining the sentiment polarity of each social media post (2) identifying prevalent topics and mapping these topics to individual posts, and (3) aggregating these two pieces of information into a fuzzy number representing the overall sentiment expressed towards each topic. Optionally, the fuzzy number can be reduced into a tuple of two real numbers indicating the "amount" of positive and negative opinion expressed towards each topic.

The framework is demonstrated on tweets published from Ostrava, Czechia over a period of about two months. This application illustrates how fuzzy numbers represent sentiment in a richer way and capture the diversity of opinions expressed on social media.

I. Introduction

MANY CITIES around the world are aspiring to become *smart*. A *Smart City* is characterized by an extensive use of information technologies to support municipal decision-makers in effective resource utilization [17]. This ICT support can be applied in many areas, including traffic and transportation, waste management, accommodation or culture.

Ideally, municipal planning involves multiple stakeholder groups: local authorities, businesses, average citizens and commuters, or environmental activists. In practice, however, decisions are mostly based on an interplay between authorities and businesses offering Smart City technologies. Opinions of average citizens are often given little weight [9, 18].

Some cities use surveys to gather opinions on at least some issues and projects. Although useful, surveys have many disadvantages. Most importantly, by asking only a predetermined set of questions and letting the respondent choose only from a low number of possible answers they limit the respondent's ability to fully express their thoughts and opinions. This prevents decision makers from serendipitously discovering unexpected issues and ideas.

Social media represent an alternative source of citizen opinions. They offer much greater freedom of expression as users can create new content whenever they want and instead of being limited by a set of questions, they can use free-form text, images, videos or audio. This freedom together with significant content creation velocity might also be a disadvantage. Relatively simple statistical methods for processing survey data are inadequate for social media. Instead, advanced techniques from fields such as machine learning, computer vision, or natural language processing have to be used.

This paper presents a prototype of a framework for extracting information from social media with the aim to support municipal decision-making. The framework combines topic modeling techniques with sentiment analysis. First, the system detects topics discussed on social media at a specific location. Then it evaluates sentiment towards each topic. To capture uncertainty arising from different people having different opinions on the same topic, this sentiment is modelled as a triangular fuzzy number (TFN). The TFN representation, however, might not be understood by people without background knowledge. Therefore a calculation of a "degree of conformity" with fuzzy sets representing the concepts of positive and negative opinion follows. The result can be interpreted as an "amount" of positive/negative opinion expressed towards a specific topic.

The remainder of the paper is organized as follows: In section II I review literature related to topic modeling, sentiment analysis and their applications in the context of Smart Cities. Section III discusses the framework design. Section IV then describes data used in experiments and preprocessing procedures. Demonstration of the framework application on test data can be found in section V. Finally, section VI discusses the limitations of the framework and future research.

II. Literature review

A. Topic Modeling

Topic modeling can be understood as (1) a "statistical technique for revealing the underlying semantic structure in a large collection of documents", or (2) "a technique comes with group of algorithms that reveal, discover and annotate thematic structure in collection of documents" [12].

In practice, topic modeling involves taking a corpora of text documents and discovering various topics discussed in these documents. Topics are usually represented by a set of most relevant terms [4]. Once topics are identified, a mapping between topics and individual documents can be created. Depending on the method used, one document can be assigned to one or multiple topics.

There is a plethora of topic modeling methods. In [12], the authors distinguish between two categories: (1) algebraic methods, usually based on some form of word-document matrix factorization and (2) statistical methods. On the other hand, [4] provides a chronological overview of the development of topic modeling methods. Other reviews, e.g., [16] then focus on selecting the best method for a given dataset or application.

One of the most popular topic modeling methods is Latent Dirichlet Allocation (LDA). This method is based on the idea that documents in a given corpora are generated by a probabilistic process. Each document can be understood as a mixture of topics, with each topic representing a probability distribution over words from some vocabulary [3]. However, the framework presented in this paper relies on a more recent method called BERTopic [8]. It outperforms LDA on multiple benchmark datasets both in coherence and topic diversity – two common topic modeling evaluation metrics [4].

B. Sentiment analysis

Sentiment analysis is "an approach that uses Natural Language Processing (NLP) to extract, convert and interpret opinion from a text and classify them into positive, negative or natural sentiment" [7]. There are two main groups of sentiment analysis methods (1) lexicon-based and (2) methods based on supervised learning models.

Lexicon-based methods use sentiment lexicons containing information about sentiment polarity of different words. Individual word polarities in a given document are looked up and then aggregated into an overall document polarity.

Methods based on supervised learning models rely on various machine learning techniques to train a classification model for predicting document sentiment. Naive Bayes is one of the most popular approaches in this category. Supervised methods require a training dataset that contains a ground truth sentiment for each document. Many product and service review websites let their users combine textual reviews with some sort of a numerical rating scale, e.g., a 5-star rating system. This data can be easily used to train a sentiment classifier.

One of the contributions of this paper lies in the application of fuzzy modelling methods in sentiment analysis. Several researchers have already explored this path. In [11] authors describe a fuzzy expert system for sentiment analysis. There have also been attempts at designing a sentiment analysis method that utilizes a fuzzy thesaurus [10]. However, to our best knowledge, fuzzy methods have not been used to aggregate sentiment expressed towards multiple documents.

There have been multiple applications of sentiment analysis in the context of Smart Cities and urban planning [5, 14]. There are many opportunities and challenges related to the use of sentiment analysis in urban planning, including visualization, multilingual audiovisual opinion mining, or peer-to-peer opinion mining tools for citizens [2].

III. Framework Design

A. Topic Modeling

As mentioned, the framework prototype uses a topic modeling method called BERTopic. Originally proposed in [8], BERTopic solves the problem of topic modeling by combining word embeddings with hierarchical clustering. The procedure consists of the following steps:

1) **Create an embedding for each document**. One of the downsides of traditional methods such as LDA is that they represent documents in an bag-of-words fashion. This representation ignores both order of words in a document and their semantic relationships. BERTopic relies on an embedding representation. Embeddings are vectors that are able to somewhat capture the semantics of words or documents. Documents with similar meaning should be represented by similar vectors. As the name suggests, BERTopic uses embeddings based on BERT [6].
2) **Reduce embedding dimensionality**. Embeddings can have hundreds or even thousands of dimensions. When it comes to clustering, high dimensionality causes multiple issues. [8]. First, the difference between the distance of the nearest point to a cluster centre and the distance between the furthest point from a cluster centre shrinks [1]. Second, lower number of dimensions leads to better performance both in terms of time and clustering accuracy. BERTopic therefore uses UMAP [15] to reduce the number of dimensions.
3) **Use a clustering algorithm to create document clusters**. BERTopic uses HDBSCAN with document embeddings reduced by UMAP as input. HDBSCAN is a hierarchical algorithm able to create a tree of cluster-subcluster structures. BERTopic user can set the number of clusters/topics to be generated by the algorithm. To provide the desired number of clusters, small similar topics are merged together.
4) **Create topic representations**. Similarly to other topic modeling methods, BERTopic represents each topic as a list of words. To find words best describing a given topic BERTopic uses a modified TF-IDF score [8] calculated as:
$$W_{t,c} = tf_{t,c} \ \log(1 + \frac{A}{tf_t}) \tag{1}$$
where $tf_{t,c}$ represents the frequency of term t in cluster c. A is the average number of words per cluster and tf_t is the total frequency of term t across all clusters.

B. Sentiment Analysis

The TextBlob[1] Python library was selected for the framework prototype. This choice was made mainly for pragmatic

[1] https://github.com/sloria/TextBlob

reasons - ease of installation, use and integration with other parts of the framework.

TextBlob offers two sentiment analysis methods: a lexicon and pattern-based one and a pretrained Naive Bayes model. In the former, TextBlob uses a polarity lexicon and structural patterns to determine both the degree of polarity and the degree of subjectivity. The Naive Bayes model was trained to classify movie reviews as positive or negative. Instead of providing degrees of polarity and subjectivity as output, this method returns the probabilities of a given text being positive and negative. Being the default, the lexicon and pattern-based method was also used in presented experiments. The output of this model carries a certain degree of uncertainty which can be exploited when aggregating sentiment analysis results with fuzzy methods.

C. *Fuzzy Aggregation*

Once sentiment polarity and topics are extracted from a set of social media posts, both pieces of information are combined to provide an overall view of what is being discussed in a given municipality and whether the population perceives a given topic positively or negatively.

Simple aggregation metrics such as arithmetic mean would lead to a loss of information. For example, there might be a controversial topic with many positive, but also some negative opinions. Arithmetic mean might present the topic sentiment as slightly positive. When presented with this information, the user cannot tell whether the aggregated opinion is slightly positive because a majority of individual opinions is slightly positive or because there are many positive opinions counterbalanced by a small number of negative opinions.

To address this issue, topic sentiment is modeled as a triangular fuzzy number (TFN). Assuming we know both the sentiment polarity of each social media post, and their topic distribution, the TFN core can be determined as a weighted mean with topic distribution percentages serving as weights. For instance, consider 3 topics with polarities and topic distributions depicted in table I. The core of the TFN representing the sentiment towards topic 1 can be calculated as:

$$m_{t1} = \frac{0.5 \cdot 0.5 + 0.35 \cdot 0.3 - 0.2 \cdot 0.2}{0.5 + 0.3 + 0.2} = 0.315 \tag{2}$$

Weighted standard deviation is then used to determine the TFN support interval. As in the case of determining the TFN core, the degree to which a given post belongs to a given topic should determine the strength of its influence on the shape of the support interval. Therefore a weighted variant of standard deviation is used, the general formula of which being:

$$\sigma = \sqrt{\frac{\sum_{i=1}^{N} w_i (x_i - x^*)^2}{\frac{M-1}{M} \sum_{i=1}^{N} w_i}} \tag{3}$$

with N representing the total sample size, x^* representing weighted mean, and M the number of non-zero weights.

Once the weighed standard deviation is known, the TFN support interval is calculated as:

$$[m_{t1} - s\sigma; m_{t1} + s\sigma] \tag{4}$$

where s is a positive real number that determines the scaling between the length of the support interval and weighted standard deviation. Its influence on the aggregation result is a subject of further research.

TABLE I
EXAMPLE OF AN INPUT FOR THE AGGREGATION PROCEDURE

	Polarity	**Topic distribution**		
		Topic 1	**Topic 2**	**Topic 3**
Post 1	0.5	0.5	0.3	0.2
Post 2	0.35	0.3	0.4	0.3
Post 3	-0.2	0.2	0.2	0.6

Taking inspiration from [19], the next step of the aggregation procedure is the calculation of a degree of conformity between the TFN describing topic sentiment and fuzzy sets representing the concepts of a positive and negative opinion. The result of this step is a tuple of two numbers from interval $[0; 1]$ that could be interpreted as the overall "amount" of positive and negative opinion expressed towards a given topic. Although there is some loss of information when compared to the original TFN, the two numbers are more likely to be understood by a layperson with no knowledge of fuzzy set theory.

The fuzzy metric of possibility [13] is used to calculate the degree of conformity, e.g.:

$$Pos(\tilde{A}, \tilde{PO}) = \sup_{x \in X} \min\left(\mu_{\tilde{A}}(x), \mu_{\tilde{PO}}(x)\right) \tag{5}$$

A denotes aggregated topic sentiment with $\mu_{\tilde{A}}(x)$ being its membership function. Similarly PO represents the concept of a positive opinion with a membership function $\mu_{\tilde{PO}}(x)$.

IV. DATA AND PREPROCESSING

Social media posts published on Twitter were used to demonstrate the proposed framework. This social network was chosen specifically because it lets researchers easily access its data through an API. Using this API, a dataset of approximately 3000 tweets published by users located in Ostrava, Czechia was created. These tweets cover the period of January and February of 2023.

Given the location, most tweets in the dataset are written in Czech. There are, however, several tweets written in other languages, such as English, Slovak or Polish. To address the issue of multilingualism, as well as the fact that TextBlob uses an English lexicon when analyzing sentiment, the DeepL Translator[2] API was used to automatically translate each post to English.

Several preprocessing steps were then applied on translated tweets:

[2] https://www.deepl.com/translator

- removal of tweets that are shorter than 60 characters under the assumption that it might be difficult to reliably extract sentiment and topics from short tweets,
- removal of non-letter characters,
- removal of hashtags, usernames and URLs,
- turning all text into lowercase,
- removal of stop words.

V. Framework Demonstration

The framework prototype was implemented as a Jupyter notebook. To summarize, after the input data was preprocessed, the following sequence of steps was applied:

1) TextBlob was used to determine the sentiment polarity of each post. Polarity of each post is represented as a real number from a $[-1, 1]$ interval with -1 representing absolutely negative polarity and positive number representing absolutely positive polarity.
2) BERTopic was used to identify topics and create a mapping between topics and individual tweets. Provided output follows the format in table I.
3) A set of TFNs representing aggregated topic sentiment was constructed. The scaling constant s in equation 4 was set to 1.
4) Degrees of conformity between each topic's TFN and the concepts "positive opinion" and "negative opinion" were determined.

Overall, BERTopic identified 42 different topics. Topics with the highest overall "mass" calculated as the sum of the topic's probability across all tweets are listed in table II.

Presented topic distribution intuitively makes sense. During given time period, one of the most dominant topics in public discourse was the upcoming presidential election which corresponds to the first topic in table II. One can also see that not all topics are necessarily relevant to municipal decision making, for example topic no. 3 in the table. At the same time, topics such as no. 9 are difficult to interpret.

TFNs representing the several aggregated topic sentiments are depicted in figure V. It can be deduced that the topic *vote, election, politics, party* is perceived quite positively and compared to topic *pay, wage, pension, live* it also has a narrower support. This indicates a lower level of opinion diversity. The latter topic is also perceived most negatively, at least among the topics displayed in the figure.

Table II also contains information about the conformity with the concepts of positive and negative opinion. The membership function of the fuzzy set representing positive opinion has a value of 0 until polarity value 0, then grows linearly to 1 until polarity reaches 0.2 and then has a value of 1. The "negative opinion" fuzzy set is its mirror image.

It can be seen that the information provided by these numbers tells a story similar to the TFN visualization. For example, when comparing topics *school, education, teacher, class* and *area, city, building, ostrava*, one could conclude that the former is not only perceived more positively, but that it is also less controversial given the lower "amount" of negative opinion.

VI. Discussion

As demonstrated, the framework prototype can be used to create a representation of opinions expressed towards different topics on social media posted by citizens of a specific municipality. The prototype, however, employs certain simplifications that should be addressed in future research.

The TFNs representing topic sentiments are currently symmetric. This is might not be the best reflection of reality. Ways of making the TFNs asymmetric should be explored. Metrics such as weighted skewness or semivariance could be used. Next, Twitter users have an option to "like" or "retweet" a post created by someone else. These actions can represent approval and could be therefore used as aggregation weights. Finally, other topic-modeling and sentiment-analysis methods should be tested and compared to the existing TextBlob+BERTopic stack. Moreover, TextBlob provides additional information beyond sentiment polarity: the subjectivity degree of each document. This metric could again be used as weight.

Framework output can be used directly by municipal decision makers to make more informed decisions. However, there are other possible applications. One of them is comparison of different municipalities. It should be possible to compare the TFNs of a specific topic across multiple cities. If additional information such as municipal budgets is available, one could also deploy methods such as Data Envelopment Analysis to evaluate their efficiency. Topic sentiments could be also aggregated into an overall sentiment expressed towards everything happening in a given municipality.

However, using the proposed framework as a replacement for other methods of gathering citizen opinion might not be the best course of action. Instead, the framework should play a complementary role, as social media users might not accurately represent the overall population. Groups such as the elderly might be underrepresented. At the same time, methods such as surveys can provide biased information too. Combining the proposed framework with surveys might lead to a better overall representation of citizen opinion than either of these methods separately.

VII. Acknowledgment

This paper was supported by the SGS project No. SP2023/078. This support is gratefully acknowledged.

PolEval

POLEVAL is an annual NLP challenge organized since 2017. The choice of the name of the challenge was deliberate: as most research concentrates on the most popular languages (especially English), the aim of PolEval was to promote work on processing Polish. By focusing on Polish, it actively promotes the creation of new resources in this language, facilitates further research and contributes to creating new and improved methods and models for Polish.

The goal of PolEval is thus to:

- develop established procedures for evaluating systems solving a wide range of tasks in NLP,
- create annotated datasets that can be used for training and evaluation of systems,
- objectively compare systems performing various tasks in the field of natural language processing,
- bring researchers from the scientific and business communities closer together and exchanging knowledge between them,
- facilitate popularization of NLP issues in the context of the Polish language.

To achieve these goals, PolEval proposes a well-formulated task framework, in which the scope, input data, expected output data, evaluation methods, training and test data are prepared by the organizers. This way the challenge aims to be a platform for objective comparison of methods, models and systems for processing Polish.

***Abstract*—This paper summarizes the 2022/2023 edition of PolEval — an evaluation campaign for natural language processing tools for Polish. We describe the tasks organized in this edition, which are: Punctuation prediction from conversational language, Abbreviation disambiguation and Passage Retrieval. We also discuss the datasets prepared for each of the tasks, evaluation metrics chosen to rank the submissions and also sum up the approaches chosen by the participants to tackle the tasks.**

I. Introduction

POLEVAL[1] [14] is a SemEval-inspired evaluation campaign for natural language processing tools for Polish. Submitted tools compete against one another within certain tasks selected by organizers, using available data and are evaluated according to pre-established procedures.

The 2022/2023 edition of Poleval was the sixth event in a series of challenges organized since 2017. During this edition three tasks have been proposed:

1) Punctuation prediction from conversational language,
2) Abbreviation disambiguation,
3) Passage Retrieval.

The participants of this edition have been very active, as we have received more than 400 submissions from 23 teams. The submissions were made through our evaluation platform[2], which has been introduced last year.

In the following part of the paper we describe each of the tasks in detail, present the datasets created for the particular challenges, discuss the evaluation metrics and we give the overview of submissions made by the participants.

II. Task 1: Punctuation Prediction from Conversational Language

A. Problem statement

Speech transcripts generated by Automatic Speech Recognition (ASR) systems typically do not contain any punctuation or capitalization. In longer stretches of automatically recognized speech, lack of punctuation affects the general clarity of the output text [24]. The primary purpose of punctuation restoration (PR), punctuation prediction (PP), and capitalization restoration (CR) as a distinct natural language processing (NLP) task is to improve the legibility of ASR-generated text and possibly other types of texts without punctuation. For the purposes of this task, we define PR as restoration of originally available punctuation from read speech transcripts (which was the goal of a separate task in the PolEval 2021 competition) [10] and PP as prediction of possible punctuation in transcripts of spoken/ conversational language. Aside from their intrinsic value, PR, PP, and CR may improve the performance of other NLP aspects such as Named Entity Recognition (NER), part-of-speech (POS), and semantic parsing or spoken dialog segmentation [5], [12].

One of the challenges of developing PP models for conversational language is the availability of consistently annotated datasets. The very nature of naturally-occurring spoken language makes it difficult to identify exact phrase and sentence boundaries [21], [23], which means that dedicated guidelines are required to train and evaluate punctuation models.

The goal of the present task is to provide a solution for predicting punctuation in the test set collated for this task.

[1] http://poleval.pl
[2] https://beta.poleval.pl

B. Task description

The workflow of this task is illustrated in Figure 1 below. Given raw ASR output, the task is to predict punctuation in annotated ASR transcripts of conversational speech.

C. Dataset

The test set consisted of time-aligned ASR dialogue transcriptions from three sources:

1) CBIZ, a subset of DiaBiz [17], a corpus of phone-based customer support line dialogs[3]
2) VC, a subset of transcribed video-communicator recordings, which are included in the SpokesBiz Corpus[4]
3) SPOKES, a subset of the SpokesMix corpus [16].

Table I below summarizes the size of the three subsets in terms of dialogs, words and duration of recordings.

TABLE I
OVERALL STATISTICS OF THE CORPUS

Subset	Corpus and license	Files	Words	Audio (s)	Speakers
CBIZ	DiaBiz (CC-BY-SA-NC-ND)	69	36 250	16 916	14
VC	Video conversations (CC-BY-NC)	8	44 656	17 123	20
Spokes	Casual conversations (CC-BY-NC)	13	42 730	20 583	19

The full dataset has been split into three subsets as summarized in Table II below.

TABLE II
TRAINING / DEVELOPMENT / TEST SET STATISTICS

Set	Files	Words	Audio (s)	License
Train	69	98 095	44 030	CC-BY-SA-NC-ND
Dev	11	12 563	4 718	CC-BY-NC
Test	10	12 978	5 874	CC-BY-NC

The punctuation annotation guidelines were developed in the CLARIN-BIZ project by Karasińska et al. [20].

Participants are encouraged to use both text-based and speech-derived features to identify punctuation symbols (e.g. multimodal framework [22] or to predict casing along with punctuation [15]. We allow using the punctuation dataset available at http://2021.poleval.pl/tasks/task1 [10].

The punctuation marks evaluated as part of the task are listed in Table III below. Blanks are marked as spaces. The distribution of explicit punctuation symbols in the training and development portion of the dataset provided is shown in Tables III–VI.

1) Data format: We provide two types of data: text and audio data. Text data is provided in the TSV format. For Audio data we provide audio files encoded in WAV and transcripts with force-aligned timestamps. The audio files can be downloaded separately from the website of PolEval.

Task 1. Model for punctuation prediction from conversations

Fig. 1. Overview of the punctuation prediction task

D. Evaluation

a) Submission format: Results were to be submitted as plain text file, where each line corresponds to a single segment. The text should include the predicted punctuation marks.

1) Metrics: The final results were evaluated in terms of precision, recall, and F1 scores for predicting each punctuation mark separately. Submissions were compared with respect to the weighted average of F1 scores for each punctuation sign. The method of evaluation was similar to the one used in a PolEval 2021 task named "Punctuation restoration from read text"[5] [10].

2) Per-document score::

$$Precision = \frac{TP}{TP + FP} \tag{1}$$

$$Recall = \frac{TP}{TP + FN} \tag{2}$$

$$F_1 = \frac{2 \cdot Precision \cdot Recall}{Precision + Recall} \tag{3}$$

3) Global score per punctuation sign p::

$$P_p = avg_{micro}Precision(p) = \frac{\sum_{d \in Documents} TP}{\sum_{d \in Documents} TP + FP}$$

$$R_p = avg_{micro}Recall(p) = \frac{\sum_{d \in Documents} TP}{\sum_{d \in Documents} TP + FN}$$

The final scoring metric was calculated as the weighted average of global scores:

$$\frac{1}{N} \sum_{p \in Punctuation} support(p) * avg_{micro}F_1(p)$$

TABLE VII
SUBMISSIONS TO THE PUNCTUATION PREDICTION TASK

Submission	Weighted-F1 score	
	Test-A	Test-B
Oskar Bujacz	79.24	**83.30**
Michał Pogoda	80.47	**82.33**
Jakub Pokrywka	67.30	**71.44**
Filip Graliński	30.88	**35.30**

[5] http://2021.poleval.pl/tasks/task1

E. Results

The winning solution submitted for Task 1 by Oskar Bujacz achieved a weighted F-measure of 83.3 (see Table VII). The author used a token classifier based on the largest variant of the HerBERT model[11] with customized output postprocessing rules.

III. Task 2: Abbreviation disambiguation

A. Problem statement

Abbreviations are often overlooked in many NLP pipelines. However, they are still an important point to tackle, especially in such applications as machine translation, named entity recognition, or text-to-speech systems.

There are at least two practical challenges in processing abbreviations. The first is the ability to find the full, expanded dictionary form of an abbreviation. In many cases, this may be done by a simple dictionary lookup, but: - the use of abbreviations is often unconventional and there is no complete list of all possible abbreviation uses, - many of the abbreviations are ambiguous. That is, the same abbreviation may have more than one meaning, translating to possibly different expanded forms.

As in many other NLP tasks, the disambiguation of abbreviations needs to include context and additional language knowledge to be feasible.

The second challenge, which is specific to languages with rich morphology, such as Polish, is the necessity to produce the expanded form of an abbreviation in correct grammatical form, in concordance with the rest of the sentence.

B. Task description

The task aimed to propose a method of disambiguating Polish abbreviations. The method should recognize if a given phrase is an abbreviation and, if so, produce its expanded form, both base, and inflected ones.

C. Dataset

1) Training data: In this task a (relatively small) training dataset was provided (see example in Figure 2), which included:

- the abbreviation
- an expanded form of the abbreviation
- a base form of the abbreviation
- context of the abbreviation, with the `′ placeholder marking the place where the abbreviation appeared.

The participants were encouraged to collect and use additional training and dictionary data and to publish it after the competition.

2) Test data: The test data consists of only the abbreviation and the context. The system aims to provide the expanded and base forms of the abbreviation.

D. Evaluation

We will calculate two measures of accuracy for each provided submission:

- Af — the accuracy of provided expanded forms of abbreviations (case insensitive string match)
- Ab — the accuracy of provided base forms of abbreviations (case insensitive string match).

Based on these measures, the final score will be calculated using a weighted average:

$$Acc = 0.25 * Af + 0.75 * Ab \tag{4}$$

E. Results

We received five submissions (see Table VIII). The final ranking was calculated based on the weighted accuracy of the Test-B dataset. The scores ranged from 92.01 to 19.09. Krzysztof Wróbel obtained the highest score of 92.01.

TABLE VIII
SUBMISSIONS TO THE ABBREVIATION DISAMBIGUATION TASK

Submission	**Weighted**	**accuracy**
	Test-A	Test-B
Krzysztof Wróbel	92.76	**92.01**
Jakub Karbowski	91.75	**91.27**
Marek Kozlowski	89.00	**88.73**
Jakub Pokrywka	65.48	**66.25**
Rafał Prońko	n/a	**19.09**

Krzysztof Wróbel utilized an ensemble of three models, each based on the byt5-base model[6], trained on different seeds, and employing a majority voting. The training of these models incorporated both the train and dev datasets, as well as a small dataset automatically generated from abbreviations sourced from various dictionaries such as Morfeusz [9], sjp.pl, and Wiktionary [7].

Jakub Karbowski (2nd place submission) trained a sequence-to-sequence model based on the plt5-base model[8]. The input to the model consisted of a context with a masked abbreviation, a target base form, and inflected forms of the expanded abbreviation. The initial training was performed on a synthetic dataset generated from the Polish Wikipedia. The dataset was created by randomly selecting contexts of varying lengths and shortening consecutive words using one of several strategies, such as using the first few letters, the first and last letters, or the first, middle, and last letters. The base form was generated using Spacy[9]. Then, the model was fine-tuned on the PolEval dataset.

IV. Task 3: Passage retrieval

A. Problem statement

Passage Retrieval is a crucial part of modern open-domain question-answering systems that rely on precise and efficient

Fig. 2. Examples from the training dataset

retrieval components to find passages containing correct answers. Traditionally, lexical methods, such as TF-IDF or BM25 [18], have been used to power retrieval systems. They are fast, interpretable, and don't require training (and therefore a training set). However, they can only return a document if it contains a keyword present in a query. In addition, their understanding of text is limited because they ignore word order.

Recently, neural retrieval systems (e.g. Dense Passage Retrieval [8]) have surpassed these traditional methods by fine-tuning pre-trained language models on a large number of (query, document) pairs. They solve the aforementioned problems of lexical methods but at the cost of the need to label training sets and poor generalisation to other domains. As a result, in a zero-shot setup (i.e. no training set), lexical methods are still competitive or even better than neural models.

B. Task description

The aim of the *passage retrieval* task was to develop a system for cross-domain question-answering retrieval. For each test question, the system should retrieve an ordered list of the ten most relevant passages (i.e. containing the answer) from the given corpus. The system is evaluated on the basis of its performance on test examples from three different domains, namely trivia, law, and customer support.

C. Dataset

1) Training set: The training set consisted of 5,000 trivia questions from the PolQA dataset [19]. Each question was accompanied by up to five passages from Polish Wikipedia containing the answer to the question. In total, the training set consisted of 16,389 question-passage pairs. In addition, we provided a Wikipedia corpus of 7,097,322 passages. The raw Wikipedia dump was parsed with WIKIEXTRACTOR[10] and split into passages at the end of paragraphs or if the passage was longer than 500 characters.

2) Test sets: The systems were evaluated on three test sets with questions from different domains. The first dataset consisted of 1,291 trivia questions similar to those in the training set.

The second dataset consisted of 900 questions and 921 passages related to the large Polish e-commerce platform - Allegro[11]. The dataset was created based on help articles and lists of frequently asked questions available on the Allegro website. Each question-passage pair was manually checked and edited where necessary.

The third dataset contained over 700 legal questions. It was created by randomly selecting the passage and manually writing a question. We also provided a corpus of approximately 26,000 passages extracted from over a thousand acts of laws published between 1993 and 2004.

D. Evaluation

The submitted systems were evaluated using Normalised Discounted Cumulative Gain for the top 10 most relevant passages [7, NDCG@10], where the score of each relevant passage depends on its position in descending order:

$$\mathrm{DCG}_p = \sum_{i=1}^{p} \frac{rel_i}{\log_2(i+1)} \tag{5}$$

$$\mathrm{IDCG}_p = \sum_{i=1}^{|REL_p|} \frac{rel_i}{\log_2(i+1)} \tag{6}$$

$$\mathrm{NDCG}_p = \frac{\mathrm{DCG}_p}{\mathrm{IDCG}_p} \tag{7}$$

where rel_i is the relevance of the i-th passage and REL_p is the list of relevant passages ordered by their relevance.

E. Results

Seven teams submitted a final solution to the task (see Table IX). All systems followed a similar architecture. First, the retriever was used to find the top N most relevant passages, and then the ranker scored these passages in order of importance to select the final 10 most relevant passages. Below are brief descriptions of the submitted systems, starting with the highest scoring ones.

Jakub Pokrywka implemented a retriever using the BM25 algorithm with text stemming using Polimorf.[12] To improve

TABLE IX
COMPARISON OF PASSAGE RETRIEVAL TASK SUBMISSIONS

Submission	Retriever	Ranker	External Datasets	Model per domain	NDCG@10
Jakub Pokrywka	BM25	mt5-3B, mt5-13B, custom	No	Yes	69.36
Marek Kozlowski	Hybrid	mt5-13B	Yes	No	68.19
Konrad Wojtasik	Hybrid	mt5-13B, custom	Yes	No	67.44
Norbert Ropiak	Hybrid	MiniLM-L12, mDeBERTa	No	Yes	63.27
Anna Pacanowska	BM25	MiniLM-L6, custom	No	No	54.23
Maciej Kazuła	BM25	MiniLM-L6	Yes	No	51.78
Daniel Karaś	Hybrid	mBERT	No	No	51.71

the ranking of answers, separate rankers were used for each domain. For the Allegro and legal domains, an ensemble of mt5-3B[13] and mt5-13B[14] models was used, considering a pool of 1,500 candidates. Conversely, for trivia domain, Jakub Pokrywka also used the mt5-3B model but it was supplemented by a custom-trained cross-encoder models, mDeBERTa[15], and mmarco-mMiniLMv2-L12-H384-v1[16]. For trivia domain, the system included 3,000 candidate passages for effective ranking.

Marek Kozlowski used a system consisting of three retrievers: a lexical retriever (BM25) and two neural retrievers based on roberta-base[17] and roberta-large[18] [3]. The BM25 retriever used the ElasticSearch engine with the Morfologik analyser[19] for lemmatisation. For the neural encoders, fine-tuning the Roberta models involved using the MultipleNegativeRankingLoss loss function, large batch sizes and training data consisting of a mixture of Poleval training and translated MSMARCO [13] data sets. After retrieval, a re-ranking step was performed, with the mt5-13B model yielding the best results.

Konrad Wojtasik used an ensemble of several retrieval algorithms, starting with the BM25 algorithm, followed by various multilingual retrievers such as mContriever [6], mDPR [1] and LaBSE [4]. To further reduce the number of passages for reranking, he trained the plT5-large model [2] on the translated MSMARCO dataset. The final ranking was performed with mT5-13B on about 350 candidate passages from different sources.

Norbert Ropiak used both lexical (BM25) and neural retrievers (mContriever) and combined the results of both for further processing. He used ms-marco-MiniLM-L-12-v2[20] and mDeBERTa cross-encoders for ranking.

Anna Pacanowska's solution was a combination of several models. First, BM25 was used on lemmatised text to retrieve 1,000 candidate passages. Various statistics were calculated on these candidates, such as BM25 on unlemmatised data or on bigrams. The retrieved passages were then translated into English using OPUS-MT[21], which allowed the English MiniLM-L6 cross-encoder[22] to be used to calculate various scores, including those on raw question/passage pairs and on pairs with answers generated using GPT-3. Finally, logistic regression was used to combine all the results into a final score.

Maciej Kazuła used the BM25 passage retrieval algorithm together with the word inflection dictionary[23] to normalise the text. He fine-tuned the MiniLM-L6 cross-encoder for the ranking process. The cross-encoder was trained on the translated MSMARCO Polish dataset. A new tokeniser was created on the Poleval dataset, as well as on the translated MSMARCO data, in order to better represent Polish words in terms of word forms.

Daniel Karaś used two retrievers, a lexical search using BM25 and neural search using a slightly fine-tuned MiniLM-v6[24] model. Both retrievers were used to find approximately 1,000 candidates per question, except for Allegro where all passages were selected. In a second step, all candidate passages were fed into the mBERT[25], which was used without any additional training.

F. Summary

All submitted systems used the BM25 algorithm as a retriever, but differed in the way they normalised the text. Many lemmatised the passages, while others favoured stemming or using a dictionary of different word forms. In addition, some teams also used the neural retrievers and combined the candidates from these two approaches.

Given a pool of retrieved candidate passages, the systems used different methods to sort them and select the most relevant ones. The most popular were the cross-encoders, either trained on the multilingual data or fine-tuned by the contestants on the Polish examples. Most teams ensembled several models to achieve better performance.

[25] amberoad/bert-multilingual-passage-reranking-msmarcoreranker

Three teams used external datasets to train their models. In all cases, they automatically translated the MSMARCO dataset into Polish.

Although the goal of the task was to create a system for cross-domain passage retrieval, it was allowed to submit different systems for different domains. Three participants chose this approach, including the winning system.

Regarding the results, it is observed that the performance of the systems was very much dependent on the ranker. The first three systems that achieved the results in the range of 67-69 NDCG points used a very large mt5-13B model as the reranker. The fourth model which achieved 63 points, used MiniLM-L12 and mDeBERTa. The last three models scoring 51-54 points used only MiniLM-L6 or multilingual BERT (with the exception of Anna Pacanowska's system, which also utilized a custom model). It seems that the retriever did not play an important role in the task, since the best system used only BM25 model. It is also interesting to observe that none of the systems used a learning-to-rank approach. One of the deficiencies of the evaluation is the lack of consideration for the computational heaviness of the approaches, which might be considered in the future incarnations of this task.

V. Conclusions and Future Plans

As each year we observe a growing interest in the PolEval challenge (the number of submissions and participating teams is growing), we plan to continue our efforts to identify new tasks, which are current and interesting in the research area of NLP and Polish language. The next editions will be specifically interesting, considering the current developments in the area of generative AI and language models.

We also plan to organize the datasets created for all the editions of the challenge in a repository to facilitate their distribution and encourage other researchers to use them for their work.

Punctuation Prediction for Polish Texts using Transformers

Jakub Pokrywka
Adam Mickiewicz University
Faculty of Mathematics and Computer Science,
Email: jakub.pokrywka@amu.edu.pl

***Abstract*—Speech recognition systems typically output text lacking punctuation. However, punctuation is crucial for written text comprehension. To tackle this problem, Punctuation Prediction models are developed. This paper describes a solution for Poleval 2022 Task 1: Punctuation Prediction for Polish Texts, which scores 71.44 Weighted F1. The method utilizes a single HerBERT model finetuned to the competition data and an external dataset.**

I. Introduction

AUTOMATIC Speech Recognition (ASR) systems produce speech transcripts, which typically do not contain punctuation. This may negatively impact the overall clarity of the transcribed text. For several reasons, punctuation is important:

- Punctuation reduces ambiguity in communication. The Sentences "Let's eat, children" and "Let's eat children" have completely different meanings, but they only vary in a comma.
- Punctuation helps in clarifying the intended meaning of a text. It provides cues to understand the structure of the text. Punctuation marks like commas, periods, question marks, and exclamation marks indicate pauses, sentence endings, and changes in tone or intent.
- Punctuation conveys tone and emotion behind the text. E.g., an exclamation mark may indicate excitement and a question mark may denote uncertainty.
- Punctuation enhances the readability of the written words. Breaking down complex sentences into smaller parts with the use of commas, colons, and semicolons creates pauses, which aids in understanding the text

Many post-processing steps may be taken to circumvent this problem and the lack of capitalization problem. Such tasks are:

- Punctuation Restoration (PR)
- Punctuation Prediction (PP)
- Capitalization Restoration (CR)

The task of Punctuation Restoration is defined as the act of reinstating the original punctuation found in read speech transcripts.

This work describes the solution to Poleval 2022 Task 1: Punctuation Prediction from conversational language. The solution is based on the HerBERT model [1] fine-tuned to the competition data and an external dataset.

II. Related Work

In the previous PolEval edition, a task similar to Punctuation Prediction was assigned, precisely PolEval 2021 Task: Punctuation restoration from read text [2]. The challenge unveiled WikiPunct, a fresh collection of text and audio corpus comprising 39 hours of audio and approximately 38,000 text transcripts. Four submissions [3], [4], [5], [6] applied transformer-based methods for token classification, from which two authors utilized ensembles. Additionally, one author explored the integration of a bi-LSTM layer at the top of the transformer, along with vectors acquired from a wave2vec model.

When it comes down to other languages, authors of [7] developed a method on Support Vector Machines with Conditional Random Field (CRF) classifiers, using part-of-speech (POS) and morphological data for Arabic texts. Authors of [8] used Deep Neural Networks and Convolutional Neural Networks for English texts and authors of [9] used transformers for English medical texts.

Recently, The Sentence End and Punctuation Prediction for many languages shared task was launched [10]. All of the teams explored neural network models, particularly transformers. The winning team described their solution in [11].

III. Competition Description

The three datasets are provided for in the competition: train, dev, and test. For each dataset, input audio WAV files with text transcribed by an ASR system are delivered. The input text is segmented, where a single space separates each word. Each word is prepended by a word start timestamp and word end timestamp in milliseconds.

The missing punctuation symbols are as in table I.

TABLE I
Punctuation symbols in the challenge.

symbol description	symbol character
Fullstop	.
Comma	,
Question Mark	?
Exclamation Mark	!
Hyphen	-
Ellipsis	. . .

The competition dataset is based on three resources summarized in Table II.

IEEE Catalog Number: CFP2385N-ART ©2023, PTI

Thematic track: Challenges for Natural Language Processing

TABLE II
THE FULL COMPETITION DATASET (TRAIN, DEV, TEST) STATISTICS.

Subset	Corpus	Files	Words	Audio [s]	Speakers	License
CBIZ [12]	DiaBiz	69	36 250	16 916	14	CC-BY-SA-NC-ND
VC	Video conversations	8	44 656	17 123	20	CC-BY-NC
Spokes [13]	Casual conversations	13	42 730	20 583	19	CC-BY-NC

The dataset is split into three subsets as described in Table III.

TABLE III
COMPETITION DATASET STATISTICS SPLIT INTO TRAIN, DEV, TEST.

Dataset	Files	Words	Audio [s]	License
Train	69	98 095	44 030	CC-BY-SA-NC-ND
Dev	11	12 563	4 718	CC-BY-NC
Test	10	12 978	5 874	CC-BY-NC

The annotation scheme is not publicly available during the competition and will described in [14].

There is one sample data from the training dataset in the subsection below.

A. Sample data

Input wav file : audio/AU1_P1_w_drodze_do_sklepu.wav

Input text : I:5880-5880 teraz:5940-6180 mamy:6330-6450 drugi:6480-6900 dzień:6960-7080 takiej:7170-7410 ładnej:7440-7650 pogody:7830-8400 Ała:8430-8430 Nie:8760-8820 bij:8850-8970 mnie:9120-9330 kijem:9450-9870 To:10020-10080 boli:10170-10260

Golden truth : I teraz mamy drugi dzień takiej ładnej pogody... Ała! Nie bij mnie kijem! To boli!

B. Utilized Data

In our final solution, we did not use any audio data. Additionally, we decided not to include start and stop timestamps as we did not observe any significant improvement in their score after conducting multiple experiments. Throughout the training process, we experimented with four different sources.

- Poleval 2022 Task 1: Punctuation Prediction from Conversational Language (this competition training dataset)
- Poleval 2021 Task 1: Punctuation Restoration from Read Text [2] (training dataset)
- Poleval 2021 Task 1: Punctuation Restoration from Read Text (test dataset)
- europarl-v7.pl-en.pl [15]

Regrettably, the europarl-v7.pl-en.pl dataset did not lead to a score improvement. Therefore, it was not utilized in our final solution.

We have carried out normalization procedures. Firstly, we transformed the text format from being split with timestamps to raw text format with timestamps included. Secondly, we replaced all three consecutive full stop characters "." (Unicode code: 81) with a single ellipsis character "…" (Unicode code: 8230). This modification was essential for utilizing the punctuation prediction library explained in Section IV.

Table IV presents the statistics for the training datasets used and competition final test data: test-B. Some punctuation marks are more popular than others, which is consequent in all the datasets. There are some differences between training and testing datasets, but they are insignificant. E.g., the Fullstop character is more common in the test-B dataset than in the train dataset (104.022 vs. 78.338). The same stays true for Comma (133.303 vs. 112.923). The PolEval 2022 dataset exhibits much more significant differences than the PolEval 2021 dataset. This is particularly evident in the Mean Words per Sample metric, as well as in most punctuation characters. While some characters like Fullstop, Comma, and Ellipsis are more prevalent in the PolEval 2022 dataset, Hyphen is less frequent, and the Exclamation mark remains relatively unchanged.

Below are samples of golden truths from each dataset, with the last two examples shortened.

1) Sample Poleval 2022 Task 1 test-B sentence: No dzień dobry pani. Tu mi się jakaś opłata za kartę pobrała.

2) Sample Poleval 2022 Task 1 train sentence: I teraz mamy drugi dzień takiej ładnej pogody… Ała! Nie bij mnie kijem! To boli!

3) Sample Poleval 2021 Task1 train sentence: w wywiadzie dla "polski" jarosław kaczyński podkreślił, że informacje dotyczące radosława sikorskiego zagrażają interesowi państwa. "to naprawdę wszystko, co mogę na ten temat powiedzieć "-odpowiedział, gdy dziennikarz pytał o bardziej szczegółowe informacje. premier kaczyński sugeruje, że dobry kandydat po na szefa dyplomacji to np. jacek saryusz- wolski wymieniony polityk zyskał uznanie braci kaczyńskich za dotychczasową działalność w charakterze dyplomaty i dużą wiedzę."

4) Sample Poleval 2021 Task1 test sentence: 801 co znaczy, że beginki "padły ofiarą reformacji"? grzesie2k wpis na słabym poziomie bzdurna informacja o 50 spalonych waldensach; po co w bibliografii pseudonaukowa książka magdaleny ogórek? fragment recenzji z księgarni gandalf: "magdalena ogórek do inkwizycji oraz kościoła ma stosunek jednoznaczny, pisząc o inkwizycyjnej pożodze oraz występkach heretyków spreparowanych przez inkwizytorów, którzy siali spustoszenie oraz o tym jak to w połowie xiii w? duchowni skupiali się na obsadzaniu stanowisk kościelnych, budowaniu zamętu przez interdykty, schizmy i walki, lekceważyli obowiązki duszpasterskie. nie ukrywa też, że jej celem jest próba rehabilitacji heretyków. takie jednoznacznie ideologiczne ustawienie problematyki nie ma wiele wspólnego z prawdą o epoce, obiektywizmem historycznym.

TABLE IV
Datatasets Statistics. The number of punctuation symbols is normalized per 1000 words.

Dataset	Samples	Mean Words per Sample	Fullstop	Comma	Question Mark	Exclamation Mark	Hyphen	Ellipsis
Poleval 2022 Task1 test-B	1642	7.90	104.022	133.303	18.493	0.848	0.154	33.981

C. Metric

The challenge metric is the Weighted F1 score. The evaluation script is implemented in the GEval evaluation tool [16]. The challenge was hosted on the gonito platform [17]. The final evaluation is done on the test-B dataset on all the domains. The metric definition is meticulously described in Poleval 2021 Task1 summary paper [2].

IV. Method

Our method was based on FullStop: Multilingual Deep Models for Punctuation Prediction [11] library. We slightly modified the library to work on a different set of punctuation marks than it was intended to. The final solution model was based on a single HerBERT [1], a neural model of transformer architecture [18] trained on a corpus of Polish texts. The model was finetuned to the data described in Section III-B with the aforementioned text preprocessing steps. We used scripts available at https://github.com/oliverguhr/fullstop-deep-punctuation-prediction/blob/main/other_languages/readme.md. The Polish RoBERTa [19] model was evaluated as well, but not used for the final solution due to worse results. Both evaluations are available in Tables V and VI. We also conducted experiments with XLM-RoBERTa [20], but unfortunately, we did not achieve better results again.

V. Results

The final model using achieved a third-place score of 71.44 in the competition's Weighted F1 category. While it falls behind the first-place score of 83.30 and the second-place score, it still surpasses the baseline score of 35.30. Frequent punctuation symbols like full stops and commas (occurring above ten times per 1000 words) consistently scored between 70 and 80 in F1. However, the F1 scores varied greatly for less frequent symbols, with scores of 16.67, 100.00, and 43.72.

The subsections below illustrate some correct and incorrect predictions from the test-B dataset.

A. Correct predictions

Predicted: Nie rozumiem powodu, dla którego komuś za ciężko jest rozbić jajko.

Predicted: A ty dasz radę zabrać to wszystko?

B. Incorrect predictions

Expected:Ona nie będzie już**,**

Predicted:Ona nie będzie już**...**

Expected:Stary d**-** delegacyjny sprzęt z czasów PRLu, ale może być przydatny.

Predicted:Stary d**,** delegacyjny sprzęt z czasów PRLu, ale może być przydatny.

Expected:Zamknęli nam łazienkę**...** dranie**...**

Predicted:Zamknęli nam łazienkę**,** dranie

VI. Conclusions

In this paper, we proposed our solution to Poleval 2022 Task 1: Punctuation Prediction for Polish Texts. The method uses a single HerBERT model fine-tuned to the competition training data and other external datasets. The achieved score is 71.44, which falls behind the two best solutions but is significantly better than a baseline.

Abstract—**The disambiguation of abbreviations and acronyms is a longstanding problem in Natural Language Processing (NLP) that has garnered significant attention from researchers. Previous approaches have employed statistical methods, semantic similarity metrics, and machine learning algorithms. Various languages and document types have been explored, with English being the most commonly studied language. Recent advances have been driven by the application of pre-trained transformer models. Standardization and addressing the challenges of multilingual and multi-document type disambiguation remain ongoing goals in the field of NLP. This paper presents an in-depth exploration of abbreviation disambiguation using state-of-the-art neural Encoder-Decoder models, specifically the ByT5 and plT5 architectures. Advanced synthetic data generation techniques are introduced and their effect on model performance is analysed. The methods are evaluated in the context of the PolEval abbreviation disambiguation competition, where the authors achieve top ranking.**

I. Introduction

THE problem of disambiguation of both acronyms and abbreviations has been the subject of interest for many researchers in the field of Natural Language Processing (NLP) for many years. Even before the era of widely used machine learning algorithms and text recognition using Deep Neural Networks (DNN), methods based solely on statistics were used. An example of such work is the paper [1] from 2004, which used a semantic similarity metric. The author determines the adequacy of abbreviation expansion candidates based on the similarity between the context of the target abbreviation and that of its expansion candidate.

The motivation for recognizing abbreviations often stemmed from the need to understand passages in documents such as provisions in law or medical notes. However, due to the richness, diversity, and uniqueness of languages, it is difficult to generalize the solution for expanding abbreviations or acronyms. Articles [2], [3] examine Jewish Law documents written in Hebrew, while [4], [5] present research on clinical papers using methods such as Support Vector Machines (SVM). Scientific papers are usually dedicated to only one language for which the datasets were prepared and the most widely used language in datasets is English. But another example of a different language is the research analysis [6] in Chinese, where the authors present their unconventional method based on Integer Linear Programming (ILP) and decode abbreviations from the generated candidates. Meanwhile, [7] analyze the Russian language by comparing methods such as SVM, Random Forest (RF), and Gradient Boosting (GB). Research has also been conducted in the Polish language, for example, in the paper [8], which utilized the bidirectional long short-term memory (LSTM) neural network architecture and compared two methods: automatically selecting all words in a text and using clustering of abbreviation occurrences.

Another aspect worth noting is the diversity of approaches to solving the disambiguation problem. As it turns out, supervised methods such as Convolutional Neural Networks (CNN), which are primarily used for image analysis, can also be used for this purpose in NLP, as evidenced by the article [9]. A diffrent example is the utilization and combination of pre-trained models such as RoBERTa and SciBERT, based on the transformer architecture, to create their own model named hdBERT, as presented in the research [10]. In this study, the authors also compared many state-of-the-art non-deep and deep learning methods up to 2017.

In 2020, the article [11] presented Google's T5 model as the Unified Text-to-Text Transformer. Since then, models with this architecture have found applications not only in text translation but also in expanding abbreviations, as shown in the publication [12]. In another article [13], expansions of acronyms were presented using pre-trained language models such as BERT and T5 for datasets consisting of four categories: Legal English, Scientific English, French, and Spanish.

The authors of the article [14] built their end-to-end acronym expander system named AcX and compared various existing methods such as Cosine Similarity (Cossim), RF, Logistic Regression (LR), and SVM. Based on this, they also prepared a benchmark on various types of datasets, including those from biomedical document, scientific papers and Wikipedia.

Based on the above considerations, research on abbreviation disambiguation over the years can be divided into three main categories:

- the type of documents from which the dataset was created, e.g. medicine, law, articles, or news
- the language in which the datasets were prepared

- the method used, which is almost always related to various machine learning algorithms

Former articles mainly focused on one type of document, one language, and one or two methods. However, today we increasingly encounter works related to multilingual models such as mT5 (multilingual T5), trained over 101 languages. However, these models undoubtedly require more memory (T5-base model - 220M parameters, mT5-base model - 580M parameters). The area of recognizing abbreviations is moving towards standardization and dealing with multiple languages and document types at once, but achieving satisfactory results in this area still poses a challenge for the field of NLP. Currently, promising models for this task appear to be encoder-decoder models like T5, pre-trained on a multi-task mixture of unsupervised and supervised tasks.

This article presents an attempt to standardize and formalize different aspects of abbreviation disambiguation, methods, challenges and limitations. State-of-the-art methods are evaluated on the PolEval 2022/23 competition, specifically in Task 2: Abbreviation disambiguation [1]. Additional dataset augmentation techniques are described, such as dictionary-lookup and algorithmic generation of arbitrary abbreviations. A unified training framework for abbreviation disambiguation is provided in a public online code repository. The additional created datasets are also provided. By combining the above methods, the authors achieve number one ranking on the PolEval contest.

II. Data

A. Training, validation and test datasets

The training, validation, and test datasets have been provided by the organizers of PolEval. As part of the PolEval competition, a training set called `train` and a validation set called `dev-0` with expected output were created, along with two test sets: `test-A` and `test-B` with implicit output. The collection and preparation of the datasets were carried out by:

- Michał Marcińczuk (Wrocław University of Science and Technology)
- Łukasz Kobyliński (Institute of Computer Science, Polish Academy of Sciences / Sages)

1) Assumptions: During the preparation, the authors of the reference corpus based their work on three assumptions:

- focus on abbreviations of common words or phrases ending with a dot (excluding initials, acronyms, and proper names)
- the context and common knowledge should be sufficient to expand the abbreviation (excluding incomplete or confusing examples)
- the base forms should follow the guidelines of phrase lemmatization from PolEval 2019 Task 2 [2] with some exceptions, such as abbreviations joined with other abbreviations or phrases

TABLE I
Examples of abbreviation disambiguation

Abbr	**Context**	**Inflected form**	**Base form**
t.	a na Dolnym Śląsku - 530-540 zł/**<mask>**	tonę	tona
gat.	czystą miedź (gat. M1) i mosiądz niklowy (**<mask>** M55N, CuZn35Ni6Mn4Si0,2)	gatunek	gatunek
j. ukr.	Kier. Natalia Szelest (nagroda burmistrza Węgorzewa) Wertep punktu naucz. **<mask>** w Baniach Mazurskich	języka ukraińskiego	język ukraiński
ład.	Żyjemy w okresie przejściowym, międzyepoce poprzedzającej nowy **<mask>**	ład.	ład.

Table I presents several examples of abbreviations disambiguation found in these datasets.

2) Input and expected output: In the system, the input data in the `in.tsv` file consists of two columns as we can see in Table II: the first column contains a phrase to be analyzed, and the second contains the context in which the phrase appears. If a masked token in an input is not an abbreviation then both columns in expected file are the same as masked token.

TABLE II
Input and expected output format

in.tsv		**expected.tsv**	
l.	ciągników serii 1523 i 1221 otrzymały sześciocylindrowe silniki o pojemności 7,2 **<mask>** Także te modele nie były wysilone mocowo i osiągały 158 KM w przypadku Belarusa	litra	litr

The occurrence of the phrase is marked by the keyword `<mask>`. The output file `expected.tsv` is also composed of two columns: the first column contains the inflected form, and the second contains the base form.

3) Data processing: The corpus was created based on the following four steps:

1. The datasets were built based on a collection of press news.
2. Regular expressions were used to collect potential abbreviations.
3. Each candidate was represented as a matched phrase and the context with several words before and after the match.
4. Candidates were selected and manually annotated.

4) Dataset cleanup: During the review, the authors removed any examples where the text was somehow corrupted, making it difficult to analyze.

1. Chi lij ski gi gant mie dzio wy (16,1 mld do **<mask>** war to ści) roz pro szył do brym zy skiem oba wy inwesto rów o je go wzrost mi mo

[1] http://poleval.pl/tasks/task2
[2] http://2019.poleval.pl/index.php/tasks/task2

2. l.,ulica,ulica,A) 9. U**l. Kościuszki** na odcinku od Lelewela do al. Krasińskiego 10. U****<mask>** Zwierzyniecka** od al. Krasińskiego do ul. Retoryka 11. Ul**. Bieżanowska** na

Above two examples of corrupted texts: the first with words divided into syllables, and the second with "**" characters within the abbreviation.

5) Challenges: The task poses several challenges that need to be addressed in order to solve it.

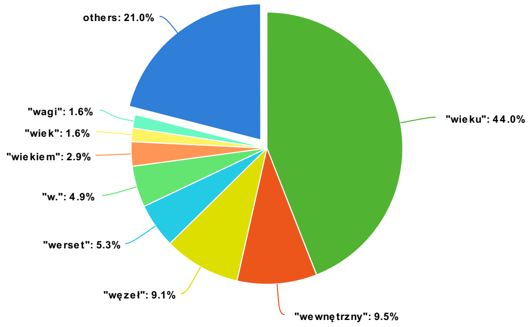
a) Challenge – ambiguous forms: When looking at one-word abbreviations, there is a large pool of words to which these abbreviations can be expanded.

TABLE III
AMBIGUOUS ONE-WORD ABBREVIATION FORMS EXPANDED TO THE LARGEST VARIETY OF WORDS (IN THE TRAIN SET)

Abbreviation	Base forms	Inflected forms
p.	38	57
w.	21	41
s.	20	36
m.	14	30

It can be observed in Table III that practically every word can be shortened to a single letter, and based on the context, one can infer the intended word. However, the challenge lies in correctly identifying this word.

Fig. 1. Distribution of abbreviation "w." extensions



The Figure 1 shows that there are multiple potential forms for each abbreviation, and the distribution is not such that one form constitutes 90% of expansions. What makes this task interesting is that there are many expansions for each abbreviation. In each case, there is a dominant word, for example, for the abbreviation `w.`, the most frequent expansion is `wieku` which accounts for 44.0% of expansions, while the remaining cases below 1.6% each sum up to 21.0%.

b) Challenge – unbounded space of abbreviations: The second element that affects the complexity of this task is the practically unbounded set of phrases that are subject to analysis. This task needs to be approached creatively because many cases not present in the training set may appear in the test set and should be handled correctly.

Based on Table IV, it can be assumed that about half of the phrases are non-abbreviated elements, while the other half are actual abbreviations that require expansion.

TABLE IV
THE NUMBER OF DISTINCT PHRASES AND ABBREVIATIONS TO BE EXPANDED

Set	Distinct phrases	Distinct abbreviations
train	∼ 1013	∼ 500
full	>1600	>900

c) Challenge – mixed abbreviations and non-abbreviations: Another challenge is distinguishing whether a given phrase is an abbreviation or not. There are also cases where a phrase can be both an abbreviation and a regular word that does not require expansion, which introduces an additional level of complexity to the task.

TABLE V
OCCURRENCES OF DIFFERENT ABBREVIATION FORMS

Set	Train set
Distinct phrases	∼ 1013
Non-abbreviations	∼ 480
Abbreviations	∼ 540
Both	26

Furthermore, certain phrases are a combination of abbreviations and non-abbreviations, marked as `others` in Table V, for example, replacing `mln. ton.` with `miliona ton.`

6) Special cases: There are several specific cases that have appeared to some extent in the corpus and go beyond the previous assumptions.

a) Special case – ambiguous forms: There are instances where certain abbreviations can be expanded into multiple words, as in the example presented in Table VI, where `m.` can be expanded into both `miejscowości` and `miasta`.

TABLE VI
AN EXAMPLE OF A CASE WITH A POSSIBLE DUAL OUTPUT

in.tsv	expected.tsv	
m. które przyszło na świat, gdy już był w więzieniu. Sam miał lat 40 i pochodził z **<mask>** Luboml pow. Kowel. Był urzędnikiem w składnicy Monop. Spirytusowego. (...) Nadmieniam,	miejscowości; miasta	miejscowość; miasto

Wherever this ambiguity can be resolved through context, such as certain signals indicating that it refers to one specific form, we expect only one form to appear in the output. However, in cases where there is no ambiguity, we assume that both forms should appear in the output, and they will be compared in this way.

b) Special case – non-abbreviation: In situations exposed in Table VII where a given phrase is not an abbreviation, we expect the output to repeat the phrase, which will be recognized as a non-abbreviation. Therefore, in this case the second part of answer is not a base form.

Both the base form and any inflected forms should be inflected in the same way as in the input, including the dot.

TABLE VII
AN EXAMPLE OF A CASE WITH A NON-ABBREVIATION

in.tsv		**expected.tsv**	
Goi.	Fascynowały ją obrazy **<mask>** Czytywała klasyków. Dowodzą tego jej, właśnie odnalezione, zapiski - pisze Bartosz	Goi.	Goi.

c) Special case – abbr and non-abbr: When there is a combination of an abbreviation and a non-abbreviated element, the abbreviated fragment should be expanded, while the non-abbreviated one should be preserved in the same form as in the input phrase.

TABLE VIII
AN EXAMPLE OF A CASE WITH A MIXED-ABBREVIATION

in.tsv		**expected.tsv**	
ws. T.	też: "Będziemy sprawdzać. czy nie fałszowano dowodów". Prokuratura bada śledztwo **<mask>** Komendy	w sprawie T.	w sprawie T.

In the example shown in Table VIII, these are initials, which we also do not want to expand.

d) Special case – lemmatization of joined abbreviations: In yet another case, there may be a combination of abbreviations that affects lemmatization. In the example below, two abbreviations appear consecutively, and each of these abbreviations should be expanded separately.

TABLE IX
AN EXAMPLE OF A CASE WITH A JOINED ABBREVIATIONS

in.tsv		**expected.tsv**	
mm. Temp. maks.	opady deszczu lub burze. Na zachodzie i południu prognozowana wysokość opadu do 25 **<mask>** od 19 do 23 st., nad morzem od 13 do 18 st. Wiatr północno-wschodni, slaby, na wybrzeżu	milimetrów Temperatura maksymalna	milimetrów temperatura maksymalna

In Table IX, the one-element abbreviation `mm.` is expanded to `millimeters` (it is an annotation error, it should be in singular: `millimeter`), and the two-element abbreviation `Temp. maks` is expanded to `Maximum temperature` which are then joined together.

B. Dictionary-based additional data

From dictionaries we extracted abbreviations with expanded forms, e.g. `bdb. -> bardzo dobry`. Then from Polish corpus CC100 [15] we extracted text fragments with inflected expanded forms of abbreviations and replaced them with abbreviations. An example is in Table X.

Only samples with unique inflected forms were taken into consideration giving 1982 new data points. The process creates also incorrect samples, e.g. `najlepszym` is abbreviated to `db..` This dataset lacks non-abbreviation examples.

TABLE X
DICTIONARY-BASED ADDITIONAL EXAMPLE

in.tsv		**expected.tsv**	
bdb.	pełno dyspozycyjny, zaangażowany, pracowity, komunikatywny, bardzo dobrze znam budowe komputera jak i **<mask>** obsługa komputera jak i programów biurowych Microsoft Office, Open Office itd. Prosze o kontakt	bardzo dobra	bardzo dobry

1) Morfeusz: Morfeusz [16] is a morphological analysis tool for the Polish language. With its help, all the abbreviations with their expanded form were filtered out from the dictionary. The pairs were selected on the basis of the morphosyntactic tags `brev:pun` or `brev:npun`. The `brev` feature indicates the base form of an abbreviation expansion, while `pun` and `npun` denote the presence or absence of a dot after the abbreviation.

TABLE XI
NUMBER OF ABBREVIATIONS FOUND IN THE MORFEUSZ DICTIONARY ACCORDING TO THE MORPHOSYNTACTIC TAGS

tag		
brev:pun	**brev:npun**	total
279	154	433

Table XI shows that there are more abbreviations without a dot at the end. Due to the problem posed in the task, `pun` abbreviations may be more useful since they can occur anywhere in a sentence, whereas `npun` abbreviations only appear at the end of a sentence, to be followed by a dot.

2) Wiktionary: Based on the free, multilingual dictionary Wiktionary [3], 554 different abbreviations were extracted with their meaning or meanings serving as an extension of the abbreviation. An example of multiple meanings in this dataset is, for example, `wyd.`, which can mean: `wydanie`, `wydawca`, `wydawnictwo`, `wydawniczy`.

TABLE XII
DISTRIBUTION OF THE NUMBER OF MEANINGS FOR ABBREVIATIONS IN THE DATASET WIKTIONARY

Number of meanings for the abbreviation	**Number of abbreviations with a given number of meanings**	
1	419	
2	83	
3	29	
4	13	
5	5	
6	1	
7	1	
8	1	
14	1	
19	1	
Number of meanings	**Number of abbreviations**	
803	554	**total**

[3] https://www.wiktionary.org

As we can see in Table XII, most of the found abbreviations have only one meaning, while in some cases, there are as many as 14 meanings for `n.` or 19 for `a.`.

In addition to the meanings, examples were also extracted from the Wiktionary, serving as context; however, this information was not utilized in solving the task.

3) SJP: More abbreviations than in previous dictionaries, a total of 1199, were found in the Polish language dictionary SJP. Just like in Wiktionary, some abbreviations had multiple meanings, for example, `woj.` could stand for `województwo`, `wojewoda`, `wojewódzki`, `wojenny`, `wojskowy`. The abbreviations were selected by reviewing all the words or phrases in the dictionary and then filtering out those that had periods at the end.

TABLE XIII
DISTRIBUTION OF THE NUMBER OF MEANINGS FOR ABBREVIATIONS IN THE DATASET SJP

Number of meanings for the abbreviation	Number of abbreviations with a given number of meanings	
1	1051	
2	97	
3	30	
4	10	
5	11	
Number of meanings	**Number of abbreviations**	
1430	1199	**total**

Table XIII shows that there are no abbreviations with as many meanings as sometimes found in Wiktionary, but the number 5 can be considered the maximum number of meanings that almost always appeared in SJP and Wiktionary.

C. Synthetic additional data

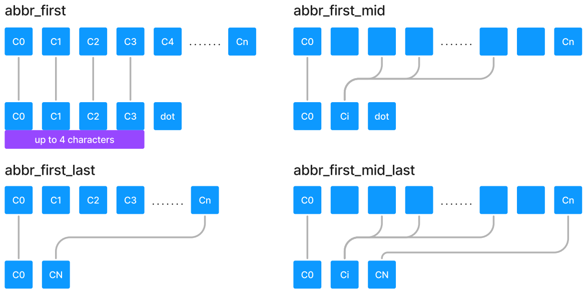
Collecting a sufficiently large and diverse dataset with accurately annotated abbreviations can be a challenging and time-consuming task. In this section, we describe the methodology used to generate synthetic data.

1) Data collection and preprocessing: The source corpus was the Polish Wikipedia. A sliding window is used to randomly select a context of 140 to 200 characters. This context length is representative of the PolEval abbreviation disambiguation dataset. Within each such context, a continuous span of words is randomly selected. These words are then processed with algorithmic abbreviation.

2) Algorithmic abbreviation: The custom abbreviation algorithm operates with four different strategies, as seen in Figure 2:

1. `abbr_first`: `profesor` → `prof.`
   Choose 1 to 4 of the first characters.
2. `abbr_first_last`: `profesor` → `pr`
   Choose the first and last characters.
3. `abbr_first_mid`: `profesor` → `pf.`
   Choose the first and one middle character.
4. `abbr_first_mid_last`: `profesor` → `pfr`
   Choose the first, one middle and last characters.

Fig. 2. Algorithmic Abbreviation Schemes



The algorithm applies a random strategy to each word in the span. It must be noted that the generated abbreviations are not guaranteed to be grammatically correct.

3) Base form prediction: The base forms of all words from the span before abbreviation are generated with the `spaCy` `pl_core_news_lg` model [17].

TABLE XIV
SYNTHETIC WIKIPEDIA EXAMPLE

in.tsv	**expected.tsv**	
bs. jest zgodny ze światem, w którym istnieje problem zła i cierpienie, a **<mask>** miłość jest ukryta przed wieloma osobami. Podobną argumentację	boska	boski

Each such context containing an abbreviated span is used as a dataset sample. Table XIV shows one generated example. The process repeats until reaching the end of the Wikipedia corpus.

4) Considerations: This synthetic dataset applies to a broader task of corrupted text restoration, where abbreviation disambiguation can be seen as a sub-task. In the context of abbreviation disambiguation, it is a low-quality dataset. This disadvantage is countered by its vast size of 14 million examples, which is 3375 times larger than the PolEval training dataset.

The exact version of the created dataset cannot be deterministically reproduced because of multi-process random number generation used during processing. A snapshot of the dataset is provided online[4].

III. EVALUATION

The process of abbreviation disambiguation i.e. replacing abbreviations with their appropriate expansions in text can be divided into two stages.

The first stage is to find the abbreviation in a dictionary and replace it with an appropriate word or phrase that is its base forms.

The second stage is to transform the result from the first stage into its correctly inflected grammatical form based on the context in which the abbreviation appears in the text.

[4] https://huggingface.co/datasets/carbon225/poleval-abbreviation-disambiguation-wiki

It is worth noting that sometimes there is more than one meaning for a given abbreviation, so in the first stage it is also important to take the context into account in order to better predict which meaning is intended in a specified example.

Two metrics were used to objectively evaluate the replacement of abbreviation with their appropriate expansion in text:

- Af - the accuracy of provided expanded forms of abbreviations
- Ab - the accuracy of provided base forms of abbreviations

The matching check for both metrics was case-insensitive.

Based on the above metrics, the ultimate formula was defined to determine the final score:

$$Acc = 0.25 \cdot Af + 0.75 \cdot Ab \qquad (1)$$

Therefore, the task of finding the appropriate base form is three times more important than the task of finding its appropriate expansion.

IV. Methods

The solutions are based on a sequence to sequence model using the T5 [18] architecture. Krzysztof Wróbel's submission used the ByT5 [19] model, while Jakub Karbowski used the plT5 [20] model.

Both submissions used a similar workflow. The input to the transformer encoder is the context with the abbreviation. The transformer decoder generates both the base and inflected forms. Multiple methods of encoding the input and output of the model were used. They are described in detail in their corresponding sections.

In order to improve the results, majority voting with multiple models has been applied. The final decision is determined by the majority vote, where each model's prediction contributes one vote, and the outcome with the most votes is selected as the final prediction. This approach leverages the collective knowledge and expertise of multiple models to improve the accuracy and robustness of predictions in scientific studies. For this task, majority voting has been applied separately for inflected and base form.

V. Experiments

A. PolEval submissions

Initial experiments were carried out with limited time because of the competition deadlines. They were the base for further post-competition research. First, the exact methods used to produce the competition submissions are described.

1) Krzysztof Wróbel submissions: Proper validation is very important in every competition. The original validation (dev-0) dataset has only 300 samples which is insufficient for tracking scores with a precision of 0.1 percentage points. Therefore, 1000 samples from the training data were moved to the validation set.

The input data was prepared as follows: an abbreviation in the sentence was surrounded by <abbrev> and </abbrev>, e.g. Komunistyczny deputowany, <abbrev>b.</abbrev> śledczy Prokuratury Generalnej. The output data is structured as follows:

- for abbreviations: inflected form, separator <sep>, and base form, e.g. były <sep> być
- for non-abbreviations: the form, e.g. b.

The tokens <abbrev>, </abbrev>, and <sep> were added to the model vocabulary.

Initial experiments using Adafactor as an optimizer showed that the plT5 models performed slightly worse than the ByT5 models.

The training dataset was augmented by extracting abbreviations from dictionaries and applying them into sentences sourced from a corpus.

The final submission was created using majority voting on 3 models:

- trained on the training data and dictionary-based additional data using the development data for selecting the best model
- trained on the training data, development data, and dictionary-based additional data with two different seeds

The training parameters were as follows:

- model: byt5-base
- max input length: 250
- max output length: 100
- batch size: 16
- gradient accumulation: 16
- epochs: 24
- learning rate: 0.001
- scheduler: linear with warmup 0.1
- optimizer: Adafactor

TABLE XV
Krzysztof Wróbel's submissions to PolEval. The name is the same as in official leaderboard.

Description	Name	test-A	test-B
train	3	90.78	
train + dict	5	91.32	
train + dev + dict, seed 1	8	92.18	91.69
train + dev + dict, seed 2	9	92.14	91.65
voting (final)	11	**92.76**	**92.01**

Table XV presents the results of Krzysztof Wróbel's submissions to the PolEval competition. The table includes different models and their corresponding scores on the test-A and test-B datasets.

The second model, named as 5 was trained on the training data along with additional dictionary-based data. This model performed better by 0.5 percentage points than model trained only on the training data.

The next two models, named as 8 and 9 were trained on the training data, development data, and dictionary-based additional data, using different random seeds for each. Model 8 achieved a score of 92.18 on the test-A dataset and 91.69 on the test-B dataset, while model 9 achieved a score of 92.14 on the test-A dataset and 91.65 on the test-B dataset.

The final model, named as `11` is the result of majority voting on three models: `5`, `8`, and `9`. This model achieved the highest scores among all the submissions, with a score of 92.76 on the test-A dataset and 92.01 on the `test-B` dataset.

2) Jakub Karbowski submissions: Input data was encoded in a similar way to Krzysztof Wróbel's submission. The only difference is that `<abbrev>` and `</abbrev>` are not added as special tokens and are tokenized as raw text by the model's tokenizer. Instead of `<abbrev>` they are called `<mask>`.

The output format was the same as in Krzysztof Wróbel's submission, except the output of the model does not differ between abbreviations and non-abbreviations. The output format is: inflected form; base form, e.g. `były; być`.

Although ByT5 was considered because of its high performance on noisy data, plT5 was chosen because of limited training hardware available to the author of the submission. Training was performed on single GTX 1080 GPU with 8 GB of VRAM within a single day. Training ByT5 on this hardware would not be feasible.

First, pre-training was carried out on the Wikipedia dataset with synthetic abbreviations.

Pre-training parameters:

- model: plt5-base
- batch size: 4
- gradient accumulation: 64
- training steps: 3300
- learning rate: 0.0000928
- scheduler: linear with warmup 2000 steps
- optimizer: AdamW
- weight decay: 0.001

The training lasted 6 hours and was terminated after just 6% of the dataset. The pre-trained score achieved on the PolEval `dev-0` dataset was 29.18%.

The pre-trained model was then fine-tuned on the PolEval `train` dataset.

Training parameters:

- model: plt5-base (wiki pre-trained)
- batch size: 8
- gradient accumulation: 32
- epochs: 223
- learning rate: 0.000015
- scheduler: linear with warmup 10%
- optimizer: AdamW
- weight decay: 0.0001

The per-device batch size could be increased because of a decrease in sequence length compared to the pre-training dataset. The score of the final submission with pre-training was 91.75% on `test-A` and 91.27% on `test-B`.

B. Post-competition experiments

After the announcement of the competition results, the top two contestants combined their work to evaluate the performance of their methods, with respect to:

- model architectures
- used datasets and their combinations
- a broad range of hyperparameters
- original optimizations and solutions

1) Setup: A unified codebase for training was created[5]. It combines all of the methods and datasets used:

- ByT5 and plT5 models
- PolEval, dictionary-based and synthetic Wikipedia datasets
- majority voting

It also contains the hyperparameters and sweep configurations used during experimentation.

2) Configurations: Eight different configurations were chosen for final assessment. All combinations of the following options were used:

- Base model:
  - ByT5
  - plT5
- Pre-training dataset:
  - None
  - Wikipedia
- Fine-tuning dataset:
  - PolEval `train`
  - PolEval `train` with additional dictionary-based data

3) Pre-training: As pre-training on the large synthetic Wikipedia dataset was computationally expensive, sweeps on this dataset were not conducted. Instead, results from fine-tuning runs and manual experimentation provided the hyperparameters for pre-training.

4) Fine-tuning: For each configuration, a hyperparameter sweep was conducted. The sweeps considered: learning rate, weight decay, epochs, optimizer (AdamW or Adafactor). To provide a fair comparison between the two model architectures, each sweep was given 24h of computational time on an A100 GPU. The four sweeps with ByT5 managed to perform 16 training runs each, while plT5 sweeps performed 80 runs each.

5) Voting: Experiments involving majority voting were conducted to evaluate the performance of the best plT5 and ByT5 models. For each model, a set of 10 models was trained using identical parameters but different random seeds.

VI. RESULTS

Table XVI shows scores for experiments using plT5 and ByT5 models trained on different datasets. The highest scores are obtained using pre-training on synthetic data and then fine-tuned on `train` data with `dictionary-based` data. The models are shared at Hugging Face[6]. ByT5 consistently achieves higher scores than plT5. The results on the `dev` dataset do not correlate with the test data due to the small size of the `dev` dataset.

Using the synthetic Wikipedia dataset for pre-training improves the performance of both models. For plT5, the `test-B`

[5] https://github.com/Carbon225/poleval-2022-abbr

[6] https://huggingface.co/carbon225/plt5-abbreviations-pl, https://huggingface.co/carbon225/byt5-abbreviations-pl

score improves by around 1% when considering both the pure PolEval `train` dataset and the additional dictionary data. For ByT5, the improvement is under 1%. Using additional dictionary data improves the scores by around 0.5%.

TABLE XVI
RESULTS FOR PLT5 AND BYT5 MODELS ON DIFFERENT TRAINING DATASETS

		plT5			ByT5	
	dev	test-A	test-B	dev	test-A	test-B
train	91.80	90.76	90.06	94.10	92.10	91.73
wiki-train	91.39	**91.76**	91.32	93.61	92.46	92.53
train-dict	91.31	91.21	90.44	94.34	92.30	92.20
wiki-train-dict	91.31	91.64	**91.37**	93.44	**92.71**	**92.92**

TABLE XVII
SCORES OBTAINED USING MAJORITY VOTING AMONG 1 TO N MODELS. MODELS ARE SORTED BY TEST-A SCORE AND USED IN THAT ORDER.

	plT5		ByT5	
Models	test-A	test-B	test-A	test-B
1	91.72	90.96	92.71	92.92
1-2	91.74	91.22	92.65	92.80
1-3	91.91	91.42	93.00	93.06
1-4	91.88	91.45	**93.33**	93.15
1-5	92.03	91.57	93.25	**93.27**
1-6	92.00	91.59	93.20	93.19
1-7	91.99	91.56	93.16	93.14
1-8	92.05	91.57	93.12	93.11
1-9	92.10	**91.62**	93.12	93.18
1-10	**92.12**	91.59	93.13	93.17

Table XVII provides the test-A and test-B scores for different combinations of plT5 and ByT5 models. The row labeled `1` represents the score obtained when only the first model is used. Subsequent rows, labeled `1-2`, `1-3`, and so on, indicate the scores obtained when additional models are included in the majority voting process. The maximum improvement observed through this process is approximately 0.5 percentage points.

TABLE XVIII
POLEVAL BEST RESULTS AND SCORES BY DIFFERENT SUBMISSIONS.

	test-A	test-B
Krzysztof Wróbel	**92.76**	**92.01**
Jakub Karbowski	91.75	91.27
Marek Kozlowski	89.00	88.73
Jakub Pokrywka	65.48	66.25
Rafał Prońko		19.09

Table XVIII presents the best results and scores achieved by different submissions in the PolEval competition. The table includes two test metrics: `test-A` and `test-B`.

Krzysztof Wróbel emerged as the highest scorer, surpassing Jakub Karbowski by 0.74 percentage points in the test-B metric. Krzysztof Wróbel's success can be attributed to the implementation of the ByT5 model, majority voting, and the utilization of a larger validation dataset. Incorporating the pretraining step and utilizing the AdamW optimizer, as introduced in Jakub Karbowski's solution, has the potential to yield scores higher by more than 1 percentage point.

A. Error analysis

The error analysis of 50 randomly selected errors made by the ByT5 model in the `wiki-train-dict` variant revealed that the model correctly predicted the answers for half of them. The dataset annotation needs to be improved.

More technical issues apply to about 1.5% of the examples. Approximately 0.76% of the examples in the dataset are annotated with multiple possible answers separated by a semicolon, such as `przeciw; przeciwko`. These cases were not properly taken into account during evaluation, About 0.72% of the examples in the dataset consist of multiword abbreviations with tokens separated by more than one space.

VII. CONCLUSIONS

In this paper, we addressed the problem of abbreviation disambiguation in Polish press news using encoder-decoder models. The task involved replacing abbreviations with their appropriate expansions in text, taking into account the context.

Our experiments included submissions to the PolEval competition and post-competition research. In the PolEval competition, we achieved first and second place rankings. In the post-competition experiments, we conducted evaluations using different configurations, including pre-training on synthetic Wikipedia data and fine-tuning on additional data, which achieved a new state-of-the-art on the PolEval competition.

In conclusion, our study contributes valuable insights into the abbreviation disambiguation task in Polish press news. We emphasize the importance of proper validation, the trade-off between optimizer choice and memory usage, importance of pre-training, and the effectiveness of majority voting as a simple technique for improving results. Further research can build upon these findings to explore more advanced architectures, optimizations, and techniques for even better performance in Polish abbreviation disambiguation tasks.

Our approach can be easily applied to other languages and various types of texts.

VIII. APPENDIX

Table XIX presents errors of the ByT5 model in the `wiki-train-dict` variant.

IX. ACKNOWLEDGMENT

The competition submissions made by the team of Krzysztof Wróbel and Paweł Lewkowicz were completely independent of Jakub Karbowski's submissions. However, after the competition, the authors decided to collaborate and write a joint article due to the similarities in the methods used.

We gratefully acknowledge Polish high-performance computing infrastructure PLGrid (HPC Centers: ACK Cyfronet AGH) for providing computer facilities and support within computational grant no. PLG/2023/016304

The research has been supported by a grant from the Faculty of Management and Social Communication under the Strategic Programme Excellence Initiative at Jagiellonian University.

Passage Retrieval of Polish Texts Using OKAPI BM25 and an Ensemble of Cross Encoders

Jakub Pokrywka
Adam Mickiewicz University
Faculty of Mathematics and Computer Science,
Email: jakub.pokrywka@amu.edu.pl

***Abstract*—Passage Retrieval has traditionally relied on lexical methods like TF-IDF and BM25. Recently, some neural network models have surpassed these methods in performance. However, these models face challenges, such as the need for large annotated datasets and adapting to new domains. This paper presents a winning solution to the Poleval 2023 Task 3: Passage Retrieval challenge, which involves retrieving passages of Polish texts in three domains: trivia, legal, and customer support. However, only the trivia domain was used for training and development data. The method used the OKAPI BM25 algorithm to retrieve documents and an ensemble of publicly available multilingual Cross Encoders for Reranking. Fine-tuning the reranker models slightly improved performance but only in the training domain, while it worsened in other domains.**

I. Introduction

PASSAGE retrieval involves the task of retrieving a set of relevant text passages from a large collection of documents based on a given query. Typically, these passages are presented in descending order of relevance. The most commonly used method for passage retrieval is through lexical approaches like OKAPI BM25. Though, lexical models cannot capture semantic relationships between words, phrases, and sentences. To address this, neural language models can be employed. These models are often pretrained on extensive text corpora and then fine-tuned specifically for passage retrieval. There are two common setups for utilizing neural models in this task: complete passage retrieval using a neural model or combining another retrieval engine to retrieve a subset of passages, followed by using the neural model to select the most relevant ones. The latter approach is employed when the reranking model is too slow to process an entire document collection.

The Poleval 2023 Task 3: Passage Retrieval challenge aims to identify the best method for passage retrieval in Polish texts. The competition's test dataset comprises three domains: wiki-trivia, legal-questions, and allegro-faq. However, only the wiki-trivia domain is provided as the training and development dataset.

In this paper, we discuss the two-stage approach that achieved a score of 69.36 NDCG@10 on the final test competition dataset. Our method involves two phases. Firstly, we use the OKAPI BM25 algorithm to retrieve relevant passages. Then, an ensemble of Cross Encoder models is employed to rerank these passages. These models are publicly available multilingual models that have been trained on various languages (including Polish) and finetuned on multilingual corpora for passage reranking, as outlined in [1]. We used these models with no further finetuning on the challenge dataset for two domains: legal-questions and allegro-faq. For the wiki-trivia domain, one model was fine-tuned and used in combination with models that had no further finetuning.

TABLE I
Dataset statistics split into given domains. rel. passages stand for relevant passages.

II. Related Work

A. Reranker models and modern neural Information Retrieval

MS MARCO [2] is a large publicly available reranking dataset retrieved by Bing. The dataset includes queries, retrieved documents by search engine, and a label on whether a user clicked a document. The corpus is in the English language. Recently, authors of mMARCO [1] translated this corpus into many languages (but not into Polish though) and trained Cross Encoder reranker models on it. The base models were multilingual. The performance was effective not only for translated languages but also for not translated languages, only visible by models in the semisupervised pretraining phase.

BEIR [3] is an Information Retrieval benchmark for Zero-shot Evaluation between different domains. The authors provided many comparisons between different retrieval architectures. Very recently, the benchmark for Polish Information Retrieval was released in BEIR-PL paper [4].

B. Language models working on Polish texts

There are a few transformer language models trained for the Polish language: HerBERT [5], plt5 [6], Polish RoBERTa [7]. There are also many multilingual language models working on Polish languages, such as XLM-RoBERTa [8], multilingual DeBERTa [9], and mT5 [10].

III. PolEval 2023 Task 3: Passage Retrieval Challenge

A. Data

The task is to retrieve the relevant passages given a query. The queries and passages are in the Polish language. There are separate domains: wiki-trivia, legal-questions, allegro-faq. In the below subsection, each domain is presented. There are the following datasets: training (train), development (dev), test-A (preliminary test set), and test-B (final test set). For the training and development dataset, golden truth data was released during the competition, but the golden truth dataset was not. After competitions, the test set golden truth was released to https://github.com/poleval/2022-passage-retrieval-secret. Training and development datasets consist of only wiki-trivia, but the test dataset consists of all three domains. Below all domains are described. Some dataset statistics are given in Table I. Domains vary greatly in the number of passages and mean relevant passages per query.

1) wiki-trivia: Questions are general-knowledge typical for TV quiz shows, such as *Fifteen to One* or Polish equivalent *Jeden z dziesięciu*. For each question, there were manually selected up to five relevant passages (the mean number for the training dataset is 3.28 with a standard deviation of 1.45). The passages corpus consists of 7097322 elements. This domain was selected for train, dev, and test datasets. There are 4041 questions in the train dataset, 599 in the dev dataset, 400 in the test-A dataset, and 891 in the test-B dataset. Below, one example question with all correct passages is presented.

Example Question: "Czy w państwach starożytnych powoływani byli posłowie i poselstwa?"
Correct passage: "Poselstwo do Chin. Chińska "Księga Późniejszych Hanów" ("Houhanshu") zanotowała informację, iż w roku 166 drogą morską przez Ocean Indyjski do kraju Jinan (Annam) przybyło poselstwo "króla Andun z Daqin" (Rzymu), oferując kość słoniową, rogi nosorożca i szylkret."
Correct passage: "Z okresu starożytnych Indii pochodzą pierwsze zachowane instrukcje na temat zadań dyplomaty (rozpoznawać i informować) oraz cech dyplomaty (wykształcony, zręczny, zjednujący sobie ludzi). Dyplomację stosowali już starożytni Grecy, od których wywodzi się termin „diplóos" oznaczający złożony we dwoje dokument – rodzaj listów uwierzytelniających w które wyposażany był poseł."
Correct passage: "Ze starożytnej Grecji pochodzi również przywilej nietykalności posła i poselstwa (immunitet), które już wtedy były uznawane za zasadę będącą elementem prawa narodów. Pierwotną formą quasi-dyplomacji była wymiana posłów przez społeczności plemienne w celu przekazania i wyjaśnienia przekazu mocodawcy, lub wynegocjowania jakiegoś porozumienia (np. o zakończeniu wojny)."

2) legal-questions: A portion of the legal questions were generated by randomly selecting provisions and formulating questions based on their content. The task is similar to SQuAD and requires only identifying relevant passages rather than answering the question. The questions were supplemented with 26287 provisions derived from over one thousand laws published between 1993 and 2004. There are 400 questions in the test-A dataset and 318 in the test-B dataset. Below, the example questions from the test-A dataset are provided.

Example Question: "Ile trwa kadencja szefa służby cywilnej?"
Correct passage: "Ustawa z dnia 18 grudnia 1998 r. o służbie cywilnej Rozdział 1 Przepisy ogólne","text":"Art. 9. 1. Szefa Służby Cywilnej powołuje, po zasięgnięciu opinii Rady Służby Cywilnej, Prezes Rady Ministrów spośró d urzędników służby cywilnej. 2. Kadencja Szefa Służby Cywilnej trwa 5 lat, licząc od dnia powołania; Szef Służby Cywilnej pełni obowiązki do dnia powołania jego następcy. 3. Kadencja Szefa Służby Cywilnej wygasa w razie jego śmierci lub odwołania. 4. Prezes Rady Ministrów odwołuje Szefa Służby Cywilnej w razie: 1) rezygnacji ze stanowiska, 2) utraty zdolności do pełnienia powierzonych obowiązków na skutek długotrwałej choroby, trwającej co najmniej 6 miesięcy. 5. Prezes Rady Ministrów odwołuje Szefa Służby Cywilnej także w przypadku, gdy przestał on odpowiadać jednemu z warunków określonych w art. 4. Odwołanie w przypadkach, o których mowa w art. 4 pkt 4 i 5, następuje za zgodą co najmniej 23 składu Rady Służby Cywilnej."

3) allegro-faq: Questions regards the large e-commerce platform- Allegro.pl were created using help articles and lists of frequently asked questions. There are 400 questions in the test-A dataset and 500 questions in the test-B dataset. In total, there are 921 passages. Here is an example question from the test-A dataset:

Example Question: "Otrzymałem rekompensatę z POK, a później zwrot od Sprzedającego. Co mam zrobić?"
Correct passage: "Jeśli wypłaciliśmy Ci rekompensatę w ramach Programu Ochrony Kupujących a Ty otrzymasz zwrot pieniędzy od Sprzedającego, masz obowiązek zwrócić nam rekompensatę. Zgodnie z punktem 6 Część IV Załącznika nr 9 do Regulaminu Allegro, na zwrot rekompensaty masz 7 dni od naprawienia szkody przez Sprzedającego."

B. Evaluation Metric

The GEval evaluation tool [11] uses Normalized Discounted Cumulative Gain for the top ten passages (NDCG@10) as the challenge metric. The challenge was hosted on the Gonito platform [12], and the final evaluation was conducted on the test-B dataset across all domains. It should be noted that the sample split between domains is not equal, which means that some domains have a greater impact on the final score.

IV. Method

The solution involves two stages: Retrieval and Reranking. Retrieval is carried out using the lexical method OKAPI BM25, which is quick but not as effective as a neural ranking model. Additionally, it does not require training. The best performing method for Reranking is through Cross Encoders, but it is slow as it requires processing every query-passage pair. Due to its time-consuming nature, it can only operate on a limited set of passages, except for the allegro-faq domain, which consists of only 921 passages.

A. Retrieval phase

For retrieval model We used OKAPI BM25 algorithm using parameters k_1=1.2 , b=0.75, ε=0.25. The utilized library may be accessed via https://github.com/zhusleep/fastbm25. The preprocessing included tokenization using the nltk library, specifically nltk.tokenize.word_tokenize, lowercase normalization, stemming using pystempel (accessed via https://github.com/dzieciou/pystempel) with the Polimorf [13] stemmer, and removal of Polish stopwords.

B. Reranking phase

The reranking phase was performed using an ensemble of multilingual reranker models based on Cross-Encoder architecture. We used different sets of the ensemble for wiki-trivia domain and legal-questions with allegro-faq questions. Both are described in the following section. The ensembles were created by summing up all the individual models' probability scores. Finetuning, if performed, was loosely based on a script from Sentence-Transformer library [14], namely https://github.com/UKPLab/sentence-transformers/blob/master/examples/training/ms_marco/train_cross-encoder_scratch.py. The process of finetuning and inference was completed on A100 GPU card. We used one 100 negative query-passage pair for each positive passage selected from the training dataset. The negative passage selection was from the top 2000 passages returned by the described OKAPI BM25 algorithm. The used Loss was BCEWithLogitsLoss with a constant learning rate scheduler of 1e-6 and 2000 warmup steps. The best-performing model was selected for inference from training for ten epochs.

1) wiki-trivia: Reranking was based on the top 3000 results from the OKAPI BM25 algorithm. Because wiki-trivia passages are relatively short, they only require a little time, although, during experiments, we observed that reranking with above 1000 passages, there is not much gain in the metric score.

The ensemble consisted of three models:

- Publicly available reranker based on multilingual T5 (mT5) model [10] (also trained on Polish corpora) and fine-tuned to automatically translated reranking corpus MS MARCO [2] into Portuguese. The model unicamp-dl/mt5-13b-mmarco-100k via https://huggingface.co/unicamp-dl/mt5-13b-mmarco-100k was used as it is without further fine-tuning to the competition training dataset. Therefore model works in a zero-shot manner as described in [1].
- Reranker cross-encoder/mmarco-mMiniLMv2-L12-H384-v1 (accesed via https://huggingface.co/cross-encoder/mmarco-mMiniLMv2-L12-H384-v1.
  The multilingual base model MiniLMv2 [15] is fine-tuned on mMARCO dataset (MS MARCO translated into multiple languages). Please note MMARCO dataset does not contain the Polish language, but MiniLMv2 was trained on Polish. However, it performed well on the dev dataset. We then fine-tuned it further on the competition train dataset, slightly improving it.
- Reranker cross-encoder/mmarco-mdeberta-v3-base-5negs-v1 (https://huggingface.co/cross-encoder/mmarco-mdeberta-v3-base-5negs-v1) based on multilingual DeBERTaV3 [9] finetuned on MMARCO dataset. During the competition, the model was publicly available but was removed before the time of writing this article. We further fine-tuned the model to the competition training dataset.

2) legal-questions and allegro-faq: Reranking was performed on top 1500 passages for legal-questions. The limit was lower than for wiki-trivia due to the length of passages collection and longer computation time. For the allegro-faq domain, reranking was performed on all the passages since the whole collection consists of only 921 passages. For both domains, the same ensemble was used. The following models were used without further finetuning to the competition dataset. We conducted experiments using models fine-tuned to wiki-trivia, but their performance dropped drastically. Finally, we used the following models:

- Model unicamp-dl/mt5-13b-mmarco-100k via https://huggingface.co/unicamp-dl/mt5-13b-mmarco-100k described in the previous section.
- Model unicamp-dl/mt5-3B-mmarco-en-pt via https://huggingface.co/unicamp-dl/mt5-3B-mmarco-en-pt, which is the same as above but in the 3B parameters version.

V. Results

The presented method scores 75.40 NDCG@10 on preliminary test-A and on 69.36 NDCG@10 on final test-B data. The experiments code is available at https://github.com/kubapok/poleval22. The analysis of single models on different reranking size limits is presented in Table III for test-A and in Table II for test-B. The results vary between domains, probably because of text nature, as well as different passage collection sizes and different size mean relevant passages per one query. All the presented reranking models score better than the OKAPI BM25 baseline. With the reranking size limit, the performance is better. However, the gain isn't great beyond the reranking limit of 500. Finetuning models increase their performance only on the wiki-trivia domain and worsen on other domains. Unfortunately, these results are not included in the presented tables as we didn't save them.

VI. Other Experiments

We have tried other approaches as well. These experiments were very preliminary and may yield better results if we spend more time on them. However, we decided to include them in this paper anyway.

TABLE II

NDCG@10 results for the whole final testing dataset test-B and split into domains. ft stands for the model fine-tuning to the competition data, whereas no-ft stands for no fine-tuning. The number at the right of the model name stands for the reranking size from the OKAPI BM25 algorithm. Some experiments were not conducted or saved. In this case, the score is labeled as "-"

A. Translating Polish texts into English.

We translated Polish passages and queries into English using a machine translation model accessed by https://huggingface.co/gsarti/opus-mt-tc-en-pl [16]. English Cross Encoder reranking models did not perform on the translated texts better than multilingual reranking models on Polish texts tough.

B. Bi Encoder models

We experimented with various publicly available Bi Encoder models, using them as one-stage retrieval models. Unfortunately, their performance was significantly inferior to that of the OKAPI BM25 algorithm operating alone. However, combining the OKAPI BM25 and Bi Encoder models as retrieval models for further reranking with the Cross Encoder model may lead to improved results and is a promising area for research. Our highest Bi Encoder score for untranslated documents was 9.26 NDCG@10, achieved using the sentence-transformers/distiluse-base-multilingual-cased-v1 model. For translated texts into English, our highest score was 21.00, obtained using the sentence-transformers/all-mpnet-base-v2 model.

C. Translating MS MARCO into Polish

MMARCO does not include translations for Polish texts. We've attempted translating MS MARCO into English using model gsarti/opus-mt-tc-en-pl and training several reranking models on this data. The approach is similar to [4]. Nevertheless, this work was published after the competition. In our case, this approach didn't yield better results than large multilingual models.

VII. Conclusions

This paper summarizes our solution to Poleval 2023 Task 3: Passage Retrieval. The system operates in two stages, utilizing OKAPI BM25 for retrieval and a multilingual ensemble of Cross Encoders for reranking. However, the system's performance varies between domains due to the limited availability of training data for only one domain. While fine-tuning the neural model can enhance results for this domain, it may have a negative impact on other domains.

Hybrid retrievers with generative re-rankers

Marek Kozlowski
National Information Processing Institute
Warsaw, Poland
Email: marek.kozlowski@opi.org.pl

Abstract—**The passage retrieval task was announced during PolEval 2022 (SemEval-inspired evaluation campaign for natural language processing tools for Polish). Passage retrieval is a crucial part of modern open-domain question answering systems that rely on precise and efficient retrieval components to identify passages that contain correct answers. Our solution to this task is a multi-stage neural information retrieval system. The first stage consists of a candidate passage retrieval step in which passages are retrieved using federated search over sparse (BM25) and dense indexes (two FAISS indexes built using bi-encoder type retrievers based on Polish RoBERTa models). The second stage consists of a re-ranking step of the previously selected passages with a neural model, mt5-13b-mmarco. The model scores each passage by its relevance to a given query. The highest-scoring passages are then retained as the final result. Our system achieved second place in the competition.**

I. Introduction

PASSAGE retrieval is a crucial part of modern information retrieval systems that rely on highly efficient retrieval components to identify passages (mostly represented as paragraph(s)) that contain correct answers.

Information retrieval is a popular research domain that focuses on obtaining relevant information from a collection of diverse data resources (mainly textual ones). When working with information retrieval tasks, one can rely on using bag-of-words (BOW) systems (such as the BM25) or different approaches supported by deep learning models (such as dense retrievers or re-ranking modules).

Recently, neural information retrieval has surpassed the lexical methods based on BOW (such as TF-IDF + cosine similarity or BM25) by fine-tuning pre-trained language models, including generative ones such as BART, T5, and representation ones such as BERT, RoBERTa. Although they beat the classical methods in terms of quality efficiency, they are not free of drawbacks, such as the need for a relevant training set. They solve many problems of lexical methods, including poor semantic capabilities, but at the cost of an expensive training process that uses a relevant number of labeled examples. There is also evidence that neural information retrieval systems are characterized by poor generalizability to other domains. This means that in a zero-shot or few-shot setup (i.e. no or little training data), lexical methods remain competitive with, or even better than, neural models.

The lack of Polish-language datasets, relevant evaluations, and benchmarks encouraged the Polish AI community to establish the PolEval initiative, a SemEval-inspired evaluation campaign for natural language processing tools for Polish. Submitted tools compete against each other using available data in tasks selected by the organizers, and are evaluated according to pre-established procedures. In 2022, the following tasks were announced: punctuation prediction from conversational language, abbreviation disambiguation, and passage retrieval.

The goal of the passage retrieval task was to develop a system for cross-domain question answering retrieval in the Polish language.

The participants were given a training set that comprised question–passage pairs from the trivia domain—the type of general-knowledge questions that are typical on popular television quiz shows. For each test question, the systems were tasked with retrieving ordered lists of the ten most relevant passages (i.e. those that contain the answer) from the provided corpus. The systems were scored based on their performance on all three test sets.

Using the PolEval data and our own (the translated MS MARCO dataset), we evaluated various approaches toward passage retrieval, where the sentence-level queries are given and the corpus is counted in millions of passages. We present the best of our submitted approaches.

This article is structured as follows: In Section 2, we discuss related work. Section 3 is devoted to presenting the datasets. In Section 4, we present our approach and the results of our evaluations. Section 6 outlines our conclusions.

II. Related Work

We commence this section from the standard formulation of the passage retrieval task. From a finite, but arbitrarily large collection of passages $P = \{p_1, p_2...\}$, the system's task, given a query q, is to return a top-N ranking of the passages that maximizes a metric of quality, such as normalized discounted cumulative gain (NDCG) or average precision. NDCG is a measure of ranking quality. Highly relevant documents are more useful than moderately relevant documents, which are, in turn, more useful than irrelevant documents. In the subsections below, we explain sparse and dense retrieval, as well as dense re-ranking.

A. Sparse retrieval

Traditionally, retrieval has been dominated by lexical approaches like TF-IDF + cosine similarity, and BM25.

BM25 is a BOW retrieval function that ranks sets of documents based on the query terms that appear in them, regardless

This work corresponds to the Poleval 2022—Passage Retrieval competition.

of their proximity [1]. BM25 is a retrieval model based on the probabilistic retrieval framework. BM25 often achieves better performance compared to TF-IDF, which rewards term frequency and penalizes document frequency. BM25 goes beyond this to consider document length and term frequency saturation.

The results [2] demonstrate that BM25 is a robust baseline. However, these approaches suffer from a lexical gap and are able to retrieve only documents that contain keywords present within the query. In addition, lexical approaches treat queries and documents as BOW by not considering word order.

To overcome this lexical gap, techniques to improve lexical retrieval systems using neural networks have been proposed. Sparse methods, such as docT5query [3], identified document expansion methods that use sequence-to-sequence models that generate possible queries for which a given document would be relevant. At base, it involves training a model that predicts questions for which the input document might contain answers. The generated questions are then appended to the original documents, which are indexed. The docT5query model takes its name from the generative model T5. The primary advantage of this approach is that expensive neural inference is pushed to indexing time.

B. Dense retrieval

Recently, dense retrieval approaches have also been proposed. They are capable of capturing semantic matches, and attempt to overcome the (potential) lexical gap. Dense retrievers map queries and documents in a single, common dense vector space. A bi-encoder architecture based on BERT-type models demonstrated strong performance for various open-domain question answering tasks.

An important recent innovation for passage retrieval is the introduction of dense retrieval models that take advantage of a bi-encoder design. Bi-encoders produce two corresponding embeddings for a given two-sentence pair (e.g. a query and a passage), which can then be compared efficiently using cosine similarity.

Bi-encoders are used whenever a sentence embedding is needed in a vector space for efficient comparison in applications such as information retrieval, semantic search, or clustering. Cross-encoders would be the wrong choice for these applications, because a cross-encoder does not produce a sentence embedding; it processes both sentences simultaneously through the Transformer network, which is very computationally expensive with such a large scale of data.

With sufficient labeled data, we can learn encoders (typically, Transformer-based models) that project queries and documents into a dense (semantic) representation space (e.g. 768 dimensions) where the relevance ranking can be recast as a nearest neighbor search over representation vectors [4].

Bi-encoders can be used also as re-rankers, working not on all documents in corpora, but only on subsets of them. There are settings in which the first-stage retriever returns a limited number of documents and passes them to the re-ranker. Re-ranking can be also performed as a second stage retrieve on a limited collection of documents from stage 1 without any top-k constraints.

The two most popular bi-encoders are DPR and ANCE. DPR [5] is a two-tower bi-encoder trained with the hard negatives and single-batch negatives of a single BM25. The Multi-DPR model is a BERT-base-uncased model trained on four QA datasets: NQ, TriviaQA, WebQuestions, and CuratedTREC. ANCE [6] is a bi-encoder that uses approximate nearest neighbor negative contrastive learning, which selects hard training negatives globally from the entire corpus.

C. Dense re-ranking

Modern search engines are developed as multi-stage retrieve & ranking architectures in which a first-stage retriever generates candidate documents that are then re-ranked by deep learning models. Re-ranking requires feeding the model both the query and the candidate text. Neural re-ranking approaches use the output of a first-stage retrieval system to create a better order of the retrieved documents.

Significant improvements in the performance of re-ranking has been achieved using the cross-encoder mechanism based on BERT-type models. However, it entails the disadvantage of high computational overhead, because cross-encoders do not scale well for large datasets.

In the generative model era, the T5 model [7] was applied in an identical manner to classical cross-encoders, and yielded SOTA results in zero-shot scenarios [8]. MonoT5 is an adaptation of the T5 model [7] proposed by Nogueira [9]. The model uses query–document pairs as input and generates probability scores that quantify the relevance between them. The model is asked to generate either a “true” or a “false” token for a source prompt that contains a query and a document, from which we can extract the probability of relevance used to sort the candidates. In [8], large re-rankers such as monoT5-3B outperform distilled ones and dense models of equivalent size on zero-shot tasks. This approach outperformed other fine-tuned re-ranking models significantly in data scarcity scenarios. The average results of monoT5-3B [8] demonstrate that strong zero-shot effectiveness in new text domains can be achieved by increasing the number of model parameters and without fine-tuning in-domain data. In summary, the monoT5 model, fine-tuned on the MS MARCO passage dataset, achieves state-of-the-art results on the TREC Deep Learning Track, as well as impressive zero-shot effectiveness on BEIR and many other datasets [4].

III. Dataset

Quality, representativeness, and quantity are crucial aspects of any dataset. Neural language models must usually be pre-trained and fine-tuned on high-quality labeled examples, such as documents, queries, or passages. For many languages, the available training and test datasets are limited or biased. In the sub-sections below, we present the dataset provided by the organizers, then our Polish translation of MS MARCO—a collection of datasets that focuses on deep learning in search.

A. The PolEval dataset

The PolEval organizers prepared datasets that consist of question–passage pairs from domains as diverse as general knowledge, legal matters, and the FAQs section of Polish e-commerce website Allegro[1].

Training dataset. The training set consists of 5000 trivia questions: the type of general-knowledge questions that are typical on popular television quiz shows. Each question in the training set has up to five passages from the Polish-language version of Wikipedia manually assigned. These contain the answer to the question. The training set consists of 16 389 question–passage pairs. Additionally, the PolEval organizers released a Wikipedia corpus of 7 million passages. The raw Wikipedia dump was parsed using WikiExtractor and split into passages at the ends of the paragraphs, or if the passage was longer than 500 characters. The training set comprises only data from the general knowledge domain[2].

Test dataset. There were three partial test sets with questions from different domains. The first consists of 1291 general knowledge questions that are similar to those from the training set. The second consists of 900 questions and 921 passages regarding the Polish e-commerce platform Allegro. The dataset was created based on FAQs available on the Allegro portal. Each question–passage pair was verified manually. The third dataset contains over 700 questions from the legal domain. The dataset was built in reverse because some part of the questions were created by random selection of the provisions and asking questions based on their content. The legal-domain-oriented passages count approximately 26 000 provisions extracted from more than 1000 laws published between 1993 and 2004.

Using those test sets, the organizers created the validation, test-A, and test-B datasets. They contain 599, 1200, and 1709 examples, respectively.

B. The Polish translation of MS MARCO

Microsoft Machine Reading Comprehension (MS MARCO)[3] [10] is a collection of datasets that focuses on the evaluation of modern machine learning methods in different search challenges. The first dataset was a question-answering set that features 100 000 real Bing questions and human-generated answers. Over time, the collection has expanded to at least one-million-questions, a natural language generation dataset, a passage ranking dataset, a keyphrase extraction dataset, a crawling dataset, and a conversational search dataset.

MS MARCO has one drawback: it is a large-scale dataset that focuses chiefly on the English language. A translation is available of these English corpora. MMARCO[4] [11] is a multilingual version of the MS MARCO passage ranking dataset that comprises 13 languages. It was created using machine translation. This dataset demonstrates good transfer learning capabilities, as well as being a popular choice for the evaluation of deep learning models. Using the machine translation approach to create new datasets minimizes the high costs of extensive manual data annotation processes. However, MMARCO does not contain data for the Polish language.

To address this at the National Information Processing Institute (with the assistance of Dr. Sławomir Dadas), we prepared the Polish training set using a translation of MS MARCO into Polish (approximately 39 million triplet translations) with two type of models: a) mbart-large-50-one-to-many-mmt (a fine-tuned checkpoint for multilingual machine translation of the mBART-large-50 model) [12] and b) our in-house English–Polish convolutional neural machine translation models trained using the Fairseq sequence modeling toolkit[5]. We used different neural machine translation models because the quality of Polish translations varies across the MS MARCO dataset. Finally, we mixed them heuristically. The process of machine translation lasted a few days and consumed 8xV100 GPUs.

IV. Approach

Our approach is inspired by [13], in which the authors describe NeuralSearchX, a metasearch engine based on a multi-purpose large re-ranking model that merges results and highlights sentences.

Our solution is a multi-stage neural information retrieval system. The first stage involves a candidate passage retrieval step in which passages are retrieved using federated search over sparse (BM25) and dense (two FAISS indices built using dedicated RoBERTa-based encoders, the result of the bi-encoders' training) indices. The second stage involves a re-ranking step of the previously selected passages with a fine-tuned neural model, mT5. The model scores each document by its relevance to a given query. The top-scoring documents are then retained as a final result.

A. Candidate passage retrieval

In the first stage, we used both the sparse and dense retrieval methods provided by the BEIR library [2]. BEIR is a heterogeneous benchmark that contains diverse information retrieval tasks. It also provides a common and easy framework for evaluation of various natural-language-processing-based retrieval models within the benchmark. We opted to use BEIR to take advantage of its support for lexical and dense retrievers.

In our solution, we use Elasticsearch[6]—which applies the BM25 method for scoring documents against queries—as a lexical retriever. BM25 is Elasticsearch's default similarity ranking algorithm. Elasticsearch is a distributed search and analytics engine built on Apache Lucene. Since its release, Elasticsearch has quickly become the most popular search engine in developed systems and is commonly used for full-text search when huge masses of textual data are involved. To support Polish language, we installed the morfologik plugin[7] in our Elasticsearch instance. This plugin is crucial for

[7] https://github.com/allegro/elasticsearch-analysis-morfologik

normalization purposes—specifically, we used it to perform lemmatization of words to improve the search efficiency.

The dense retrievers in the proposed approach are Sentence-BERT-type encoders. We trained them in the Bi-encoder architecture, and used them with FAISS index[8] support. FAISS is a library for the efficient similarity search and clustering of dense vectors. Bi-encoder architectures are used because sentence embedding in a vector space is needed for efficient comparison during semantic search or clustering. The queries and passages are passed independently to the sentence transformer to produce fixed-size embeddings. These can then be compared using cosine similarity to identify matching passages for a given query. The training of the dense retrievers is performed by fine-tuning encoders—specifically, we fine-tuned the RoBERTa model used in our bi-encoder architecture. During training, we used a loss function called MultipleNegativesRankingLoss, $number\_of\_epochs = 1-10$ and $batch\_size = 32$. We pass triplets in the format: $(query, positive\_passage, negative\_passage)$, where negative passage is a hard negative example (not positive one, but lexically similar to the positive one) that is retrieved by lexical search in the whole passage corpora. We used Elasticsearch to obtain ($max = 10$) hard negative examples for given positive passages. We trained two types of dense retrievers: a) using RoBERTa-base-v2[9] as a transformer model, and training one epoch on 500 000 triplets (135 000 Poleval ones and 370 000 Polish MS Marco ones randomly selected); and b) using RoBERTa-large-v2[10] as a transformer model, and training 10 epochs on a few million triplets (several million Polish MS Marco ones randomly selected). We then fine-tuned for one epoch on all 135 000 PolEval triplets.

More information on how to train bi-encoders effectively can be found in the sentence-transformers github[11].

Since all of the retrievers are independent, we could run them in parallel—therefore not creating a significant overhead in the process and maintaining an adequate latency.

In the last phase, we collected the top-K results from three retrievers (one sparse and two dense), where the limit K is set for each retriever, respectively.

B. Re-ranking

After the candidate passage retrieval, the next step involved merging all of the candidate passages into a single list, and then ranking the documents so that the most relevant ones were at the top of the results list. To re-rank, we used generative models of type T5 [7]—specifically, the multilingual version of mT5: the mt5-13b-mmarco-100k model[12]. Re-ranking is performed in the Polish language, however, we used the multilingual language model already fine-tuned as a re-ranker, using the following prompt:

Algorithm 1 Batch re-ranking relevance predictions using the T5 class model, function: get list of query–passage pairs to verify and return list of probabilities of their relevance.

```
def predict(self,
        query_passage_pairs: List[Tuple[str, str]],
        batch_size: int = 16) -> List[float]:

    probability_scores = []

    # create batches
    batches = []
    for i in range(0, len(query_passage_pairs),
                       batch_size):
        batches.append(
        query_passage_pairs[i: i + batch_size])

    for batch in tqdm(batches):
        #"Query: {q_txt} Passage: {p_txt} Relevant:"
        prompts = [f"Query: {q_p_pair[0]} " \
                f"Document: {q_p_pair[1]} Relevant:"
                for q_p_pair in batch]

        res = self.modelT5.predict_in_batch(prompts)

        for label, prob in zip(res[0], res[1]):
            final_prob = prob
            if label != 'true':
                final_prob = 1 - final_prob

            probability_scores.append(final_prob)
    return probability_scores
```

$$Query : \{query\_text\}\ Document : \{pass\_text\}\ Relevant :$$

The model was asked to generate for a given prompt either a "true" or a "false" token, from which we could extract the probability of relevance used to sort the candidates. Some pseudo-code of the batch prediction is contained in Listing 1.

The mT5 model used in our solution contains 13 billion parameters; in other words, it is an XXL model. It is based on the T5 model [7], and its adaptation to re-ranker was proposed by Nogueira [9]. It has recently been demonstrated that this model yields state-of-the-art results in zero-shot scenarios [8]. We used a variant based on the multilingual version of T5 called mT5, which was pre-trained on the multilingual mC4 dataset. The mt5-13b-mmarco-100k has been already fine-tuned for re-ranking, using the mMARCO dataset, a multilingual version of the MS MARCO passage ranking dataset that comprises 13 languages and was created using machine translation.

The mT5-based re-ranker computes the relevance (as a probability) of each passage for a given query. After all passages are scored, the list of results is re-ordered according to those scores.

V. Results

Using the validation, test, and train PolEval datasets and our own (the translated MS MARCO dataset), we present the various approaches toward a specific information retrieval challenge: the problem of passage retrieval where the sentence-

7	**25**	**25**	**75.32**
7	45	45	74.83

level queries are given and the corpus is counted in millions of passages.

First we evaluated various re-ranking methods on the PolEval validation dataset. In table I, we present some of the results, where we have one fixed retriever (BM25) plugged with the morfologik analyzer to introduce Polish lemmatization[13]. We tested the following re-rankers:

1) a bi-encoder based on RoBERTa-base, fine-tuned for one epoch on approximately 500 000 triplets, combining 135 000 PolEval training triplets and randomly selected triplets from the Polish MS Marco dataset;
2) a bi-encoder based on RoBERTa-large, initially fine-tuned for 10 epochs on a few million triplets (several million Polish MS Marco triplets randomly selected), and next fine-tuned for one epoch on 500 000 triplets, combining 135 000 PolEval training triplets and not-yet-used triplets from the Polish MS Marco dataset;
3) a generative model: GPT3 (curie), fine-tuned for one epoch on approximately 200 000 triplets, combining 135 000 PolEval training triplets and randomly selected triplets from the Polish MS Marco dataset;
4) a generative model: mT5-base-mmarco, fine-tuned for one epoch on 135 000 PolEval training triplets (Polish MS Marco was omitted because it is covered semantically by the mMARCO multi-language dataset);
5) a generative model: mT5-13b-mmarco, no fine-tuning.

As presented in Table I, the best results were achieved by mT5-13b-mmarco, an mT5-XXL model, fine-tuned on mMARCO (the multi-language version of MS Marco). Impressive results were achieved in the NeuCLIR track of TREC 2022 by the Unicamp team [14]. Despite the mT5 model being fine-tuned only on query–document pairs of the same language, it proved to be viable for cross-lingual information retrieval tasks, where query–document pairs are in different languages. The results in [14] demonstrate outstanding performance across all tasks and languages. For that reason, we used the same model for the Polish language—even though the mMARCO dataset does not contain Polish. We attempted to fine-tune the mT5-13b-mmarco model using the PolEval training dataset, but this process demanded very expensive infrastructure: at least four GPUs with high RAM capacity (such

[13] https://github.com/allegro/elasticsearch-analysis-morfologik

as the A100 80GB), and $ddp\_sharded$ strategy during fine-tuning to shard the entire model weights across all available GPUs. This approach enables the model's size to be scaled while using efficient communication to reduce overhead. Our initial experiments toward distributed fine-tuning failed to demonstrate any statistically significant improvement. This means that we could have trained it better. Ultimately, our solution used the original mT5-13b-mmarco, without fine-tuning on the PolEval datasets.

After selecting the best re-ranker, we analyzed how to improve the retrieval phase. After a number of experiments, we realized that bi-encoders as dense retrievers complement the BM25 results. Table II presents the evaluation of different retrievers' settings (sparse—BM25, and two dense retrievers based on bi-encoder architecture, as well as two types of RoBERTa models) in our solution. The results suggest that all three retrievers are needed. The first three rows of the table present different distributions of all 57 results sent for re-ranking: a) in the first row, we almost eliminated the BM25 results; b) in the second and third rows, we used only one dense retriever; c) we used seven results from BM25, and 25 from each of the dense retrievers; and d) we attempted to verify whether more dense retrievers results would help the results. Results a) and b) prove that all of of the retrievers are neeeded; result d) proves that increasing the number of dense retrievers by too many fails to improve the final NDCG metric.

VI. Conclusion

The goal of the PolEval 2022 Passage Retrieval task was to develop a system for cross-domain question answering retrieval in the Polish language.

The participants were given a training set that comprised question–passage pairs from the general knowledge domain, as well as three separate test sets with unpaired questions and passages from different domains: general knowledge, legal matters, and customer support. For each test question, participants were tasked with retrieving ordered lists of the ten most relevant passages from the provided corpora. The systems were scored using the NDCG metric.

Our solution was a multi-stage neural information retrieval system. The first stage involved a candidate passage retrieval step in which passages were retrieved using federated search over sparse (BM25) and dense indices (two FAISS indices built using dense retrievers based on bi-encoder architecture and Polish RoBERTa models). The second stage involved a re-ranking step of the previously-selected passages with a neural model, mt5-13b-mmarco. The model scored each passage by its relevance for a given query. The top-scoring passages were then retained as the final result.

Our system achieved second place in the competition. The results between top three entries did not differ significantly, and the quality of the solutions was high.

Acknowledgment

We thank Dr. Slawomir Dadas for his support—particularly in the bi-encoder training, and the Polish translation of the MS MARCO dataset.

***Abstract*—This paper presents the solution to PolEval 2022 Task 3: Passage Retrieval. The main goal of the task, was to retrieve relevant text passages for the query. There were three different domains of passages: wikipedia passages, allegro faq and legal documents. The proposed solution incorporated both dense and lexical indexes, as well as, reranking model and reached 67.44 NDCG@10 score in official evaluation.**

I. Introduction

INFORMATION retrieval is a task that aims at finding relevant information from a collection of documents. It involves searching through the whole collection based on a query provided by a user. The query is usually a question, and the system has to provide the documents or text fragments that contain the answer to the question.

The landscape of existing information retrieval datasets is predominantly populated by English language resources. This presents a challenge for the development and evaluation of models designed to handle a variety of languages. In response to this, the BEIR benchmark[11] was developed, a unique benchmark that focuses on the evaluation of information retrieval models in a zero-shot setting. The primary training dataset utilized in this benchmark is MS MARCO[8], a large-scale dataset in English, while a diverse array of other datasets are employed for zero-shot evaluation.

Recognizing the need for multilingual resources, a multilingual version of MS MARCO[1] was created. This version was translated into various languages using state-of-the-art automated machine translation techniques, expanding the reach of the dataset beyond English. However, it was observed that the Polish language was conspicuously absent from this collection.

In an effort to fill this linguistic gap and foster the development of Polish language information retrieval models, a Polish version of the dataset was introduced in the BEIR-PL benchmark[13], as well as Massive Automatically-created Polish Question Answering Dataset[10], which is a large collection of question and passage pairs.

The main goal of PolEval 2022 Information Retrieval task was to propose a cross-domain question-answering retrieval system in Polish language. The task encompassed three distinct domains of queries and documents. The training set was exclusively composed of data related to the trivia domain. The other domains, namely legal and customer support, were approached from a zero-shot perspective.

II. Related Work

The most common approach to the information retrieval systems is incorporating the two-step retrieval process with reranking. With this two-step process, the information retrieval system can provide more accurate and relevant results, enhancing the overall effectiveness.

A. Retrieval

In the retrieval phase of information retrieval, the system matches a user's query with the indexed collection of documents to identify the initial set of relevant items. It should be fast and efficient, as the collections may contain millions of documents.

One way to perform retrieval is lexical matching. Usually, it utilizes the Best Matching 25 (BM25), which compares the frequency of terms in the query and the document. BM25 is a ranking function used by search engines to estimate the relevance of a document to a given search query based on the terms it contains.

Elasticsearch[1], an open-source search engine, is a popular implementation of this approach. It uses BM25 as its default scoring function. This method has become a standard baseline approach for most retrieval benchmarks due to its good performance, effectiveness and lack of training.

Recent trends indicate that neural retrievers are capable of surpassing the performance of lexical term matching[6]. The neural network, based on pre-trained transformer model, encode both the query and the document into a low-dimensional space. The encodings are compared using inner product or cosine similarity. By pre-encoding the corpus into the index, retrieval can become very efficient and run online with millisecond level latency with libraries that support similarity search of dense vectors, such as FAISS[2]. Neural retrievers are trained as bi-encoders with contrastive loss, which makes the representations of passages and queries with the same information similar.

B. Reranking

The reranking phase is a subsequent process that follows the initial retrieval. It involves reordering the retrieved documents based on more complex models or additional features to

[1] https://www.elastic.co/

[2] https://github.com/facebookresearch/faiss

improve the ranking and elevate the most relevant documents to the top positions in the ranked list. The reranking problem can be formulated as a classification problem, where the query and the document are passed jointly to the model and the result is a binary classification, if the document is relevant for the query or not. Pretrained transformer models, like BERT model, can be effectively utilized for this task. The BERT model[9], trained using cross-entropy loss, is capable of performing the classification based on the representation of the [CLS] token. Additionally, a single-layer neural network is employed to compute the probability of a passage's relevance to a given query. This approach leverages the power of transformer architectures to capture complex semantic relationships in the data, thereby enhancing the accuracy of the classification task. Encoder-decoder models, such as T5, have also been employed for the reranking task. In the context of classification tasks, the tokenizer is augmented with two unique tokens. The first token, representing a 'true' value, is generated when the text passage demonstrates relevance to the query in question. On the other hand, the second token, denoting a 'false' value, is generated in instances where the passage does not exhibit relevance to the query.

III. Dataset

Data domains in PolEval 2022 Information Retrieval task:

- trivia domain - knowledge based general questions from a popular quizzes and passages from Wikipedia pages. The corpus contains 7M passages.
- customer support domain - FAQ based customer questions from the allegro.pl platform. The corpus includes 921 passages.
- legal domain - dataset was constructed based on legal documents, with questions formulated around the content of these documents. The corpus comprises a total of 26287 passages.

The training set contained only data related to the trivia domain, other domains were treated as zero-shot approach.

IV. Solution

The final solution incorporates three dense indexes, where documents are embedded with different neural encoders and one lexical BM25 index. The reranking is performed by the multilingual T5 model.

A. Experiment Setup

Most of the experiments were performed on NVIDIA RTX 3090 with 24GB GPU memory, except the final submission with mT5-13B model, which was run on A100 with 80GB GPU memory, due to the model size and computational complexity.

B. Experiments

The system was constructed from a combination of various dense indexes, each created with different models, as well as a lexical index created using the BM25 algorithm. From each index, the top documents were retrieved, and the collective set of all these documents was then forwarded to the reranking model for further refinement.

TABLE I
Retrievers results on TEST A without reranking. Combined* represents a score of all taken set of all returned passages from all retrievers at top k.

Retriever	NDCG@10	Recall@10	Recall@100	Recall@1000
BM25	50.77	37.55	45.29	51.65
mContriever	**58.43**	**56.03**	**70.05**	**77.93**
LaBSE	29.84	32.01	50.59	62.87
mDPR	31.42	33.95	51.32	66.09
Combined*	-	*63.84*	*75.15*	*81.34*

Experimental results shown in the table I demonstrated that, the best performance achieve mContriever dense retriever. Other dense retrievers got lower NDCG@10 and Recall@10 metrics than BM25, but they achieve better recall score at higher number of retrieved passages. Combined* results show recall when all top passages are combined from all four retrievers. In practice, due to duplicates, there are on average 3 times of the k passages. So for Recall@10, there were on average 30 passages taken into account for each query.

In the final solution, the following three dense retriever models were employed:

- mContriever-base-msmarco [3] - mBERT[7] based retriever trained in unsupervised manner with contrastive loss on multilingual data and afterward fine-tuned on English MS MARCO dataset[5].
- LaBSE [4] - is a language-agnostic BERT model for sentence embedding[3].
- mDPR-question-nq [5] and mDPR-passage-nq [6] - mDPR is a multilingual Dense Passage Retriever[15], a bi-encoder network where query and passage are encoded with different encoders trained in contrastive manner.

For reranking stage, different rerankers were taken into account. Initial testing were performed with following rerankers fine-tunned on MS MARCO dataset to reranking task:

- mMiniLMv2 [7] - multilingual MiniLMv2 model[12].
- mDeBERTa - improved multilingual DeBERTa model[4].
- mBERT[8] - multilingual BERT model[7].
- plT5[9] - T5-based language model train on Polish corpora[2]. Fine-tunned on Polish MS MARCO from BEIR-PL.
- mT5[10] - multilingual text-to-text transformer[14].

As shown in the table II, the bigger model, the better result. That is why, in the final solution, the mT5 model[11] with 13 billion parameters was employed. This model is very

	NDCG@10 TEST A	NDCG@10 TEST B
Final solution	**74.28**	**67.44**

computationally expensive to run, that is why there are no additional experiments performed on this model.

The final solution was achieved by retrieving the top 100 passages for each query from each dense retriever, and the top 100 reranked passages using the plT5-large model from the top 1000 retrieved from the BM25 index. The use of plT5 was dictated by the computational complexity of the mT5-13B model. As shown in table I, combined retrievers achieve already very high 75.15 recall at top 100 passages from each retriever.

Subsequently, the set of all top 100 passages from all sources was reranked using the mT5-13B model. The total number of passages to rerank was approximately 310 instead of 400, as some passages were duplicated. The final results are shown in the table III.

V. CONCLUSION

The optimal strategy to enhance the results of information retrieval involves the utilization of various dense retrievers, in conjunction with lexical BM25 matching. This approach amplifies the overall recall of the system, ensuring that passages not deemed relevant by one model may be identified as such by another. Another key insight is the importance of employing an effective reranker. The performance of the reranker is often correlated with the size of the model, with larger models typically achieving superior scores compared to their smaller counterparts. However, this advantage is accompanied by an increase in computational cost, which must be taken into account. Furthermore, reranking a larger number of top retrieved passages enhances the likelihood that a relevant passage is included in the set of reranked passages. This strategy, while potentially more computationally intensive, can significantly improve the precision of the retrieval system at the top ranks, which is often a critical requirement in many information retrieval applications.

Passage Retrieval in question answering systems in Polish language

Anna Pacanowska

Abstract—**This paper describes the submissions to Task 3 of PolEval 2022. Passage Retrieval is a problem of retrieving a passage relevant to the given query. It is an important problem with many practical use cases, especially in question answering. It is very beneficial if a model is generalizable, that is effective in various domains, even the ones it was not trained on. This is a challenge for many state-of-the-art models. In this paper I describe and test many different methods of approaching this problem – from standard techniques, such as BM25 and lemmatization to recently developed methods based on deep learning and transformers.**

I. Introduction

The aim of Task 3 of PolEval 2022 was to find a tool that retrieves the passages that contain the answer to the given question. The tool should work well not only on the domain it was trained on, but also other domains. The passages and queries are in Polish. I tested and compared different techniques and their combinations in order to find out which one will be the most effective – from the standard statistical approaches to advanced neural network based solutions. My goal was to find a solution that is not only effective, but also does not require great amount of resources to use – it should be memory and time efficient.

The best solution consisted of two stages. In the first I retrieved 1000 candidate passages using BM25 from Elasticsearch[1] on a corpus and queries lemmatized using Morfeusz2 [3]. In the second stage I calculated different scores and joined them using logistic regression. The scores were BM25 on lemmatized texts (with Elasticsearch), on unlemmatized texts and on bigrams. The rest of the scores were calculated using miniLM [13] on the texts translated with OPUS-MT [12]. They were computed on pairs (question, passage), (generated_answer, extracted_answer), (generated_answer question, extracted_answer passage). The answers were generated with GPT3 [1] and extracted with DistilBERT [10]. The code is available on GitHub[2].

II. Task

A. Description

The model's task was to retrieve 10 passages that were most relevant to the given question. To encourage generalizability the data was split into three distinct domains: Wikipedia passages, legal articles and Allegro FAQ. All training and development data came from the first domain and the other domains were present only in the test dataset.

TABLE I
Dataset sizes and number of questions from each domain

domain	questions source	passages source	avg length	corpus size
wiki-trivia	Jeden z dziesięciu	Wikipedia	44	7097322
legal-questions	generated from passages	legal acts	153	26287
allegro-faq	FAQ	help articles	48	921

B. Domains

Each domain contains a separate corpus of passages and different kinds of questions. The domains are very diverse – the samples in each of them have unique characteristics that influence the solution. They vary in passage length, corpus size, question types, number of matches and other important details (Table I).

1) wiki-trivia: The questions come from "Jeden z dziesięciu" and are classical trivia questions. They have short, factoid answers and require only common knowledge. The passages are fragments of articles from Polish Wikipedia extracted using WikiExtractor. The passages are quite short, but the corpus is very large: it contains over 7 million passages. The questions were created first, and the passages were independently matched later. That means that the answer is usually worded in a different way. Sometimes it requires good understanding of the text to notice the passage does in fact contain the answer. Usually there are multiple relevant passages to each question.

2) legal-questions: The passages are Polish legal acts. The questions were artificially generated from passages by people – a volunteer first looked at the provision, and then generated a question for it. This means that, unlike in wiki-trivia, the answers are usually similarly worded and the passage contains a direct answer. The language is quite heavy and contains specialist vocabulary. Answering the questions requires in-depth knowledge of Polish law, not only common knowledge. The questions sometimes are ambiguous and make sense only in the context of the passage they were generated from, for example "Kto sprawuje nadzór nad Akademią?" (which Academy?). The passages are often very long, but the corpus is significantly smaller with about 26 thousand passages.

3) allegro-faq: The questions and passages are fragments of FAQ and help articles from Allegro. There are a lot of 'How to' questions. These questions are often open-ended, there are multiple possible responses that can be worded in many different ways. The answers are usually specific to Allegro. For most questions there is only one matching passage. This is the smallest dataset with only 921 passages.

[1] https://www.elastic.co/
[2] https://github.com/aniapacanowska/passage-retrieval

C. Evaluation

The submissions were evaluated using NDCG@10 with binary relevance scores. The overall score was a mean of the NDCG@10 score for each question in the test set. For the test-A dataset only the total score was visible – the correct answers were not public. BM25 was the baseline solution provided by the task's authors.

III. Methods

In this chapter I describe all the methods I used in the experiments.

A. BM25

In the first experiments I tried to improve the baseline solution by using lemmatization. Lemmatization can be used to improve the performance of BM25 – similar technique was used in the best solution to the Question Answering task in 2021 PolEval [7]. There are many different models capable of lemmatizating texts. I tried four different options – Morfeusz2 [3], spaCy [2], a hybrid of these two and modified Morfeusz2.

Morfeusz2 is a dictionary-based morphological analyzer for Polish language. SpaCy is an open-source library for natural language processing. It features much more complex techniques, such as state-of-the-art neural networks.

One of major distinctions between these models is how they handle ambiguity (words with multiple possible lemmas). Morfeusz2 is not capable of choosing the correct lemma based on the context. In the ambiguous cases it simply provides all possibilities. At first I tried to take all of the provided lemmas. This may be beneficial for two reasons. There is no risk I will lose a potential match because of choosing the wrong lemma. The other benefit is that words in the same inflected form always have identical set of lemmas, so they will often result in multiple matches. That means they will be more valuable than words in different grammatical form that have only one matching lemma. This way the words in different forms will still count as a match, but less than ones with exactly the same inflection. On the other hand, it will also result in many false matches of lemmas that are incorrect in the given context.

SpaCy on the other hand always tries to pick the correct lemma. However, it is sometimes wrong and picks the wrong one. It can also return words that are not valid lemmas or even do not exist in the Polish language. Morfeusz2 never makes up invalid words – it has a very large dictionary, but in case the model encounters an unknown word it is returned unchanged.

The hybrid approach tries to get the advantages of both models. It uses spaCy to pick the correct lemma from the ones provided by Morfeusz2. If the spaCy result was not returned by Morfeusz2, it takes the most popular lemma in the corpus. The popularity was measured on the corpus lemmatized using only Morfeusz2. Lastly, I wanted to check if spaCy is really useful in the hybrid model. Perhaps simply always choosing the most frequent lemma could work just as well.

B. Bigrams

I tested also a variation of the BM25 scoring function in which the terms are bigrams instead of words. This might be useful, because a bigram match is a stronger indicator that the passage is relevant than a single word match. This is not a sufficient method on its own, but can be useful in addition to other scores.

C. Deep learning

The next step was to use more advanced and recent models. Each of the following experiments consisted of two stages. In the first stage I retrieved top 100 passages with standard BM25 from Elasticsearch on texts lemmatized with Morfeusz2 lemmatizer (the basic approach). This was necessary, because many of these models require a lot of computing power, so it would not be feasible to run them on each possible pair. The second stage was re-ranking the retrieved passages using the selected method.

D. BERT

The first approach was to utilize BERT in a way that was outlined in [6]. A passage and a query separated with SEP token are encoded by a pre-trained model. The CLS vector is passed to a simple classification layer to predict whether the passage is relevant to the query. The model is fine-tuned on this task. I wanted to find out whether this approach would work well for the wiki domain and if it would be capable of generalizing to other domains. I used HerBERT [4] as the pre-trained Polish model.

E. Translation

Most state-of-the-art architectures for passage retrieval are very large and training them requires a lot of time and computing power. For this reason I decided it would be beneficial to use a pre-trained model. However, I could not find a good model for passage retrieval in Polish. There is much greater choice of models for passage retrieval in English. I used the OPUS-MT model [12] from Huggingface[3] in order to translate all of my data into English. I tested if translating the data and using more powerful models would improve the results.

F. miniLM

MiniLM [13] is a small model trained using knowledge distillation with BERT-base. One of its variants was fine-tuned on MSMARCO passage ranking dataset [5] with the ensemble of BERT-base, BERT-large and ALBERT-large as teacher models. This version achieved the best results for most IR tasks according to the BEIR paper [11], which is why miniLM was my first choice. An additional benefit is that small number of parameters makes the inference really efficient. MiniLM calculates a relevance score for a pair of query and passage.

[3] https://huggingface.co/Helsinki-NLP/opus-mt-pl-en

TABLE II
LIST OF ALL SCORES USED (IN DIFFERENT COMBINATIONS) WITH LOGISTIC REGRESSION

Logistic regression features
BM25 (elasticsearch) for lemmatized texts
BM25 for unlemmatized texts
BM25 for bigrams (unlemmatized)
miniLM for (question, passage)
miniLM for (GPT3_answer question, DistillBERT_answer passage)
miniLM for (GPT3_answer, DistillBERT_answer)
miniLM for (chatGPT_answer question, DistillBERT_answerpassage)
miniLM for (chatGPT_answer, DistillBERT_answer)

G. Answer generation

There are two types of question answering models: extractive, which extract the answer from the given passage and generative, which generate the answer based only on the model's knowledge. Similarity between the answer generated by a generative model and the answer extracted from given passage could help miniLM decide whether the passage is relevant. If these answers are the same or similar it can be a good indicator that the passage is relevant. It can be misleading as well – the answer from either model may be incorrect or the same only by accident. I tested two variants. In the first I concatenated the generated and extracted answers to the beginning of the question and the passage, respectively. In the second I calculated the relevance score only between the answers.

As the extractive model I used DistilBERT [10], which is a distilled version of BERT. I tested two different generative models, both based on GPT: GPT-3 and chatGPT (based on GPT-3.5). These models are not open source – it was necessary to use the API provided by OpenAI to connect with them. Even if they were available I would not be able to run them locally as they are too large.

H. Ensamble

The last idea to improve the results was to gather the scores from multiple methods instead of relying on a single model. The test dataset is very different from the train set, so the function combining the scores had to be simple. I decided to use logistic regression.

IV. Experiments

A. BM25 with lemmatization

These experiments were conducted with the use of Elasticsearch. I created and indexed a lemmatized corpus of passages with each lemmatizer (Morfeusz2, spaCy, hybrid and Morfeusz2-freq). Next I lemmatized the questions and retrieved the most relevant passages using Elasticsearch. The results on the dev dataset are shown in the Table III.

Lemmatizing the texts significantly improved the results. The impact considerably depended on the chosen model. The score with Morfeusz2 and spaCy was similar, with spaCy slightly higher. Morfeusz2 is even 20 times faster (on CPU) than spaCy, which makes it much easier to use. This is because Morfeusz2 is dictionary-based and spaCy is a complex neural network.

TABLE III
DIFFERENT LEMMATIZATION METHODS (DEV DATASET)

method	NDCG@10
no lemmatization	18.62
spaCy	21.41
Morfeusz2	21.15
hybrid	24.47
Morfeusz2-freq	**25.24**

The hybrid approach clearly outperformed both models. Morfeusz2 almost always provides the correct lemma, but usually together with a few incorrect ones. SpaCy on the other hand sometimes returns incorrect or even invalid lemmas. The hybrid approach eliminates both these issues – Morfeusz2 is used to check if the spaCy lemma is valid. If it is not, the most popular lemma gets chosen.

Surprisingly, the last technique turned out to be the best. The lemma was picked solely based on its frequency in the corpus lemmatized with Morfeusz2. That means spaCy was not necessary at all in the hybrid approach – the alternative method of choosing the correct lemma worked even better.

All methods have problems with proper names (such as surnames or places). There are too many of them for any model to know, so they are not properly lemmatized. For example, the lemmas from texts 'Bilbo Baggins' and 'Bilba Bagginsa' will be different.

B. Deep learning

In the following experiments I tested approaches based on deep learning and transformers. The passages to be re-ranked were fetched using Elasticsearch on a corpus lemmatized with Morfeusz2 (basic approach). I worked with the Huggingface library [14]. The submissions are collected in the Table IV. I did not calculate the results of all models on the dev dataset, because it would unnecessarily take a lot of time and resources. Test-B data appeared in the last two weeks, so I tried only the models that did well on test-A.

The submissions were evaluated on the PolEval website. The other scores in this section were calculated with my script. There are slight differences (around 0.5) that are a result of different behavior on questions where the correct passage is repeated.

In the following sections I describe in detail all of the methods I used.

C. BERT re-ranking

The first method to re-rank the passages was to fine-tune a BERT model (3 in Table IV). The input consisted of a question (sentence A) and a passage (sentence B). On top of BERT there was a simple classification layer (BertForSequenceClassification head), which was trained to predict whether the input pair is relevant based on the CLS vector. I fine-tuned the HerBERT-base model on the train dataset for one epoch. The model did better than the previous methods on the dev

TABLE IV
SUBMISSIONS SENT TO POLEVAL. SIZE: NUMBER OF PASSAGES TO RE-RANK, COMBINATION: METHOD OF JOINING THE SCORES FROM DIFFERENT MODELS, LR-DEV: LOGISTIC REGRESSION TRAINED ON THE DEV DATASET, LR-DEV: LOGISTIC REGRESSION TRAINED ON THE TRAIN DATASET

dataset, but the results on the test dataset dropped three times compared to baseline. The model learned well for the wiki domain, but was completely unprepared for the legal and allegro datasets. It would suggest that this technique of BERT re-ranking generalizes very poorly to other domains.

D. Translation

For the next experiments I had to translate the data to be able to use the models trained in English. The maximum length of the input for OPUS-MT model is 512 tokens. There are many longer passages in the datasets (especially in the legal corpus), so they had to be split. I tried to avoid splitting the sentences – passing only a fragment of a sentence might confuse the translator. However, I noticed that OPUS-MT does not work well for long texts – even if they fit in the limit. It often translates only some fragment of the input and leaves out the rest. This was not problematic for Wikipedia passages, which are usually short, but started to be noticeable for longer texts. So I split the passages into even smaller pieces (at most 0.3*512) and translated each separately. Then I joined all translated fragments.

E. miniLM

The first model I tested on the translated data was miniLM[4] with 6 layers fine-tuned on MSMARCO. Again, there were some problems with passages that were too long to fit into the model (the input can be at most 512 tokens). I split the passages into overlapping smaller pieces. Each fragment starts in the middle of the previous one – that way I want to avoid a situation where part of the answer is in one fragment and the rest is in the other. The fragments are at most 0.7*512 words to take into account that some words translate into multiple tokens. When ranking the passage, its score is the maximum of its fragments' scores. Re-ranking based on the scores computed by miniLM made a significant improvement over the baseline (4 in Table IV).

F. Logistic regression

I tried to join the results from the models I tested so far. This way I could aggregate the information stored in different scores. The features I considered were:

- BM25 (elasticsearch) for lemmatized texts
- BM25 for unlemmatized texts
- BM25 for bigrams (unlemmatized)
- miniLM score

I used the logistic regression model from sklearn library [8] and trained it on the train dataset (5). This resulted in a small, but noticeable improvement. Surprisingly, even larger improvement (on the test dataset) was achieved by training on the dev dataset instead (6). It might be because the train dataset is over 7 times larger and logistic regression started overfitting to the wiki-trivia domain.

In the next experiments I continued to use logistic regression and simply added new scores as additional features.

G. Answer generation

The next step was to use the question answering models. I generated an answer for each question using a generative model and extracted the answer from each (question, passage) pair using an extractive model. I did not want to exceed the free quota of the generative models, so the answers were generated only for the dev and test datasets. I was able to fit all my requests into the free trial. I calculated the miniLM score for each pair ('generated_answer question', 'extracted_answer passage') as well as just (generated answer, extracted answer). These results were then added as additional features to the logistic regression (trained on the dev dataset). As the extractive model I used DistilBERT[5] fine-tuned on the SQuAD dataset [9].

1) GPT3: The first generative model I tried was GPT3 – specifically gpt3-davinci, which is described in the documentation as the 'most capable'. I used the API provided by OpenAI. Each prompt was based on the question translated into English.

Normally, the answers given by the model are quite elaborate and if it does not have the requested information, the answer is 'unknown'. I wanted the answers to be concise and informative – even if the model had no information, I wanted it to guess the answer. I decided the short answers are better, because they do not contain unnecessary descriptions which could confuse miniLM. This also significantly reduced the cost of each query, because the responses are priced by the number of tokens. The guessed answers, even if incorrect, still might contain some useful information, such as the type of the answer (a number, a name etc.). I modified the prompts in order to get the desired results. To each question I added "Shortest answer. NOT unknown.". Temperature was set to a low value of 0.1. This way the model would usually get the true answer if it had enough knowledge, but was able to guess if necessary.

[4] https://huggingface.co/cross-encoder/ms-marco-MiniLM-L-6-v2

[5] https://huggingface.co/distilbert-base-cased-distilled-squad

Adding these answers to the dataset and calculating the scores as described above resulted in another small improvement (7 in Table IV). By inspecting the answers I noticed that they are usually correct for wiki-trivia questions, but often wrong for questions from other domains. This makes sense, because the wiki questions are based on common knowledge. Other domains require specific knowledge of Polish law or the policies of Allegro. The questions can be open-ended, which also makes it more difficult to guess the correct answer.

2) ChatGPT: I tried also the new chatGPT model. This time the questions could be in Polish as well as in English because this model is multilingual. I decided to use the Polish ones because chatGPT is likely better in translation than OPUS-MT that I used until now. However, it can have a downside – the translations might be inconsistent. The same expression in Polish could be translated differently in the answer by chatGPT than in the passage by OPUS-MT.

As before, I wanted to receive a concise answer in English. Interesting thing is that unlike GPT3, chatGPT almost never answers ’unknown’. It is guessing even without the suggestion in the prompt I had to add before. For the system prompt I left the default "You are a helpful assistant". To the questions in the legal domain I added "W Polsce" and in allegro domain "W allegro" in hopes it would help the model answer correctly. I finished each user prompt with "Shortest answer in english". Surprisingly, it turned out that this addition not only did not improve the results, but in fact made them much worse (8).

H. Combining scores

I compared a few different methods of combining the scores I gathered so far. The method should be quite simple to avoid overfitting to only wiki domain. I tried training a simple two layer neural network for classification. This turned out to be much worse than logistic regression (9). Ranking only by miniLM score with GPT3 answers also gave considerably worse results (10).

I. Bigger data

Sometimes the relevant passages are not included in the top 100 retrieved using BM25. The number of relevant passages found in the different positions in the ranking created using BM25 scores can be found in the Table V. The results were calculated using the training dataset and different lemmatizers.

The passages that fall outside of the top 100 will of course never be found by the re-ranker. On the other hand, adding a lot of new possible passages can result in false positives. I repeated some of the previous experiments on the top 1000 passages (retrieved by Elasticsearch with Morfeusz2, as before). In every case the outcome was considerably better. Re-ranking top 1000 passages with miniLM and GPT3 combined with logistic regression resulted in the best score I was able to achieve (11).

The main downside of this solution is a much larger computational cost. The most expensive task is translation, which was a problem especially for wiki domain that has the largest corpus. Another problem was that Elasticsearch sometimes retrieves less passages than requested when the corpus is small compared to the requested size. It is especially visible for allegro-faq, where there are only 921 passages, but Elasticsearch often retrieves even less. This happened for the top 100 as well, but rarely.

TABLE V
NUMBER OF RELEVANT PASSAGES IN DIFFERENT RANKING FRAGMENTS

lemmatization	:10	11:100	101:1000	1001:10000	10001:
none	2918	2755	2648	2078	4049
spaCy	3447	3476	2930	2023	2572
Morfeusz2	3385	3341	3044	2181	2497
hybrid	3952	3841	3064	1897	1694
Morfeusz2-freq	4073	3863	3091	1839	1582

I tried to simplify the re-ranking method and pass only the features that seemed most important: unlemmatized BM25 score, bigrams BM25 score, miniLM score and miniLM score on pairs concatenated with answers. This turned out to be only minimally worse than providing all scores (12).

J. Incorrect answers

In this section I analyze the incorrect answers given by the best model. The data is far too large to fully analyze it manually, so these are only some observations. The model always provides exactly 10 passages even though the number of correct ones is smaller. This means that retrieving a passage without the answer is not an error as long as it is lower in the ranking than the relevant passages. The incorrect passages are often relevant to the topic, but do not contain the answer to the given question. Sometimes the passage describes something similar, but not the same – for example the results for the question about the host of the show ’Zrób to sam’ talk about the hosts of shows such as ’Sam tego nie rób’.

There are also some errors in the annotations. Some passages that were correctly retrieved by the model were not marked as relevant. There were also cases in which the annotated passage did not contain the answer. Other times it did have the answer, but without the necessary context. For example for the question "In which book Adam Mickiewicz describes Jankiel’s concert?", one of the annotated passages says only that Jankiel is a character in "Pan Tadeusz" movie – does not mention the concert or the book’s author. This does not happen only in the allegro domain because there the passages were verified manually. However, I think that despite these problems the datasets are still useful in measuring the performance of the models.

K. PolEval results

The final results are in the Table VI. My models clearly outperformed the baseline. The score of my best model is around the middle between the basic BM25 and the best solution of PolEval 2022.

After the contest ended, the answers for the test datasets were published. I compared the performance of my best model and the baseline on different domains (Table VII). It turned out that wiki domain was clearly the most difficult. The first reason

TABLE VI
FINAL RESULTS

model	test-A	test-B
baseline BM25 (Elasticsearch)	50.38	38.84
my best model	62.51	54.23
PolEval best solution	75.40	69.36

TABLE VII
SCORES ON DIFFERENT DOMAINS

	test-A			test-B		
model	wiki	legal	allegro	wiki	legal	allegro
baseline BM25 (Elasticsearch)	19.76	81.10	49.16	18.45	80.32	48.05
my best model	38.27	77.70	69.96	37.11	79.00	67.92

for that is a very large corpus (over 7 million passages). The other can be that the passages and the questions were created independently and matched later, so the answers are often indirect or differently worded. The score on allegro domain was much better, probably because of a very small number of possible passages (only 921). On both of these domains my model was much better than BM25. The legal domain was definitely the easiest. I believe it is because the questions were generated based on the passages, so the wording was usually very similar. Additionally, the questions often contained some unique words that pointed to a certain passage. It is the only domain where the new solution was slightly worse. The differences between the domains explain the lower score on test-B, where the majority of passages came from the wiki domain.

V. CONCLUSIONS

In this article I have explored various methods of passage retrieval, both traditional statistical approaches as well as recent models based on transformers.

The standard statistical methods, such as BM25 are a good starting point. They can be improved by means such as lemmatization. The choice of the lemmatizer largely impacts the performance. These methods don't have a problem with generalizability, because they are independent of the domain. Deep learning approaches are definitely more capable, but it comes at the cost of a much higher computational complexity. The most optimal way to use them is together with less accurate, but faster statistical methods. A good approach is to fetch a subset of passages with BM25 and then re-rank it with an advanced model, such as miniLM. Retrieving more passages to re-rank improves the results, but significantly increases the necessary resources, so it is important to find a balance. Knowledge distillation is an incredibly useful technique to reduce the computational cost of using a model. Translation is a good method when there are no models pre-trained in the correct language. It can be a great alternative to training a model from scratch, especially with limited resources.

Question answering is another good way to boost the results. Generative models are powerful, but expensive to use. However, they need to be used only once per question, unlike other methods that need to calculate a score for each pair of passage and query. It is important to choose the right model – GPT3 answers helped the re-ranking, but chatGPT did the opposite. Crafting a good prompt matters as well.

The best result was achieved by joining different techniques using logistic regression. Even a model that is less accurate on its own can still be useful to increase the score of a better model.

VI. NOTE

This paper is taken from my master's thesis written under the direction of dr Paweł Rychlikowski at the University of Wrocław.

FedCSIS 2023 Challenge: Cybersecurity Threat Detection in the Behavior of IoT Devices

Andrzej Janusz

Marcin Michalak

CYBERSECURITY Threat Detection in the Behavior of IoT Devices was the 9th competition organized in association with the FedCSIS conference series at KnowledgePit.ai. The goal was to detect attacks on IoT devices on the basis of data provided by Efigo company, describing the changing behavior of devices, and known moments of cyberattack attempts. The data set was generated as a part of a SPINET project aiming at improving the cybersecurity of IoT device networks.

The increasing significance of many IoT device applications motivates scientists to develop techniques for cyber safety improvement in many ways. In our case, based on the changing device behavior, it was expected that the profile of processes running on the device should change during the attack attempts.

The competition data was collected in a simulated environment - IoT devices were emulated in a separated network, where attacking servers were also plugged in. The scenario of attacks was known, so it was possible to tag the behavioral data as “normal” and “unusual”. Based on that information participants tried to develop classification models to predict whether the device is being attacked or not.

The top four competitor groups were invited to submit a paper describing their solutions to our special event at the FedCSIS 2023 conference. These papers are included in this chapter of the conference proceedings and are preceded by a paper describing in detail the competition, authored by the organizers. The most of presented approaches were based on gradient-boosting algorithms. That is not surprising - such models play an essential role in different fields of application. However, they are not so easy to interpret which may cause difficulties in better understanding the nature of IoT devices’ behavior change during cyberattacks.

***Abstract*—The paper discusses a data science competition centered around the development of an anomaly detection system for IoT devices. The competition utilized a unique environment that allowed for the operation and monitoring of real IoT devices, including scheduling of attacks on these devices. The environment was used to collect the data, which included both normal and attack-induced behavior of IoT devices. The paper presents the background of the competition, the top models submitted, and the competition results. The paper also includes a discussion about restrictions related to the use of synthetic attack data as input for constructing anomaly detection systems.**

***Index Terms*—data science competitions; KnowledgePit.ai platform; cybersecurity; ML applications in log analysis; ML data quality**

I. Introduction

THE INCREASING number of Internet of Things (IoT) devices being used in present times implies the need to pay attention to ensure a proper level of their safety. The market review indicates that there is a lack of products that can increase the security of IoT devices while reducing the risk of successful attacks. This conclusion led to the idea of an IoT-dedicated system for detecting anomalies, which could be the result of an attack.

The consortium of EMAG, QED, and EFIGO runs a project focused on IoT devices cybersecurity – SPINET. Within that project, an environment that allows running and monitoring real IoT devices as well as collecting data describing their behavior has been developed. The environment also offers the possibility to schedule and perform attacks on monitored devices. The collected data, which describes both normal and attack-induced behavior of IoT devices, became the basis of the FedCSIS 2023 challenge.

This paper briefly presents the background of the competition, showcases the best models submitted to the challenge, and discusses the competition results and their potential impact on further system development.

II. Related Literature

Anomaly detection is a well–known approach for data analysis in many specific domains. As the IoT issues are becoming more and more interesting it is intuitive that any new or improved models should be tested on some data with anomalies to evaluate their capabilities. During the last decades, dozens of datasets related to network traffic security, operating systems or IoT monitoring were published. A brief summary is presented in Table I.

To reflect the nowadays trends in the data, we limited our search to datasets not older than 6 years and closely related to the IoT domain. Their short descriptions are presented below.

The environment for Bot–IoT [4] data capturing consisted of three components: network platforms, simulated IoT services, and extracting features. The network platforms included normal and attacking virtual machines. The IoT services simulating various IoT sensors were connected to the public IoT hub. The network environment that the dataset was collected from contained a combination of normal and botnet traffic. The dataset provides original packet capture (PCAP) files, generated Argus files and CSV files. The files separation is based on attack categories and subcategories. The dataset

files include denial-of-service (DoS) and distributed denial-of-service (DDoS) attacks, operating system and service scanning, keyloggers and data exfiltration.

The TON_IoT datasets [14] are IoT and Industrial IoT (IIoT) datasets which files contain heterogeneous data sources collected from IoT and IIoT sensor telemetry data sets, Windows 7 and 10 operating systems datasets, as well as Ubuntu 14 and 18 Transport Layer Security (TLS) and network traffic datasets. The data was collected in a realistic and large-scale network. A testbed network was created for the Industry 4.0 network, which includes IoT and IIoT networks. The test platform was deployed using multiple virtual machines and hosts of Windows, Linux, and Kali operating systems to manage connections between the three tiers of IoT, Cloud, and Edge / Fog. Various attack techniques such as DoS, DDoS, and ransomware targeting web applications, IoT gateways, and computer systems on the IoT/IIoT network were conducted. The datasets were collected in parallel processing to collect several normal and cyber-attack events from network traffic, Windows audit trail, Linux audit trail, and IoT telemetry data.

The IoT-23 [20] is a dataset of network traffic from Internet of Things devices. The dataset consists of 23 captured different IoT network traffic scenarios. These scenarios were divided into twenty network captures from infected IoT devices that the malware samples were performed in each scenario and three network captures of the actual network traffic of the IoT devices. In each malicious scenario a specific malware sample was run on a Raspberry Pi. Scenarios included the following malware samples used to infect the device (Mirai, Torii, Trojan, Gagfyt, Kenjiro, Okiru, Hakai, IRCBot, Linux Mirai, Linux Hajime, Muhstik, Hide and Seek).

Malware on IoT [2] is a dataset of the monitoring of real IoT devices infected by malware. The dataset consists of labeled network traffic files stored during the long-lived real IoT malware traffic. It is divided into five subsets containing results of network traffic capturing during the Mirai malware attack and two subsets of honeypot network traffic capturing logs including protocols (HTTP, SSL, TCP, UDP) and connections statistics. The honeypot was a network camera.

The WUSTL-IIOT-2021 dataset [18] contains network data from industrial Internet of Things (IIoT) monitoring. The dataset was developed on test bench involving the industrial control systems (ICS) model including supervisory control and data acquisition (SCADA) systems. The testbed was dedicated to controlling a water storage tank, which is a part of the process of water treatment and distribution. The dataset was preprocessed and cleaned (rows with missing or corrupted values and extreme outliers removed. Artificially generated Command Injection, reconnaissance and DoS attacks were recorded in the set. It accounted for about 8% of network traffic.

The Edge-IIoTset is a dataset [19] containing monitoring data from IoT devices and IIoT applications. The IoT data was generated from more than 10 types of IoT devices such as low-cost digital temperature and humidity sensors, ultrasonic sensors, water sensors, level detection sensors, pH meters, soil moisture sensors, heart rate sensors, flame sensors, etc. Fourteen attacks related to IoT and IIoT communication protocols were identified and analyzed (divided into five threats) including DoS/DDoS attacks, information gathering, man-in-the-middle, injection attacks, and malware attacks.

The number of available datasets from IoT and IIoT devices monitoring is still relatively small in comparison to the rapidly growing number of such devices in the world (it is estimated that this year, their number will reach approx. 17 billion devices). Most of the available datasets contain data from network monitoring during normal operations and attacks. The data sets described in detail contain data from the audit of real and simulated IoT devices and their network environment. The available datasets providing kernel event monitoring data are from Solaris (DARPA 98-99).

It is also worth noting that this data science competition is the second cybersecurity-related challenge organized on the KnowledgePit.ai platform [21]. The first one, IEEE BigData 2019 Cup: Suspicious Network Event Recognition, was organized in 2019, jointly with Security-on-Demand company [22]. The platform also hosted a competition related to the monitoring of network devices [23]. Furthermore, KnowledgePit.ai has been a host to a number of data science competitions related to monitoring hazardous environments using networks of sensors [24].

III. FedCSIS 2023 Challenge

The challenge data were generated within the simulation environment which was an extension of the software framework described in detail in [25]. This real components simulation environment consisted of an IoT device (Raspberry Pi) and additional devices responsible for HTTP traffic generating and performing the attacks. The whole environment was plugged into a separated network to assure no other influences on the monitoring device.

It was necessary to model a normal way of device operation as well as to simulate some attacks to assure that the collected dataset contains both, safe and unsafe states of device usage.

In order to obtain a data sample describing both the normal operations of devices and the moments when attacks were carried out, it was necessary to ensure typical network traffic and triggering processes characteristic for it, as well as to prepare a scenario of external attacks on the device.

Typical operation conditions were generated continuously in several independent ways:

- SSH sessions: with the interval from 10 seconds up to 12 hours an administrator logs into the device and runs from 3 up to 10 commands (the time between each command varies from 0.5 to 11.5 seconds), later the administrator logs off;
- HTTP WAN traffic: the device has a built-in HTTP server, so it was possible to simulate cyclic queries; queries based on the real (other) WAN-connected device and their intervals were also taken from the historic data;
- file transfer: the file transfer service was run on the device (the endpoint) to simulate a periodic software update: a binary file of a size varying from 512 to 1,024 bytes was sent with the random interval from 1 to 12 hours;
- specialized HTTP queries: the device contained a dedicated endpoint for outer status checking/device clock synchronizing so it was possible to send the query that implied the “date -date now” command run (such a query was released with 9.5–11.5 second interval).

The environment provided the ability to perform two kinds of attacks: remote code execution and path traversal. In the case of the first one, the attack is carried out through a vulnerable endpoint “clock.php” and a query that uses a command injection vulnerability is invoked. Then, a reverse connection (with the attacking host) is established and an interactive session of the console “sh” program is run. Afterward, random commands are invoked with an interval of up to 20 minutes.

A path traversal vulnerability is used to upload the file into an unusual location (path) on the device. Files were saved into one of the following locations:

- /dev/shm/
- /var/tmp/
- /tmp/

The name of the file was random, as well as its size (from 20 to 5,024 bytes). Also, the number of files was varying (from 1 to 10) and the time between uploads was between 0.5 and 10 seconds.

A. Data preparation

System logs of each device were extracted, saved, and preprocessed resulting in a tabular dataset consisting of statistical characteristics of each feature aggregated over a rolling window of a fixed size.

The data created in such a way had certain characteristics typical of simulated data:

- The generated dataset contained a huge amount of information. Within this data, only a small fraction was collected during attacks on IoT devices. This resulted in big files which were hard to operate on containing only a small amount of data that could serve as valuable training data.
- Because the number of continuous attacks was small (not exceeding 20) it is reasonable to assume that the dataset makes it impossible to train a general-purpose IoT-attack-detection model. The methods chosen for generating attacks represent only a small fraction of the attack classes identified in the wild [26].
- Most of the created data was highly repeatable, resulting in a dataset of low diversity. This is normal behavior for IoT devices that operate in a repetitive manner.
- The training and testing data were created from a single source. This made it possible to achieve a near 100% accuracy on the testing data by identifying the process id (PID) values of processes that were targeted during an attack and using this knowledge to identify malicious activities in system logs. This is a highly improbable scenario in reality since restarting a process (or restarting the whole system) results in a new PID being assigned to the processes.

B. Evaluation procedure

The task in this challenge was to design an accurate method to predict whether system logs from an IoT system indicate the occurrence of cyberattacks or not. The quality of submissions was evaluated using the ROC AUC measure. The solutions were evaluated online and the preliminary results were published on the public leaderboard. The preliminary score was calculated on a small subset of test records, which was the same for all participants. The final evaluation was conducted after the completion of the competition using the remaining portion of the test records.

C. A baseline solution

Two baseline scores were established. The first one assumes a realistic scenario, while the second one was tailored to the dataset used in this competition, leveraging the knowledge that classification of PIDs enabled achieving a near 100% accuracy score on a portion of the test dataset.

1) Baseline score 1: The first baseline was calculated using an XGBoost model. Since the problem is a highly unbalanced classification task, the XGBoost's prior score was set according to the proportion of the system logs containing attacks (≈0.97).

The XGBoost model in this scenario was selected after comparing its results to Random Forest models (with and without class weights according to the proportion of the system logs containing attacks) and an XGBoost model without a prior score.

The baseline score achieved this way was 0.691 (ROC AUC). Examining the feature importances revealed that over 65% of the result was dependent on features created using the 'SYSCALL_pid' column which led to investigating the PID-based dependencies in the data and creating another classifier which gave the second baseline score.

2) Baseline score 2: Since the data used in this experiment was generated from a single artificial source, the PIDs corresponding to attacks were constant over time. For this reason, it is possible to list the PIDs of processes present during attacks and classify them in the test dataset as attacks.

This technique can also be altered by not strictly looking for all malicious PIDs in the test dataset but looking for PIDs that frequently occurred during attacks. Such an approach makes it possible to introduce a margin of error and thus filter out PIDs that could be falsely labeled in the training dataset as being part of an attack.

Performing a search-based classification as described above without any ML model resulted in a ≈0.93 ROC AUC score. Since a frequency-based method of classifying malicious PIDs was used; this score can be easily improved by further examining the PID values distribution in the training dataset.

IV. Challenge Outcomes

The competition was quite successful, with 78 participating teams and nearly 600 correctly formatted submissions. The majority of submitted solutions follow a general pattern of processing/cleaning the data → performing feature engineering → feature selection → model construction. However, there were some differences in the approach due to the hierarchical/complex form/format of the dataset. The internal data structure, i.e., a single observation is given as a separate file with a variable number of entries imposed the need for some form of aggregation. Among the submissions, we could observe different approaches in this regard. Some of the teams aggregated each of the input data files resulting in a representation where each observation (each file) was represented as a single row, while other teams concatenated all input files performing the aggregation only at the very end on the basis of predictions of classifiers working the level of file entries. The feature extraction/engineering stage was also approached differently by different teams. The total number of constructed features ranged from as few as several to several hundred thousand (including binary-encoded features). The most popular machine learning models used among the contestants fall into the category of gradient boosting machines - with particular implementations provided by commonly used open-source libraries like XGBoost, LightGBM, and CatBoost. However, also several other models could be encountered, including classical ones like decision trees, random forest, kNN, and logistic regression, as well as, custom methods, e.g., using micro-predictors build on top of features constructed using target guided binning, which achieved one of the best final scores.

TABLE II
Final results of the competition. The scores of the top 10 teams and their number of submitted solutions are shown.

Rank	Team name	Preliminary	Final score	#subs
1	MathLogic	1.0000	0.9999	76
2	dymitr	1.0000	0.9997	59
3	The Fellowship of the Cybersecurity	0.9997	0.9995	5
4	DML	0.9999	0.9993	176
5	Y-Team	1.0000	0.9986	8
6	Cyan	0.9940	0.9966	69
7	PisaTeam	1.0000	0.9957	10
8	hieuvq	0.9772	0.9718	101
9	Stan	0.9190	0.9293	14
10	baseline	0.9633	0.9257	-
...	...	...	...	...

Most of the competition participants decided to use the PID analysis-based approach to solve the task due to its high effectiveness. In such a case, the most significant differentiating factor between solutions from different teams was their approach to feature engineering. The final results of the top 10 teams are shown in Table II.

V. Conclusions and Future Work

The method of constructing the simulation environment and creating the competition dataset was sufficient to train and compare various machine learning models, but only to determine potential directions for future research and development specifically for cybersecurity data from IoT devices. It should be noted that such data is not suitable for training general-purpose machine learning models.

Based on the results of the competition and techniques employed, we plan future work to focus on the aspect of training data sets quality. Specifically - on tuning techniques for creating synthetic data sets that reflect various characteristics of real-life data. We plan to explore a hybrid approach, in which such synthetic data is used to augment data gathered from production IoT systems, in such a way as to create training sets that are optimal for training of a production system for analysis of anomalies in IoT behavior.

The end goal is to create a system that will be usable in various fields of application - most notably one that works on data gathered from utility providers (electricity, gas, water), manufacturers of video surveillance devices, and smart city infrastructure (interactive road signs, passenger information systems, control systems). Those companies will receive a toolkit that can be implemented in their own products. Additionally, the solutions can be utilized for protecting home devices such as smart lighting, electrical installations, alarm systems, and others.

***Abstract*—Internet of Things (IoT) based systems are vulnerable to various cyber-attacks and need advanced and smart techniques in order to achieve their security. In the FedCSIS 2023 big-data competition, participants are asked to construct scoring models to detect whether anomalous operating systems were under attack by using logs from IoT devices. These log files are variable-length sequences with high cardinality features. Through in-depth and detailed analysis, we find out concise and efficient methods to handle these huge volumes, variety, and veracity of data. On the basis of this, we create detection rules using the fundamental knowledge of mathematical statistics and train gradient boosting machine (GBM) based classifier for attack detection. Experimental and competition results prove the effectiveness of our proposed methods. Our final AUC score is 0.9999 on the private leaderboard.**

***Index Terms*—Internet of Things; Cyber security; Machine Learning; Variable-length Sequences; High-cardinality Features**

I. Introduction

INTERNET of Things (IoT) plays an essential role in remote monitoring and control operations. IoT based systems are widely used in the fields of environment, home automation, healthcare, smart grid, transportation, agriculture, military, surveillance, etc. In 2023, the number of devices connected to networks is expected to be 3 times higher than the global population [1]. With the IoT, sensors collect, communicate, analyze, and act on information. This offers new ways for technology, media and telecommunications businesses to create value. But it also creates new opportunities for that information to be compromised. The IoT connect systems, applications, data storage, and services become a new gateway for cyber-attacks as they continuously offer services but lack of adequate security protection. In 2020, nearly 1.5 billion cyber-attacks on IoT devices were reported [1]. These attacks may steal important and sensitive information that causes economic and societal damages. To address critical challenges related to the authentication and secure communication of IoT, many people (such as Jarosz et al.[2]) have developed various authentication and key exchange protocols for IoT devices. But software piracy and malware attacks remain high risks to compromise the security of IoT. This brings with it a particular challenge: securing IoT based systems against cyber-attacks.

In the FedCSIS 2023 challenge: Cybersecurity Threat Detection in the Behavior of IoT Devices [3], participants are asked to construct scoring models to detect whether anomalous operating systems were under attack by using logs from IoT devices. This competition has important theoretical and practical value for increasing IoT cyber security. It provides rich and detailed data for participants to analyze cyber-attacks from various perspectives and to train and test their models. Thereby we can understand attacker's intent, learn their behavior, and track the tactics, techniques, and procedures that they utilize to achieve their goals. We believe that all predictive models thoughtfully and elaborately constructed by each participant will definitely help to detect attacks as early as possible, determine the scope of the compromise rapidly and predict how they will progress, and eventually empower organizations to better respond to attacks.

In the past decade, traditional machine learning techniques (such as Support Vector Machine, Decision Tree, K-Nearest Neighbor, Random Forests, Naive Bayes, etc.) have been widely used by the cyber security community to automatically identify IoT attacks. Many papers (such as [4]) have provided various reference implementation on state-of-the-art machine learning methods for data preprocessing, feature engineering, model fitting, and ensemble blending. And paper [5] discusses in detail the existing machine learning and deep learning solutions for addressing different security problems in IoT networks. However, with the continuous expansion and evolution of IoT applications, attacks on these IoT applications continue to grow rapidly.

The complexity and quantity of attacks push for more efficient detection methods. In the recent years, deep learning techniques have been used in an attempt to build more reliable systems. For example, Martin Kodys et al. proposed a novel solution which deployed two CNN architectures (ResNet-50 and EfficientNet-B0) on the same data to observe how their performance differs to detect the intrusion attacks against IoT devices [6]. Kumar Saurabh et al. developed Network Intrusion Detection System (NIDS) models based on variants of LSTMs (namely, stacked LSTM and bidirectional LSTM and validated their performance) [7]. Compared with traditional machine learning, the deep learning brings an end-to-end approach combining feature selection and classification which can speed up the defense response against the fast-evolving cyber-attacks. However, some authors declare that deep learning methods have proved far better than the traditional machine learning models in terms of accuracy, precision with the ability to handle large amounts of data, and the inability to scale the data poses a large limitation to the extensive use of any conventional machine learning model [7]. This is not always the case.

In this competition, we apply basic data processing approaches, and leverage the feature selection and model building methods mentioned in our ICME2023 paper [8], combined with fundamental knowledge of mathematical statistics for cyber security threat detection. Our methods are fast and accurate, and achieve near-perfect prediction results. Our work provides examples for processing large scale data and extracting effective features to get better detection accuracy with less computational cost.

The paper is structured as follows: Section II introduces data analysis and processing methods. Section III applies basic knowledge of mathematical statistics to construct rules for attack detection. Section IV discusses how to perform feature selection and build binary classification models for threat prediction. Section V explains the experiment design and presents the results of the experiments. Section VI discusses the pros and cons of our proposed approaches and suggests future research directions.

II. Data Analysis and Processing

The available training data and test data in this competition contain 15027 and 5017 log files respectively. Each log file includes 40 fields and it contains 1-minute logs of all related system calls. There are a total of 28,339,158 and 10,060,209 lines of records in the training and test sets, respectively. The size of the data set is over 21.4 gigabytes. Therefore, one of the main tasks of this competition is to analyze and process these data efficiently and thereby construct effective features for attack detection.

In the training set, 522 files were identified as being under attack. Therefore, the chance of cyber-attack is 3.47375%. After the end of the competition, the organizer published the labels of the test set for the participants to do further research. There are 176 files which are under attack in the test set. It seems that the data set is divided by a "stratified K-Fold" manner to let the test set has the same proportion of target variable as the entire data set.

Among the 40 fields, 17 fields only have unique values (for example, 'SYSCALL_arch' always equals to 'aarch64'). These fields are useless. Besides, (1) 'SYSCALL_timestamp' indicates the number of milliseconds relating to the datetime 2023-04-12-00:00:00. It should not be used for prediction, otherwise it will cause over-fitting. (2) Column 'SYSCALL_exit' and 'SYSCALL_exit_hint' take almost similar values, so column 'SYSCALL_exit_hint' can be ignored.

For the remaining columns, we split their values into the smallest units. We call these smallest units "basic items". It is obvious that every unique combination of basic items represents a new kind of attribute, which can dramatically increase the amount of data. These will cause the high cardinality problem which means that there can be many possible values for a single column. To solve the high cardinality problem, a simple and straightforward approach is to subdivide the content of each column, and left the problem of digging the correlations between these basic items to the subsequent algorithms. Take the following line of record as an example:

```
53824,aarch64,openat,yes,6.0,ps,/usr/bin/ps,>systemd>/usr/sbin/
cron>/usr/sbin/cron>/bin/sh>/usr/bin/bash,"['/proc/uptime',
'/proc/meminfo', '/proc', '/proc/647524/status']", "['/lib/aarch64-
linux-gnu/libprocps.so.8', '/lib/aarch64-linux-gnu/libdl.so.2',
'/lib/aarch64-linux-gnu/libc.so.6',
'/lib/aarch64-linux-gnu/libsystemd.so.0',
'/lib/aarch64-linux-gnu/librt.so.1',
'/lib/aarch64-linux-gnu/liblzma.so.5',
'/lib/aarch64-linux-gnu/libzstd.so.1',
'/lib/aarch64-linux-gnu/liblz4.so.1',
'/lib/aarch64-linux-gnu/libgcrypt.so.20',
'/lib/aarch64-linux-gnu/libpthread.so.0',
'/lib/aarch64-linux-gnu/libgpg-error.so.0',
'/lib/aarch64-linux-gnu/libnss_files.so.2']",root,root,6,649165,0,0,0,
0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,[],,,,,/usr/bin/ps,,
```

We split the content of field 'PROCESS_PATH' (column 7) into the following small items:

systemd
/usr/sbin/cron
/bin/sh
/usr/bin/bash

and 'CUSTOM_openFiles' (column 8) into these items:

/proc/uptime
/proc/meminfo
/proc
/proc/647524/status

and 'CUSTOM_libs' (column 9) into these items:

/lib/aarch64-linux-gnu/libprocps.so.8
/lib/aarch64-linux-gnu/libdl.so.2
/lib/aarch64-linux-gnu/libc.so.6
/lib/aarch64-linux-gnu/libsystemd.so.0
/lib/aarch64-linux-gnu/librt.so.1
/lib/aarch64-linux-gnu/liblzma.so.5
/lib/aarch64-linux-gnu/libzstd.so.1
/lib/aarch64-linux-gnu/liblz4.so.1
/lib/aarch64-linux-gnu/libgcrypt.so.20
/lib/aarch64-linux-gnu/libpthread.so.0
/lib/aarch64-linux-gnu/libgpg-error.so.0
/lib/aarch64-linux-gnu/libnss_files.so.2

As for the columns 'SYSCALL_exit' (column 4) and 'SYSCALL_pid' (column 13), since 'exit code' and 'pid' take a very large range of values, we use the simple method of data binning to combine every 100 values into one group. After this, we count the occurrence of each basic item in the training log files and in files which are under attack, respectively. Examples of the obtained statistics are shown in Table 1.

Table 1. Example of statistical analysis results of column 2 ('SYSCALL_syscall')

Under attack times	Total occurrence	Items
491	14199	write
132	3521	exit
266	8123	bind
517	14942	exit_group
514	14701	socket
515	14939	execve
0	19	kill
520	14977	openat
501	14406	connect
522	15026	close
517	14956	clone
517	14962	mmap
0	51	listen
519	14963	munmap
0	49	bpf

These results can be further applied to construct detection rules and create features for classification.

III. Building Rules for Attack Detection

List all the basic items with attacked chance equal to 100% and number of occurrences >= 5 and are not included in other items, we can get the following list:

Table 2. Rules used for attack detection

Colum n index	Occurrence in training set	Occurrence in test set	Items
8	169	18	/proc/647524/stat
8	145	50	/proc/573203/stat
8	106	45	/proc/671015/stat
8	59	54	/proc/600849/stat
13	6	1	[576000000-576099999]
13	5	1	[574500000-574599999]

From the list we can find that basic item "/proc/647524/stat" appears 169 times in different log files, and all these files are identified as being under attack. From this we can infer that if a log file contains "/proc/647524/stat", it definitely indicates a cyber-attack has occurred.

Suppose "/proc/647524/stat" is an ordinary event, then the probability that "/proc/647524/stat" consecutively occurs 169 times in and only in the attacked files is 0.0347^169 = 0. According to the impossibility principle of small probability events, a small probability event is practically impossible to happen in a single trial. And once it does happen, we can reasonably reject the null hypothesis. In fact, it only needs five consecutive occurrences, then we can reasonably infer that an event has close relationship with cyber-attack.

By applying the above 6 rules, we are able to accurately detect 169 compromised files from the test set.

Furthermore, using the same method, we can confirm that 4003 files are secure (i.e., there are no attack events in these log files).

Applying these simple rules for threat prediction yields an AUC = 0.9985 on the test set.

IV. Feature Selection and Model Building

The aforementioned rule-based intrusion detection methods use only a small fraction of the data and cannot take advantage of the complex nonlinear relationships between various features. In this section we apply the sequential floating forward and backward (SFFB) feature selection method [8] for feature selection, and train a binary classification model based on GBM for attack prediction.

When creating features, we use the target encoding method to replace the categorical values with the mean of the target variable, and introduce a smoothing parameter to regularize towards the unconditional mean. We found this to be helpful in improving the predictive performance of the subsequent algorithms. We also find that the "K-fold target encoding" preferred by many people cannot mitigate over fitting risks. In fact, for high cardinality features "K-fold target encoding" method will lead to serious data leakage. This can be easily verified.

After feature encoding, we calculate the maximum, minimum and average chance of being attacked of each field. We also count their number of the contained basic items. Subsequently, these features are concatenated to form a feature set of equal length. We then use SFFB method to select features. The optimal subsets selected by the SFFB method are somewhat random. In most cases, the selected subset will only contain 10 features, such as:

PROCESS_comm_count, PROCESS_exe_count,
PROCESS_PATH_mean, CUSTOM_openFiles_max,
CUSTOM_openFiles_min, SYSCALL_pid_min,
SYSCALL_pid_mean, SYSCALL_pid_count,
PROCESS_name_mean, PROCESS_name_count.

*_max, *_min and *_mean means the maximum, minimum and average attacked chance of the fields. *_count means the number of basic items of the fields.

Training a GBM model with these 10-dimensional features leads to a classification result of AUC=0.9997 on the test set. Figure. 1 shows the gain contribution of these features.

V. Experiment Design and Experiment Results

Cybersecurity threat detection always is a majority-minority classification problem. Class imbalance in the dataset can dramatically skew the performance of classifiers. Therefore a reliable cross-validation method is essential to train a good classifier.

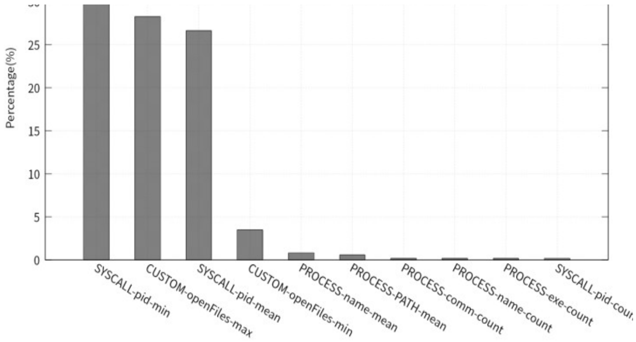

Fig. 1. Gain contribution of the 10 selected features

In our experiments, we estimate the performance of the classifier by using 3-fold cross-validation. At each fold, we completely hide the validation set when processing data and performing feature engineering. The average AUC score of 3-fold cross-validation is 0.9997 in local test. However, the classifiers trained in this way cannot achieve optimal scores on the public leaderboard. In fact, when the score of local CV is greater than 0.998, the changing trends of the local CV score is not consistent with the trends of the public leader-board. To address this problem, we randomly select 2/3 of the data from the training set at a time to train several classifiers, and then weighted averaging the prediction result of each classifier. In this way, we try to eliminate the effects of class imbalance and sample bias.

Finally, we ensemble the results obtained from the rules prediction with those predicted by the GBM model, and achieve an AUC score 0.9999 on the private leaderboard. After the organizer published the labels of the test set, we found that by correctly ensembling the prediction results from sections 3 and 4, we could obtain an AUC score 0.99995 on the test set. This is equivalent to the total accuracy can up to 99.88%. The ensemble method is:

1. If rule-based prediction results are equal to 1, then:

*ensemble results = 0.85 + 0.15*GBM prediction results.*

2. If rule-based prediction results are equal to 0, then:

*ensemble results = 0.15*GBM prediction results.*

3. Otherwise,

ensemble results = GBM prediction results

The total time (includes data processing, feature construction, feature selection, classifier training, and target prediction) required to obtain this result on our i7-10700 desktop is less than 30 minutes.

VI. Conclusion and Future Work

In this cyber security threat detection challenge, we only apply the fundamental methods of machine learning, but achieve near-perfect detection results. Many big-data competition participants like to apply ready-to-use GBM or deep learning frameworks. They prefer the end-to-end approaches that automates data processing, feature selection and classification, and expect to get good answers just by tuning the parameters. But our experiments show that each algorithm has a different application scenario.

In this competition, we conduct in-depth, detailed analysis of the massive-volumes data, and propose concise and efficient methods to process these data. (A significant portion of our work is C++ programming. To master the methodologies and techniques of contemporary C++ in the age of new technologies and challenges, one can start by reading paper [9].) Our proposed approaches are useful for solving variable-length, high-dimensional and high-cardinality problems.

However, our detection method still has obvious limitations: it is good at detecting known attacks but may fail at detecting attacks which have not been seen before. As more and more IoT devices are added, the potential for new and unknown threats grows exponentially. For this reason, an intelligent security framework for IoT networks must be developed that can identify such threats (e.g., detect any anomaly which rises from any deviation from normal behavior of the IoT network, or monitor network traffic to identify potential threats). In these research directions, conventional machine learning methods will still play an important role.

Acknowledgements

Many thanks to Łukasiewicz Research Network, EFIGO, and QED Software for their great efforts in organizing this challenging competition. Thanks to all the participants. They all did an amazing job.

Beating Gradient Boosting: Target-Guided Binning for Massively Scalable Classification in Real-Time

Dymitr Ruta, Ming Liu, Ling Cen
EBTIC, Khalifa University, UAE
{dymitr.ruta,liu.ming,cen.ling}@ku.ac.ae

***Abstract*—Gradient Boosting (GB) consistently outperforms other ML predictors especially in the context of binary classification based on multi-modal data of different forms and types. Its newest efficient implementations, including XGBoost, LGBM and CATBoost, push GB even further ahead with fast GPU-accelerated compute engine and optimized handling of categorical features. In an attempt to beat GB in both the performance and processing speed we propose a new simple yet fast and robust classification model based on predictive binning. At first all features undergo massively parallelized binning into a unified ordinally compressed risk representation, independently optimized to maximize the AUC score against the target. The resultant array of summarized micro-predictors, resembling 0-depth decision trees, directly expressing oridnally represented target risk, are then passed through the greedy feature selection to compose a robust wide-margin voting classifier, whose performance can beat GB while the extreme build and execution speed along with highly compressed representation welcomes extreme data sizes and real-time applicability. The model has been applied to detect cyber-security attacks on IoT devices within FedCSIS'2023 Challenge and scored 2^{nd} place with the $AUC \approx 1$, leaving behind all the latest GB variants in performance and speed.**

I. Introduction

THE RISE of AI to prominence in access and control of just about everything is upon us and so is the expanding infrastructure network of fixed and mobile sensing and computing devices, capable of sending and receiving data, known as the Internet of Things (IoT). In such digitized environment security and integrity of every individual node as well as the whole network is critical and hence the cyber-security against the internal and external threats of different nature and scale is of crucial importance. A survey presented in [1] offers a thorough overview of different security threats IoT devices are exposed to, reviews the current security mechanisms, trying to address them, and identifies a continuous challenge in this very fast evolving ecosystem, in which the evidence based designed security solutions are always playing a catch-up game and leave a lagged gap, in which new threats or attacks may inflict a lot of damage before they are detected, analysed and neutralized. Machine Learning (ML) has been growing in parallel to these revolutionary changes and since the outset offered methods for automated detection of security threats based on data, both by learning from historically labelled attack examples and by discovering and flagging anomalies from normal operation of the IoT devices. Several reviews of ML deployment in the IoT cyber-security environment have been presented recently like in [2] assessing various ML models while focusing further on the SVM application to smart city traffic flows prediction, or in [3] where similar classification, utility and suitability analysis of the most common ML methods, applied in various aspects of IoT cyber-security, is carried out with perhaps a deeper focus on deep learning.

To our surprise, however, gradient boosting methods developed around the start of our century by the pioneering work in [4], [5], that have ever since consistently been winning big data and ML competitions ([6]-[11]), have been rather scarcely covered in the literature dedicated to cyber-security. We can argue that in more practical realistic ML applications to cyber-security like detecting threads based on complex log-extracted data, the old favourite models like SVM are simply not scalable enough [2], [11], while high-performing deep learning networks cannot easily encode the multi-modal unstructured data coming in a variety of forms and types, i.e. in quite different form than regular images or time-series, deep learning are performing well for. For such data GB models appear much more suitable and easy to be applied.

In this paper, however, we attempt to go a step further than a standard application of the optimized gradient boosting models. Inspired by the essence of what makes GB work well we propose the target guided binning (TGB) process that transforms all input features into an array of independent AUC-optimized and robust micro-predictors of the binary target with which a simple voting can outperform the latest GB variants both in terms of performance, transparency, data handling overhead and the processing speed. While binned features resemble somewhat 0-depth decision trees, they leave TGB process already AUC-pre-optimized to maximally suppress unnecessary complexities within the original feature domains while maximally exposing and summarizing its predictive power against the known binary target.

Neither optimising with respect to AUC [16], [17] nor binning [17], [18] is new in the context of classification. Since the advantages of AUC-optimized classifier design have been widely exposed [16], there was a fast-paced evolution towards AUC-optimized classification that eventually culminates with the advent of CATBoost [17], and the ingenious way it handles high cardinality categorical data utilising target statistic as a robust form of feature re-engineering. We build up on this direction by more explicit target guidance in a form of predictive binning uniformly applied to both categorical and numerical features, yet to guard against performance damaging *target-leakage*, extensively investigated in [18], we simply build the cross-validation process into the binning process.

We intend to comparatively demonstrate the advantages of the proposed TGB over GB in an objectively evaluated FedCSIS'2023 challenge dedicated to predicting cyber attacks on IoT devices based on logs data files that the latest GB variants should perform very well for. We specifically focus on and optimise TGB for scalability utilizing massive parallelization of the processing pipeline that can be deployed along multiple dimensions to approach real-time readiness even for such large scale problems as the cyber-security attacks prediction. For that reason we deliberately leave, typically critical, feature engineering aspects unexplored to great depths, instead focusing on TGB algorithmics and comparative experimentation applied to only one family of features, that nevertheless produced excellent results that scored the 2^{nd} place in the competition after leading throughout the whole preliminary phase.

The remainder of the paper is organized as follows. The FedCSIS'2023 Challenge is briefly described in Section II. The critical element of the proposed target guided bining process along with its fast, massively parallelized implementation are discussed in Section III. The composition of wide-margin voting classifier from TGB-binned features that includes important aspects of feature selection and the evaluation criteria they use, are covered in Section IV, followed with the description, presentation and discussion of the experimental results in Section V and the conclusions drawn in Section VI.

II. FedCSIS'2023 Challenge

The FedCSIS'2023[1] competition focused on detecting cyber-security threats based on the behavior of IoT devices captured in their detailed logs data. Over 20k of log files have been provided to the competitors, each of which representing a single data sample of timestamped variable-length sequence of events capturing specific IoT device interaction/operation over a fixed period of time. System calls, system and user processes' details, lists of open files and libraries, counts of various events, errors, integrity checks are just some of 24 raw features included in the log files both in numerical and categorical (text) format. Out of the total 20044 samples the correct binary target label (*ATTACK*) was provided for 15027 training samples, leaving the remaining unlabeled 5017 examples for AUC testing on the KnowledgePit.ml platform, hosting the competition. Before the final evaluation of the submitted full solutions, i.e. throughout the competition, KnowledgePit.ml operated a leader-board of competitors' solutions evaluated based on the preliminary set of unknown 10% of the full testing set. FedCSIS'2023 Challenge is sponsored by the Łukasiewicz Research Network - Institute of Innovative Technologies, EMAG and EFIGO sp. z o.o. companies.

III. Target-guided binning (TGB)

Given the data examples are provided in a composite form a variable-length table of time-ordered event features it was imminent that any kind of feature engineering strategy would involve some form of aggregation over the whole log table of typically thousands of records. Moreover given relatively large number of unique values observed for several categorical features it is expected that potential number of possible derived features could be large. In an attempt to extract possibly fullest predictive value form such evidence we decided to reduce feature engineering to measuring the per-log-frequency of all observed unique feature values and simultaneously transform these frequencies into summarized ordinal target-risk levels monotonically increasing with the target likelihood conditioned on the intervals or subsets contained within each risk level. Such predictive TGB transforms all feature space irrespective of their form or data type into unified, numerically stable and additive micro-predictors of the target.

Target-guided binning focuses on a single, very simple goal: how to exploit the guidance of the binary target to bin the input feature in a way that maximally improves its generalized predictive power over the target. An objective, scale- and threshold- invariant measurement of feature predictive power in binary classification is the area under the receiver-operator curve (AUC). Denoting by x and $y(x) = y_x$ our input variable and the binary target, respectively, and by $AUC(y_x, x)$ the empirical AUC between y_x and x, the target-guided binning process can be formally defined by the transformation function T that maps all values of x into $x_T \in \{1, 2, .., k\}$ such that the $AUC(y_x, x_T)$ is maximized:

$$T: \quad x_T = T(x, y_x), \quad x_T = \arg\max_{x_T} AUC(y_x, x_T) \quad (1)$$

At the first glance, this task seems trivial given the relation of AUC and the Wilcoxon-Mann-Whitney statistic [14], [15], that gives an AUC a simple interpretation of the probability of a random *positive* $x_+ = \{x_i : y(x_i) = 1\}$ being larger than the random *negative* $x_- = \{x_j : y(x_j) = 0\}$:

$$AUC(y, x) = P(x_+ > x_-) \quad (2)$$

It is trivial to show that to maximize such probability it is sufficient to simply transform x to the ranking of target rates along all unique values of x. The recipe for (y) target-guided binning of x that maximizes $AUC(y, x)$ seems, therefore, to be just finding unique values of x: x_u, computing target rates y_{xu} for all x_u, and replacing x with the positions they appear in x_u sorted by y_{xu}. Assuming Matlab coding syntax, finding x_T becomes straightforward:

```
[∼,j]=sort(y_xu); [∼,x_T]=ismember(x,x_u(j));
```

Although such logic is in principle correct it ignores a fundamental property of a good predictor: the generalization ability and would likely fail on two accounts. First, the binning for numerical variable has to provide the mapping for the entire domain, not just unique values observed in the training set, otherwise the binning is unable to allocate previously unseen values of x into any bin. Second, a feature binned as described above essentially over-fits the observed data with the degree dependent on the the number of unique inputs x_u. In the extreme case of (almost) all unique values, that is typical for continuous floating point features, the target rates will be

[1] https://knowledgepit.ml/fedcsis-2023-challenge

extremely unreliable as computed on the basis of just a single or a few examples and would wildly differ in the unseen testing set, on which the binning should be designed to perform well.

To address these two cases our target guided binning would operate on the intervals (subsets) that at all times span the entire domain (universal set) of numerical (categorical) feature and attempt to efficiently and optimally define their numbers, edges (set members) and label-permutation that maximises AUC, but not over the training data (x_u, y_{xu}), on which the bins are built and merged, but on the previously unseen validation set (v_u, y_{vu}). The bottom-up approach is proposed for our TGB algorithm, which starts from singleton intervals (subsets) exclusively covering all unique values x_u and then greedily merge to maximise $AUC(y_x, x_T)$ but only until monitored validation set performance $AUC(y_v, v_T)$ starts falling.

A. Massively parallelized TGB implementation

Target guided binning has been developed with extreme efficiency and scalability in mind. Each feature is binned independently and in parallel using the same binary target as a guidance in such a way that the AUC score of its binned representation against the target is maximized in a generalization sense, i.e. AUC is measured via cross-validation on different data partitions than those on which the bin definitions were built.

TGB starts from building singleton intervals (or subsets for categorical features) containing all unique values and reordering them along the rising likelihood of positive target. Then the intervals/subsets proceed to greedy merger process which continues until no further gain in validation AUC can be achieved through further mergers. Figure 1 illustrates a sample TGB process for numerical feature which starts from individual singleton intervals and then proceeds through the greedy neigboring interval merger until no more validation AUC improvement is possible, which in the depicted sample scenario converges to 6 intervals. The AUC-optimized intervals are then mapped to ordinal bin labels calibrated or scaled according to user preferences yet always monotonic with the conditional positive target rate. Feature 1 also illustrates readiness for massively parallelized implementation of the TGB process which could be efforlessly applied along the feature level, cross-validation partitions or testing for optimal merger along running pairs of neighboring intervals.

The missing data (NaNs) are mapped to a bin that has the closest posterior target probability as the one observed for missing data. Similarly previously unseen data are provisioned to receive bin that has the target posterior probability the closest to the target prior. Greedy interval merger follows very fast vectorized test of the impact of the decomposed AUC score implemented on matrix formulation that allows to compute all simulated pairs merger in a single step per round resulting in tabular formatted bin definitions mapping all original feature domain into optimised incrementally summarized intervals/subsets labelled with target-monotonic ordinal risk levels. Given the final bin definitions, transforming any new data into bins is equally lightning fast and, importantly, represented by *uint8* data type reducing the binned data complexity to just 1 byte per value. Compared to the original data typically coming in double precision or text format, TGB typically reduces the size of the memory required to hold the data around 100-fold, while obfuscating the original values behind ordinal risk mask.

IV. Wide-margin voting classifier composition

Constructing a robust classifier based on TGB-transformed (binned) data is straightforward and in its simplest form can be executed by a simple voting i.e. by adding up all feature bin values (risk votes). Further AUC-measured performance gains can be achieved by more or less sophisticated feature selection strategies, which for the voting classifier simply translates into finding a sum of binned features that maximises AUC against the binary target. Two highly scalable heuristic optimisation methods have been developed to execute such robust additive selection of binned features and both can deal with hundreds of thousands of features in seconds if supported by multi-core parallel processing and/or dedicated capable GPU.

A. Greedy forward selection (GFS)

Greedy forward selection of binned features starts from the strongest feature and keeps adding features that maximally improve the appended sum's AUC against the target in each round until this is no longer possible. The process of testing for optimal addition is fast since the current best subset is constantly retained in the form of collapsed running sum and stored indices of selected members, while testing the AUC improvement when adding another binned feature is vectorized and massively parallelized with additional speedups possible when executed on the GPU. In practical applications, when faced with tens to hundreds of thousands of features, each round of finding a binned feature that maximally improves the pool's AUC usually takes around 1s. In the latest implementation this greedy search was additionally improved by reducing the data type of vectors holding the sums to *uint16* and allowing each feature to be added multiple times - thereby equipping the method with a fast feature weighting capability.

B. Fast probability based incremental learning (FPBIL)

Probability based incremental learning (PBIL) is a simple population based heuristic optimization that is perfectly suited for simple evaluation functions based on binary encoded feature selection. Beyond that fit, PBIL has been chosen to help with feature selection also for two other reasons. Its critical operation is constant sampling from the probability vector that involves generation of random number matrices of enormous sizes that can be massively accelerated on the GPU. Moreover, evaluation of the population of solutions at each generation involves preparation of the intermediate voting sums corresponding to binarized selection vectors sampled from the evolving probability vector, all of which has been very efficiently vectorized and passed on to equally optimized and parallelized evaluation of the AUC. Operating such PBIL on the GPU with the Philox based random number generator

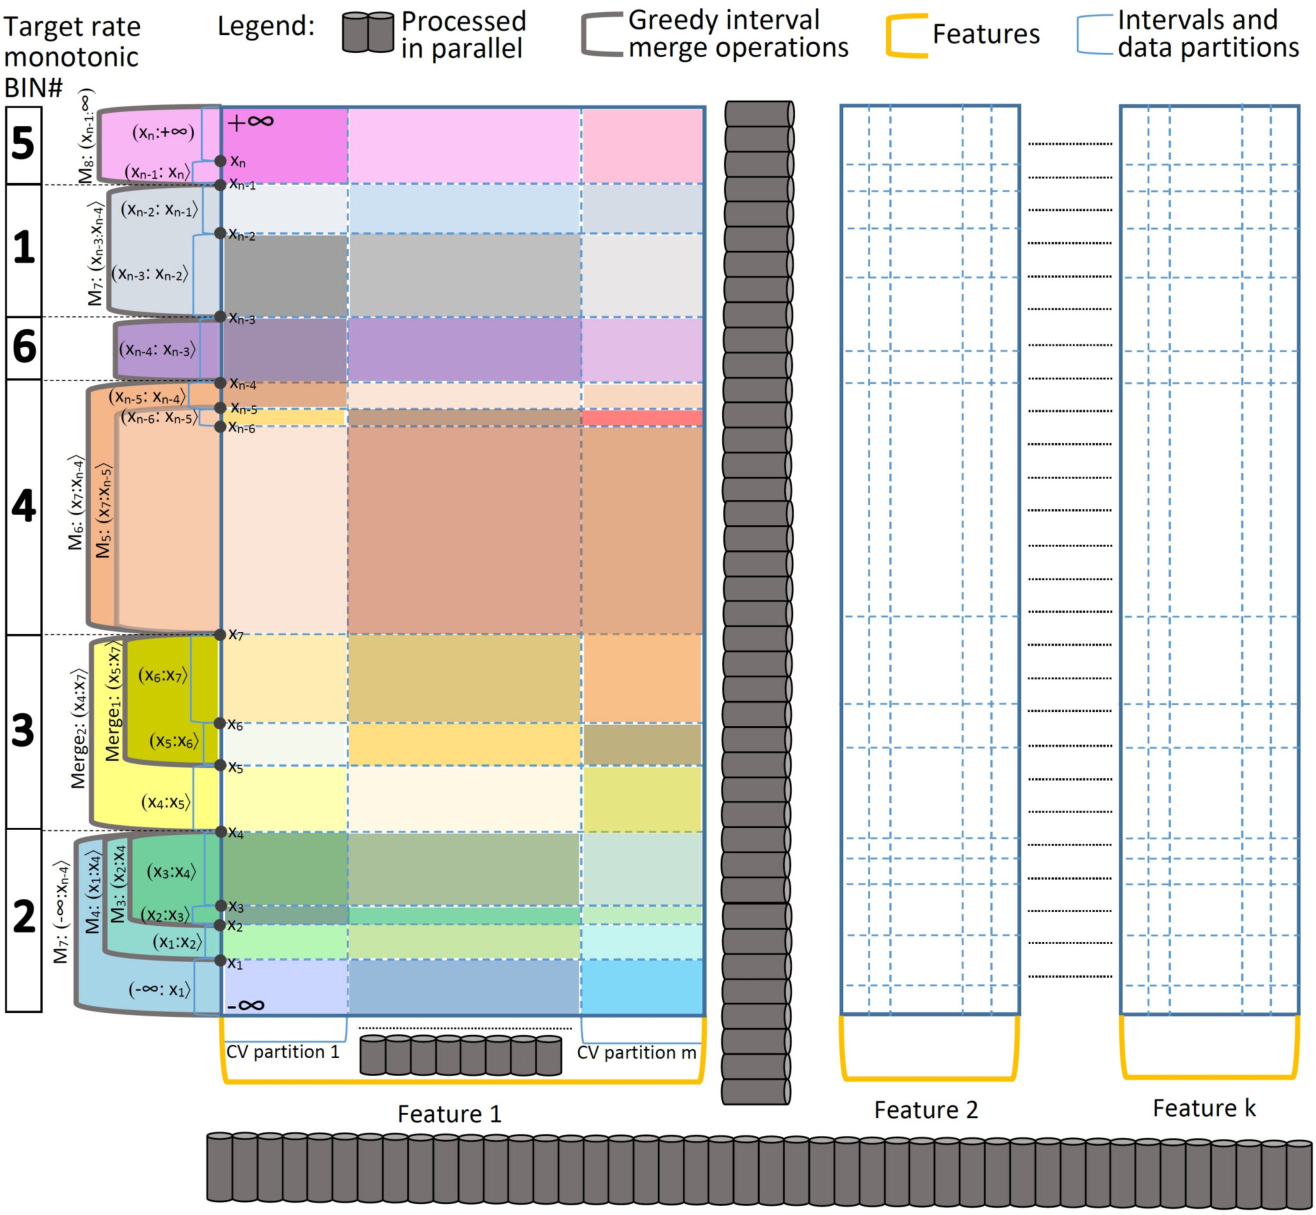

Fig. 1. An annotated example of the target guided binning (TGB) for numerical feature x. In the orginal domain $(-\inf, +\inf)$ first all unique values: $\{x_1 : x_n\}$ are found and wrapped within singleton intervals: $(-\inf : x_1], (x_1, x_2], .., (x_n : +\inf)$. Then neigboring intervals are greedily merged along multiple cross-validation partitions until the validation sets AUC against the target no longer improves leaving the final optimised intervals ordinally labelled to represent target-monotonic risk levels. The process is ready for massive parallelization along multiple dimensions: independent features, cross-validation partitions and the neigboring pairs of intervals examination for optimal merger. Distinct colors are representing the conditional target rate heatmap and the effect of its aggregation after mergers.

on a population of 1000 100k-elements solutions with a learning rate of 0.5-1 typically converges after a couple of hundreds of generations at the pace of multiple generations per second. Compared to the greedy forward selection which normally converges with up to 200 out of 100k features, accelerated PBIL-based selection converges with thousands of features and typically better AUC-score

C. Criteria for feature selection evaluation

Ideal evaluation criterion for feature selection is the actual classifier performance for the selected features. The only reason why much simpler proxy measures are normally used is that evaluating the classifier with different set of features is expensive and normally requires a rebuilt of the whole model from scratch to extract new classifier output. For our case, however, the voting classifier only needs to add the newly selected feature values to the cumulative sum from features already in the pool to update the classifier output, hence it follows an online update process and is therefore very fast. For this reason TGB with voting enables us to use directly the powerful threshold independent classifier performance measures like AUC as a feature selection criterion which supports classifier robustness while keeping it simple and fast.

1) Area under the ROC curve (AUC): AUC measure has already been discussed above as the prime threshold-less indicator of the overall predictive power of a feature x against the binary target y. In the context of target guided binning for the reason of being AUC-optimized and also due to the fact that computing AUC for binned features likely involves fewer unique bin-label ordinal values, we have introduced a dedicated summarized representation of the relationship between x and y for the purpose of AUC computation called feature predictive structure $P = [u, c, v]$ that contains a sorted list u of unique values of x, and the corresponding lists of their counts c as well as the counts of the positive targets $v = \sum(y|x)$. For simplicity we will replace the original x and y with their summarized representation in P such that $P = [x, c, y]$. Note that such summarized representation significantly reduces the sizes of both the feature x with respect to the target y down to the essential statistics sufficient to evaluate its full predictive power. Given P, the cumulative true and false positive vectors can be readily computed for multiple features or targets by this vectorized Matlab code:

```
tp=[0;cumsum(flipud(y))];
fp=bsxfun(@minus,[0;cumsum(flipud(c))],tp);
tp=bsxfun(@rdivide,tp,sum(y));
fp=bsxfun(@rdivide,fp,sum(y));
```

such that the AUC can be accurately and rapidly computed for multiple features or targets using a 1-liner:

```
auc=sum(diff(fp).*(tp(1:end-1,:)+tp(2:end,:))/2);
```

2) Kolmogorov-Smirnov Distance (KSD): Kolmogorov-Smirnov distance, test or statistic in our context expresses simply the maximum absolute difference between the cumulative rate of positive targets and the cumulative rate of negative examples along the sorted unique inputs x. Given our compact predictive structure $P = [x, c, y]$ KSD can be rapidly computed for multiple inputs/targets using:

```
y=cumsum(y); s=y(end); c=cumsum(c)-y; n=c(end)-s;
ksd=bsxfun(@rdivide,y,s)-bsxfun(@rdivide,c,n);
ksd=max(abs(ksd));
```

3) Classification Impurity Score (CIS): This new measure utilizes the specificity of working with binned feature votes and is designed to stimulate stable wide margin classifier especially for very high performance close to AUC=1. The measure works on the sorted predictor outputs (sums of bin votes) and focuses on the interval, within which samples are not classified 100% correctly. For every sample falling within this interval it then simply adds up distances between the prediction (sum) for these samples and the interval boundary that if reached would eliminate the misclassification for any threshold. Since our voting classifier simply holds the sum of selected binned features, the logic of this measure is to evaluate how many votes need to be added (for false negative) to or subtracted (for false positive) from the current sum of votes such that the sample would be correctly classified irrespective of the applied threshold. Formally, assuming sorted classifier outputs x_i, $i = 1, .., n$, the corresponding binary targets y_i and the interval of indices $j = k, .., l$ such that $1 \leq k < l \leq n$ and

$$\begin{aligned} &\underset{s:x_s \leq x_k}{\forall} y_s = 0 \\ &\underset{s:x_s \geq x_l}{\forall} y_s = 1 \end{aligned} \tag{3}$$

then the CIS can be defined by:

$$CSI = \sum_j (x_l - x_j) y_j + \sum_j (x_j - x_k) \bar{y_j} \tag{4}$$

Using Matlab code the above definition can be readily captured as follows:

```
i=find(x<x(find(y,1,'first')),1,'last');
if isempty(i) i=1; end
j=find(x>x(find(~y,1,'last')),1,'first');
if isempty(j) j=numel(x); end
l=i:j;
cis=sum(x(j)-x(l(y(l)))) + sum(x(l(~y(l)))-x(i));
```

Note that in case of 100% accurate classification the impurity measure could be adjusted to receive negative values proportional to the gaps or margins in votes that needed to be bridged to observe classification impurity, hence such measure can be very effective for very high performance wide-margin classification with AUC scores very close to 1, which happens to be the case of the FedCSIS' 2023 Challenge.

V. Experimental results

All features have been generated in the exactly same form capturing the frequency (counts) of unique values observed within the log files. For the datetime and other continuous numerical variables the domain has been split into 100 equipercentile intervals and the derived features measured de-facto frequencies of observed percentile values. For features listing all open filenames and libraries with paths the two variants of unique elements were applied: the whole unique paths separated by commas and, in the second variant, all the unique path sub-strings separated by \ character. Such feature engineering process resulted in over 300k 1-hot-encoded style features that after reduction by eliminating duplicates and constant features shrunk to a set of about 40k of unique raw features. These features have then been passed on to the TGB process allowing up to 20 (and later 100) unique bins applied only on the training set of 15027 labelled samples and resulted with bin definitions re-applied on both the training and testing sets to achieve the final transformed training and testing sets taking ordinal values from 1 to 20 (100).

Feature selection process followed on the binned training set in all combinations of the presented feature selection methods and evaluation metrics, however, we only show the results for AUC and CIS since KSD produced the results similar to AUC.

The feature subset sums obtained as a result of all the selection-evaluation combinations along with outputs from many other variants of restricted feature subsets and gradient boosting models applied for comparison have been normalized within (0,1) interval and submitted for evaluation on the preliminary testing set containing only 10% of all testing samples. The feedback received was in line with the results received from the validation sets with the top scored model variants, notably achieving leaderboard's top AUC=1.0 submitted as final solutions for the evaluation on the full testing set.

Comparative AUC performance results of our target guided binning (TGB) with gradient boosting (GB) variants classifiers and various combinations of feature-selection and evaluation criteria are presented in Table I. For both the training and validation sets we have observed GFS performing slightly better with AUC than CIS criterion however the opposite was observed for FPBIL selection method. The FPBIL applied with CIS metric typically returned solutions of a couple of thousands of features with the final converged impurities of just about 50-500, while starting from impurities in the order of millions. On the other hand the GFS typically converged with about only 100-200 features, for which the added score produced the AUC reaching extremely close to 1. What produced the best results, however, was sequentially applied GFS interchangeably with AUC and CIS criteria, until no further improvement in the validation AUC could be achieved. Although results for 100-bin TGB appear to show slightly better validation results than for TGB with up to 20 bins, final testing revealed later that 20-bin TGB could have performed better, i.e. 100-bin TGB appeared to be slightly over-fitted with too fine granularity and the best results could be expected somewhere in between for example 50-bin TGB. Although in our validation TGB on its own i.e. with simple voting outperforms all GB model variants, final testing revealed that CATBoost could climb to similar performance levels if applied on top of the 20-binned rather than raw features and could most likely have improved our final combined testing score thanks to a significant diversity with TGB-generated results.

TABLE I
COMPARATIVE PERFORMANCE OF GB/TGB VARIANTS COMBINED WITH DIFFERENT FEATURE SELECTION/EVALUATION CRITERIA.

Classifier	FSelection	Criterion	AUC Score	
			VAL	TST
XGBoost	ALL-LogLoss		0.9992	0.9980
LGBM	ALL-LogLoss		0.9967	0.9954
CATBoost	ALL-LogLoss		0.9994	0.9983
TGB20-SUM	GFS	AUC	0.9996	0.9985
	GFS	CIS	0.9994	0.9982
	FPBIL	AUC	0.9992	0.9981
	FPBIL	CIS	0.9994	0.9983
	GFS	AUC-CIS	0.9997	0.9991
TGB100-SUM	GFS	AUC-CIS	0.9997	0.9989
	FPBIL	CIS	0.9998	0.9979
XGB-BIN20	ALL-LogLoss		0.9992	0.9985
CATBoost-BIN20	ALL-LogLoss		0.9994	0.9993
MEAN(TOP5(TGB))	NA		1	0.9997

VI. CONCLUSION

Presented target guided binning rapidly transforms any input evidence into a robust array of 1-feature micro-predictors of the binary target and offers readily available, high quality classification by voting with ordinal-risk represented binned feature outputs in near-real time. Further performance gains are available through fast parallelized gready feature selection and gpu-optimized FPBIL features selection methods utilizing both AUC and newly introduced CIS as evaluation criterion to achieve stable high margin perfomance. In the competitive setup of detecting cyber-security attacks on the IoT devices based on log files data the presented methodology appears to consistently beat gradient boosting models in all aspects: the speed of building the model, the classification performance, simplicity, transparency and added security layer, topping the preliminary evaluation on the leader-board of the FedCSIS'2023 Challenge with the score of AUC=1 and eventually scoring the 2^{nd} place with AUC=0.9997 in the final testing.

***Abstract*—In the ever-growing realm of the Internet of Things (IoT), ensuring the security of interconnected devices is of paramount importance. This paper discusses the process of spotting cyber breaches in IoT devices, a significant concern that needs urgent attention due to the susceptibility of these devices to hacking and other cyber threats. With billions of IoT devices worldwide, the detection and prevention of cybersecurity breaches are critical for maintaining the integrity and functionality of networks and systems.**

In this paper, we showcase the outcomes achieved by employing the LightGBM technique for a cyberattack prediction challenge, which was a part of the FedCSIS 2023 conference.

***Index Terms*—cybersecurity, data mining competition, LightGBM**

I. Introduction

As we step further into the digital era, the Internet of Things (IoT) continues to reshape the landscape of our daily lives, driving advancements in various sectors such as healthcare, transportation, smart homes, and industrial automation. Despite the remarkable benefits, the rapid proliferation of IoT devices has significantly heightened the stakes in the domain of cybersecurity. The interconnected nature of these devices poses unique vulnerabilities, making them attractive targets for cyberattacks. An essential part of combating this growing threat involves the ability to effectively identify and predict cybersecurity breaches in IoT systems.

Numerous machine learning methodologies can be deployed for the prediction of cyberattacks [1]. However, we opted for a gradient boosting algorithm, specifically LightGBM [2], due to its impressive combination of speed and precision. In this paper, we aim to highlight the effectiveness of our strategy. Our discussion will serve to underscore the integral role of data science in augmenting cybersecurity measures in an increasingly interconnected world. By delving into this topic, we hope to provide valuable insights for future research endeavors and practical applications aimed at advancing the field of cybersecurity for IoT.

The organization of this paper is as follows: after this introduction, we review relevant literature and provide a brief overview of the FedCSIS 2023 challenge. In Section IV, we delve into the processes involved in data handling and preparation. We detail the model deployed in our experiment in Section V, followed by a comprehensive presentation of our findings in the succeeding section. We conclude in Section VII by summarizing our observations and contemplating potential avenues for future exploration.

II. Related work

The practice of automatically detecting cyberattacks has a well-established history in the field. A diverse range of methods have been employed to accomplish this task. It has been suggested through numerous studies that machine learning techniques could be potentially beneficial, with many researchers opting to use unsupervised algorithms to navigate identification challenges [3], [4]. However, there is a notable drawback to using unsupervised machine learning methods for recognizing anomalies in a network, distinguishing between standard cyberattacks, and detecting outliers. The sparse occurrence of these outliers can have an asymmetric impact on both the success rate and the identification of abnormalities.

To achieve more dependable results, supervised machine learning methods are often employed. These algorithms are trained using metadata with labels indicating whether the given instances have previously been classified as cyberattacks. Examples of such supervised learning algorithms include Support Vector Machines and Artificial Neural Networks [5], Random Forests [6], the k-Nearest Neighbor (k-NN) technique [7], the Naive Bayes algorithm [8], and LightGBM [9].

In our solution, we decided to use LightGBM (Light Gradient Boosting Machine) due to several reasons [2], [10], [11]:

- **Efficiency**. LightGBM uses a novel technique of Gradient-based One-Side Sampling (GOSS) to filter out the data instances for finding a split value, which can result in a more efficient learning process. This is particularly useful when dealing with large volumes of data generated by IoT devices.
- **High Performance**. LightGBM can handle large data sets while maintaining high efficiency. It uses the leaf-wise tree growth algorithm, unlike the traditional level-wise tree growth algorithm, which can result in a better performance in terms of speed and accuracy.
- **Handling Categorical Features**. LightGBM can naturally handle categorical features, which can be very beneficial when dealing with IoT data, as IoT devices can produce a variety of data types.

- **Scalability**. LightGBM is highly scalable and can work well with large datasets that often characterize IoT networks.
- **Accuracy**. LightGBM can achieve lower prediction errors by employing complex tree architectures, boosting its accuracy, which is crucial for detecting subtle signs of cyberattacks in IoT networks.

It is also worth noting that gradient-boosting models have been used in previous data mining competitions. In the IEEE BigData 2019 Cup: Suspicious Network Event Recognition, the best solutions used tree-based boosting models [12]. In particular, first place went to an ensemble of two models [13], LightGBM and XGBoost [14]. In another competition, the FedCSIS 2020 Challenge: Network Device Workload Prediction [15], the situation was similar. The 2nd and 3rd place solutions used XGBoost models. Of course, it is important to remember that proper preprocessing is required to use these models. Furthermore, we have used a similar approach (LightGBM + appropriate preprocessing) for other competitions with outstanding results [16].

III. Challenge description

A. Data

The data provided consists of CSV table log files, each with a randomized uuid4 name. All original timestamps have been standardized to a specific timestamp, which is 2023-04-12-00:00:00. A separate TXT file was provided for the training set, containing the names of log files associated with cyber attacks. After the competition concluded, similar information regarding the test set was also made available. The sizes of the datasets are as follows:

- training data: 15 027 files (522 indicates cyberattack),
- test data: 5 017 files (176 indicates cyberattack).

As we can see, a small number of files indicated a cyberattack (3.48% for the training dataset and 3.50% for the test dataset).

B. Task

Our goal is to develop an accurate method that can detect cyberattacks on an IoT system based on its logs.

C. Evaluation

In this competition, participants submitted their solutions to the online evaluation system as text files that included predictions for the test instances. Each test instance in the solution file was accompanied by a single number within the $[0, 1]$ range, representing the probability of a cyberattack. These predictions were arranged according to the lexicographic ordering of the log files from the test set.

The effectiveness of the submitted entries was assessed using the ROC AUC (Receiver Operating Characteristic Area Under Curve) metric, a widely used evaluation metric for binary classification problems [17]. The ROC curve is a plot that illustrates the diagnostic ability of a binary classifier system as its discrimination threshold is varied. It is created by plotting the true positive rate (TPR), against the false positive rate (FPR), at various threshold settings. Precisely

$$\mathrm{TPR} = \frac{\mathrm{TP}}{\mathrm{TP} + \mathrm{FN}},$$
$$\mathrm{FPR} = \frac{\mathrm{FP}}{\mathrm{FP} + \mathrm{TN}},$$

where TP is the number of True Positives, FN is the number of False Negatives, FP is the number of False Positives and TN is the number of True Negatives.

Calculation of the AUC (Area Under the ROC Curve) is slightly more complex as it involves integration over all possible classification thresholds. But practically, it's usually calculated using the trapezoidal rule [18]. An AUC of 1 indicates a perfect classifier, while an AUC of 0.5 signifies a classifier that performs no better than random chance [19].

Initial scores were evaluated via the KnowledgePit online platform [20] and published on a challenge leaderboard calculated on a small subset of the test set fixed for all participants. The final score was published after the challenge using the remainder of the test data set.

IV. Data preprocessing

Due to the format of the data (we have a separate file for each observation, and therefore a separate table with data), we had to process it in an appropriate way. We focused on the approach to have one row of data for a single observation. Each file contains 40 columns: 21 numeric, 17 string, and 2 with only null values (based on training data). We skip these two columns with nulls and now proceed to preprocess the data by type.

A. Numerical data

We focused on the numerical data first. For each file, we took the smallest, largest, and average values (omitting features with the same values, we obtained 17 features). With this simple approach, we will get very good predictions. So, we now move on to data of string type.

B. String data

The main idea was to focus on finding significant differences in this data type without considering numerical data. Of particular note is the "Custom_openFiles" feature. To begin with, we selected unique values for this feature separately for the files that represented the logs with and without the attack. Then, from the unique values from files with attacks, we removed all the values that were present in files without attacks. Finally, for each file, an indicator was created indicating whether any value from the "Custom_openFiles" column belonged to that set. Using the same set this was repeated for the test data. Passing this indicator as the probability of a cyberattack, we obtained a score of 96.77% (by ROC AUC measure) on the public part of the test set.

C. *Addtional preprocessing*

In the test set, the shortest log file contains 68 items. So we took only those files from the training set that are not shorter than it. Thus, we get rid of 65 (0.43%) files from the training set. In addition, we replaced one of the string-type features with a numeric one. Namely, in the feature "SYSCALL_exit _hint" we have numeric and string type values. So in place of the string, for example, "ENOENT(No such file or directory)", we inserted nulls. Then we calculated the average, minimum, and maximum as in Section IV-A.

V. Model

We used the gradient boosting model for testing, and the choice was LightGBM [2]. We used Microsoft's FLAML library [21] to optimize the hyperparameters.

With the above preprocessing, the models achieve high predictive quality very quickly. We can see a comparison of the performance of the models for different subsets of features with hyperparameter optimization taking 3 minutes in Table I.

TABLE I
STRATIFIED 5-FOLD CROSS-VALIDATION RESULTS FOR DIFFERENT FEATURE SETS (3 MIN OF HYPERPARAMETER OPTIMIZATION, AUC MEASURE) AND THE RESULT ON THE TEST SET.

Feature set	Cross-validation	Test set
IV-A	0.99932	**0.99954**
IV-A + IV-B	0.99993	0.99951
IV-A + IV-C	0.99813	0.98224
IV-A + IV-B + IV-C	**1.00000**	0.99603

In Table II, we have a list of optimized hyperparameters and values for the best model from Table I.

TABLE II
FINAL MODEL HYPERPARAMETERS FOR FEATURE SET IV-A AT 3 MINUTES OF OPTIMIZATION (TO FIVE DECIMAL PLACES).

Hyperparameter	Value
n_estimators	1098
num_leaves	120
min_child_samples	5
learning_rate	0.19275
max_bin	1023
colsample_bytree	0.73337
reg_alpha	0.00098
reg_lambda	0.24821

VI. Experimental results

We see that the first two cases in Table I gave the best results on the test set. In both cases, we have another feature that is most relevant according to gain importance [14]. The most significant feature for the 1st model is "SYSCALL_pid_max" (which is the maximum of the "SYSCALL_pid" feature from each file) as we see in Figure 1.

On the other hand, the graph for the second model appears quite similar, except that the newly added feature (indicator based on "Custom_openFiles", described in IV-B) is now positioned at the beginning.

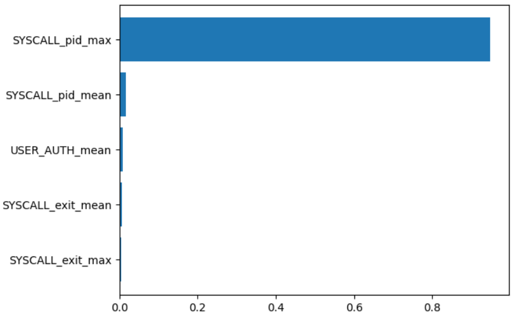

Fig. 1. Top 5 features by gain for the first model. The values were divided by the sum of all gains.

We now set the search times for hyperparameters to 30 minutes. We can see the results in Table III.

TABLE III
STRATIFIED 5-FOLD CROSS-VALIDATION RESULTS FOR DIFFERENT FEATURE SETS (30 MIN OF HYPERPARAMETER OPTIMIZATION, AUC MEASURE) AND THE RESULT ON THE TEST SET.

Feature set	Cross-validation	Test set
IV-A	0.99946	**0.99959**
IV-A + IV-B	0.99996	0.99901
IV-A + IV-C	0.0.99888	0.0.98733
IV-A + IV-B + IV-C	**1.00000**	0.99660

The outcomes show minimal variation from the 3-minute version, as demonstrated more accurately in the learning curve of one feature set presented in Figure 2.

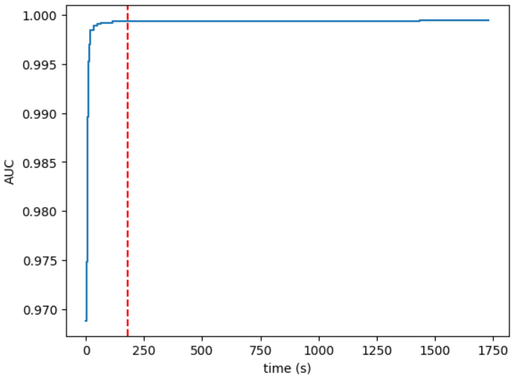

Fig. 2. Learning curve for model trained on IV-A feature set. The red line marks 3 minutes.

We have 4.5 times more false positives than false negatives (in the case of the first model), which is good behavior since it is better to verify claims with no attacks than to omit those with attacks. We can see this in the confusion matrix in Figure 3.

VII. Conclusions

To detect cyberattacks, we utilized the renowned LightGBM model along with some data preprocessing. Our approach

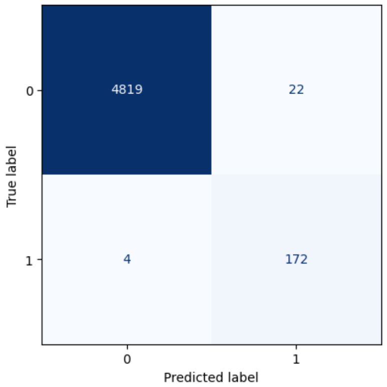

Fig. 3. Confusion matrix for model trained on IV-A feature set.

was successfully trained within a mere 3 minutes, securing a commendable 3rd place in the competition. The top 4 results were closely matched, with only a marginal difference of 0.0002 between the following positions.

The achieved result was already commendable, making it difficult to anticipate a substantial enhancement in performance. Nonetheless, for future endeavors, it is crucial to concentrate on extracting valuable insights from string-type attributes. Furthermore, it is possible to expect that more advanced data preprocessing techniques may contribute to marginal enhancements in performance.

Gradient boosting models for cybersecurity threat detection with aggregated time series features

Ming Liu, Ling Cen, Dymitr Ruta
EBTIC, Khalifa University, UAE
{liu.ming,cen.ling,dymitr.ruta}@ku.ac.ae

***Abstract*—The rapid proliferation of Internet of Things (IoT) devices has revolutionized the way we interact with and manage our surroundings. However, this widespread adoption has also brought forth significant cybersecurity challenges. IoT devices, with their interconnectedness and varying functionalities, present a unique threat landscape that requires tailored detection techniques. Traditional approaches to cybersecurity, primarily focused on network monitoring and anomaly detection, often fall short in effectively identifying threats originating from IoT devices due to their dynamic and complex behaviors. This paper addresses our solution for FedCSIS 2023 Challenge: Cybersecurity Threat Detection in the behavior of IoT Devices. First, we aggregated time series features, and then at the feature selection stage, we filtered and combined different categorical and numerical features to generate four different feature sets. The Gradient boosting models, i.e. lightgbm, catboost and xgboost, are applied and trained individually with hyper-parameter tuning. The final three submissions are two best individual lightgbm models with the AUC scores of 0.9999 and 0.9998, respectively on the different feature sets, which secured the 4th place with a final score of 0.9993, and one ensemble result with a AUC score of 0.9998 from combination of xgboost, catboost and lightgbm, which has the final score of 0.9997 while unluckily was missing in the final three evaluation entries.**

***Index Terms*—Cybersecurity threat detection, Gradient Boosting Trees, CatBoost, XGBoost, LightGBM, Stacking, Ensemble Learning.**

I. Introduction

WITH the exponential growth of Internet of Things (IoT) devices, ensuring the security and integrity of these interconnected systems has become a paramount concern. The dynamic and heterogeneous nature of IoT devices presents a unique challenge for traditional cybersecurity approaches.

The survey paper in [1] comprehensively discusses the security issues faced in IoT environments and presents an overview of the existing security mechanisms and solutions. It covers various aspects of IoT security, including authentication, access control, privacy preservation, secure communication, and intrusion detection. The paper also highlights the unique security challenges posed by IoT and provides insights into ongoing research efforts to address those challenges.

Machine learning (ML) techniques have emerged as promising solutions for addressing IoT device security challenges. ML algorithms can analyze vast amounts of data collected from IoT devices to identify patterns, detect anomalies, and make predictions. By leveraging ML, IoT security can be improved through proactive threat detection, effective intrusion detection, and robust anomaly detection. In [2], various machine learning methods applied into IoT have been explored and a Support Vector Machine (SVM) application use case is presented. In [3], this survey paper offers insights into the application of various ML/DL techniques, such as deep learning, support vector machines, and decision trees, in enhancing IoT device security. It discusses the challenges faced in securing IoT devices and highlights the potential of ML methods in addressing those challenges. The paper also provides an overview of different use cases, datasets, and evaluation metrics used in the context of IoT device security.

In this paper, a model utilizing gradient boosting decision trees in conjunction with effective feature engineering and optimized model hyper-parameters, forming an ensemble learning approach has been developed for predicting the cybersecurity breaches to address the task given in the FedCSIS 2023 Challenge [4][1]. The objective of the challenge, which is sponsored by Łukasiewicz Research Network - Institute of Innovative Technologies EMAG and EFIGO sp. z o.o. companies, is to detect the cybersecurity breaches in log data from IoT devices.

The remainder of the paper is organized as follows. The FedCSIS 2023 Challenge is briefly described in Section II. Time series data aggregation and feature engineering is presented in Section III, followed with the description of the gradient boosting models and ensemble learning in Sections IV and V, respectively. The experimental results in Section VI. Concluding remarks are provided in Section VII.

II. FedCSIS 2023 challenge

The FedCSIS 2023 data mining competition focused on the detection of cybersecurity breaches in log data from IoT devices. The data sets contain 1-minute logs of all related system calls. The task for the competition participants is to develop a model that assesses the chances that a cyber attack was ongoing during the monitored period. Such a model could play a vital role in improving the safety of IoT systems. The knowledgepit.ai platform, on which the competition was hosted operated a leaderboard, which provided the feedback to the competitive model prediction submissions in a form of the preliminary AUC score [2] computed over the small subset of the testing set, while the final AUC score for the complete testing set - constituting the final results, were provided after the submissions' closure.

[1] https://knowledgepit.ml/fedcsis-2023-challenge

[2] https://en.wikipedia.org/wiki/Receiver_operating_characteristic

III. Data aggregation and feature engineering

The available training data provided by the competition organizers contain 15027 log files each given in a .csv table format with a uuid4 random name, in which the 1-minute logs of all related system calls are listed together with the timestamps given in the datetime formmat of yyyy-mm-dd-hh:mm:ss, eg. 2023-04-12-00:00:00. A small fraction in the training data is indicated to be hit by a cyberattack. The test data contains 5017 log files having the same format and naming scheme as the training files, while the cyberattack indication is not given.

To consolidate the feature sets, we wrote a python code to aggregate the time series log files, a generic aggregation filter fitting into all columns of the dataset as described below:

1) For numerical columns eleven self-explanative aggregators were applied, including:
   - *minimum*,
   - *maximum*,
   - *mean*,
   - *median*,
   - *sum*,
   - and *standard deviation*

   across all timestamps.
2) For categorical columns the aggregation treatment was made dependent on the most common frequency number of unique values.

In this way, each of the log files has been converted to a vector of aggregation features, representing a sample in both training and testing datasets. A binary label is given to each training sample, which represents whether or not a cyberattack is experienced.

IV. Gradient boosting models

Gradient boosting decision trees (GBDT) algorithms have emerged as a powerful and widely used technique in machine learning and data mining. GBDT combines the strengths of decision trees and boosting, resulting in a highly accurate and robust predictive model. This approach has been successfully applied in various domains, including finance, healthcare, and online advertising [5]. In [6], it provides a comprehensive overview of GBDT algorithms, explaining their theoretical foundations, practical implementation details, and empirical results. The fundamental idea behind GBDT is to iteratively train weak decision trees and sequentially add them to an ensemble, where each subsequent tree aims to correct the mistakes made by the previous ones. This process is guided by a loss function that measures the discrepancy between the actual and predicted values. By minimizing the loss function, GBDT optimizes the model's ability to make accurate predictions. One of the key advantages of GBDT is its ability to handle both numerical and categorical features effectively. Through a process called feature engineering, GBDT algorithms transform raw data into meaningful and informative representations, enhancing the model's predictive capabilities. Efficient feature engineering techniques play a crucial role in improving the accuracy and interpretability of the GBDT model. We applied three popular GBDT algorithms XGBoost, CatBoost, and lightGBM to construct the ensemble learning model for predicting the cybersecurity breaches for this challenge. Moreover, for years our team has been participating in the data science competitions series organized by the KnowledgePit platform[3] using GBDT related algorithms for classification, regression and other related tasks [7] - [22] with outstanding results. Gradient boosting decision trees algorithms, with their ability to handle diverse data types, efficient feature engineering, and model hyper-parameter optimization, have proven to be a powerful tool for predictive modeling in various domains.

Initial tests conducted on the primary dataset provided evident findings, demonstrating that gradient boosting models outperformed other methods in terms of predictive accuracy, while also exhibiting favorable computational efficiency. Notably, when compared to simple linear regression and deep networks, the performance of gradient boosting models was significantly superior. Within the category of gradient boosting models, specifically XGBoost, LightGBM, and CatBoost, were employed and subsequently fine-tuned during the competition. Different variations of these models, trained with diverse parameters, were utilized in second-level ensembles, employing both simple aggregation and stacked retraining techniques.

Modern Machine Learning models have reached a level of sophistication where they offer extensive customization and adaptability to cater to diverse options, versions, and parametric configurations during the model construction process. Gradient boosting models serve as prime examples of such models, as they provide numerous algorithmic, representational, modeling, and statistical parameters that can be fine-tuned to effectively capture and represent the data. The ultimate goal is to learn a reliable regression function that accurately predicts continuous output based on the input variables, ensuring robust generalization on unseen data.

In order to handle the challenge of tuning a large number of parameters for each distinct model, we opted to utilize a fast and efficient rotational grid search approach built on the general grid search hyperparameter tuning [23] for the gradient boosting models: XGBoost, CatBoost, and LightGBM. This method involves assigning up to a set of unique values to each optimizable parameter, covering a comprehensive range within the parameter's search space, regardless of whether it is numerical or categorical.

Unlike an exhaustive parametric grid search, which would be computationally infeasible given the number of parameters involved, our approach focuses on incrementally finding local optima for a specific parameter while keeping the remaining parameters fixed. This process continues in a rotational manner, moving on to the next parameter only after no further improvement can be achieved from any local changes. By adopting this strategy, we can efficiently explore the parameter space without exhaustive evaluation.

[3] https://knowledgepit.ai/

To enhance the reliability of the best parameter configurations discovered, we applied Repeated Stratified 10-Fold cross validator. This technique helps eliminate the possibility of accidentally selecting configurations with unusually high performance. However, to mitigate the additional computational cost associated with cross-validation, we simplified the process of searching for local optima for each parameter. Specifically, we only performed a pair of neighboring checks for each turn, evaluating the performance above and below the current parameter value. The optimal value was then adjusted to the value that exhibited the maximum performance improvement.

By employing this rotational grid search hyperparameter tuning approach and integrating 10-fold cross-validation, we aimed to efficiently and effectively determine the most suitable parameter configurations for the gradient boosting models, ensuring reliable and high-performing models for our purposes.

Optimizing the hyper-parameters of the GBDT model is essential to achieve superior performance. Determining the appropriate values for hyper-parameters such as the learning rate, tree depth, and regularization parameters can significantly impact the model's predictive accuracy and generalization ability. Therefore, model hyper-parameter optimization is a crucial step in harnessing the full potential of GBDT algorithms.

This parameters optimization process is terminated when no improvement in cross-validated AUC performance was found from any local changes of parameters.

V. Ensemble model

For the final ensemble construction, we employed three fundamental gradient boosting models: XGBoost (XGB), LightGBM (LGBM), and CatBoost (CatB). To enhance the generalization performance of these models, we applied filters. The purpose of filter techniques is to expand the classifier into multiple versions that differ from each other, train them on either the entire training set or subsets of it, and then apply them to the testing set. The outputs of these model versions are subsequently aggregated together.

To further enhance diversity and seek improved predictive performance, we trained all baseline regression models on different feature subsets generated by our feature engineering engine. The primary distinction between these feature subsets was that the second set included a greater number of sparse columns obtained from an extensive application of one-hot-encoding to categorical features. This approach aimed to introduce more varied and complementary information for prediction.

By employing the combination of baseline gradient boosting models, diversification filters, and diverse feature subsets, we aimed to construct a final ensemble that not only exhibited enhanced diversity but also delivered superior predictive performance.

Furthermore, in order to explore additional avenues for performance improvement, we introduced an additional stacked layer consisting of simple linear regression. This layer was trained using the outputs generated by the baseline models. To facilitate the stacking layer's integration, we divided the training data into two distinct parts. The first part was utilized to construct the baseline models, while the second part was reserved specifically for learning the parameters of the linear regression model within the stacking layer.

In the end, we merged the outputs of each individual model and the outputs from the linear regression-based stacking by taking their average. The architecture, represented as a flow chart, showcasing the structure of the final ensemble, can be observed in Figure 1.

VI. Experimental results

Throughout the competition, we used sklearn packages, xgboost, lightgbm and catboost under Python3 Jupyter Notebook[4] in a Windows Server Virtual Machine with 128G RAM memory and Intel(R) Xeon(R) Gold 6230R CPU@2.10GHz, 2 Processors to run simulations. We did intensive feature aggregation and different feature combination by removing or filtering some columns as mentioned below in Table I.

The different features sets, along with their corresponding impact on the performance of individual models on the limited and sparse training and testing datasets, is summarized in Table II.

While numerous parametric variants demonstrated strong performance throughout the competition, we obtained our best individual model scores by utilizing specific model parameters, as indicated in Table III.

It can be easily seen from Table II, the performance of each model for different feature datasets has only slightly difference, even for 40 features only we can also achieve AUC 0.9999, it is most probably due to the very limited and unbalanced training and test dataset, and as AUC score is near 1, so honestly speaking it is very difficult to improve the model performance consider the trade off potential or already model overfitting problem which is very much challenging in terms of considering model stability rather than accuracy performance.

To be safe and ensure our model is more robust enough, we only consider the full aggregated features of 149 features and the compact version of 40 features, and also build our ensemble model on top of the three individual model LGBM, XGB and CatB to make it more robust. Our chosen datasets, (AUC) results, along with the optimal model parameters determined for each model are described below:

1) Feature set 1 with 149 features:
   - CatB (learning rate 0.02, depth 3, iterations 1000): 0.9983
   - LGBM (learning rate 0.02, depth 3, iterations 1000): 0.9999
   - XGB (learning rate 0.01, depth 3, iterations 3000): 0.9976
2) Feature set 2 with 40 features:
   - CatB (learning rate 0.02, depth 3, iterations 1000): 0.9986
   - LGBM (learning rate 0.02, depth 3, iterations 1000): 0.9998

[4] https://jupyter.org/

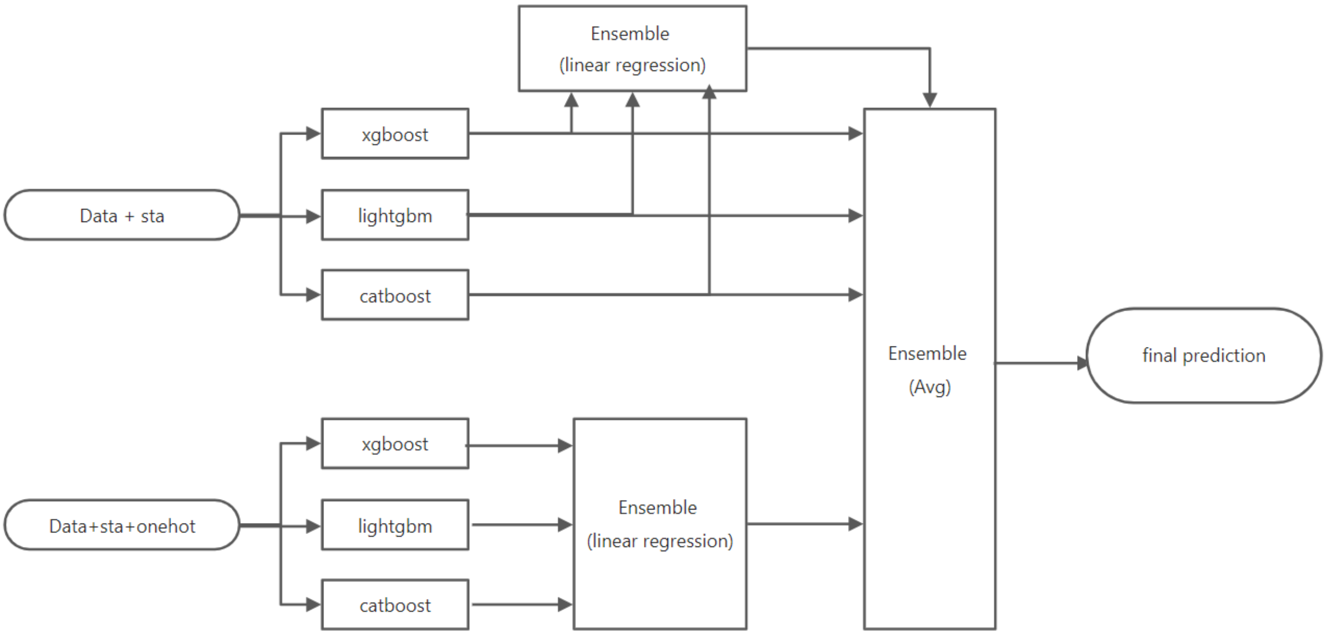

Figure 1. Flowchart of the final ensemble model.

Table I
VERSION OF FEATURES COMBINATION DATASETS

Version	Number of Features	Ignored Columns Numbers	Ignored columns names
V1	149	0	Full aggregated columns
V2	40	19 columns ignored on top of V1	"USER_AUTH","USER_MGMT_COUNT","CRED_COUNT", "USER_ERR_COUNT","USYS_CONFIG_COUNT","CHID_COUNT", "SELINUX_ERR_COUNT","SYSTEM_COUNT","SERVICE_COUNT", "DAEMON_COUNT","NETFILTER_COUNT","SECCOMP_COUNT", "AVC_COUNT","ANOM_COUNT","INTEGRITY_COUNT", "KERNEL_COUNT","RESP_COUNT","SELINUX_MGMT_COUNT", "CUSTOM_openSockets"
V3	28	2 columns ignored on top of V2	"KILL_process","KILL_uid"
V4	23	5 columns ignored on top of V3	"SYSCALL_exit_hint_common", "USER_ACTION_op_common", "USER_ACTION_src_common", "USER_ACTION_res_common", "USER_ACTION_addr_common"

Table II
FEATURES AND AUC-MEASURED INDIVIDUAL MODEL PERFORMANCE

Version	Number of Features	LGBM	XGB	CatB
V1	149	0.9999	0.9983	0.9976
V2	40	0.9998	0.9988	0.9986
V3	28	0.9993	0.9975	0.9982
V4	23	0.9990	0.9976	0.9981

Table III
OPTIMIZED INDIVIDUAL MODEL PARAMETERS

Model	Encoder	Iterations	Learning Rate	Tree Depth
LGBM	onehot	1000	0.02	3
XGB	ordinal	3000	0.02	3
CAT	onehot	1000	0.01	3

- XGB (learning rate 0.01, depth 3, iterations 3000): 0.9988

And, stacking ensemble models based on linear regression were trained using the outputs from the diversified individual models. These stacking models exhibited preliminary AUC performance as follows:

- Stacking model with 149 features: 0.9998
- Stacking model with 40 features: 0.9996

The final predictions are obtained by averaging the outcomes of both stacking models and diversified individual baseline models using an ensemble approach. This ensemble averaging results in an AUC of approximately 0.9998 in the preliminary score. However due to some mistakes, this ensemble model submission was missing in the three final entries, so we only submitted two entries of LGBM which scored the 0.9993 as the 4th place, while this ensemble model can achieve 0.9997 AUC score evaluated with the final released test labels which means the ensembled model is more robust than the single model.

VII. Conclusions

We endeavored to enhance the predictive performance of the already robust regression models within the gradient boosting family, namely XGBoost, LGBM, and CatBoost. To accomplish this challenge, we applied a range of GBDT methods, combined with different ensemble combination techniques and observed improved performance achieved through aggregating the expanded set of diverse model versions. Additionally, we employed linear regression-based stacking and selected the most effective ensemble candidates based on the trade-off between performance and diversity.

We applied this proposed ensemble approach to the challenging task of advance prediction of cybersecurity breaches in IoT device log data, which involved various types and forms of data. Our solution was implemented and evaluated within the competitive framework of the FedCSIS 2023 data mining challenge. In the preliminary leader-board of the challenge, our proposed solution achieved the fifth position with an AUC of 0.9999, while in the final ranking we are 4th place with AUC score 0.9993 even though unluckily our ensemble model entry was missing in the final three entries and this ensemble model can achieve the AUC score 0.9997 with most stable and robust compared the AUC score 0.9998 in the preliminary leader-board. Our solution holds potential for enabling network service providers to better anticipate hacker threats and bolster their cybersecurity measures.

Center for Artificial Intelligence Challenge on Conversational AI Correctness

CENTER for Artificial Intelligence Challenge on Conversational AI Correctness was organized as part of the 1st Symposium on Challenges for Natural Language Processing. The goal of this competition was to develop Natural Language Understanding models that are robust against speech recognition errors.

Regardless of near-human accuracy of Automatic Speech Recognition in general-purpose transcription tasks, speech recognition errors can significantly deteriorate the performance of a Natural Language Understanding model that follows the speech-to-text module in a virtual assistant. The problem is even more apparent when an ASR system from an external vendor is used as an integral part of a conversational system without any further adaptation. The contestants were expected to develop Natural Language Understanding models that maintain satisfactory performance despite the presence of ASR errors in the input.

The data for the competition consist of natural language utterances along with semantic frames that represent the commands targeted at a virtual assistant. The approach used to prepare the data for the challenge was meant to promote models robust to various types of errors in the input, making it impossible to solve the task by simply learning a shallow mapping from incorrectly recognized words to the correct ones. It reflects real-world scenarios where the NLU system is presented with inputs that exhibit various disturbances due to changes in the ASR model, acoustic conditions, speaker variation, and other causes.

This chapter includes the paper discussing the objectives, evaluation rules and results of the competition, authored by the organizers followed by the detailed description of the leading solution contributed by the winners of the challenge.

***Abstract*—This paper describes a challenge on Conversational AI correctness with the goal to develop Natural Language Understanding models that are robust against speech recognition errors. The data for the competition consist of natural language utterances along with semantic frames that represent the commands targeted at a virtual assistant. The specification of the task is given along with the data preparation procedure and the evaluation rules. The baseline models for the task are discussed and the results of the competition are reported.**

I. Introduction

REGARDLESS of the near-human accuracy of Automatic Speech Recognition in general-purpose transcription tasks, speech recognition errors can significantly deteriorate the performance of a Natural Language Understanding model that follows the speech-to-text module in a virtual assistant. The problem is even more apparent when an ASR system from an external vendor is used as an integral part of a conversational system without any further adaptation. The goal of this competition is to develop Natural Language Understanding models that are robust to speech recognition errors.

The approach used to prepare data for the challenge is meant to promote models robust to various types of errors in the input, making it impossible to solve the task by simply learning a shallow mapping from incorrectly recognized words to the correct ones. It reflects real-world scenarios where the NLU system is presented with inputs that exhibit various disturbances due to changes in the ASR model, acoustic conditions, speaker variation, and other causes.

II. Related Work

The robustness of Natural Language Understanding models to various types of errors is a subject of several publications. Some authors proposed to use word confusion networks to improve models' robustness to ASR errors [1], [2], [3], [4]. Reference [5] developed a learning criterion that prefers NLU models that are robust to ASR errors by adding a loss term that measures the distance between the prediction distribution from transcriptions and ASR hypotheses. Reference [6] studied the performance of intent classification and slot labeling models with respect to several kinds of perturbations, such as substituting abbreviations and synonyms, changing casing and punctuation, paraphrasing, and introducing misspellings and morphological variants. Speech characteristics are among three aspects of robustness investigated by [7] in the assessment of task-oriented dialog systems. Reference [8] investigated data-efficient techniques that apply to a wide range of natural language understanding models used in large-scale production environments to make them robust against speech recognition errors, using domain classification as an example. The authors compared the effectiveness of several such techniques in terms of time-varying usage patterns and distribution of ASR errors.

Several benchmarks exist to evaluate NLU models regarding their robustness to ASR errors. RADDLE [9], a benchmark for evaluating the performance of dialog models, prefers models robust to language variations, speech errors, unseen entities, and out-of-domain utterances. ASR-GLUE [10] is a benchmark consisting of 6 different NLU tasks, for which the input data were recorded by six different speakers and at three different noise levels.

Mitigating the impact of ASR errors on downstream tasks was the subject of several contests. In [11], the authors proposed a challenge for improving the recognition rate of an ASR system on the basis of incorrect ASR hypotheses paired with reference texts. Post-edition of ASR output was also the objective of the shared task held by [12]. Speech-aware dialogue state tracking was the topic of a recent competition conducted by [13].

The data preparation procedure outlined in Section III involves combining a TTS model and an ASR system. Augmentation of speech corpora with the use of synthesized speech was investigated by [14] and [15]. Reference [13] uses synthesized inputs along with spoken utterances in their challenge.

Holding competitions as a method for finding promising solutions to scientific problems has a long history in computer science, particularly in natural language processing [16], [17].

This research was partially funded by the "CAIMAC: Conversational AI Multilingual Augmentation and Compression" project, a cooperation between Adam Mickiewicz University and Samsung Electronics.

This contest is organized under the 1st Symposium on Challenges for Natural Language Processing (CNLPS), a part of the 18th Conference on Computer Science and Intelligence Systems (FedCSIS 2023). FedCSIS Conference Series hosted a wide range of data mining competitions through the years that covered topics such as identifying key risk factors for the Polish State Fire Service [18], network device workload prediction [19], and predicting the costs of forwarding contracts [20]. In the process of running our CNLPS challenge, we followed the best practices set out by the organizers of FedCSIS data mining competitions.

III. Data

The data for the task are derived from the Leyzer dataset [21]. The samples consist of user utterances and the semantic representation of the commands targeted at a virtual assistant (VA). A fraction of the utterances in the training set is contaminated with speech recognition errors; however, we left most of the utterances intact to make the task more challenging. The erroneous samples were obtained from user utterances using a TTS model followed by an ASR system.

A. Preparation of Base Text Corpus

We used the second version of the Leyzer corpus, which consists of more utterance variations when compared to the version described in the original paper. The second version of the corpus introduced two additional sub-intent differentiation levels called *naturalness level* (or simply *level*) and *verb pattern*. Although we have not implicitly used this information in this contest, it allowed us to create more variant corpus for the task. Leyzer consists of 20 domains across three languages: English, Spanish, and Polish, with 186 intents and a wide range of samples per intent. Domains can be grouped into several topics that can be found in the most popular VAs:

- **Communication** with Email, Facebook, Phone, Slack, and Twitter domains in that group, which all relate to communication and the transfer of ideas,
- **Internet** with Web Search and Wikipedia that groups domains related to the search for information on the web; therefore, these domains will have a lot of open-title queries,
- **Media and Entertainment** with Spotify, YouTube, and Instagram domains in that group, which relate to multimedia content with named entities connected to artists or titles,
- **Devices** with Air Conditioner and Speaker domains, which represent simple physical devices that can be controlled by voice,
- **Self-management** with Calendar and Contacts, which consist of actions that involve time planning and people,
- **Other**, uncategorized domains (Fitbit, Google Drive, News, Translate, Weather, Yelp) represent functions and language not shared by other categories. In this sense, the remaining domains can be understood as intentionally not matching the other domains.

Using scripts provided in the Leyzer repository, we generated the text corpus from JSGF grammars. The corpus was divided into `train`, `valid`, `test-A`, and `test-B` parts using the splitting script provided in the Leyzer repository. First, we differentiate `test-B` from the rest of the corpus. For `test-B`, a minimum of 1 test case and up to 20% of the total available sentences for each intent, level, and verb pattern were selected, and the remaining test cases were left in the development corpus. From the development part of the corpus, we further differentiate `test-A` using the same procedure as for `test-B`, which extracted a minimum of 1 and up to 20% of test cases for each intent, level, and verb pattern triplet. The remaining corpus was divided into `train` and `valid` subsets. The `valid` subset is 20% of randomly selected test cases without assuring that it contains at least 1 test case for each intent, level, and verb pattern triplet.

B. Augmenting Corpus with Back-transcription

Back-transcription is a technique that can be used to produce speech transcripts from text-only data. Textual data are fed to a TTS engine to produce a speech signal, which in turn is fed to an ASR system, producing an augmented text. Depending on the performance of both models and differences in text normalization performed on the input text, as well as inside these models, the resulting text can be identical to the input or may contain differences introduced in either processing stage. The technique has been used to develop post-processing [22] and error correction [23] models for ASR systems.

We use back-transcription to simulate a virtual assistant user's behavior. The user speaks to the system, and their speech is converted into text by an ASR model, which is subsequently processed by an NLU model (see Fig. 1). NLU text prompts from the Leyzer corpus are synthesized using a TTS engine. The resulting sound signal is used as input to an ASR model producing back a text with an augmented NLU prompt. The procedure is illustrated in Fig. 2. To perform Text-To-Speech synthesis, we used the FastSpeech 2[1] model [24] for English, the VITS model [25] for Polish, and Tacotron 2 [26] for Spanish, both from the Coqui TTS library [27]. Speech recognition was performed using the Whisper[2] model [28] for all three languages.

C. CAICCAIC Dataset

The training data are located in the `train` directory of the contest's repository[3]. The `train` directory contains two files:

- `in.tsv` with four columns:
  1) sample identifier: *306*,
  2) language code: *en-US*,
  3) data split type: *train*,
  4) utterance: *adjust the temperature to 82 degrees fahrenheit on my reception room thermostat.*
- `expected.tsv` with three columns representing:

[1] https://huggingface.co/facebook/fastspeech2-en-ljspeech

[2] https://huggingface.co/openai/whisper-large

[3] https://github.com/kubapok/cnlps-caiccaic

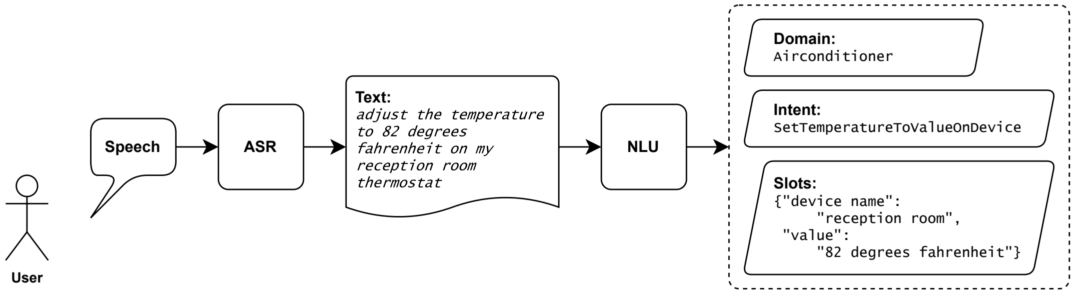

Fig. 1. Spoken Language Understanding.

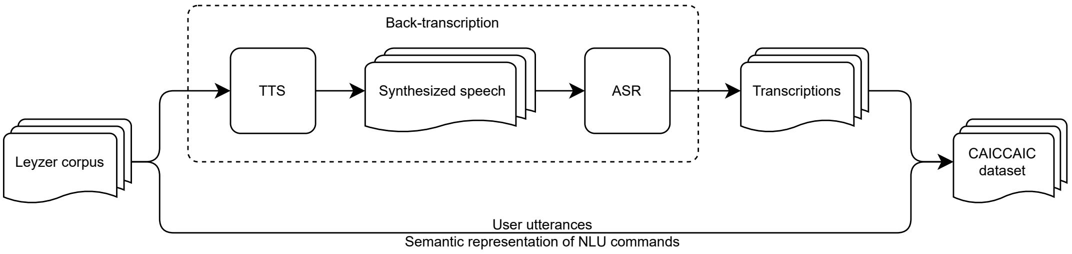

Fig. 2. Dataset preparation pipeline.

1) domain label: *Airconditioner*,
2) intent label: *SetTemperatureToValueOnDevice*,
3) slot values:
`{"device_name": "reception room",`
`"value": "82 degrees fahrenheit"}`

For experimentation, we provide the validation dataset in the `dev-A` directory of the contest's repository. It was created using the same pipeline as the `train` dataset. The test data are located in `test-A` and `test-B` directories and contain only input values, while expected values hidden for contestants are used by the evaluation platform to score submissions.

IV. Baseline Models

We use XLM-RoBERTa Base [29] as a baseline model for intent detection and slot-filling. The XLM-RoBERTa model, also known as XLM-R, is a transformer-based multilingual masked language model that employs a multilingual masked language model (MLM) objective using only monolingual data. During training, streams of text from each language are sampled, and the model is trained to predict the masked tokens in the input. Subword tokenization is applied directly to raw text data using SentencePiece [30] with a unigram language model. The model does not use language embeddings, which allows it to handle code-switching better. It uses a large vocabulary size of 250K with a full softmax.

XLM-R was pre-trained on 2.5 TB of filtered CommonCrawl data containing 100 languages. This large-scale training led to significant performance gains for various cross-lingual transfer tasks. The model significantly outperforms multilingual BERT (mBERT) on various cross-lingual benchmarks.

Our baseline models were trained independently on the entire training set and optimized on the evaluation set. All baseline models have 12 layers, 768 hidden units, and 12 attention heads, totaling 270M parameters, and a size of 1.1 GB.

We use the `leyzer-fedcsis`[4] dataset from the Hugging Face Model Hub in the baseline training process. Each language-specific portion is processed individually, retaining only the `utterance` and `intent` columns. The processed datasets are then merged and split into training, validation, and testing sets. The model is defined for a sequence classification task using the `AutoModelForSequenceClassification` class, with the number of labels corresponding to the unique intents in the training dataset. Training hyperparameters were set to a learning rate of 2×10^{-5}, a training batch size of 16, a weight decay of 0.01, and 10 training epochs. Evaluations are performed after each epoch.

Finally, performance metrics such as accuracy and F_1 score are computed to assess the model's effectiveness in its classification task. The final epoch checkpoint evaluation results on the test set are presented in Table II in the "official baseline" row. All baseline intents models achieved results above 90% accuracy, with Spanish, Polish, and all-language models achieving above 95%. We analyzed misclassification errors and found that most of them could be resolved if a model resisted token distortion and could separate syntactically similar classes.

The error analysis of the intent recognition models for English, Spanish, and Polish languages reveals similarities and differences across the models. The *Spotify* domain tends to be the most problematic for all three languages, suggesting that these models may struggle with understanding and predicting

intents related to music streaming or the specific language used in this domain. *Slack* and *Console* domains also prove problematic for the English and Polish models, while for the Spanish model, the recognition of the *Airconditioner* and *Email* domains was the most challenging. Regarding specific intents, the English model has the most trouble with *ConsoleEdit* and *AddAlbumToPlaylist*, the Spanish model struggles with *PlayAlbumOfTypeByArtist* and *TurnOn*, and the Polish model with *SetPurposeOnChannel* and *PlayAlbumOfTypeByArtist*. These intents may be harder to recognize due to their semantic complexity, similarity to other intents, or underrepresentation in training data.

All models are available on the Hugging Face platform with details of how each model was trained and how to execute them:

- intent: en-US[5], es-ES[6], pl-PL[7], and all[8] that was trained and evaluated on all three languages together
- slot: en-US[9], es-ES[10], pl-PL[11]

V. Evaluation

The solutions for the task were submitted via the Gonito platform [31] challenge available at https://gonito.csi.wmi.amu.edu.pl/challenge/cnlps-caiccaic. For `in.tsv` file located in `test-A` directory, the participants were expected to provide `out.tsv` file in the same directory containing the predictions. The format of `out.tsv` was the same as the format of `train/expected.tsv`. Participants were allowed to use any publicly available data and models. Manual labeling was forbidden. A maximum of five submissions per day were allowed.

The submissions were scored using *Exact Match Accuracy* (EMA), i.e., the percentage of utterance-level predictions in which domain, intent, and all the slots are correct. Besides EMA scores, we also report the following auxiliary metrics:

- *domain accuracy*, i.e., the percentage of utterances with correct domain prediction;
- *intent accuracy*, i.e., the percentage of utterances with the correct intent prediction;
- *slot word recognition rate*, i.e., word recognition rate (WER) calculated on slot annotations, which is the percentage of correctly annotated slot values.

All scores were calculated using the GEval [32] library, which was also made available to participants for offline use.

VI. Results

We received 28 submissions from 9 teams. Table II presents the final ranking with cumulative metrics for all languages[12]. Notably, most submissions are based on pre-trained Transformer models [33] adapted to the task, with the Flan-T5 model [34] being the preferred choice. However, the winning

solution [35] used the mBART model [36] as its basis to train a joint, text-to-text model of domain, intent, and slots. This model achieved an Exact Match Accuracy of 0.754 across all the samples, with top results attained for Polish and Spanish NLU commands (0.799 and 0.884 EMA, respectively). It demonstrated outstanding performance in slot recognition with a slot WRR of 0.872 (0.067 better than the second-best solution). Although the winning solution performed well overall, it was within the accuracy of XLM-RoBERTa baseline models regarding domain and intent accuracy. This observation is intriguing and could be a valuable starting point for future research on developing joint models for domains, intents, and slots.

To gain more insight into the differences between the winning model and the baseline, we performed the analysis using the Geval tool [32]. Geval's "most worsening feature" function was used to analyze cases for which one of the models is problematic while the other behaves correctly. The function calculates the difference in a chosen metric between two models being compared, on cases containing a specific feature. The results are reported for cases for which the difference is statistically significant. Table III shows the features that had the most negative impact on the winning results compared to the baseline submission. It appears that numbers in their written form in English input are problematic for the mBART model. Also, it is not surprising to see that English inputs, in general, are easier for the baseline solution compared to the winning one, considering the overall results presented in Table II. Additionally, the mBART model has problems with one of the image-finding intents, which is consistent with the problematic word "images" in input sentences. Conversely, Table IV presents features that were problematic for the winning submission while being easier for the baseline model. The most problematic features are connected with the *Email* domain. It looks as baseline model has problems with identifying all kinds of slots of commands used for sending emails. These observations should prompt the authors of the winning submission and anyone else who wants to improve on these results to take a closer look into the specific causes of these particular types of errors and work towards addressing them.

***Abstract*—This paper describes the winning submission to the challenge CAICCAIC: Center for Artificial Intelligence Challenge on Conversational AI Correctness. The aim of the challenge was to design a mechanism of natural language understanding capable of interpreting user prompts. The prompts were the output of an automatic speech recognition system and therefore contained errors. In this scenario, it was necessary to apply techniques of accounting for these errors. As per the results of the challenge, the most effective technique proved to be an original use of a sequence to sequence model. The key idea was the concatenation of labels before passing them to the model for training and prediction.**

I. Problem formulation

AUTOMATIC Speech Recognition (ASR) systems are immensely popular in today's world. They find use in assistant applications for phones, cars or at home. The ASR techniques have been perfected over many years to achieve maximum available output quality. However, it is not always possible to recognize speech with perfect accuracy due to numerous factors, such as:

- external noise,
- individual voice features (prosody),
- ambiguity of spoken language

and many others. Problems with the accuracy of ASR may also arise from using imperfect models which produce sub-optimal output quality.

In such scenarios it is well justified to apply an error proof natural language understanding (NLU) module on the results of ASR. The goal of that module is the conversion of the text output of ASR into semantically meaningful objects. Typically, NLU modules operate on ASR output which is assumed to be correct. If ASR makes an error, NLU is not necessarily expected to interpret the output of ASR correctly. In this challenge, however, the text input to NLU is noisy.

This simulates the real-life data which is typically presented to ASR systems in the form of user commands. Being able to counter the challenges of processing this data allows for the creation of more robust and usable voice command interpreters. This research has potentially very high impact on the experience of the users of those systems who are often left frustrated by the ASR module not functioning properly. This frustration not only lowers the user's satisfaction but often causes the user to refrain from using the system completely. Proper handling of ASR errors can enable the usage of voice commands more frequently and in more different scenarios.

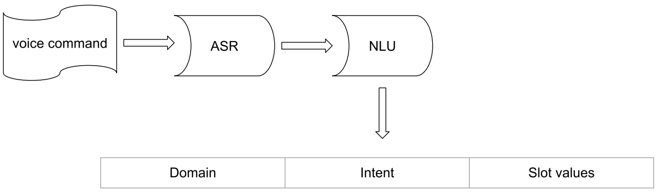

Fig. 1. The usage of the ASR system

The CAICCAIC: Centre for Artificial Intelligence Challenge on Conversational AI Correctness [1] was organized to spark the research on ASR error correction. The challenge was published on the Gonito.net platform [2]. The data set consisted of utterances of user commands annotated with the following data:

- Domain
- Intent label
- Slot values

The usage of the ASR system is presented in Figure 1 (source of the figure: [1]).

Domain is a general indication of the environment that the user is interacting with. For instance, this may be the name of the voice operated appliance, such as *Airconditioner*.

Intent is the specific action the user would like to see accomplished by using a voice command. The intent in the data set is given as a string label representing a specific function of the appliance. In the domain of an air conditioner, the example intent label is *SetTemperatureToValueOnDevice*.

Slot values are pieces of specific information being passed along with the voice command. Exemplary slot values are presented below:

```
{'device_name': 'reception room',
'value': '82 degrees fahrenheit'}
```

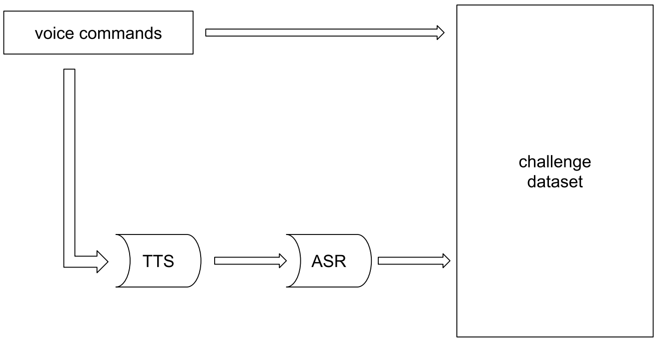

Fig. 2. Challenge data preparation

TABLE I
STATISTICS OF THE DATA

Language	Set	Utterances	Mean length
English	test	3344	9.95
English	train	13022	9.34
English	valid	3633	9.28
Spanish	test	3520	13.21
Spanish	train	15043	13.37
Spanish	valid	3546	13.15
Polish	test	3494	8.93
Polish	train	12753	8.97
Polish	valid	3498	9.02

Some of the annotated user commands in the data set of the challenge were intentionally distorted by the task organizers. However, in order not to let the participants of the challenge train NLU modules on those distortions, majority of user commands were left intact.

Distortion was achieved by first feeding the original utterances into a Text-To-Speech (TTS) system in order to obtain their audio versions. These, in turn, were converted back to text with the means of an ASR system. Since both TTS and ASR are prone to errors, the final text output was distorted. The utterances were prepared according to the scheme presented in Figure 2 (source of the figure: [1]).

The data was prepared in English, Spanish and Polish. Annotated utterances were split into train, test and validation sets. The statistics of the data are presented in Table I.

II. Related research

The problem of identifying the domain and intent can be seen as classification of distorted data. Such problems were typically approached with the use of statistical methods. One such solution is described in [3]. This work was dealing with the problem of thematic classification of texts. The texts were articles from a collection of digital libraries and were output of an OCR mechanism. Noisy data was not corrected but instead classified as is with the use of Latent Dirichlet Allocation.

The same text data was also used in another research - automatic prediction of the year of publication of the article. This was organized as the RetroC challenge [4] on the aforementioned Gonito.net platform. Winning submissions to this challenge also did not venture to correct OCR errors but instead performed the classification on the raw text data.

The problem of filling the slots, on the other hand, requires not only classification but deeper understanding of spoken language. The article [5] describes the challenges of this task and lists current solutions. Among the main challenges is the nature of ASR errors. These errors are significantly different than those observed in text (typing, spelling or grammar mistakes). In ASR whole words and phrases are substituted with fragments sounding similarly but carrying completely different meaning.

According to the authors [5], majority of researchers approaching the problem of interpreting noisy ASR output focus on correcting the errors first with the use of text correction tools, such as in [6]. The corrected ASR output is then interpreted using a NLU module. However, in recent years a new trend is observed. Experiments with direct understanding of spoken language (SLU - Spoken Language Understanding) have yielded impressive results (see for instance [7]).

The approach assumed in the CAICCAIC challenge, however, is based only on text processing. This has the following advantages over SLU:

- independence of the ASR module,
- not requiring specialistic speech-to-meaning data sets,
- ability to take full advantage of recent advances in text modelling and generation.

Among natural language processing techniques known to operate well on text containing errors we can mention character-based neural networks. The paper [10] presents research on error correction using character-based attention architecture. Thanks to operating on the character level, the solution is able to deal with out-of-vocabulary words.

III. Solution

This section describes the author's solution to the problem formulated by the CAICCAIC challenge which was evaluated as the winning submission.

The classic solution to this problem would involve training three separate classifiers – for domain, intent and slot values. The problem of identifying the domain is relatively the easiest. It can be viewed as a classification problem with few classes (there were not many distinct domain labels in the data set). Such problem could have been solved with classic text feature extraction methods (TF-IDF) and statistical classification mechanisms, such as SVM. Since the domain is heavily dependent on some specific keywords in the user prompt (e.g. temperature - air conditioner, event - calendar etc.)

Similarly, the intent classification could probably also be approached this way. Here, however, the spectrum of possible values of the intent label is wider. Moreover, the intent is not necessarily well correlated with specific words in the user prompt. This is due to the fact that a single intent can be expressed in many ways by the user. Consider the following example: the intent of checking the current temperature on an air conditioner can be expressed in the following ways (examples taken from the training set of the challenge):

- how many fahrenheits degrees are on my cooling system
- show me the temperature on the playroom thermostat
- give me temperature on my air conditioning

This makes the problem of classifying the intent label more difficult than the classification of the domain.

Moreover, the problem of filling the slot values is even more challenging. In this case it is not sufficient to guess a value from a narrow set. This problem consists in interpreting the user prompt and extracting the most important piece of information. This problem should rather be approached using text generation techniques.

This the exact idea behind the author's solution to the whole problem. In the rise of sequence to sequence language models the problem was approached with this exact technique.

Instead of training three separate models, only one is trained. During training, the expected output was concatenated into one sequence. Thus, the model was trained with the sequences in the format presented in Table II. The output of the model was then split into domain, intent and slot values.

In order to take full advantage of a sequence to sequence model it was necessary to use one created with sizeable training data. This was done in hope of achieving the best possible results especially in the task of filling the slot values. Apart from that, the model had to be multilingual as the data set contained sentences in English, Spanish and Polish. The language of the prompt was in fact annotated in the data but author's solution was aimed at providing a language-independent NLU module. The use of a large-scale model was also motivated by the fact that the input is sometimes distorted. Such models are known to deal well with the task of text generation even for noisy prompts.

At first, the FLAN-T5 [8] model was used. It was observed, however, that the results it renders fall below expectations for a specific technical reason. For Polish prompts, the outputs rendered by FLAN-T5 had erroneous Polish character encoding. This caused a significant and unnecessary drop in the quality measures of the CAICCAIC challenge. This motivated the switch to the Facebook mBART [9] model which yielded much better results altogether.

IV. Evaluation of the solution

As all submissions to the CAICCAIC challenge, the author's challenge was evaluated according to a detailed procedure described in [1]. The metric used to rank the submissions was Exact Match Accuracy (EMA), i.e. "the percentage of utterance-level predictions in which domain, intent, and all the slots are correct". Apart from that, the following additional metrics were reported for each submission:

- Domain accuracy (the percentage of utterances with correct domain prediction)
- Intent accuracy (the percentage of utterances with the correct intent prediction)
- Slot Word Recognition Rate (Word Recognition Rate calculated on slot annotations which is the percentage of correctly annotated slot values).

The evaluation scores for top five submissions are presented in Table III.

V. Error analysis

This section presents the analysis of some of the errors that the author's solution has committed. An error is counted when as per the Exact Match Accuracy metric. This means that error is reported when any of the labels is predicted incorrectly by the system.

A. Example: cold/weather

Command:

```
it is too cold in here
```

Expected output:

```
Airconditioner ChangeTemperature {}
```

System's output:

```
Weather OpenWeather {}
```

This example shows incorrect attribution of domain, intent and slot values. This error is caused by the confusion related to the word "cold" which can be associated with both air-conditioning and weather.

B. Example: temperature

Command:

```
20 degrees celsius would be ideal
temperature because it is too cold in here
```

Expected output:

```
Airconditioner SetTemperatureToValue
{'value': '20 degrees celsius'}
```

System's output:

```
Weather SetTemperatureToValue
{'value': '20 degrees celsius'}
```

This example shows incorrect attribution of the domain only. This is caused by the association of the word "temperature" with weather instead of air-conditioning. Based on this and the previous error example it is possible to conclude that the author's solution could benefit from a separate model to predict the domain only. Such model would have higher probability of predicting the domain correctly in these cases and this information could be used to affect the predictions of intent and slot values.

C. Example: expected result is not the only correct

Command:

```
give me information about my events
```

Expected output:

```
Calendar CheckCalendarOnDate {}
```

System's output:

```
Calendar OpenCalendar {}
```

The system's output is also acceptable.

TABLE II
EXAMPLE DATA FOR A TEXT2TEXT MODEL TRAINING

Input	Output
change the maximum temperature on my thermostat	Airconditioner ChangeTemperature {}
check the temperature on the keeping room sensor	Airconditioner GetTemperatureFromDevice {'device_name': 'keeping room'}

TABLE III
TOP FIVE SUBMISSIONS IN THE CAICCAIC CHALLENGE

Description	Slot WRR	Intent	Domain	EMA
author	0.87	0.92	0.96	0.75
flanT5-large	0.80	0.92	0.97	0.69
baseline	0.75	0.95	0.98	0.68
flanT5-large	0.77	0.90	0.95	0.67
flanT5-large	0.74	0.82	0.93	0.57

D. Example: minor mistake

Command:

```
update me when an appointment
in the calendar in location thornton begins
```

Expected output:

```
Calendar NotifyOnEventInLocation
{'location': 'thornton'}
```

System's output:

```
alendar NotifyOnEventInLocation
{'location': 'tornton'}
```

This error is a minor phonetic mistake.

VI. CONCLUSIONS

In general, the results achieved by the first five submissions prove the hypothesis that the problem of domain classification was relatively the easiest, intent label classification slightly more difficult and slot filling significantly more challenging than the first two problems. Also, the FLAN-T5 language model was a popular choice among the participants. This followed from the fact that the idea behind the Gonito.net platform is full collaboration between participants. Taking the solution of another participant, improving it even slightly and then uploading it as one's own is not only not forbidden but encouraged.

It can be observed that the author's solution scored significantly better in the most important EMA metric and on par with the best solutions in all other metrics. Best results in intent and domain classification individually were achieved by the baseline provided by the organizers of the challenge.

A good idea for future experiments would be a combination of solutions from the baseline and from the winning submission. Some errors identified during the error analysis process could also be corrected.

Temporal Image Caption Retrieval Competition

TEMPORAL Image Caption Retrieval Competition was organized as part of the 1st Symposium on Challenges for Natural Language Processing. The goal of the competition was, given a picture from a newspaper and the newspaper's publication daily date, to retrieve a picture caption from a given caption set.

Multimodal models, especially combining vision and text, are gaining great recognition. One such multimodal challenge is Text-Image retrieval, which is to retrieve an image for a text query or retrieve a text for a given image. In this challenge, we introduce a task in the Text-Image retrieval setup, additionally extending the modalities with temporal data.

Language models rarely utilize any input information except for text. E.g additional data could be a text domain, document timestamp, website URL, or other metadata information. However, models trained solely on text data may be limited in usage. Additional temporal information is useful when factual knowledge is required, but the facts change over time.

The presented task is based on the Chronicling America [1] and Challenging America [2] projects. Chronicling America is an open database of over 16 million pages of digitized historic American newspapers covering 274 years. Challenging America is a set of temporal challenges built from the Chronicling America dataset.

This chapter includes the paper discussing the objectives, evaluation rules and results of the competition, authored by the organizers followed by the detailed description of the leading solution contributed by the winners of the challenge.

***Abstract*—Multimodal models, which combine visual and textual information, have recently gained significant recognition. This paper addresses the multimodal challenge of Text-Image retrieval and introduces a novel task that extends the modalities to include temporal data. The Temporal Image Caption Retrieval Competition (TICRC) presented in this paper is based on the Chronicling America and Challenging America projects, which offer access to an extensive collection of digitized historic American newspapers spanning 274 years. In addition to the competition results, we provide an analysis of the delivered dataset and the process of its creation.**

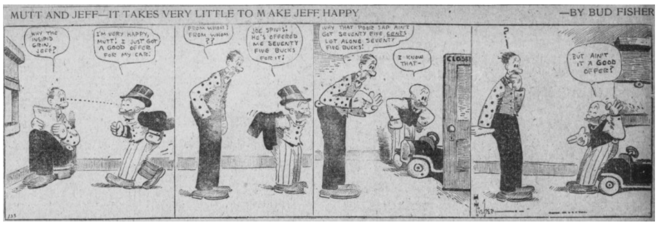
I. Introduction

MULTIMODAL models are gaining great recognition, especially those combining image and text. A recent example is the image generation model, DALL·E 2 [1]. Tasks executed by such multimodal models usually consist of text-image retrieval, namely, either retrieving an image from its text description or retrieving a text caption for a given image. In this challenge, we introduce a task in the caption retrieval setup, additionally extending the model with temporal data.

Language models rarely utilize metadata, such as text domain, timestamp, or website URL. Additional temporal information may prove helpful when factual knowledge is required, and the facts rely on time (e.g., the answer to the question: "Who is the president of the U.S.A?" depends on the date). Temporal information may also be relevant in case of language semantic changes (e.g., the meaning of the word "gay" has shifted from "cheerful" to referring to homosexuality).

The presented task is based on the projects: Chronicling America [2] and Challenging America [3]. Chronicling America is an open database of over 16 million pages of digitized historic American newspapers covering 274 years. Challenging America is a set of temporal challenges based on the Chronicling America dataset.

The described competition was conducted using the Gonito platform [4], and its results are available at https://gonito.csi.wmi.amu.edu.pl/challenge/cnlps-ticrc. The competitions started on Feb 20, 2023, and ended on June 14, 2023. The training dataset was published in two batches (train and train2). Participants were allowed to use the delivered development dataset (dev) for training. The preliminary testing dataset (test-A) was available from the beginning of the competition. The final testing dataset (test-B) was released in the last two weeks of the competition. The golden truth for the testing datasets has not been made public. The Gonito platform is open to post-competition submissions.



MUTT AND JEFF—IT TAKES VERY LITTLE TO MAKE JEFF HAPPY
—BY BUD FISHER
WHY THE INSIPID GRIN, JEFF?
I'M VERY HAPPY, MUTT! I JUST GOT A GOOD OFFER FOR MY CAR!
FROM WHOM? FROM WHOM ??
JOE SPIVIS! HE'S OFFERED ME SEVENTY FIVE BUCKS FOR IT!
WHY THAT POOR SAP AIN'T GOT SEVENTY FIVE CENTS LET ALONE SEVENTY FIVE BUCKS!
I KNOW THAT-
CLOSET
?!
BUT AIN'T IT A GOOD OFFER?

Fig. 1. Sample picture with a caption above. This picture comes from a newspaper issued dated Jan 11, 1928.

II. Motivation

From a linguistic and historical standpoint, Temporal Image Caption Retrieval (TICRC) holds significant value and brings various benefits. Firstly, TICRC facilitates the analysis of language evolution over time by associating image captions with specific temporal periods. Through this approach, researchers can investigate changes in vocabulary, grammar, and linguistic styles, thereby gaining insights into the adaptation and evolution of language across different historical contexts.

Secondly, TICRC contributes to the preservation and documentation of historical knowledge. Image captions accompanying visual content often contain valuable historical information. By leveraging TICRC, historians and researchers can effectively search and analyze these image captions, enabling a deeper understanding of specific historical periods, events, or cultural contexts. This process enhances the documentation of historical knowledge and enriches our comprehension of the past.

Furthermore, TICRC facilitates cross-referencing and integration of visual and textual sources. By associating image captions with specific temporal intervals, the competition makes it possible to establish connections between relevant textual documents, such as diaries, newspapers, or historical records. The interlinking of visual and textual data enhances contextualization and aids in interpreting and analyzing visual content from a historical perspective.

Moreover, TICRC offers valuable contextual information regarding the depicted scenes, individuals, or objects in images. By retrieving relevant captions based on temporal information, researchers gain a more comprehensive understanding of the context in which the images were captured. This contextualization further strengthens the interpretation and analysis of visual content within its historical framework.

In summary, Temporal Image Caption Retrieval enables the analysis of language evolution, enhances historical documentation and preservation, facilitates the integration of visual and textual sources, provides contextualization of visual content, and supports the study of cultural and societal changes over time.

III. Related Work

A. Temporal language datasets and models

Several textual benchmarks concerning the date of text publication have been published in recent years. Challenging America [3] presents a set of three temporal tasks. Authors of [5] introduce a temporal question answering task and dataset, in which the query's answer depends on a year, e.g., *Who is the current president of the USA?*. Both benchmarks contain a baseline temporal language model trained on a text with a date timestamp prepended as text. In [6], the authors propose another text classification task, including temporal information. In addition to the timestamp in the textual form the model is also trained on temporal input embeddings. The authors of [7] modify the transformer architecture, proposing a temporal attention component.

B. Multimodal vision-language models

Recently, the quality of vision-language models has improved greatly thanks to introducing models such as CLIP [1], EVAL-CLIP [8], ALIGN [9], BASIC [10], LiT [11], Flamingo [12], or GPT-4 [13] and [14].

MS COCO [15] and Visual Genome [16] are two large-scale, high-quality vision datasets annotated by humans. YFCC-100M [17] is an even larger dataset that contains user data collected from Flickr, not specifically designed for model training. Authors of CC12M [18] and LAION-5B [19] apply cleaning procedures to adapt user data for the purpose of model training. The works mentioned did not prioritize the importance of temporal data.

IV. Task Definition

The task here is to retrieve a relevant caption from a caption set for the given picture from a newspaper and the newspaper's publication daily date. For each picture, only one caption is relevant.

The dataset is provided on the challenge GitHub repository https://github.com/kubapok/cnlps-ticrc.

Figure 2 presents an example source picture with a caption.

A. Sample Data

In this section, we provide sample data. A picture and the publication date (in the YYYY-MM-DD format) of a given newspaper issue are given, as well as the collection of all captions for the given dataset type (train, train2, dev-0, test-A, or test-B). In the caption collection, a newline character is represented as \n. The challenge participant is supposed to return the list of captions from the given dataset in descending probability order.

BUT AIN'T IT A GOOD OFFER?
Fisher

Fig. 2. Sample input picture

Date timestamp: 1928-01-11

Set of all possible captions:

- "China Dinner Sets."
- "MUTT AND JEFF — IT TAKES VERY LITTLE TO MAKE JEFF HAPPY"
- "PARIS MILLINERY\nfrom every Parisian modiste,\nof note - embracing every \nstyle tendency of the fall \nand winter season \nand \n GOWNS COATS WRAPS \nTAILORED SUITS AND \nDRESSES"
- ...

Correct Output: "MUTT AND JEFF -– IT TAKES VERY LITTLE TO MAKE JEFF HAPPY"

More examples are provided in Figure 8.

B. Metric

The metric for the competition is Mean Reciprocal Rank:

$$MRR = \frac{1}{|Q|}\sum_{i=1}^{|Q|}\frac{1}{rank_i},$$

where: |Q| — number of queries, $rank_i$ — rank position of the relevant document for the i-th query. The metric is implemented in the GEval evaluation tool [20] and available for offline use (details are provided on the competition page).

V. Data Annotation Process

The data was taken from the Challenging America project, according to the data processing rules provided there. The annotation was done manually in the Doccano [21] system, which helped effective processing of annotation pairs: image and text. The annotation platform required the annotation of the entire newspaper pages. A sample page from which a picture was selected is presented in Figure 3. The annotation of images was carried out according to given guidance rules divided into three aspects: Objects to be annotated (what to annotate), technical parameters of the image area (what technical requirements are imposed on annotated objects), and rules of text transcription (how to transcript caption texts).

These were the annotation guidance rules:

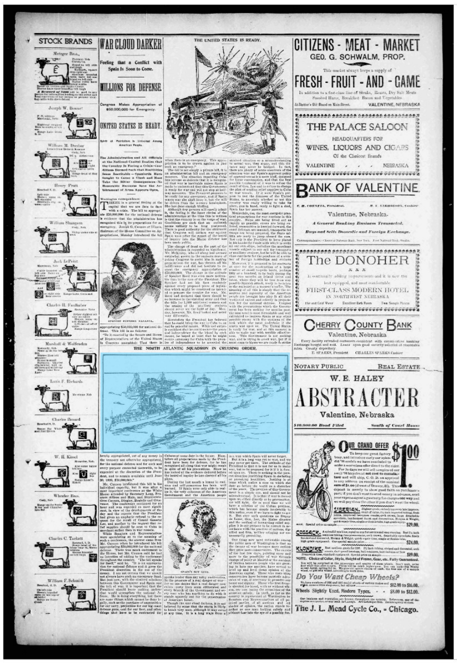

Fig. 3. Picture selected on the whole page.

a) Objects to be annotated:

- Images may be selected for annotation only if they occur along with the corresponding caption.
- The caption text should be maximum a few sentences long. In case of longer captions, the annotator should select and mark the most relevant fragment of the caption.
- The caption text should – at the discretion of the annotator – be relevant to the image in content.
- The annotator should select at most one image per page.
- If the annotator has already encountered the same image on one of the previously annotated pages, the image should not be annotated again.
- The annotator should minimize the number of portraits.

b) Technical requirements for the image area (bbox):

- The picture frame should encompass the image in its entirety (the picture should not be cut off).
- The image frame should not cover more area than the image.
- The frame must not cover the caption text.

c) Rules for text transcription:

- The transcription should preserve the character size of the original
- Punctuation and line-break characters should be preserved as in the original.
- Paragraph indentation in the text should be ignored. If the words are divided by a hyphen or line break, the original spelling (separated words) should be preserved.

The dataset was annotated mainly by one annotator, and his work took 70 hours.

TABLE I
DATA SPLIT STATISTICS

Type	**Name**	**Instances**	**Ratio**
Training	train	675	70.0
	train2	2054	
Development	dev-0	646	16.6
Testing	test-A	92	13.4
	test-B	435	

VI. Data Analysis

The dataset comprises 3902 instances, each consisting of a picture, a caption, and a date timestamp. The pictures and corresponding captions were extracted from scans of newspapers dating back to 1853, which appends the element of fuzziness in image recognition to the challenge and makes the temporal aspect even more relevant (as the image quality depends on the publication date).

A. Data Split

Five datasets have been prepared for the competition – two training sets (train, train2), a development set (dev-0), and two test sets (test-A, test-B). The final split ratio is illustrated in Table I. Precautions similar to those described in [3] have been taken to ensure that there is no detrimental overlap between the datasets.

B. Datasets Statistics

For the sake of statistical analysis, the two testing datasets and the development dataset have been combined into one dataset, referred to as the testing dataset in this section. Similarly, the two training datasets have been combined into one.

Figures 4 and 5 provide insight into the temporal variance in the frequency distributions of the instances. Whereas both datasets are negatively skewed (as suggested by the mean ≈ 1895.82 and median $= 1897.0$ of the testing dataset and mean ≈ 1903.52, median $= 1905.0$ in the case of the training dataset), the latter covers a significantly greater period containing data points between 1853 and 1922. The testing dataset spans from 1880 to 1900. Moreover, the testing dataset's standard deviation ≈ 4.18 is also less than $\frac{1}{3}$ of the training dataset's standard deviation ≈ 12.97.

The captions are measured in the number of words and characters. The captions from the testing dataset captions tend to be longer, with mean ≈ 11.77 and median $= 8.0$ words per caption and mean ≈ 66.79, median $= 44.0$ characters per caption. The respective parameters for captions from the training dataset have the following values: mean ≈ 9.80, median $= 7.0$ and mean ≈ 56.54, median $= 43.0$. There is no significant difference in the corresponding frequency distributions, as can be seen in Figures 6 and 7.

VII. Baselines

The official competition baseline is included in the competition repository and relies on the transformer model clip-ViT-B-32 [14] model without fine-tuning. The secondary baseline is the randomized caption order.

VIII. Shared Task Results

Five teams participated in the competition. Three solutions scored above the official competition baseline. The final results are provided in Table II.

TABLE II
Final competition results. The test-B dataset is used for winner determination, whereas the test-A dataset is only preliminary.

The competition's winner is Patryk Kaszuba, who was invited to prepare a report for publication in the conference proceedings and presentation at FedCSIS 2023. His solution is based on EVA02_CLIP_E_psz14_plus_s9B model [8]. The model was used without fine-tuning to the competition dataset.

IX. Conclusions

In this paper, we introduced a new benchmark for temporal image caption retrieval, called TRIC (Temporal Image Caption Retrieval). TRIC includes a three-modal (vision-language-time) dataset, divided into two train sets, two test sets and a development set. The proposed task consists in selecting a caption relevant for a given image, from a given set. The temporal information is significant for the task as the data comprise scanned texts spanning the period of 274 years.

We organised the competition based on the benchmark. Five participants participated, with three of them scoring above the baseline. The benchmark is still open for further improvement of the obtained results.

We believe that TRIC will have a positive impact on the analysis of language evolution and support the study of cultural and societal changes over time.

Multimodal Neural Networks in the Problem of Captioning Images in Newspapers

Patryk Kaszuba
Faculty of Mathematics and Computer Science
Adam Mickiewicz University
Poznań, Poland

***Abstract*—This paper presents the effectiveness of different multimodal neural networks in captioning newspaper scan images. These methods were evaluated on a dataset created for the Temporal Image Caption Retrieval Competition, which is a part of the FedCSIS 2023 conference. The task was to predict a relevant caption for a picture taken from a newspaper, chosen from a given list of captions. The results we obtained show the promising potential of image captioning using CLIP architectures and emphasize the importance of developing new multimodal methods for problems that combine multiple disciplines, such as computer vision with natural language processing.**

I. Introduction

IMAGE captioning is the task of transforming the visual information of an image into a natural language description of the image. This process combines the fields of natural language processing and computer vision. Artificial intelligence models, similarly to humans, can describe images with varying levels of detail. The variation in image descriptions generated by different models is due to differences between model architectures and training data sets. These factors affect the models' ability to extract different image features and focus attention on different aspects, resulting in diverse interpretations and semantics in the generated descriptions. Early methods were based on feature extraction techniques in which low-level visual features such as Histogram of Oriented Gradients (HOG) descriptor [1], attribute representation [2] or Support Vector Machine (SVM) [3] were combined with language models to generate captions. These methods had difficulties capturing higher-level semantic terms and processing images with varying content. The development of neural networks in the past decade led to the development of more successful methods in image captioning. Using deep neural networks eliminated the need for manual feature extraction, which resulted in the automatic creation of better representations and improved results. The first models used a combination of Convolutional Neural Networks (CNNs) with Recurrent Neural Networks (RNNs) containing layers such as Long Short-Term Memory (LSTM) [4] or Gated Recurrent Units (GRU) [5]. Later models used attention mechanisms [6] or reinforcement learning [7] [8].

In this paper, we will focus on the use of multimodal neural networks in the problem of image captioning. In the following sections, we will discuss in detail the competition in which we participated, describe the methods that utilized three popular pre-trained neural network models CLIP, and in the last sections, present the results and describe the conclusions.

II. Related work

Understanding and interpreting the meaning of the content in an image based on the image itself is one of the more challenging problems in the field of artificial intelligence. However, in recent years, the development of deep neural networks has brought remarkable advancements in this field, and as a result, multimodal neural networks have emerged. Combining text and image representations in a joint embedding space results in significant improvements in image captioning, as demonstrated by methods such as those described in [9] or [10]. Nevertheless, the most significant results have been achieved using contrastive learning in papers presenting methods such as VILLA [11], ERNIE-ViL [12], Oscar [13], ALIGN [14] and CLIP [15].

III. FedCSIS 2023 Competition

A. Problem description

In the Temporal Image Caption Retrieval Competition, organized during FedCSIS 2023, the goal is to select the correct caption for the image. The dataset contains temporal information along with images, which can be used to accurately assign the most relevant captions to each image based on historical data.

The evaluation metric for this competition is Mean Reciprocal Rank (MRR).

$$MRR = \frac{1}{|Q|}\sum_{i=1}^{|Q|}\frac{1}{rank_i}$$

where $|Q|$ is the total number of images in the dataset and $rank_i$ is the position of the correct caption in the ranked list for each image.

B. Dataset description

The competition dataset is based on the project “Challenging America” [16], which was initially created for three tasks. The first task, known as “RetroTemp”, focused on temporal classification. The objective was to predict the publication date based on given newspaper titles and text excerpts. In the second task, “RetroGeo”, the goal of the task was to predict the latitude and longitude coordinates of the place of issue using normalized newspaper titles, text excerpts, and fractional publishing dates. The last task, "RetroGap", involved predicting the missing word within a provided normalized newspaper title, text excerpt, and year of publication in fractional format.

For the competition, the organizers expanded the original dataset with test sets that had never been published before. The purpose of this action was to prevent participants from accessing the data during the competition.

All the collected data for the dataset comes from the "Chronicling America" [17] database, which contains digitized newspapers from 1690 until now, encompassing approximately 150,000 bibliographic title entries, as well as 600,000 library holdings records.

C. Dataset structure

The organizers of the competition split the dataset into 5 sets as follows: two training sets *train* and *train2*, a development set *dev-0*, and two test sets *test-A* and *test-B*. The total number of samples in the entire dataset was 3902 samples.

Each of the splits contained the following amounts of data:

- train - 675 samples
- train2 - 2054 samples
- dev-0 - 646 samples
- test-A - 92 samples
- test-B - 435 samples

Every single record consisted of three features: a picture, a caption text, and a publication date. The images were in grayscale, with a minimum and maximum width of 2 and 1162 pixels, respectively. For the height, the minimum value was 5 pixels, and the maximum was 1592 pixels. The header text contained both lowercase and uppercase letters, as well as symbols and special characters. The number of words in the headers varied, with the shortest containing 1 word, and the longest containing 83 words. For the publication date, the ISO 8601 (YYYY-MM-DD) format was used. The oldest publication date was 1853, and the latest one was 1922.

IV. Methods

Our solution is based on three different multimodal neural networks: **CLIP-ViT**, **OpenCLIP** [18] and **EVA-CLIP** [19]. We used the above pre-trained models for a zero-shot classification task, experimenting with their various parameter variants. As part of data preprocessing, we converted newline characters to spaces. The solution is described in the form of pseudocode in Algorithm 1.

In the initial step, we preprocess all the captions and extract their embedded vector representations obtained from the neural network's output. Then, for each image, we execute the same process to obtain its embedded vector representation. Finally, we calculate cosine similarity between an individual embedded image vector and all embedded caption vectors to determine the most similar images with captions, which we then sort based on their similarity values in descending order.

Algorithm 1 Pseudocode of our solution for image captioning

```
Require: Image vector $I = (I_1, I_2, ..., I_n)$, caption vector $T = (T_1, T_2, ..., T_m)$
  for each $t \subset T$ do
    $t \leftarrow preprocess(t)$
    $Emb_t \leftarrow CLIP(t)$
  end for
  for each $i \subset I$ do
    $Emb_i \leftarrow CLIP(i)$
    for each $t \subset Emb_t$ do
      $sim \leftarrow cosinesimilarity(Emb_i, t))$
      $Y_i.insert(sim)$
    end for
  end for
  for each $c \subset Y$ do
    $Y_c \leftarrow sort(c)\ descending$
  end for
```

A. CLIP-ViT models

We utilize the CLIP-ViT pre-trained models, based on the Vision Transformer architecture. These models were pre-trained by OpenAI on a set derived from a subset of the YFCC100M [23] dataset, with four different model parameters:

- **ViT-B-16** - 12 vision layers, 12 text layers, 512 embedding dimensions, image patch size 16x16, image resolution 224^2
- **ViT-B-32** - 12 vision layers, 12 text layers, 512 embedding dimensions, image patch size 32x32, image resolution 224^2
- **ViT-L-14** - 24 vision layers, 12 text layers, 768 embedding dimensions, image patch size 14x14, image resolution 224^2
- **ViT-L-14-336** - 24 vision layers, 12 text layers, 768 embedding dimensions, image patch size 14x14, image resolution 336^2

B. OpenCLIP models

The main difference between CLIP-ViT by OpenAI is that these models were pre-trained on the LAION-2B [24] dataset. Three new models have been created with the following parameters:

- **ViT-H-14** - 32 vision layers, 24 text layers, 1024 embedding dimensions, image patch size 14x14, image resolution 224^2
- **ViT-g-14** - 40 vision layers, 24 text layers, 1024 embedding dimensions, image patch size 14x14, image resolution 224^2
- **ViT-G-14** - 48 vision layers, 32 text layers, 1280 embedding dimension, image patch size 14x14, image resolution 224^2

C. EVA-CLIP models

The models differ from the previous ones by the implied techniques, such as the LAMB [20] optimizer, random input token dropping [21], and flash attention [22]. The **EVA02_CLIP_E_psz14_plus_s9B** model, just like the previous OpenCLIP models, was pre-trained on the LAION-2B dataset, but in the case of models **EVA02_CLIP_B_psz16_s8B** and **EVA02_CLIP_L_psz14_s4B**, they were pre-trained on the Merged-2B dataset, which combines 1.6 billion samples from the LAION-2B dataset with 0.4 billion samples from the COYO-700M dataset. The models have the following parameters:

- **EVA02_CLIP_B_psz16_s8B** - 12 vision layers, 12 text layers, 512 embedding dimension, image patch size 16x16, image resolution 224^2
- **EVA02_CLIP_L_psz14_s4B** - 24 vision layers, 12 text layers, 768 embedding dimension, image patch size 14x14, image resolution 224^2
- **EVA02_CLIP_E_psz14_plus_s9B** - 64 vision layers, 32 text layers, 1024 embedding dimension, image patch size 14x14, image resolution 224^2

V. Results

The results from the evaluated models on three subsets are presented in Table I. The metric provided in the results is the same as the one used in the competition ranking. All models evaluated by us achieved a higher score than the baseline. The best result on the test-B set, which was 0.344423 MRR, was achieved by the **EVA02_CLIP_E_psz14_plus_s9B** model, due to having the highest number of parameters among all the other models.

We also conducted an error analysis for images on which our top model struggled the most. The four images that achieved the worst MRR score are shown in Fig1. The model had difficulty choosing the correct caption for the images in cases where the caption was the author's subjective interpretation of the image and did not directly relate to the description of the elements in the photo. This can be observed in Fig. 1a and Fig. 1b. Another problem related to the model was low-resolution images, which could result in difficulties in object detection and, consequently, making inferior decisions regarding the accurate labeling of the image, as seen in Fig. 1c and Fig. 1d.

VI. Conslusion

In this paper, we presented our solution for the Temporal Image Caption Retrieval Competition. We evaluated various multimodal pre-trained models with different parameter sizes. The model with the highest Mean Reciprocal Rank metric on the dev-0 set was submitted to the competition system and ranked first place. Our approach indicates that multimodal neural networks are effective for image captioning in newspapers. For future work, we suggest improving results by fine-tuning the pre-trained models using the training data provided by the organizers. Additionally, better results may be achieved by using temporal data as an extended input for the neural network and making predictions based on historical information.

3rd prediction: *PORTABLE MILLS For Corn Meal STRAUR & CO., P. O. Box 1430, Cincinnati.*

(d) **Correct caption:** *FOR MEN ONLYYOUNG MEN OLD MEN OUR NEW BOOK*
1st prediction: *BEWARE OF THE RANGE PEDLER! THE MALLEABLE RANGE MADE IN SOUTH BEND*
2nd prediction: *HOSTETTER'S CELEBRATED STOMACH BITTERS*
3rd prediction: *Doctor Henderson OVER 27 YEARS OF SPECIAL PRACTICE Seminal Weakness & Sexual Debility,Syphilis,Book Free Museum of Anatomy,Stricture Rheumatism*

Fig. 1: The figure presents four images from the dev-0 set in which the model achieved the worst results in predicting the correct caption
