TABLE I: Selected Repositories for Analysis

Repository	Type	Stars	Issues	PRs
TensorFlow [19]	AI software	187k	37k	31.1k
PyTorch [20]	AI software	86.1k	31.1k	85.7k
Scikit-Learn [21]	AI software	60.8k	9.9k	16.9k
Keras [22]	AI software	62.4k	11.9k	7.3k
Node.js [23]	Traditional	109k	16.1k	33.4k
Bootstrap [24]	Traditional	171k	23.9k	15.1k
Facebook-React [25]	Traditional	232k	10.4k	15.5k
Angular [26]	Traditional	96.7k	27.9k	25.2k

Selection criteria included high repository activity, star count indicating popularity, contributor diversity, and clear domain classification.

B. Data Preparation

Issues, PRs, and comments from the repositories were extracted. For issues, the title, body, state (open/closed), timestamps (created, updated, closed), and associated labels were collected. For PRs, the title, body, state, timestamps, and merge details were gathered. Additionally, comments associated with both issues and PRs were extracted and used for sentiment analysis.

The data collected from the repositories underwent several data preprocessing stages to ensure its quality and suitability for analysis. These steps included data cleaning, data filtering, data formatting, data balancing, and data validation techniques.

Records with incomplete or missing critical information were either supplemented with placeholder text or discarded. Duplicate entries were identified and removed to ensure the uniqueness of each record.

Text processing techniques such as tokenization, stopword removal, and lemmatization were applied to the comment data. A custom `clean_text` function was used to standardize text data by converting to lowercase and removing unnecessary characters such as punctuation marks and numbers.

Several filters were applied to ensure the dataset remained focused and relevant. Records with fewer than five comments were removed to focus on meaningful discussions. Issues or PRs that had not been updated in the last year or were created before 2020 were removed to ensure current relevance. Only merged or closed PRs and issues were retained for further analysis. Extreme outliers with unusually high or low comment counts were removed to prevent skewing results.

Dates and times were standardized to ISO 8601 format. Additional features such as time-to-close for issues and PRs were created. Categorical variables were encoded numerically for machine learning models.

To ensure fair representation of both AI software and traditional repositories, the dataset was carefully balanced using a stratified approach. Datasets from each category were combined in proportional measures, maintaining equal representation of issues and PRs across both repository types.

Data validation steps included spot checks using functions like `sample()` and `head()`, statistical summaries of key attributes, and missing data analysis using the k-nearest neighbors (KNN) imputation for numerical values and mode imputation for categorical values.

The dataset was enhanced by integrating process mining data, structured into event logs containing key attributes such as case ID, activity, timestamp, and resource attributes. These logs were validated using process mining tools like Disco [27] and PM4Py [28] to ensure they met the necessary quality standards for analysis.

C. Data Modelling

The data model for this research integrates various data entities, each representing key elements of the GitHub repository workflow. Figure 1 illustrates the interconnections among users, repositories, issues, PRs, commits, and comments.

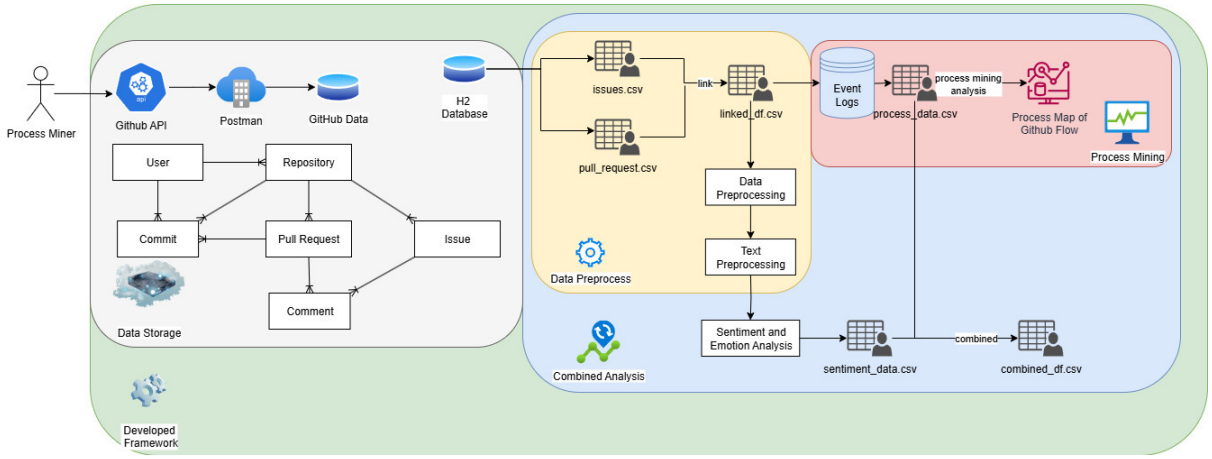

Fig. 1: Overview of the Developed Framework for GitHub Workflow Analysis

The core entities in the data model include users, repositories, issues, PRs, commits, and comments. A user can own or contribute to multiple repositories and can create or be assigned to various issues. Similarly, users can create or review multiple PRs, as well as produce numerous commits and comments.

Each repository in the model can contain multiple issues, PRs, and commits. Issues are typically associated with multiple comments, forming a one-to-many relationship. Similarly, PRs can encompass multiple commits and comments, with each commit associated with a specific PR.

Moreover, comments are crucial for communication during the development process. They are linked to either an issue or PR, serving as feedback or further discussion on a specific task. These interactions enable developers to refine code, resolve issues, and collaborate effectively.

The data is collected using the GitHub API, with retrieval performed via Postman. The collected data is stored in an H2 Database [29]. Subsequently, the raw data is transformed into two files: issues.csv and pullrequest.csv. These files are integrated into a third file, linkeddf.csv, which links issues to their corresponding PRs for analysis. This integration is crucial for understanding the relationship between issues and PRs and enables the analysis of their lifecycle within the repository.

The dataset is subjected to extensive data cleaning and text processing to prepare it for sentiment and emotion analysis. Additionally, the processed data is analyzed using process mining techniques to generate visual process maps, helping to trace the flow of actions such as issue or PR creation, updates, closures, and their relationship with sentiment.

D. Predictive Process Modeling

The structured dataset formed the basis for training various machine learning models aimed at analyzing the workflow in GitHub repositories. The predictive models developed in this study focused on two primary tasks: classifying issues and PRs, and predicting sentiment and emotional tone from text data. This section outlines the steps followed in the modeling process, which include feature engineering, model selection, and model training.

1) Feature Engineering: The first step in predictive modeling was feature engineering, where key attributes from the 'issues.csv' and 'pull_request.csv' files were extracted. The features considered for classification include text-based attributes such as the length of issue descriptions, the titles of PRs, and the presence of specific keywords that may indicate the nature of the task (e.g., "bug", "feature", and "documentation"). These features are crucial for distinguishing between different types of issues and PRs.

Additionally, sentiment-related features were generated from the text data. Sentiment scores (positive, negative, neutral) were extracted using sentiment analysis tools, which helped gauge the emotional tone of the text.

2) Predictive Model Selection and Training: A variety of machine learning models were considered to classify issues and PRs into categories such as "bug", "feature request", or "documentation update". Models such as Random Forest, Support Vector Machines (SVM), XGBoost, Naive Bayes, and Logistic Regression were selected for their proven effectiveness in text classification tasks.

Sentiment analysis was performed on comments within issues and PRs using the Valence Aware Dictionary and sEntiment Reasoner (VADER) [30] model in this study. VADER is well-suited for evaluating sentiment patterns, as it is specifically designed to detect the intensity of sentiments expressed in social media-like content. The analysis categorized comments as positive, neutral, or negative, with aggregated results providing insights into sentiment trends throughout the issue resolution and PR processes.

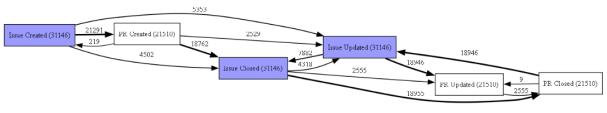
To complement sentiment analysis, emotion analysis was conducted using a pre-trained Bidirectional Encoder Representations from Transformers (BERT) [31] model, which had been fine-tuned for emotion classification. BERT was chosen due to its ability to capture subtle contextual nuances in text, making it particularly effective for analyzing the emotional tone of developer comments. The model identified several

emotions, including neutral, sadness, surprise, anger, joy, fear, and disgust.

VADER and BERT have limitations with domain-specific technical language and context length variations common in software development discussions.

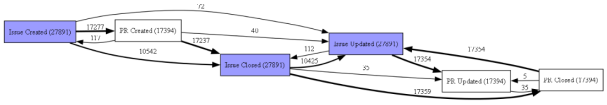
These emotional insights were then correlated with key metrics such as issue resolution times and overall repository activities, aiming to explore the potential impact of developer emotions on workflow efficiency.

The final step in the modeling phase involved deploying the best-performing models in a real-time environment. These were integrated into an automated pipeline that classifies incoming issues and PRs, predicts their sentiment, and performs process mining analysis.



IV. Results and Discussion

A. Process Discovery of Software Repositories



Event logs of repositories are used to discover the process map of the repositories using DFG Miner of the PM4Py library [28]. Figure 2 illustrates the process maps of PyTorch (AI software repository) and Angular (traditional software repository), showing common states including issue created, issue updated, PR created, issue closed, PR updated, and PR closed.

The flow of issues typically follows a consistent pattern: creation, updates, and eventual closure. However, certain issues are directly closed without further updates, while others may lead to the creation of corresponding PRs before they are closed. Similarly, PRs generally undergo creation, updates, and closure, although some are updated shortly before closure.

Notably, Angular exhibits a higher frequency of issues and PR interactions, indicating a more rapid and iterative development approach, which may be typical for traditional software development practices. In contrast, PyTorch demonstrates fewer PR updates and fewer instances where PRs are generated following issues, suggesting a more cautious and deliberate workflow, potentially attributed to the complexity and specificity of AI-related code. These findings emphasize key differences in workflow efficiency and developer behavior between AI software and traditional repositories.

(a) PyTorch Process Map

(b) Angular Process Map

Fig. 2: Process Maps for AI software and Traditional Repositories

B. Sentiment Analysis of the Repositories

Figure 3 depicts the distribution of sentiments across varying time-to-close durations for issues. AI software repositories exhibit a greater density of issues with neutral to positive sentiment and shorter resolution times. In contrast, traditional repositories exhibit a wider spread and with more cases of longer time-to-close, regardless of sentiment.

The data shows that issues with positive or neutral sentiment are generally resolved more faster in both types of repositories, possibly due to their less critical or complex nature. However, traditional repositories have a more distributed model, suggesting variability in the handling and resolution of issues, which may reflect different workflows or resource allocations.

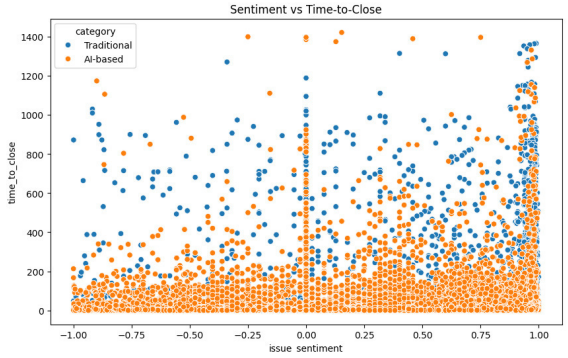


Fig. 3: Comparison of Issue Resolution Times

Figure 4 illustrates the distribution of sentiment scores. We see that AI software repositories have a significant peak around the neutral sentiment (0), with a lower positive sentiment peak, suggesting that issues in AI repositories often maintain a balanced or positive view, even with their complexity. In traditional repositories, there is a larger spread towards positive sentiments, potentially reflecting trust in established development practices and community support.

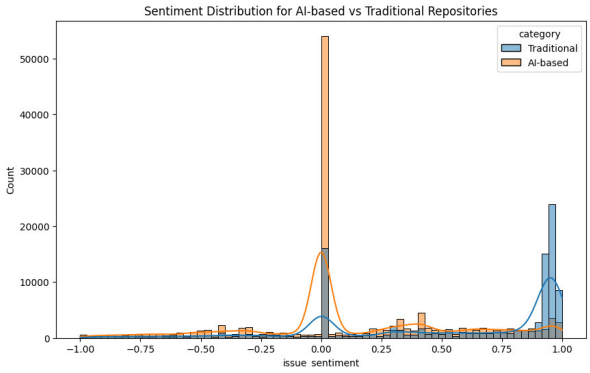

Fig. 4: Sentiment Polarity Distribution

C. Emotion Analysis of the Repositories

Figure 5 provides insight into the common emotional responses in AI software and traditional repositories. In particular, "sadness" and "fear" emotions are high in both categories.

However, AI software repositories show a significantly higher frequency of "sadness" compared to traditional repositories. Also, "anger" and "surprise" are observed more in AI software repositories, while traditional repositories show slightly higher levels of "fear".

This distribution suggests that problems in AI software repositories may trigger stronger negative emotions. This is probably due to the complexity and rapid evolution characteristic of AI projects. Contributors may experience frustration and even hesitation when working with advanced models and algorithms, which may increase emotional reactions. Traditional repositories, in contrast, seem to reflect a more balanced emotional distribution, possibly because they are dealing with well-established technologies and often face problems with familiar, predictable solutions.

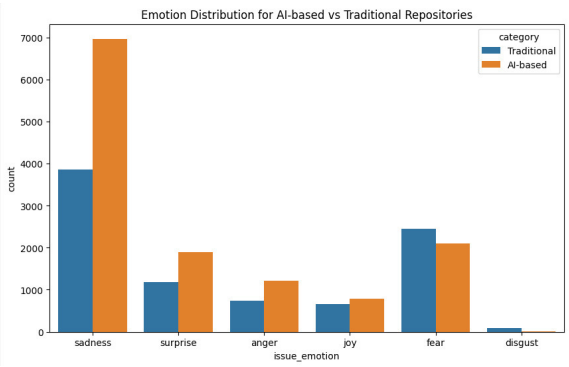

Fig. 5: Emotion Distribution for AI software vs. Traditional Repositories

D. Comparison of Issue Labels the Repositories

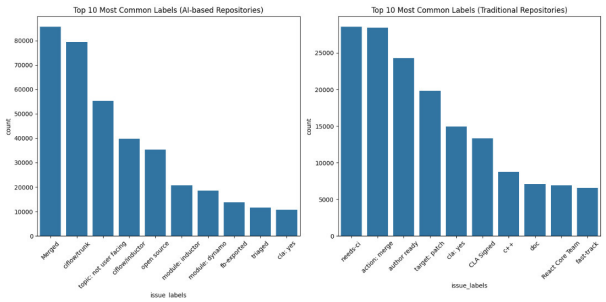

Figure 6a displays the top 10 most common issue labels in and Figure 6b also displays the top 10 labels with the highest average sentiment for both AI software repositories (left) and traditional repositories (right).

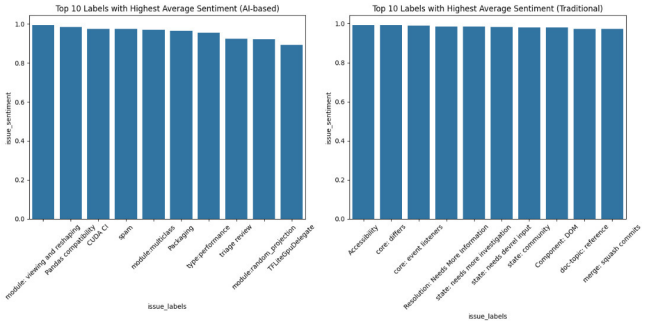
Figure 6 compares issue labels. AI software repositories frequently use "Merged," "ciflow/trunk," emphasizing automated testing crucial in ML projects. Traditional repositories show "Needs-ci," "action: merge," emphasizing formal CI processes.



The comparison reveals that while both AI software and traditional repositories focus on merging contributions and continuous integration, AI software repositories have a greater emphasis on modularity and rapid integration of changes, while traditional repositories follow more structured, incremental workflows. These distinctions align with the experimental nature of AI development versus the stability and predictability required in traditional software engineering.

High-sentiment labels differ: AI software repositories focus on performance optimization ("CUDA CI," "type-performance"), while traditional repositories emphasize core functionality ("Accessibility," "core: event listeners").

The comparison reveals that while both AI software and traditional repositories foster positive sentiment toward issue resolution, their focus areas differ. AI software repositories emphasize modularity, performance optimization, and compatibility across frameworks, which are crucial in cutting-edge AI/ML development. In contrast, traditional repositories concentrate on core stability, accessibility, and detailed issue investigation, which aligns with the needs of more mature, stable software projects.

(a) Most Common Labels

(b) Highest Sentiment Labels

Fig. 6: Label Analysis in AI software and Traditional Repositories

E. Resolution Time Comparison

We compare the resolution time of issues and PRs for each repository type and list them in Table II and III. AI software repositories take longer to close issues (55.04 vs 43.63 days) but close PRs faster (36.68 vs 40.43 days). Both show similar median times (2-3 days), indicating most items are resolved quickly regardless of domain.

TABLE II: Time to Close Comparison for Issues

Category	Mean (days)	Median (days)
AI software	55.04	2
Traditional	43.63	2

TABLE III: Time to Close Comparison for Pull Requests

Category	Mean (days)	Median (days)
AI software	36.68	3
Traditional	40.43	3

V. Conclusion

This study provides a comparative analysis of AI software and traditional GitHub repositories, focusing on workflow efficiency and sentiment dynamics.

A comparison between AI software repositories, such as PyTorch, and traditional repositories, such as Angular, highlighted significant differences in development practices. The process maps indicated that workflows in AI software repositories are often more deliberate and cautious, with fewer PR updates, while traditional repositories tend to exhibit more iterative processes with frequent PR updates. These findings are instrumental for assessing workflow efficiency and serve as a foundation for exploring how sentiment and emotion analysis might impact productivity and developer behavior within these repositories.

These findings demonstrate how software domain characteristics influence development patterns, workflow efficiency, and contributor sentiment.

Despite these promising results, this study has several limitations. The dataset is limited to eight repositories due to GitHub REST API rate limits (5,000 requests/hour), potentially restricting the generalizability of the findings. Additionally, the analysis does not account for code coverage of AI code of the repositories and variations in team size, project complexity, or contributor demographics, which may influence repository performance.

Future research could address these limitations by exploring a broader range of repositories and incorporating additional contextual factors. Furthermore, integrating explainable AI methods to assess issue complexity dynamically could provide deeper insights into the decision-making processes of contributors and administrators.

***Abstract*—Open Source Software (OSS) quality evaluation is essential for ensuring the adoption and effective use of OSS projects across various domains. Most works on OSS quality evaluation have focused on the development of models or frameworks rather than providing practical implementations. These proposals can be challenging to use for inexperienced users, which highlights the need for user-friendly tools. This paper presents preliminary findings from a Systematic Literature Review (SLR) that investigates the characteristics, limitations, and gaps of current Quality Evaluation Tools (QETs) for OSS. Our analysis reveals the diversity of quality models underlying these tools and the absence of standardization, which impedes the comparability and reliability of evaluation results. This work also informs the next steps in improving OSS quality evaluation practices.**

I. Introduction

DEVELOPMENT and the use of open source software (OSS) has become widespread, with more than 100 million public projects available on GitHub alone. However, the abundance of options makes selecting the right OSS challenging. Unique characteristics of OSS, such as full availability of source code, version history, and community-driven and decentralized development, further complicate the selection process. These traits limit the effectiveness of standard software quality evaluation tools, which are typically designed for closed-source software and do not account for OSS-specific characteristics. As a result, tools specifically designed or adapted for OSS are needed to support more accurate, consistent, and relevant evaluations.

Specialized quality evaluation tools are also critical, as quality evaluation directly impacts OSS adoption, maintenance, and contribution decisions. Developers, organizations, and users rely on these evaluations to determine whether an OSS project is reliable, secure, and maintainable enough to integrate into their systems. Without appropriate tools, OSS quality evaluations have a risk of becoming inconsistent, overly subjective, and difficult to compare across projects.

To allow for ease in OSS selection and comparison, various quality models and frameworks have been proposed. A systematic literature review published in 2020 [1] identified 35 primary studies that proposed an OSS quality evaluation model or framework. Another published in 2022 [2] identified 36 primary studies with the same purpose. However, manually applying these models can be challenging for the average user, creating a barrier to their practical adoption. To facilitate the use of these quality models, an easy-to-use and preferably automated method for adopting these quality models is necessary. To this end, some quality evaluation tools have been proposed along with studies about quality models.

In [2] it was discovered that out of 36 primary studies, 16 of them (44%) were supported by a tool. Additionally, [1] revealed that among the 35 primary studies analyzed, 22 referenced the availability of toolsets.

Nevertheless, proposing tools is not enough; the tools must be published and maintained for long-term usage. Only two tools mentioned in the reviewed papers in [1] had active, up-to-date web pages. Only one tool remains accessible in 2025.

In addition to tool availability, aspects such as usability, clear evaluation criteria, and compatibility with evolving OSS practices are essential for real-world adoption. Tools that are difficult to install, bound to outdated standards, or lacking documentation further reduce their utility to practitioners and researchers alike. These challenges highlight the need for a structured investigation into the current state of QETs.

Previous study [2] investigated literature up to 2020 and focused on Quality Evaluation Models or Frameworks (QEMoF) for OSS. It provided valuable insights into OSS quality assessment approaches by investigating various aspects of QEMoF, including their goals, structure, and evaluation criteria. However, it only briefly examined the existence of supporting tools as a sub-question, and did not have a dedicated focus on Quality Evaluation Tools (QETs).

Given the strong connection between QEMoFs and QETs, we build upon this prior work by conducting a new Systematic Literature Review (SLR) that explicitly focuses on QETs for OSS. Our work expands on [2] by:

1) Introducing new research questions specifically targeting QET characteristics.
2) Extending the investigation coverage beyond 2020 to include more recent developments.
3) Modifying the search strategy to specifically identify studies that propose practical, user-accessible tools rather than only conceptual models.

This study was supported by Scientific and Technological Research Council of Turkey (TUBITAK) under the Grant Number 746360. The authors thank to TUBITAK for their supports.

To that end, in comparison to 13,146 studies initially retrieved in [2], our updated search retrieved 15,036 additional works. After applying inclusion and exclusion criteria, we selected 19 primary studies on QETs, which are published between 2006 and November 2024, for detailed analysis.

This paper presents initial findings from this SLR on QETs for OSS, highlighting key challenges, limitations, and gaps in existing tools. We discuss the lack of maintenance, accessibility, and standardization among the QETs and outline a vision for future research towards developing standardized, user-friendly tools to improve OSS quality evaluation practices.

II. Research Design

Goal of this research was to comprehensively examine and characterize existing quality evaluation tools for OSS by their content, structure and practical use. The research design followed the SLR methodology [3] and took advantage of PICOC (population, intervention, comparison, outcomes and Context) template [4].

Population: OSS quality evaluation

Intervention: OSS quality evaluation tools

Comparison: Characteristics of OSS quality evaluation tools

Outcomes: Basic characteristics and structure, degree of guidance provided, basic characteristics in evaluation, development method, and validation method of the proposals.

Context: Academia (scientific literature)

A. Research Questions

Given the strong connection between QEMoFs and QETs, some questions were taken from [2] and were adapted to be more in line with our focus on tools. Aim of this adaptation was to ensure that our study builds upon prior research while addressing the gap in practical tool implementations.

B. Search String

To make search results comparable with those of the SLR done for QEMoFs in 2020, the search string in [2] was taken as a basis. In order to focus the search on QETs in this SLR, the phrase *(tool OR framework OR application)* was added to the search string in [2] to obtain the final search string. This adjustment ensured that the search captured studies proposing implemented and potentially usable tools, rather than solely conceptual models. The final search string was:

> **(tool OR framework OR application)** AND
> ("quality") AND
> ("evaluation model" OR "assessment model" OR "measurement model" OR "evaluation framework" OR "assessment framework" OR "measurement framework") AND
> ("OSS" OR "FOSS" OR "FLOSS" OR "open source software")

This query was executed across seven major scientific databases: IEEE Xplore, ACM Digital Library, ScienceDirect, Scopus, Springer, Web of Science, and Google Scholar.

C. Inclusion and Exclusion Criteria

As a result of the updated search string, our SLR retrieved 15,036 additional studies that were published between 2020 and 2024, beyond those analyzed in [2]. While the study count is relatively high for a four year period, most of the results came from Google Scholar which is prone to result duplication.

1) Exclusion Criteria (EC): The following criteria were applied to remove irrelevant or duplicate studies:

EC1: Duplicate studies

EC2: Studies that were not published in English

EC3: Studies that are not accessible in full text

EC4: Secondary studies (e.g., SLR, meta-analyses)

EC5: Books and theses

EC6: Studies that discuss OSS quality evaluation without proposing, applying, or describing a specific QET

EC7: Studies on OSS quality evaluation that do not reference a known quality model or standard

EC6 aims to exclude purely conceptual or theoretical discussions that lack reference to any practical tool or implementation. EC7 was introduced to distinguish dedicated OSS quality evaluation tools from generic tools that only incidentally evaluate software quality (e.g., security scanners, static analysis tools).

2) Inclusion Criteria (IC): A study was included if:

IC1: It explicitly focused on OSS quality evaluation.

IC2: It proposed a tool specifically designed for evaluating OSS quality.

D. Data Extraction

After screening, 19 primary studies on QETs were selected, these primary studies are listed in a supplementary material (see Data Availability section). To ensure a systematic review process, data extraction was guided by the predefined research questions (RQs) which are introduced and answered in Section III. A structured spreadsheet was used to record the extracted data, with each sub-question represented as a column. For each study, relevant information was manually extracted from the full text.

The data extraction was performed by the first author, and ambiguous cases were reviewed and discussed with the second author to promote consistency and reduce bias. The RQs were designed to capture key characteristics of each QET, including:

- Basic characteristics (RQ-1)
- Structural attributes (RQ-2)
- Guidance and usability (RQ-3)
- Evaluation methods (RQ-4)
- Development details (RQ-5)
- Current accessibility and maintenance status (RQ-6)

This structured approach ensured that findings are comparable across different QETs and can be synthesized effectively.

III. Results

This section presents the preliminary findings of our study. The results are structured based on the defined RQs and cover aspects that were specified in the previous section.

The following subsections systematically address each RQ, summarizing the key insights extracted from the reviewed studies. An overview of the results is provided in table format, along with full references to primary studies, on Zenodo (see Data Availability section).

The findings highlight recurring issues such as lack of standardization, limited usability, and sustainability concerns; reinforcing the need for more consistent, well-maintained, and user-friendly QETs.

A. RQ-1: What are the basic characteristics of the QET proposed for OSS?

Data were extracted from each primary study to determine the main purpose of the QET and assess the use of AI techniques in its evaluation logic. Understanding these is essential for distinguishing between broadly applicable tools and those tailored to specific evaluation goals or contexts.

1) RQ-1.1: What is the main purpose of the QET in the study?: Each QET was categorized based on its primary evaluation focus. Tools were labeled as either:

- G: General-purpose i.e., designed to evaluate overall OSS quality, or
- S: Domain-specific i.e., targeting one or more focused quality attributes such as maintainability or security.

The findings indicate that out of the 19 tools analyzed, 13 (68%) of the QETs were designed for general-purpose evaluation, while 6 (32%) focused on a specific quality aspect. This distribution suggests a trend toward designing general-purpose evaluation approaches, although domain-specific tools remain relevant for targeted quality evaluations.

2) RQ-1.2: Does the QET utilize AI?: For AI usage, we checked if the tool explicitly described the integration of AI-based techniques (e.g., machine learning, natural language processing (NLP)) in its implementation. Identifying the potential use of AI integration with this sub-question helps to asses how modern and scalable these tools are, and highlights opportunities for future research.

Out of 19 QETs, only one utilized AI methods. The work used NLP to extract data from community channels. While there are other works that talked about incorporating AI to their tools in the future, they have not released a version that contains it yet. This suggests that although the application of AI in OSS quality evaluation is recognized as promising, its actual implementation in the published QETs remains rare.

B. RQ-2: How is the QET for OSS structured?

1) RQ-2.1: Which quality model is the QET based on?: We analyzed if the QETs referred to formal software quality models—such as ISO/IEC 25000, ISO/IEC 9126, or Dromey—or used custom or OSS-specific models such as OpenBRR, QSOS, or OSMM.

This sub-question was included to assess if the QETs are grounded in standardized definitions of software quality, which supports consistency and comparability across different tools and evaluation contexts. When tools rely on outdated or informal models, their results may not align with current quality standards or be usable beyond their original context. Thus, this analysis helps determine how closely existing QETs align with widely accepted software quality frameworks and whether there is a need for standardization or modernization.

Results indicate that 47% of the QETs used ISO/IEC 9126 [5] as at least one of their base models; however, ISO/IEC 9126 has been replaced with ISO/IEC 25010 [6] and new models should take this standard as the basis. Only 16% of the tools were based on the newer ISO/IEC 25010 standard. Several tools referenced OSS-specific quality models like QSOS, OpenBRR, and OSMM, which were designed to address OSS evaluation challenges but may no longer align with current international standards. This suggests a lag in the adoption of up-to-date quality models within the QETs.

2) RQ-2.2: From what aspects can OSS be evaluated by the QET?: The QETs were classified based on the quality aspects they evaluated, including product quality, quality-in-use, community-related factors, a combination of these, or a single specific attribute.

This sub-question was included to evaluate how comprehensively each tool assesses OSS quality. OSS differs from proprietary software not only in its technical traits, but also in how it is developed, used, and maintained by its community. As such, a meaningful OSS quality evaluation should ideally include technical, user-facing, and community aspects. By analyzing which aspects each QET covers, we can evaluate if a tool is too narrowly focused or provides a more comprehensive assessment aligned with the unique nature of OSS.

The analysis revealed that 84% of the QETs addressed product quality (e.g., maintainability, reliability), 58% considered quality-in-use (e.g., usability, user satisfaction) and 74% incorporates community-related metrics (e.g., maintenance capacity, sustainability). Seven tools specifically used a mix of each of these quality aspects and two tools focused only on a single attribute such as security. These results indicate that while most tools emphasize code-level characteristics, many also acknowledge the importance of user experience and community health, which are both critical to the success and adoption of OSS projects.

C. RQ-3: What degree of guidance is provided for the evaluation of OSS by the QET?

This question examined how clearly the QETs explain their evaluation procedures and whether they demonstrated the tool's application through practical examples. Clear guidance is essential for consistent use and broader adoption; without it, even technically sound tools may remain unused.

1) RQ-3.1: Is the evaluation procedure of the QET adequately described in the study?: To assess the transparency of the evaluation process, each study was analyzed to determine whether it provided an adequate (yes), partial, or no description of how the QET could be used to assess OSS. A well-documented evaluation process increases the likelihood that a tool can be adopted by practitioners or extended by other researchers.

Less than half (47%) of the QETs were determined to include a detailed evaluation procedure, while 32% provided partial descriptions, and 21% lacked a guideline. These findings indicate that the majority of tools do not offer sufficient instructions, which can make them harder to apply in practice and reduce the consistency and reproducibility of their results.

2) RQ-3.2: Is a demonstration of the evaluation using the QET provided in the study?: Demonstration of the tool in practice is critical for illustrating how the tool functions, validating its usefulness, and helping users understand expected outcomes.

The analysis revealed that 47% of the studies included some practical demonstration. The remaining 53% lacked detailed examples of how the tool was applied, which limits users' ability to assess its effectiveness and real-world applicability.

D. RQ-4: What are the basic characteristics of the QET for evaluating OSS?

1) RQ-4.1: Is the license type of the OSS product used as an evaluation criterion?: Licensing type is a very important characteristic in OSS, as it can potentially restrict or influence the licensing of other software that incorporates it. Seven (37%) of the QETs explicitly incorporated license type as a factor in quality evaluation, while the rest did not consider licensing constraints in the assessment process.

2) RQ-4.2: Does the QET support subjective or objective evaluation?: The studies were analyzed to determine whether the QETs relied on subjective assessments (e.g., taking user opinions into consideration) or objective assessments (e.g., metric-based analysis). Objective assessments tend to support consistency and automation, while subjective ones can capture nuanced user perspectives that are difficult to quantify.

The results indicate that 53% of the QETs combined subjective and objective approaches, while 16% supported entirely objective evaluation and 32% relied on subjective assessments. These results suggest that while many tools aim for a balanced approach, a significant portion still depends heavily on subjective input. Subjective input is risky as it can limit standardization or automation in large-scale OSS evaluations; however, some tools knowingly allow subjective input to include diverse user perspectives.

3) RQ-4.3: Does the QET support qualitative or quantitative evaluation?: This sub-question assessed the QET's reliance on quantitative methods (e.g., numeric metrics, automated analysis) or incorporation of qualitative insights (e.g., user interpretations, expert reviews). The evaluation approach influences how scalable, replicable, and interpretable the tool is in practice.

The analysis reveals that 89% of the QETs primarily relied on quantitative evaluation, using methods such as automated code analysis and structured data collection. Remaining two tools combined both approaches for a more comprehensive evaluation. The predominance of quantitative evaluation aligns with the goal of automation but may limit the capture of context-dependent or user-centered insights.

4) RQ-4.4: What quality attributes are used for evaluation by the QET?: The inclusion of different attributes reflects how the tool defines "quality" and which aspects of OSS it prioritizes. The most frequently addressed quality attributes were maintainability (68% of the tools), reliability (58%), efficiency (47%), and security (42%).

These results suggest that most QETs focused on code-centric attributes commonly emphasized in traditional software quality models. This focus was likely due to relative ease of automatically extracting code-related metrics. However, for tools specialized in evaluating OSS, it is important to consider OSS-specific attributes. RQ-4.5 will show that while there are tools that consider community activity metrics, which are unique to OSS, code related metrics still play a more prominent role.

5) RQ-4.5: What software metrics are used for evaluation by the QET?: To further understand how the QETs measure and apply quality criteria, we investigated the specific software metrics used in evaluation. These metrics serve as the foundation for generating evidence-based quality assessments. Across the reviewed studies, commonly used metrics included:

- Code quality indicators (e.g., complexity, code smells),
- Community activity metrics (e.g., issue tracking, pull request volume),
- Bug tracking statistics,
- Support responsiveness and service quality.

Details of these distributions can be seen more clearly in the summary table (see Data Availability section).

6) RQ-4.6: What aggregation methods are used for evaluation by the QET?: Metric values gathered using various techniques tend to be heterogeneous in nature, making combining and comparing them difficult. To combine different metric values into a single score, aggregation methods are used. Weighted arithmetic mean was the most used aggregation method among the studies (63%), with some using other techniques such as overall sum or other mathematical equations.

The widespread use of weighted mean indicates a preference for simple and interpretable methods of combining quality metrics. At the same time, the presence of alternative aggregation methods, such as summation or custom formulas, reflects a lack of standardization in how overall quality is calculated. This variation can reduce the transparency and comparability of results across different QETs.

7) RQ-4.7: Does the QET support evaluation at a single point in time or throughout the evolution of OSS?: Evaluating quality over the course of a project's development is particularly relevant for OSS, where code and community activity evolve continuously. Tools that support analysis throughout evolution can help detect trends, regressions, or improvements, and are valuable for maintainers making long-term decisions.

The results indicate that 79% of the QETs performed single-point evaluations, while 3 tools (16%) allowed tracking quality over time, enabling historical analysis of OSS quality.

A study made on OSS project size growth patterns [7] observed that many OSS repositories reach approximately 75% of their final code size within the first 25% of commits, which

might suggest that a snapshot taken after this period could capture much of the system's core. However, there is no guarantee that the snapshot will be taken at the right time, potentially causing significant early changes to be missed. Additionally, one-time evaluations risk overlooking later community-driven refinements or regressions.

8) RQ-4.8: How are data collected for OSS evaluation in the QET?: Data collection methods were categorized as manual (e.g., form entries, expert-provided ratings etc.) and automated (e.g., metric extraction from repositories, codes, or APIs). The method of data collection directly affects a tool's usability, scalability, and potential for continuous evaluation. Automated tools typically require less user effort and support more consistent and repeatable assessments. However, not all the data can be retrieved automatically, which might limit the data to be taken into consideration in fully automated tools.

The findings showed that 47% of the QETs relied on manual input, 47% used fully automated data retrieval, and one did not specify it. This even split suggests that while many tools aim to automate evaluation, a significant number still depends on user-provided data; which can limit scalability and introduce subjectivity, but also allow for the inclusion of qualitative or context-specific information that automated methods may not be able to access.

9) RQ-4.9: What is the required skill level of users who evaluate OSS using the QET?: Usability and accessibility are critical for encouraging widespread adoption of the tools, especially in OSS communities, where users may include non-experts.

The analysis showed that 58% of the QETs required a medium to high level of expertise, such as familiarity with software quality models, metric interpretation, or manual configuration. This suggests that many tools are geared toward expert users and may pose a barrier for broader adoption, particularly among smaller or less formal OSS projects.

It should be noted that in cases where the required skill level was not explicitly stated, it was inferred based on the tool's interface, configuration requirements, technical documentation and results from RQ-3.

10) RQ-4.10: How are the results of the evaluation provided to the user in the QET?: The format of the results significantly influences the clarity, practical usefulness, and availability of quality assessments—especially for non-expert users or decision-makers.

The analysis showed that the QETs presented their results using the formats listed below. Some used more than one format to show their results; these were counted in the percentages:

- Indexed values in range (e.g., 0-1, 0-100) in 53%,
- Ordinal scales (e.g., ranked scores) in 42%,
- Nominal scales (e.g., "good," "fair," "poor") in 11%.

These findings indicate a tendency toward numeric outputs, which are well-suited for integration into automated systems or dashboards but may reduce usefulness for stakeholders needing more descriptive evaluations.

E. RQ-5: What programming tools and frameworks were used while developing the QET?

The technologies used to develop the QETs were analyzed, including programming languages, frameworks, and external libraries. This information is important for assessing the maintainability, accessibility, and extensibility of the tools. It can also provide guidance for future QET developers.

Most papers did not specify the technologies used. To address this, the source code of the tools—when available—was examined to manually extract the necessary information.

Most commonly used technologies were found to be Python, Java and JavaScript. However, due to limited reporting and missing source code links, a complete analysis could not be performed for all the QETs.

F. RQ-6: What is the current status of the QETs for OSS?

Evaluating the current state (i.e., maintained, discontinued, or still in progress) of each tool is essential to understand its sustainability, potential for long-term use, and relevance to practitioners.

A five-year threshold was used to assess maintenance status, i.e., the tools that had no updates within the last five years were classified as no longer actively maintained. According to this criterion, only six of the tools (32%) were found to be actively maintained. Out of the six active tools, only one was published before 2019. Additionally, out of these, only four tools have had updates within the last five years.

For tools that were discontinued, an archived version was searched on platforms such as Wayback Machine and GitHub. This process aimed to determine whether older versions of the tools were still accessible for reference, analysis or use. The results indicate that 63% of the discontinued tools had an archived version available, while an archived version could not be found for the remaining 37%.

These results highlight a significant sustainability issue: Many QETs are not maintained over time, and in several cases, their disappearance makes it difficult for others to study, reuse, or build on them. This poses a barrier to both reproducibility and practical adoption of the QETs for OSS evaluation.

IV. Discussion

This SLR on Quality Evaluation Tools for OSS reveals several practical and methodological challenges that limit the tools' effectiveness, adoption, and long-term utility.

A key issue is the short lifespan and limited maintenance of many QETs; several tools are either no longer accessible or have not been updated in recent years. This result might be influenced by our focus on academic literature, where prototypes might not be sustained beyond a single study. However, to support reliable and replicable evaluation in real-world OSS contexts, QETs must remain accessible over time. Even if they are not maintained, at a minimum, tools should be archived and publicly available to enable reproducibility and research. Ideally, QETs should also be hosted in open-source repositories, like the OSS projects they assess. Without this,

both practitioners and researchers face significant barriers in applying existing tools or advancing the field.

A second major concern is the lack of standardization across the tools. The QETs are based on a wide range of quality models, ranging from outdated standards (e.g., ISO/IEC 9126) to OSS-specific frameworks such as QSOS or OpenBRR. This diversity, while reflective of differing needs, leads to inconsistent and non-comparable evaluation results. The absence of a shared framework or terminology makes it difficult to compare evaluations across tools or projects, limiting the potential for creating universal benchmarks or guidelines. This puts users in a position where they might need to evaluate the QETs before they can use the QET to evaluate OSS quality.

Finally, usability remains an issue. While some tools were aimed to be user-friendly, many require medium to high levels of technical expertise to use, limiting accessibility for non-expert users. This usability gap limits the widespread adoption of the QETs. Future tools should prioritize intuitive interfaces, quality model templates, clear documentation, and automated data collection to lower the barrier for inexperienced users.

Taken together, these findings highlight the need for more sustainable, standardized, and accessible Quality Evaluation Tools for OSS. Addressing these issues would not only improve the reliability and comparability of OSS evaluations, but would also promote widespread adoption and continuous quality improvement in OSS ecosystems.

V. Threats to Validity

This study, like any other SLR, is subject to several potential threats to validity. One potential threat is the completeness of our search strategy. While we carefully designed our search string to capture relevant QETs for OSS, some studies might have been missed due to variations in terminology or indexing issues in databases. Additionally, the digital libraries we used may not cover all relevant papers, particularly those from lesser-known conferences or non-indexed journals.

The scope of the dataset also presents limitations. Our findings are based on a finite set of primary studies, which may not fully represent all existing QETs for OSS. Some tools may exist only as industry applications without academic documentation, leading to a possible bias toward research-focused tools rather than those used in practice. Additionally; EC7, as stated in Section II.C, further limits the scope. Per EC7, this review focuses on QETs that reference known quality models or standards. That is, tools that evaluate OSS quality using non-standard methods (including some that might be widely used in practice) may not be represented. This choice was made to prioritize comparability and structure, but limits generalization of the results to all tools.

It should also be noted that some aspects of the analysis involved interpretive judgment, especially when tool characteristics (e.g., required skill level in RQ-4.9 or maintenance status in RQ-6) were not explicitly stated in the studies. In such cases, we inferred answers based on indicators like documentation detail, user interface design, or repository activity. For example, the five-year threshold in RQ-6 is an arbitrary cutoff and may not fully reflect a tool's usability, especially if it has remained functional without frequent updates.

Lastly, the study does not assess the real-world effectiveness of the identified QETs through hands-on user testing. While we analyzed their documentation and reported functionality, actual usability, reliability, adoption, and performance of the tools remain unverified. Future studies could address this by running case studies or user surveys to validate our findings.

VI. Conclusion

This study provides preliminary insights into the states of Quality Evaluation Tools for Open Source Software, identifying key challenges in tool sustainability, standardization, and usability. While OSS quality evaluation models are well-studied, practical implementation is still an issue due to outdated tools, inconsistencies, and complexity.

Moving forward, future research should focus on improving the longevity and accessibility of the QETs, ensuring that tools remain accessible even if they are not actively maintained. Additionally, establishing standardized frameworks and meta-models could help make evaluation results more comparable across different tools. Finally, incorporating automation and AI-driven approaches, which are not yet widely implemented in the QETs for OSS, has the potential to improve scalability and reduce the manual effort required for quality assessment.

Addressing these gaps will help create more sustainable, standardized, and user-friendly QETs, ultimately contributing to more effective evaluation and selection of OSS products, greater trust in OSS systems, and broader adoption of quality assessment practices.

***Abstract*—In this paper, we propose a novel method for abnormality detection in Unmanned Surface Vehicles (USVs) based on a Multi-Modal Bayesian generative model to enhance safety and monitoring. During the training phase, we use a Null Force Filter and an unsupervised clustering algorithm on multimodal data collected from Global Positioning System (GPS) and motor current sensors. In the testing phase, we use a Coupled Modified Markov Jump Particle Filter (CM-MJPF) to infer the GPS position and motor current of the USV, as well as to detect abnormalities in both modalities. Due to the coupled methodology, the system is able to learn the statistical similarity between the evolving GPS and motor current data. As a result, the causality of defects is inherently captured within the dynamical inference, making the proposed approach explainable.**

***Index Terms*—Bayesian generative model, anomaly detection, unmanned surface vehicle, unsupervised clustering, explainable AI.**

I. Introduction

IN Intelligent Transportation Systems (ITS), the goal of improving transport safety has led to groundbreaking developments such as autonomous surface vehicles. Since unmanned surface vehicles are autonomous, they are prone to mechanical or electrical faults [1]. If such faults are not detected accurately and in a timely manner, they may not only cause malfunction of the agent but also cause critical hazard. Therefore, to minimize potential risks and ensure robust functionality, the agent might relay on its exteroceptive and proprioceptive sensors, like motor current and GPS, to monitor its internal states while interacting with the external environment.

An anomaly is an unexpected event or behavior that could indicate a problem or fault (deviation from normality) [2], [3]. Recently, as part of machine learning, Bayesian Networks have proven well suited for anomaly detection because they support both discrete and continuous variables, model uncertainty, and allow for representation of time series data [4]. Sensors mounted on the agent help it sense and perceive the environment, and the signal measured by the sensors can reflect the agent condition. Relaying only on one sensor for the detection of operational failures can lead to inaccuracies due to inadequate information. Similarly, considering multiple sensors independently also provides limited information. Therefore, it is important to have a comprehensive system that integrates multiple interacting sensors [5].

In this work, we propose an interactive Multi-Modal Bayesian generative model based on time series data, which can detect USV operational faults. Unlike studies in literature, our approach utilizes the interaction of multiple sensors using the Bayesian learning mechanism. Additionally, our method is able to differentiate the main source of the defect by exploiting the causal behavior of Bayesian networks. The main contributions of this paper are the following.

- A novel data-driven Bayesian generative model for USVs is proposed.
- The proposed method uses an interactive multi-modal approach, where we combine both GPS and motor current for learning the model.
- The proposed framework can trace the cause of the abnormality in an explainable way.
- The proposed method can be generalized to any kind of multi-modal sensors.

The remainder of the paper is organized as follows: Section 2 presents a review of related work on probabilistic inference approaches for abnormality detection in autonomous vehicles. Section 3 describes the proposed method in detail. After this, the simulation and experimental results obtained from the proposed approach, along with a discussion, are presented in Section 4. Finally, Section 5 concludes the paper and outlines directions for future work.

II. Related Work

Model-based fault diagnosis uses physics-based or mathematical models to detect and identify system faults. These models describe the expected behavior of vehicle components under normal conditions, allowing for comparison with real-time sensor data. In [6], the authors propose a steering wheel fault diagnosis method for autonomous vehicles, using a model-based residual generator with an SVM (Support Vector Machine) classifier. Similarly, in [7], they use Position Estimation Models, along with an Extended Kalman Filter (EKF), to detect faults by computing residuals (Mahalanobis distance) between estimated positions from sensor pairs. Abci

Topical area: Advanced Artificial Intelligence in Applications

B. et al. [8] also formulate a model-based fault detection and isolation (FDI) system for autonomous mobile robots that can detect and isolate sensor and actuator faults using an informational framework. Although model-based fault diagnosis applications are useful, they have some drawbacks, such as inaccuracies in modeling complex scenarios.

Due to the improvement of machine learning and computational techniques, there has been growing interest in data-driven fault diagnosis. This paper, therefore, takes advantage of data-based abnormality detection methods focused on autonomous vehicles. While only a few studies in the literature directly address the operational fault diagnosis for USVs, as examined in this paper, several related works share similar characteristics and offer relevant insights. In [10], the authors use a data-driven Neural network to detect and isolate faults, based on the differences between the measured and estimated outputs (residuals). Furthermore, in [9], Gaussian process regression to generate the residuals is used.

The methods mentioned above focus on a single data source. However, as systems become more complex, relying on data from just one source is not sufficient for effective monitoring. To address this limitation, fault diagnosis systems now employ multi-sensor technology to capture a wider range of characteristic data. In [13], the authors propose convolutional neural network (CNN) architectures for the fault diagnosis of an induction motor, using different combinations of multi-sensory signals such as vibration, current, voltage, and speed. Similarly, Ö. Gültekin et al. [5] utilize time–frequency representations of time series data obtained from both vibration and sound sensors, and use a CNN model for the classification process to diagnose the operational faults of autonomous transfer vehicles. Shaoxuan Xia et al. [14] applied a hierarchical attention-based multi-source data fusion method for fault diagnosis in Autonomous Underwater Vehicles (AUVs), addressing challenges like multi-source data heterogeneity and strong coupling. They used a Bidirectional Long Short-Term Memory (BiLSTM) network for feature extraction and a Multilayer perceptron (MLP) for fault detection. Although multisensory fusion provides more information compared to using a single type of sensor, previous studies in the literature often consider each sensor independently. Moreover, they did not explain the cause of a defect. Unlike most of the papers available in the literature, our method is an interactive and multi-modal approach, and is able to explain the cause of a defect.

III. Methodology

A. Experimental Setup

We use a telemetry system to collect the necessary data for our experiment, as shown in fig. 1. Data from the inverter are gathered via the Controller Area Network bus (CANbus) communication protocol. This is achieved by sending a request to the inverter for a specific parameter reading, after which the inverter responds with the corresponding measurement. Moreover, the GPS module communicate via universal asynchronous receiver / transmitter (UART). Data provided by

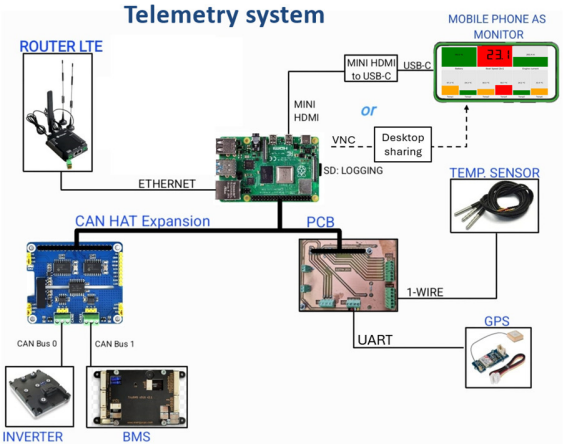

Fig. 1: Experimental setup-Telemetry system

GPS are encoded according to the NMEA (National Marine Electronics Association) standard.

B. Preliminaries

- Generative models: There are two types of models in machine learning, i.e., discriminative and generative. Discriminative models focus on learning the probability of a specific class label given an input, which is the approach commonly used in classification tasks. Conversely, generative models learn the underlying data distribution, enabling them to produce new data samples that follow the same pattern.
- Bayesian Networks (BNs): They are a type of generative model that allow us to model causal relationship between random variables.
- Dynamic Bayesian networks (DBNs): They are a particular type of BN which can describe dynamic processes that evolve over time.
  The main advantage of a DBN is its capability to formulate causal relationships between semantic information (high level) and sensory data (low level) in a hierarchical level. DBNs with hierarchical structure are called Hierarchical Dynamic Bayesian networks (HDBNs). Fig. 2 shows a DBN representation for three hierarchical variable levels. The nodes represent the random variables for a continuous level state (X_t and Z_t) or a discrete level state (S_t). The links represent conditional dependencies between nodes.

C. Proposed DBN for Learning Interaction

1) Training phase: Initially, the USV perceives its surroundings under the static assumption that the environmental state does not change. Therefore, the USV predicts its position (GPS) and internal state (motor current) using a null force filter with the following model:

$$X_t^n = X_{t-1}^n + W_t^n, \tag{1}$$

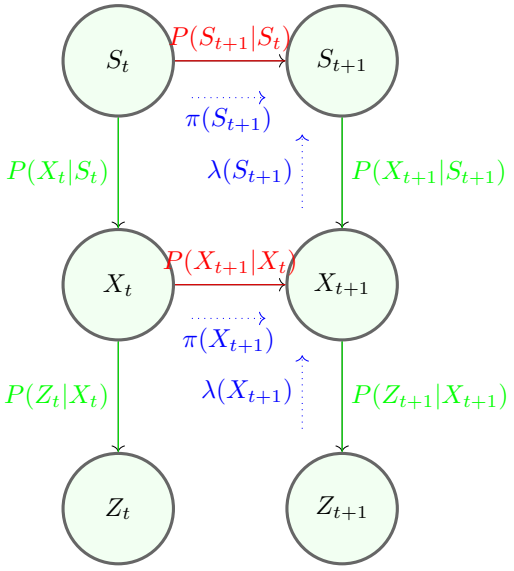

Fig. 2: Three level DBN. The links highlighted in red are inter-slice links, and the ones in green are intra-slice links at different times.

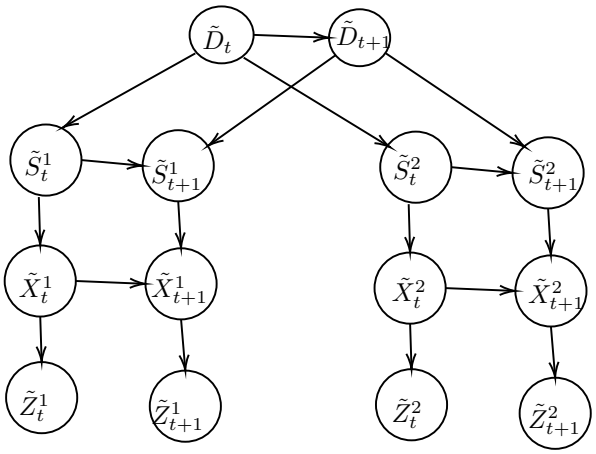

Fig. 3: Learning interactions among GDBN Models for both modalities (1 for motor current and 2 is for GPS), where $\tilde{D}$ is the Interaction Discrete level, $\tilde{S}$ is the Superstate Discrete level, $\tilde{X}$ is the continuous level and $\tilde{Z}$ is the measurement level

where W^n_t represents the noise accounting for the measurement uncertainty of the n-th sensor (with n=1 for motor current and n=2 for GPS) at time t.
In order to explore the dynamic rule through time in the environment, a new rule should be created by exploiting the generalized error, which is the difference between prediction and observation. Generalized errors $\tilde{X}_t$ are expressed as:

$$\tilde{X}_t = [X_t, \dot{X}_t]^T \tag{2}$$

where X_t is calculated using equation (1), and $\dot{X}_t$ can be considered as the innovation of the null force filter calculated

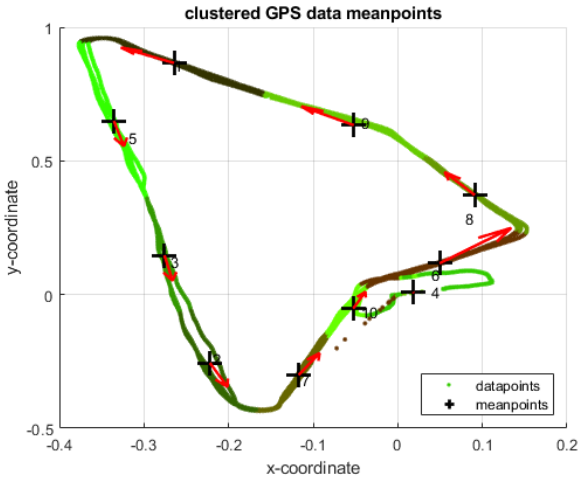

Fig. 4: Clustered GPS data

using this equation:

$$\dot{X}_t = H^{-1} Z_t - X_t \tag{3}$$

where Z_t is the measurement acquired from the sensors at time t and H is matrix that maps the observation to the state X.

Consequently, the Generalized errors collected from previous experience are used as input to an unsupervised clustering algorithm (i.e., Growing Neural Gas (GNG)), which encodes them to discrete variables or neurons ($\tilde{S}^n$) called super states (letters):

$$\tilde{S}^n = \tilde{S}^n_1, \tilde{S}^n_2, ..., \tilde{S}^n_M \tag{4}$$

where M is the total number of superstates.

Each generalized superstate $\tilde{S}^n_t (\tilde{S}^n_t \in \tilde{S}^n)$ is associated with its corresponding statistical properties mean $(M^{\tilde{S}^n_t})$ and covariance matrix$(Q^{\tilde{S}^n_t})$, as shown in figure 4.

Following the clustering of each sensor's generalized errors, a word or meta cluster ($\tilde{D}_t$) is formed, containing the superstate clusters (letters) of the two sensors, motor current and GPS ($\tilde{S}_t{}^1$ and $\tilde{S}_t{}^2$), at time t.
After meta-clustering, a $P \times P$ word transition matrix (Π) is defined as:

$$\Pi = \begin{bmatrix} \pi(\tilde{D}_t = \tilde{D}_1) \\ \vdots \\ \pi(\tilde{D}_t = \tilde{D}_p) \end{bmatrix} = \begin{bmatrix} \pi_{11} & \cdots & \pi_{1P} \\ \vdots & \ddots & \vdots \\ \pi_{P1} & \cdots & \pi_{pp} \end{bmatrix} \tag{5}$$

where P is the number of unique words in the dictionary. This matrix is learned by estimating the transition probabilities $\pi_{ij} = P(\tilde{D}_t = j | \tilde{D}_{t-1} = i), j, i \in \tilde{D}$ over time.

2) Testing phase:

- *Real time Joint Position and Motor current inference:* In order to perform inference at different hierarchical levels, an interactive modified Markov Jump Particle Filter (IM-MJPF) has been employed, as illustrated in figure 3, to extract the knowledge embodied in the

coupled GDBN (C-GDBN). The MJPF is a switching model that uses a combination of a particle filter (PF), to predict discrete superstates, and Kalman Filters (KF) for continuous states prediction and estimation. Such a switching behavior, between the dynamic transitions at discrete/continuous levels and observations, enables the updating of the belief about the motor current state and its corresponding position by passing local messages in simultaneous inference modes, namely the predictive or causal inference (top-down) and the diagnostic inference (bottom-up). The top down messages from $\tilde{D}$ to $\tilde{X}$ depend on the clustered values, including super states with their corresponding mean and covariance statistics. The temporal predictive messages $(\pi(\tilde{D}_t) = P(\tilde{D}_t|\tilde{D}_{t-1}))$ and $(\pi(\tilde{S_t}^n) = P(\tilde{S_t}^n|\tilde{S}^n_{t-1}), \pi(\tilde{X_t}^n) = P(\tilde{X_t}^n|\tilde{X}^n_{t-1}))$ for both modalities depend on the dynamic rule stored in the model (intra-slice messages) as shown in figure 2.
The particle filter is employed to predict the discrete values (or words) relied in the word transition matrix encoded in the dynamic model as a proposal distribution. Once the word is predicted, each superstate of the two modalities is inherently contained within the word. Then, for each particle, a Kalman filter is employed to predict continuous states (position and motor current) of the agent using this equation: (6).

$$\tilde{X}^n_t = A\tilde{X}^n_{t-1} + BU^{\tilde{S}^n_t} + W^n_t \tag{6}$$

where A and B are the dynamic model matrix and the control model matrix, respectively. And $U^{\tilde{S}^n_t}$ is a control vector which represents the dynamic rules of the signal temporal evolution encoded in the superstate.
Once the evidence is observed, a message is backward-propagated from the bottom level towards the higher levels (λ messages as shown in figure 2). This message (reasoning) is based on likelihood models consisting of messages $(\lambda(\tilde{D}_t), \lambda(\tilde{S_t}^n), \lambda(\tilde{X_t}^n))$, in which all continuous nodes are Gaussian-distributed variables and the two GDBN models are conditionally independent given the interaction node:

$$\lambda(\tilde{D}_t) = \prod_{i=1}^{n} \lambda(\tilde{S_t}^n) \tag{7}$$

$$\lambda(\tilde{S_t}^n) = \lambda(\tilde{X_t}^n) P(\tilde{X_t}^n|\tilde{S_t}^n) \tag{8}$$

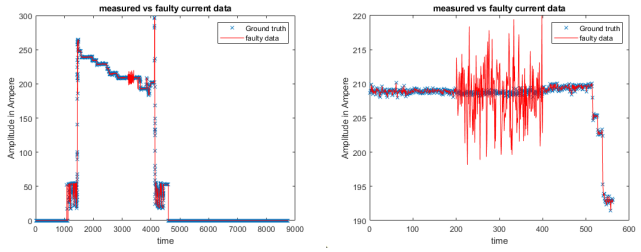
$$\lambda(\tilde{X_t}^n) = P(\tilde{Z_t}^n|\tilde{X_t}^n) \approx N(\mu_{\tilde{Z_t}^n}, \Sigma_{\tilde{Z_t}^n}) \tag{9}$$

Consequently, each posterior distribution ($belief = \pi(.) * \lambda(.)$) at word, superstate, and state level is updated according to $\lambda(\tilde{D}_t), \lambda(\tilde{S_t}^n), \lambda(\tilde{X_t}^n)$, respectively. Furthermore, these beliefs will represent the initial states on the next time instance.

- *Multi-modal Abnormality Measurements:*
  During the journey, the USV checks whether it is in an optimal state or experiencing an abnormality by predicting the motor current and GPS signal. When new data arrive, the trained model uses the GDBN to make sense of it and spot different types or levels of unusual patterns. To measure the motor current or GPS deviation we use an abnormality indicator at superstate level defined as a distance between the predictive message $(\pi(\tilde{S_t}^1))$ and the diagnostic message $(\lambda(\tilde{S_t}^1))$ entering the node $\tilde{S_t}^1$.
  We use the symmetric Kullback-Leibler Divergence (KLDA) to measure the similarity between the two discrete probability distributions $(\pi(\tilde{S_t}^1)$ and $\lambda(\tilde{S_t}^1))$ defined by:

$$\begin{aligned} KLDA = D_{KL}\left(\pi(\tilde{S_t}^1) \parallel \lambda(\tilde{S_t}^1)\right) \\ + D_{KL}\left(\lambda(\tilde{S_t}^1) \parallel \pi(\tilde{S_t}^1)\right) \end{aligned} \tag{10}$$

  where $\parallel$ identifies the divergence.
  Similarly, we use the Bhattacharyya distance (BD) to measure the probabilistic distance between the two continous probability distributions $(\pi(\tilde{X_t}^1)$ and $\lambda(\tilde{X_t}^1))$ defined by:



$$BD(p,q) = -ln\left(\sum_{i=1}^{k} \sqrt{p_i * q_i}\right) \tag{11}$$

  where $p = \pi(\tilde{X_t}^1)$, $q = \lambda(\tilde{X_t}^1)$, and k represents the number of elements considered in the computation. Furthermore, this can be calculated for all other possible sensors attached to the agent including GPS.
- *Evaluation matrices:*
  To assess the performance of our multi-modal abnormality detection approach, we use the Receiver Operating Characteristic (ROC) curve. The ROC curve visually shows how a model performs at different classification thresholds. It is created by plotting the true positive rate (TPR) against the false positive rate (FPR) for all possible threshold values. The AUC, or Area Under the Curve, summarizes this graph into a single number, indicating the model's ability to distinguish between classes. An AUC of 1.0 reflects perfect classification, whereas an AUC of 0.5 suggests the model is no better than making random guesses.

IV. Simulation and Experimental Results

A permanent magnet synchronous motor (PMSM) is a motor known for its outstanding dynamic performance and high reliability. It is extensively applied in areas such as electric vehicles, rail transportation, smart manufacturing, and more [11]. Our USV uses PMSM as its core engine.

An inter-turn short circuit (ITSC) fault in a stator typically happens when the insulation between the windings of the same phase breaks down. In this section, we perform the simulation of the ITSC fault to test our abnormality detection framework. ITSC in the stator results in a huge eddy current in the short circuit [12]. This will increase the RMS (Root Mean Square) current amplitude in the motor. This is simulated by adding Gaussian noise to the real motor current data, as shown in figure 5.

(a) Normal current data vs faulty (b) Chunked version-Visualization

Fig. 5: Normal vs Faulty RMS Current signal

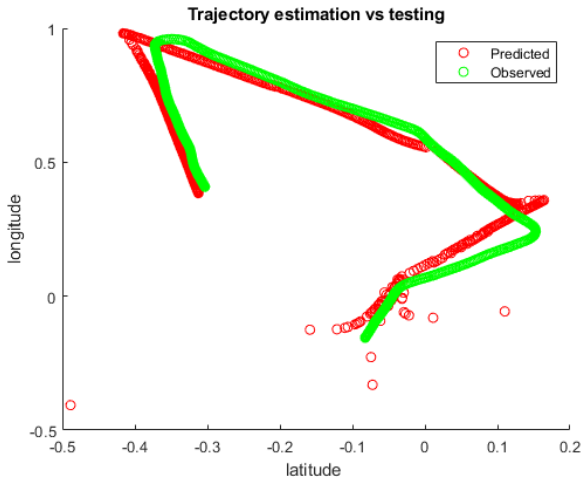


Fig. 6: Trajectory (chunk of the GPS data) estimation vs observed

The multi-sensor tracking capability of the USV is demonstrated by the spatio-temporal prediction of the trajectories, as in figure 6. Consequently, the motor current can be estimated based on the interaction between the two sensors as shown in figure 7.

To enable scalable, efficient, and stochastic learning of the posterior, we divided our dataset into 8 examples (mini-batches) during the training of the Bayesian generative model. During testing, we use one of the batches containing a simulated motor fault as the test set.

The decision making process of the autonomous agent is illustrated in figures 8 and 9, in which the abnormality is detected if it passes the predefined threshold (set during training). This demonstrates the effectiveness of our framework in detecting abnormalities. Moreover, the cause of the abnormality can be traced to either a GPS error or a motor current fault. This makes our framework explainable.

In addition, we carried out a performance test for the continuous state (motor current) abnormality detection. The ROC curves shown in both figures 10 and 11 indicate that our framework achieves good abnormality detection efficiency.

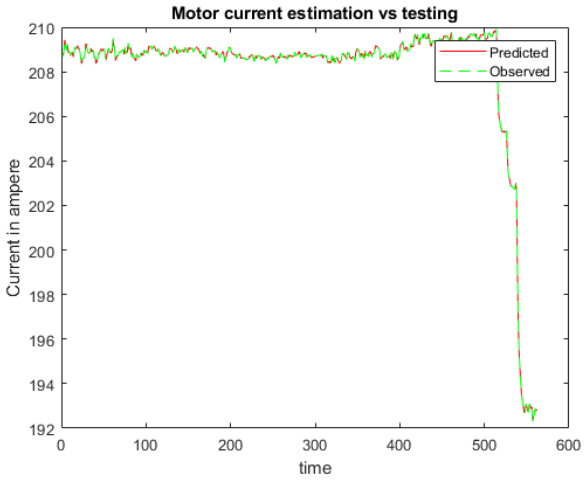

Fig. 7: Motor current estimation vs observed (chunk of motor current data cross ponding to GPS shown in figure 6)

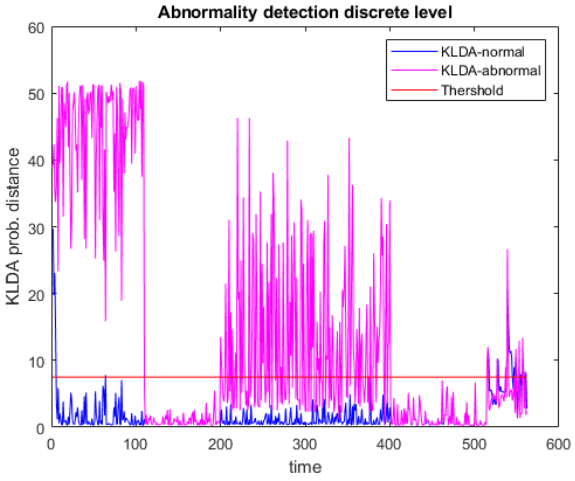

Fig. 8: Tracking abnormality at cluster level (Superstate level)

V. Conclusion and Future Work

This paper proposes a multi-modal Bayesian generative model for fault detection and probabilistic inference of system states in an Unmanned Surface Vehicle (USV). The proposed approach uses coupled Dynamic Bayesian Networks (DBNs) to assimilate different observations over time, enabling incremental learning and inherent explainability. The method predicts future states based on past observations, providing an interpretable explanation of the model's reasoning.

The performance of the proposed method is evaluated using real-world data and simulated faults that mimic actual motor malfunctions. The results indicate that the approach can predict and detect faults in a USV with high accuracy. Furthermore, it is capable of identifying the root cause of the defect.

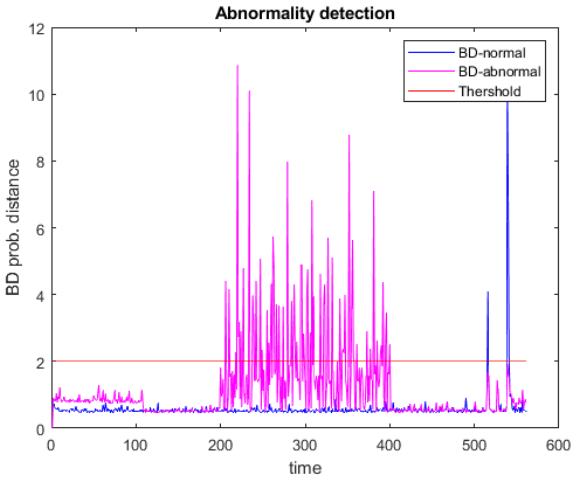

Fig. 9: Tracking abnormality at continuous level

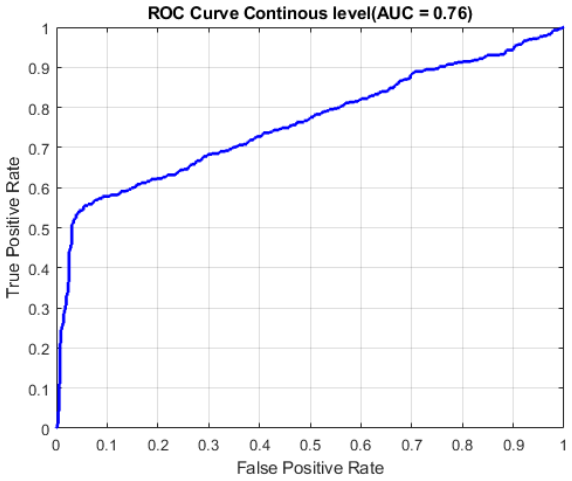

Fig. 11: ROC (BD) curve for motor abnormality detection

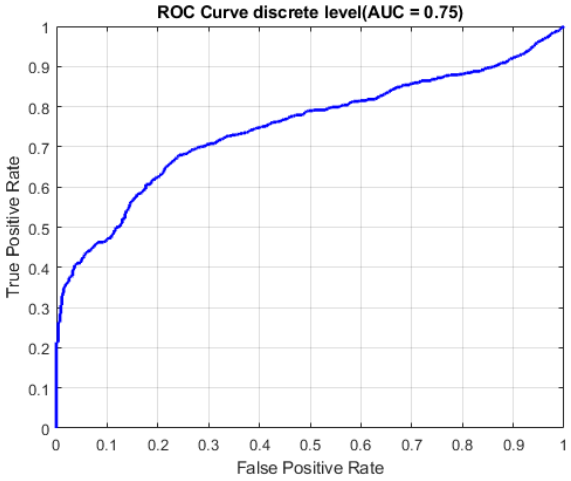

Fig. 10: ROC (KLDA) curve for motor abnormality detection

In our future work, we are planning to calculate meta-cluster level (word level) abnormality to detect possible anomalies on the agent and to learn the time evolution synchronization between the multi-modal sensors used in our approach.

***Abstract*—As the adoption of renewable energy continues to rise, precise forecasting of solar power generation is essential for optimizing energy storage and distribution. This article explores the prediction of energy output in photovoltaic systems using machine learning models that leverage environmental and geographical factors. The study utilizes data from 9,182 private photovoltaic installations across Poland and publicly available weather records. Additionally, a data preprocessing method was introduced to filter out non-useful data, such as records indicating malfunctioning installations, ensuring that only relevant information is used for prediction. Key variables considered include temperature, cloud cover, wind speed, and solar panel efficiency. This paper studies the effectiveness of data-driven energy production forecasting methods, namely linear regression, polynomial regression, decision tree regression, random forest regression, and multilayer fully connected artificial neural network, designed to make predictions for various installations with different parameters and geographical locations, considering atmospheric conditions in contrast to frequently published articles in which predictions are fitted on data from a single photovoltaic installation. Due to this, our work has broad research value, explores the boundaries and limitations of such approaches, and can be considered a reference for energy engineers, computer scientists, and researchers.**

***Index Terms*—Photovoltaic Infrastructure, Machine Learning, Prediction, Feature Selection, Data-Driven**

I. Introduction

RENEWABLE energy has experienced substantial growth in recent decades, driven by the increasing global population and the recognition of the finite nature of fossil fuel resources. The transition to renewable energy sources is widely regarded as a viable strategy to reduce dependence on fossil fuels while mitigating the environmental impacts of their extraction and consumption. Technological advancements in renewable energy have been considerable, with numerous solutions already implemented in practical applications in private and industrial sectors. Additionally, reliable environmental and production data availability has improved significantly, caused by the growing adoption of monitoring systems in private photovoltaic installations.

Among renewable energy sources, solar and wind technologies have been recognized for their substantial potential to meet global energy demands. As noted by Gross et al. [1], these technologies were considered to have the most significant impact within the renewable energy sector. However, subsequent research by Olabi and Abdelkareem [2] emphasised that both solar and wind energy are highly dependent on environmental conditions, introducing variability and limiting their reliability as primary global energy sources.

One of the critical challenges in integrating renewable energy sources is the efficient management of energy storage and distribution to maintain a stable balance between generation and consumption. As discussed by Roberts et al. [3], the variability of renewable energy output, primarily influenced by environmental conditions, requires the implementation of adaptive and responsive strategies for storage and distribution. At a macro-level, particularly within centralised energy systems such as Nord Pool [4], this involves determining optimal periods for storing energy for future use versus distributing it to external sectors to meet immediate demand. In addition, these strategies should include dynamic pricing models that account for fluctuations in energy demand and the availability of generation resources, thereby enhancing the overall efficiency and reliability of the energy system.

Therefore, accurate forecasting of solar energy production has become a critical component in the efficient operation of modern energy systems. Reliable predictions enable better planning for energy storage, grid balancing, and market operations. Forecasting supports decision-making processes by providing information on expected energy availability, essential for maintaining supply stability, reducing reliance on backup fossil fuel generation, and optimising energy pricing and distribution strategies.

Two primary methodologies are commonly used to forecast

Topical area: Advanced Artificial Intelligence in Applications

the energy production of solar installations. The first is a deterministic approach, which involves the development of a physical model that represents the electrical behaviour of photovoltaic cells. This method simulates the underlying physical processes to estimate the energy output based on the known specifications and characteristics of the solar panel. A wide range of physical models can be applied to predict the performance of photovoltaic systems with varying configurations, as examined by Dolara et al. [5], [6].

An alternative approach to forecasting solar energy production involves using statistical and machine learning models, which are developed based on historical data from photovoltaic installations and relevant environmental variables that influence energy generation. These methods aim to identify and model the underlying relationships between features in the dataset to enable accurate prediction. Linear regression and artificial neural networks (ANNs) are the most commonly used models in this domain. Both approaches have been extensively applied in various research contexts with notable success. For example, Gratidi et al. [7], Barrera et al. [8], and Zazoum [9] each developed accurate prediction models tailored to different datasets, photovoltaic system architectures, and methodological frameworks. These studies highlight the flexibility and effectiveness of machine learning techniques in capturing the complexity inherent in solar energy production forecasting.

Despite significant advancements and promising outcomes in solar energy forecasting, considerable room for improvement remains. Studies by Gratidi et al. [7] and Barrera et al. [8] commonly relied on data collected from small-scale installations located in research centres, which, while controlled and consistent, may limit the model's ability to generalise to real-world scenarios. For predictive models to be applicable globally, it is crucial to incorporate diverse datasets drawn from various geographic locations and installation types. Additionally, many existing studies utilize well-structured solar radiation data complemented by ambient temperature measurements. Although this data can enhance model accuracy, it often depends on specialized infrastructure that may not be available in all regions. This reliance poses a challenge to scalability, particularly in areas lacking comprehensive meteorological monitoring systems. It highlights the need for models capable of operating effectively with more readily accessible environmental data.

A. Novelty of this paper

This work examines the effectiveness of statistical and machine learning models for predicting energy output in photovoltaic systems that leverage environmental and geographical factors. New to previous work dealing with similar topics, the study was conducted on a large dataset containing installations located almost all over a medium-sized European country. Our goal was to create a predictive model that can effectively predict energy production based on data such as the power of an installation, its geographic location, and weather data to improve forecast accuracy [10]. Thus, in this work, we study the effectiveness of data-driven energy production forecasting methods designed to make predictions for various installations with different parameters and geographical locations, taking into account atmospheric conditions, in contrast to frequently published articles in which predictions are fitted on data from a single photovoltaic installation [11]–[15]. Due to this fact, our work has broad research value, explores the boundaries and limitations of such an approach, and can be considered a reference for energy engineers, computer scientists, and researchers.

II. Materials and Methods

The foundation of this study is a dataset that accurately represents real-world conditions of photovoltaic installations. The data were collected from multiple private solar installations and supplemented with commonly observed meteorological variables to ensure a comprehensive analysis. The selected methodology prioritizes data that are accessible to the average user, eliminating the need for specialized professional measuring equipment. The dataset from photovoltaic installations covers the year 2020 and, due to licensing and legal restrictions, cannot be publicly shared with other researchers.

A. Data set

The initial database comprised 145,068,684 records from 9,182 photovoltaic installations in Poland through the PVmonitor monitoring system. The measurements taken from these installations were aggregated every three minutes, capturing various parameters such as energy production, efficiency over specific time intervals, the cumulative sum of energy generated since monitoring began, and the corresponding timestamps. Each installation was assigned a unique ID and included localization details and the manufacturer's power specifications for the photovoltaic panels.

The weather dataset was gathered to use only commonly available environmental information like temperature, cloudiness, or wind speed. To achieve this, the data was collected from a publicly available AccuWeather archive using a data scraping technique. This source was selected due to its frequent measurements and broad coverage of features relevant to this study. A notable characteristic of this dataset is the cloudiness variable, which is provided as a percentage. This numerical representation is more precise and requires less preprocessing than categorical cloud cover classifications.

B. Preprocessing

Since the installations dataset was collected from private users, it relied heavily on user input, with no control over the accuracy of the solar panel setup or the calibration of the monitoring devices. This resulted in a necessity to validate and prune data strictly. Several conditions must be satisfied to determine whether or not an installation is active and whether it should be considered.

- Power of Installation provided by a user cannot be equal to zero,

- Installation should at least once in a month reach over 40% efficiency,
- Installation's mean efficiency in winter (October through March) should be over 5%,
- Installation's mean efficiency in summer (April through September) should be over 10%,
- Installation has to be monitored throughout the entire year.

Applying these conditions reduced the number of installations to 32. Although this significantly decreased the amount of data available for energy production predictions, ensuring that the dataset contained only high-quality records was necessary. Despite the reduction, the remaining installations still contributed 181,306 measurement points, providing sufficient data for accurate predictions.

The next step was to combine both datasets into a consistent database. Since installation measurements were made every three minutes and weather data was aggregated hourly, it was necessary to aggregate the measurements to match this time frame. Aggregation was achieved by calculating the mean value of each efficiency of each Installation and the sum of power (P) and power increment (DPV). Finally, the data were aligned based on geographical location.

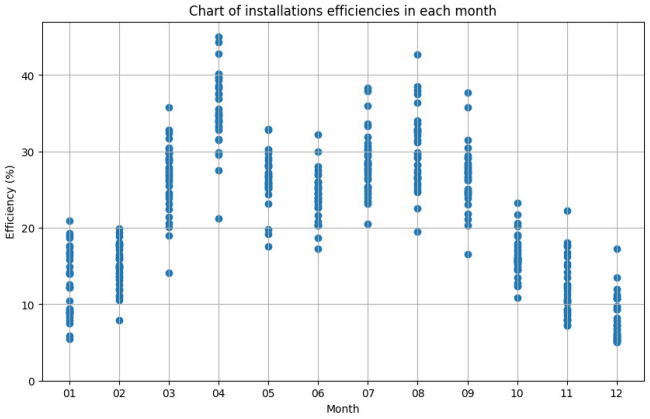

Fig. 1. Chart of mean installations' efficiencies aggregated monthly

After proper data filtering, it was possible to distinguish a desired trend in efficiency throughout the year presented in Figure 1. This trend is a direct result of yearly changes in the solar azimuth angle because photovoltaic installations are more efficient when the radiation reaches solar panels at around 90° angle [16], [17] (as a combination of azimuth and tilt angles) that occurs at the spring and autumnal equinox in Poland.

C. Experimental setup

The dataset was divided into training and testing sets in an 80%-20% ratio based on installation indexes, ensuring that instances from the same installation did not appear in both sets, thus maintaining a clear separation for evaluation. Due to the data being inconsistent regarding values range, the action taken to ensure good performance of models was scaling both training and test data using the Equation 1.

$$Z = \frac{x - \rho}{\sigma} \tag{1}$$

where:
x is the value of sample,
ρ is a mean values of all samples and
σ is the standard derivation.

The linear regression model was proposed as a baseline model for comparison, as it is a simple machine learning model that does not require additional hyperparameters tuning. Another models we also evaluated were polynomial regression, K-nearest neighbour regression (KNN), decision tree regression, random Forest regression (RFR) and artificial neural network (ANN). The architecture of implemented ANN is detailed in Table I.

TABLE I
ARCHITECTURE OF IMPLEMENTED ARTIFICIAL NEURAL NETWORK

Layer	Layer Type	Number of Neurons	Activation Function
Input	Input	7 (number of features)	
Hidden n°1	Dense	10	ReLU
Hidden n°2	Dense	10	ReLU
Hidden n°3	Dense	10	ReLU
Output	Dense	1	Linear

D. Metrics used to evaluate models' performance

Evaluating machine learning models using standardised metrics is essential to ensure comparability. The performance of the models was assessed on the following metrics:

- Normalized Root Mean Squared Error

$$NRMSE_{minmax} = \frac{\sqrt{\frac{1}{N}\sum_{i=1}^{N}(y_i - \hat{y}_i)^2}}{y_{max} - y_{min}},\ y_{max} \neq y_{min} \tag{2}$$

- Mean Squared Error

$$MAE = \frac{1}{N}\sum_{i=1}^{N}|y_i - \hat{y}_i| \tag{3}$$

- R-squared

$$R^2 = 1 - \frac{\sum_{i=1}^{N}(y_i - \hat{y}_i)^2}{\sum_{i=1}^{N}(y_i - \bar{y})^2}, \exists i, j \text{ such that } y_i \neq y_j \text{ for } i \neq j, \tag{4}$$

where:
N is a number of testing samples,
y_i are the predicted values,
$\hat{y}_i$ are the actual values,
$y_{\max}$ and $y_{\min}$ are the maximum and minimum values in the dataset,
$\bar{y}$ is mean of the observed values.

III. RESULTS

Table II presents the evaluation metrics calculated for the training and test datasets. The NRMSE$_{minmax}$ metric is the primary indicator of predictive accuracy, as it assesses the performance of the models relative to the data scale. In addition,

TABLE II
EVALUATION OF MODELS ON TRAINING AND TEST DATA

Test Set			
Model	**NRMSE$_{minmax}$**	**MAE**	**R^2**
Linear Regression	0.1809	17.4593	0.2390
Regression with Polynomial Features	0.1210	11.1261	0.6591
K-Nearest Neighbors (KNN)	0.1304	10.5962	0.6045
Decision Tree Regressor (DTR)	0.1237	9.8932	0.6445
Random Forest Regressor (RFR)	**0.1113**	**9.1079**	**0.7122**
Artificial Neural Network (ANN)	**0.1137**	**9.4136**	**0.6994**
Training Set			
Model	**NRMSE$_{minmax}$**	**MAE**	**R^2**
Linear Regression	0.2019	17.4593	0.2290
Regression with Polynomial Features	0.1260	10.1974	0.6996
K-Nearest Neighbors (KNN)	**0.0637**	**4.0101**	**0.9231**
Decision Tree Regressor (DTR)	0.1179	7.9926	0.7228
Random Forest Regressor (RFR)	**0.0254**	**1.5648**	**0.9877**
Artificial Neural Network (ANN)	0.1189	8.7776	0.7322

MSE and R^2 serve as complementary metrics, offering further insight into the overall effectiveness of the models.

In the test set, the NRMSE$_{minmax}$ values indicate that the best-performing models are RFR and ANN, with RFR showing a slight advantage. This suggests that RFR is particularly effective at capturing the dataset's complexity while maintaining high predictive accuracy. In contrast, models such as DTR and polynomial regression obtained satisfactory results but did not achieve the same level of accuracy as RFR and ANN.

Comparison with training data provides insight into the generalisability of the models. Although RFR and KNN achieve exceptionally high performance on the training data, their performance on the test dataset is noticeably lower. Among the evaluated models, ANN exhibits the most consistent performance in both training and test datasets, indicating a strong balance between predictive accuracy and generalisability.

There is a notable improvement between the baseline model (linear regression) and the more advanced models, emphasizing the effectiveness of non-linear approaches. Among the models tested, RFR demonstrates the best overall performance, closely followed by ANN. Additionally, based solely on the evaluation metrics, regression with polynomial features and KNN exhibit strong performance for this dataset. Further insights into the models can be obtained by analysing Figures 2 and 3, which compares the real and predicted values for each model across training and test datasets. These visualizations offer a clear representation of the models' generalization capabilities and enable a direct comparison of their performance on training versus test data.

To objectively evaluate the performance of the models, it is

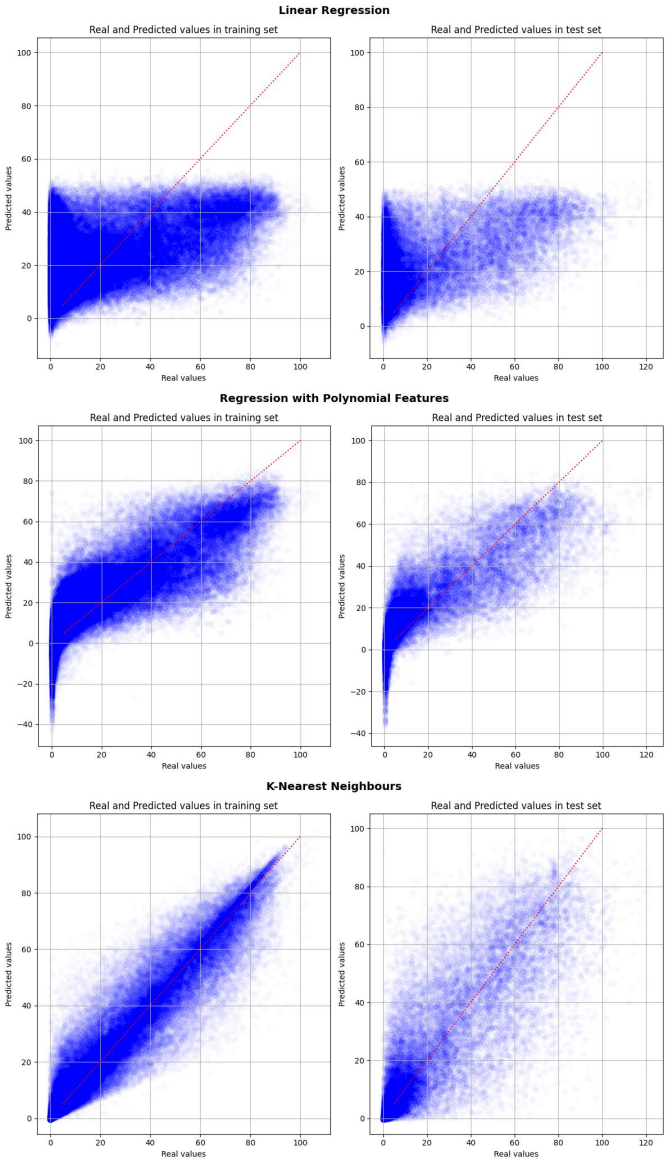

Fig. 2. Comparison of training and test predicted values vs actual values - linear regression, regression with polynomial features and K-nearest neighbour

crucial to compare the results with those reported in other studies. Table III presents a performance summary of the selected models in various data sets and methodologies. The comparison is based on NRMSE values, with linear regression serving as the baseline, normalised to 100% using the min-max method in this study and different normalisation approaches reported in the studies [7], [18], [19]. The relative performance of other models is then expressed as a percentage improvement or decline relative to this baseline. This approach ensures the comparability of the metric between different methodologies.

IV. DISCUSSION

The comparison between the training and test results (Table II) provides insights into the generalisation capabilities of the

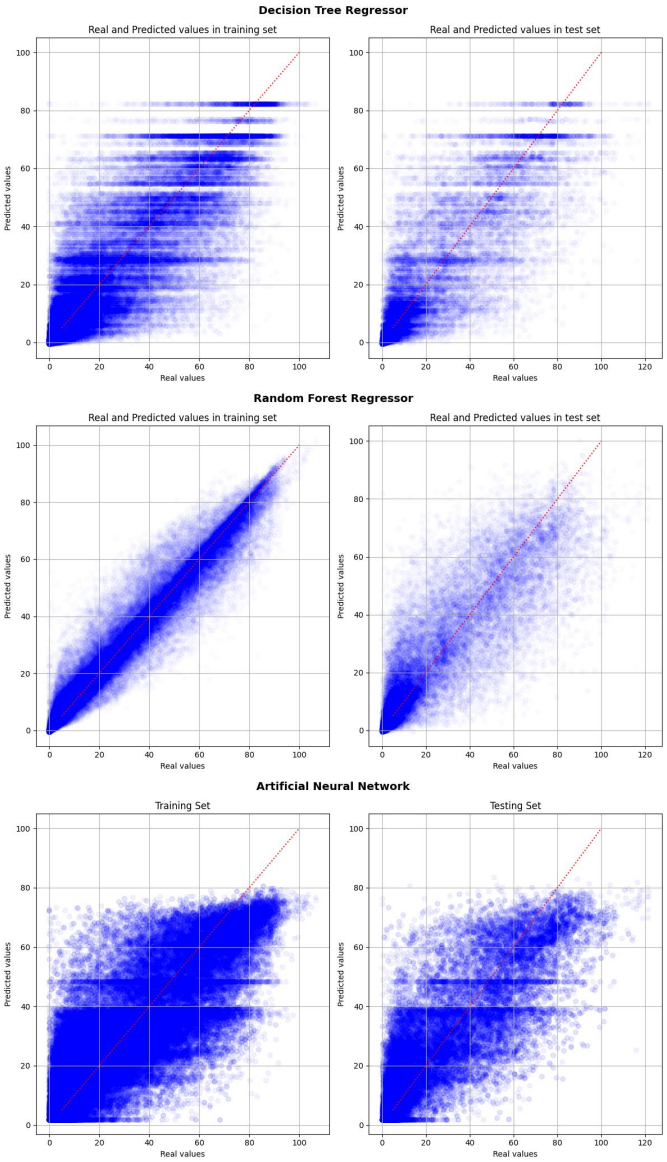

Fig. 3. Comparison of training and test predicted values vs actual values - decision tree regressor, random forest regression and artificial neural network

models. Although RFR and KNN achieve high performance on the training set, their test performance declines, indicating overfitting. This suggests that these models capture patterns specific to the training data but struggle to generalise to unseen data. In contrast, ANN exhibits the most consistent performance across both datasets, highlighting its robust generalisation ability. This suggests that ANN effectively learns underlying relationships in the data without overfitting, making it a more reliable model for photovoltaic energy prediction.

The observed differences in model performance may be attributed to the nonlinear nature of photovoltaic energy generation, which is influenced by multiple environmental factors [20], [21]. Although decision tree-based models like RFR effectively handle complex interactions, their sensitivity to training data can lead to overfitting. On the other hand, the ANN model, with its ability to capture nonlinear dependencies, demonstrates a better balance between flexibility and generalisation.

TABLE III
COMPARISON OF MODEL PERFORMANCE BASED ON NRMSE VALUES, WITH LINEAR REGRESSION SERVING AS THE BASELINE (100%), AND THE PERFORMANCE OF OTHER MODELS EXPRESSED AS A PERCENTAGE IMPROVEMENT OR DECLINE RELATIVE TO THIS BASELINE

Model	relative performance (in %)			
	S	S_1 [7]	S_2 [18]	S_3 [19]
LR	100	100	100	100
KNN	138.7			173.33
RFR	162.53		160.8	288.89
ANN	158.10	71.38	350.33	236.36

In Figures 2–3, there is a noticeable increase in point density for lower efficiency values in all models. This can be attributed to the dataset's characteristics, where higher efficiency values are less frequent than lower ones. Power generation is typically most efficient during specific periods, particularly in summer and around midday, if weather conditions are favourable. This distribution reflects the natural variability of photovoltaic systems, which is strongly influenced by seasonal and temporal factors. The effect is even more pronounced in the training set, probably because of the smaller number of samples available. The uneven distribution of training samples in the dataset is an unfavorable phenomenon for machine learning. It could have impacted the training and final performance of the models considered.

Table III compares the findings of this study with related works. Graditi et al. [7] analysed a single photovoltaic installation under controlled conditions, where linear regression performed well due to simple variables. Jebli et al. [18] used historical weather and radiation data and found ANN to be the best performer, reinforcing the advantage of nonlinear models. Similarly, Chaaban and Alfadl [19] studied solar power plant data, with RFR and KNN outperforming linear regression, aligning closely with the findings of this research.

The presented metric provides valuable information on the dataset's characteristics and underscores the performance improvements of RFR and ANN models in this specific problem setting. Compared to other studies, this research's outcomes are satisfactory, as the observed trends across different models align well with the findings reported in the literature.

V. CONCLUSION

The aim of this study was to create machine learning models to predict energy production in photovoltaic infrastructures with different parameters, locations, and under the influence of variable weather conditions. It is an area of study of growing importance, given the increasing adoption of renewable energy as a primary energy source across a large number of sectors. Its significance is particularly evident for energy management systems, which depend on accurate energy production predictions to adjust distribution strategies accordingly to resource availability.

We have shown that a single data-driven predictive model can accurately predict the output of many different installations. Among the evaluated models, the ANN showed the most consistent performance across both training and test datasets, demonstrating strong generalisability. This indicates that ANN-based approaches are particularly suitable for solar energy forecasting. In contrast, the Random Forest and K-Nearest Neighbors models exhibited indications of overfitting, as evidenced by a notable difference in performance between training and test sets. However, the RFR remains a highly accurate model in general, showcasing strong predictive capabilities.

There is still room for improvement in models' performance that was not addressed in this study. For future work, it would be beneficial to incorporate data from installations that span a broader geographical area. This would enhance the generalisation capability of the models, enabling them to make accurate predictions across diverse contexts and conditions. In their current form, the models developed in this project are not well-suited for deployment in locations beyond Poland and nearby areas.

***Abstract*—Hedge funds (HF) are actively managed investment vehicles employing diverse and often complex strategies. Accurate returns forecasting is essential for optimizing their performance and managing risk. This paper investigates the application of nonlinear dimensionality reduction (DR) methods in forecasting HF strategy performance, building upon prior work in financial time series analysis. We evaluate the effectiveness of Kernel Principal Component Analysis (KPCA), t-Distributed Stochastic Neighbor Embedding (t-SNE), Uniform Manifold Approximation and Projection (UMAP), and autoencoders on predictive performance of machine learning models. The extracted features are fed into several forecasting models, Support Vector Machine (SVM) with linear and nonlinear kernels, Neural Network (NN), and Extreme Gradient Boosting (XGB), to predict returns of five diverse HF investment strategies: Commodity Trading Advisors, Equity Long Short, Equity Market Neutral, Fixed Income Arbitrage, and Global Macro. The results demonstrate that nonlinear DR methods, particularly autoencoders, and KPCA combined with NN, significantly outperform other techniques. Our findings highlight the value of nonlinear transformations in enhancing predictive accuracy for HF returns time series.**

***Index Terms*—dimensionality reduction, hedge funds, PCA, KPCA, t-SNE, UMAP, autoencoders.**

I. Introduction

THE hedge fund industry has experienced substantial growth [1], due to investors' demand for alternative sources of return and portfolio diversification. Compared to traditional financial market forecasting, hedge funds introduce further layers of complexity, including the lack of transparency, and very diverse strategies [2]. A wide array of factors in investment models often lead to noise and overfitting causing poor decision-making. However, by effectively using DR techniques, hedge fund analysts can enhance predictive model accuracy, gain deeper insights into portfolio risk, and make smarter investment decisions.

DR techniques in machine learning (ML) are typically implemented for several key reasons: to mitigate the curse of dimensionality, prepare data for ML algorithms, boost model performance, and enhance interpretability and explainability [3]. DR algorithms are commonly distinguished based on linearity, interpretability, computational cost, data type, hyper-parameters, etc. [4], while the success of DR algorithms is highly dependent on data characteristics, quality and size [5]. A recent survey [3] highlights approaches developed for time-series analysis e.g. autoencoders, Principal Component Analysis (PCA) and KPCA, while PCA and UMAP are commonly used for financial times series [6]. Popular nonlinear techniques, t-SNE and UMAP, are shown to be successful for both visualization and DR in financial time series analysis [7]. Finally, more transparent approaches, e.g. based on fuzzy sets and fuzzy rough sets, are proposed in literature [8]. Still, the authors conclude that while nonlinear DR approaches often yield superior results on artificial datasets, this performance does not necessarily translate to real-world datasets [5].

In forecasting, DR algorithms serve as inputs to predictive models to enhance forecasting performance. The widespread adoption of ML models in financial forecasting is driven by their ability to capture nonlinear relationships and adapt to rapidly changing market conditions. According to a recent review [9], the predominant ML algorithms for stock market prediction are SVM and NN, followed by deep learning models. In [10], the authors demonstrate benefits of using ML approach to forecasting stock returns; the best performing models are boosting techniques and neural networks. Finally, many approaches tend to incorporate DR in their ML framework, e.g. [11]

In this research, we examine the effect of nonlinear DR techniques, selected from various category groups on performance of hedge fund returns forecasting. In our study, PCA will serve as a linear benchmark, and KPCA, t-SNE, UMAP

Topical area: Advanced Artificial Intelligence in Applications

and autoencoders will be exploited to uncover the underlying structure of the data, modeling nonlinearity from different perspectives. As part of ML forecasting framework, predominant ML algorithms are selected based on the surveyed research papers, i.e. linear and kernel SVM are chosen to match diverse combinations of linear/nonlinear DR algorithms, NNs as most effective in hedge fund return prediction, and XGB as advanced representative of boosting algorithms. The datasets used in this research contain time series of monthly returns for the period of 1999-2023 for 5 HF investment, diverse in types of risks, financial instruments and investment philosophy [12]. The research addresses the following questions aimed at exploring the effectiveness of nonlinear DR in case of hedge funds' returns forecasting:

RQ1: How does the selection of nonlinear DR techniques affect the predictive power of ML forecasting models for hedge funds' return time series?

RQ2: Which ML forecasting models demonstrate best performance when utilizing specific DR techniques?

RQ3: How do forecasting outcomes contribute to investment decision making for hedge fund managers in terms of explainability and meaningful insights?

By evaluating the performance of nonlinear DR in forecasting HF returns, this paper aims to address the broader investment community interested in the intersection of ML and financial modeling.

The rest of this paper is organized as follows. In Section II we outline the theoretical background of DR techniques, highlighting their benefits and drawbacks. In Section III we cover the problem setup, dataset analysis, and experimental design. Main results and discussion appear in Section IV.

II. Theoretical Background

Due to the increasing challenges set by enormous amounts of financial data, dimensionality reduction is one of the necessary steps during data preprocessing. When it comes to various technical and fundamental analysis indicators, information from social networks, as well as numerous historical data, this is a significant technique for improving the performance of algorithms, reducing model training, eliminating noise and irrelevant data for specific problems.

A. Principal Component Analysis

PCA is the widely used linear orthogonal DR technique with main goal to identify the principal components (PCs) that capture the maximum variance of data [13]. During transformation, the first PC represents a linear combination of the original features and explains the biggest amount of variance. Each subsequent component is performed with the next highest score of variances.

The main advantage of PCA is its speed and ability to efficiently process large datasets, as well as a clear mathematical interpretation of the variance of the data [13]. However, the principle of linearity limits its ability to capture nonlinear relationships that are present in many real-life datasets. Hence, this inability to model nonlinearity drives the need for the development of more advanced, nonlinear dimensionality reduction techniques, such as KPCA [14].

KPCA is a nonlinear approach of generalizing PCA. Using the kernel method, KPCA first maps data to a higher dimensional space [14]:

$$\mathbb{R}^d \rightarrow \mathbb{R}^D, \ where \ D \gg d \tag{1}$$

Once the kernel method has been applied to transform data into a linearly separable form, PCA is used to dimensionality reduction [5]. KPCA uses several kernel functions like RBF kernel, polynomial and sigmoid. The choice of the kernel function plays an important role, since the performance of the methods depends on the choice.

B. t-Distributed Stochastic Neighbor Embedding

t-SNE is a nonlinear technique of DR with primary purpose to visualize high dimension datasets into low dimension spaces, usually two or three-dimension spaces [15]. Furthermore, the main aim of t-SNE is to preserve complex relationships between original data.

Firstly, t-SNE applies SNE to the dataset which assigns a higher probability to similar pairs of high-dimensional objects, and a lower probability to different data points [5]:

$$p_{a|b} = \frac{exp\frac{-\|x_b - x_a\|^2}{2\sigma^2}}{\sum_{a \neq k}\frac{-\|x_k - x_a\|^2}{2\sigma^2}} \tag{2}$$

where $p_{a|b}$ is conditional probability, x_a high-dimensional data, x_b low-dimensional data and σ^2 given variance. This is achieved with a Gaussian kernel, which represents the similarity between data points as a conditional probability. Thereafter, t-SNE defined SNE in a low-dimension map using the Student's t-distribution to avoid the crowding problem.

Even though this method is widely recognized for its excellence in visualizing and preserving local structure, t-SNE produces high computational costs and time complexity, which is limited for large datasets.

C. Uniform Manifold Approximation and Projection

UMAP is one more nonlinear method for DR based on advanced mathematical concepts, manifold theory and topological data analysis. UMAP stands out in preserving local and global data structure, which is a significant advantage over t-SNE, which focuses on local structure [16]. At the same time, UMAP overcomes the limitation of t-SNE such as execution speed and feature limitation [17].

The algorithm consists of two key steps, graph construction for the high dimensional space and optimization of low dimensional graph layout. In the first step, UMAP constructs a probability distributions graph of nearest neighbors, while the optimization step implies stochastic gradient descent on individual observations [17]. Precisely, initial construction of the graph is crucial in ensuring preservation of both local and global structure. Moreover, two hyperparameters are key for embedding results and control of structure preservation, the number of nearest neighbors that the algorithm takes and the minimum distance between data points in a low-dimensional space [17].

D. Autoencoders

An autoencoder is an unsupervised NN architecture designed to compress (encode) input data into its essential attributes and then reconstruct (decode) the original input from this compressed representation [18]. Therefore, this NN consists of three components: encoder, code and decoder [19]. The encoder is defined by the function that reduces the input data into projection within latent space, while the decoder is defined by the function that decodes the projection into its reconstruction [19]. The code part incorporates the projection as the output from the encoder to the decoder. The output is the reconstruction of the input data [18].

Training of autoencoders aims to minimize the reconstruction loss which measures the difference between the decoder's reconstruction and the original input [19]. This loss function is used to optimize model weights via gradient descent during backpropagation. Furthermore, the performance of autoencoder depends on the tuning of the hyperparameters.

One of the main advantages of autoencoders is the denoising in the data as well as the detection of anomalies and adaptation to changing distributions. However, their implementation requires careful consideration of resources, given the computational complexity.

E. Comparative analysis of dimensionality reduction methods

For easier comparison of techniques, a comparative analysis is provided in Table I. The table summarizes all relevant aspects of applied DR methods, including goal, explainability, computational complexity, linearity, topology, strengths and weaknesses. This review allows a clear insight into the limitations of each method, as well as advantages depending on the specific requirements.

III. Problem Statement and Methodology

A. The problem setup

Our specific case study addresses a problem of forecasting HFs' returns using complex and broad feature space. For investment managers, both predictive accuracy and understanding of key drivers are important for informed investment decision making as they enable effective risk management and portfolio optimization. Given the inherent complexity of financial data, dimensionality reduction becomes a necessary step to simplify data, remove noise and redundancy, and adapt data for building robust and scalable forecasting models for HFs investment returns.

Thus, we address the research questions Q1-Q3 (section 1) and analyze the effectiveness of advanced nonlinear DR techniques in predictive ML models' performance i.e. accuracy and interpretability. The case study includes the analysis of HFs returns for five various investment strategies that suit different investment styles and risk tolerance, as to provide credible and general insights.

B. Datasets

As a follow-up, we further analyze the five datasets from our previous research in [12].

Similarly, this case study is intended to analyze and predict monthly returns of five hedge funds strategies from Morning CISDM Database: Commodity Trading Advisors (CTA), Equity Long Short (ELS), Equity Market Neutral (EMS), Fixed Income Arbitrage (FIA), and Global Macro (GM) strategies. Each strategy suits a different investment style and risk tolerance, allowing traders to choose approaches that align with their financial goals, time horizons, and market outlooks. CTA mostly uses managed futures contracts and trend-following approaches to forecast commodity price. ELS and EMN strategies primarily focus on analyzing and trading companies' stocks listed on stock exchanges. ELS typically involves taking long positions in undervalued stocks and short positions in overvalued ones, while also utilizing options to hedge risks and leverage to enhance potential returns. EMN aims to maintain minimal correlation with the broader equity market by hedging against factors such as currency fluctuations, sector exposure, and market volatility. FIA targets undervalued debt securities of traded companies, such as bonds and other fixed income products. To mitigate risks associated with high-yield positions, FIA may also involve equity positions in the issuing firms as a hedging mechanism. Finally, the GM strategy is based on analyzing macroeconomic trends in countries or regions, using instruments like stocks, bonds, and commodities, and managing risk through derivatives.

TABLE I.
DEFINING CHARACTERISTICS OF FIVE DIMENSIONALITY REDUCTION METHODS

Method	Goal	Explainability	Computational Complexity	Linearity	Topology	Strength	Weakness
PCA	Maximize variance	Medium	$O(d^2n+n^3)$	Linear	Random projection	Computational efficiency	Linear projection
KPCA	Linearly separate data	Low	$O(n^3)$	Nonlinear	Manifold	Capturing nonlinear patterns	High training time
t-SNE	Preserve local structure	Low	$O(n^2)$	Nonlinear	Manifold	Exceptional visualization	Provide only 2 to 3 features
UMAP	Preserve local and global structure	Low	$O(n^{1.14})$	Nonlinear	Manifold	Strong mathematical foundations	Finding the spurious structure of the multiplicity
Autoencoder	Effective compression	Low	Depends on the structure	Nonlinear	Manifold	Denoising	Training data required

Following the recommendations of financial experts and literature review, for each HF strategy we include data on four groups of factors describing trends, debt, capital market conditions, and macroeconomic aspects. Several factors were selected from each group:

- **Interest rates** are represented by a 3-month treasury bill, 5-year constant maturity, and 10-year constant maturity rates, minus federal funds rates.
- **Credit rating categories** include investment grade, high yield below investment grade, and high yield below investment grade.
- **Elements of Fama-French 5-factor model** [20]: NYSE, AMEX, and NASDAQ stock exchanges minus federal funds rate, average return on the small capitalization stock portfolios minus the average return on the large stock portfolios, average return on the value portfolios minus the average return on the growth portfolios, average return on the robust operating profitability portfolios minus the aver-age return on the weak operating profitability portfolios, and average return on the conservative investment portfolios minus the average return on the aggressive investment portfolios.
- **Primitive trend following strategies** on bonds, commodities, interest rates and stocks.

The data was collected monthly over a period of 25 years, from January 1999 to December 2023. For each HF, the final dataset consists of 15 features and 300 instances in total.

C. Data preprocessing and experimental setup

As part of the data preprocessing, the five HFs returns series were divided into training set which include the first 22.5 years, and test set, i.e. the last 2.5 years. Since the data are on different scales, we applied min-max normalization as the preprocessing step. The data also shows peaks and drawdowns, such as “dotcom” stock market bubble in the 2000s, he global economic crisis from 2007 to 2009, and Covid-19 in 2019 [12]. There is also evidence of strong correlations between factors within interest rate group and credit rating categories, as well as performance of conservative against aggressive portfolios and performance of value against growth portfolios.

To address the research questions, we aim to identify a ML prediction algorithm that performs best on transformed data. The forecasting algorithms are implemented in Python, using default hyperparameter values to isolate the influence of DR techniques. The selected algorithms range from simple linear models, such as linear SVM (epsilon value 0.1), to more complex ones, NN with two hidden layers with 64 and 32 neurons and a RELU activation function, as default hyperparameters.

We also employ nonlinear SVM (RBF kernel and epsilon value 0.1) to account for the nonlinear nature of financial data and to explore how a nonlinear feature extraction technique aligns with a relatively simple nonlinear predictor. Finally, we utilize XGB (100 decision trees with a maximum depth of 6), as a representative of ensemble learning methods particularly effective in prediction tasks.

The success of the proposed methods will be measured using standard evaluation metrics for regression: mean absolute error (MAE) and relative root mean squared error (RRMSE). RRMSE is normalized error using the average of actual values and is often expressed as a percentage.

IV. Experimental results

The effectiveness of DR methods is validated by comparing predicted values with actual hedge fund returns across all five HF strategies. The performance of ML predictive models, using RRMSE and MAE, is shown in Tables II and III.

As expected, more sophisticated techniques, such as autoencoders, deliver better performance in all cases except for the ELS strategy. This exception may stem from the Fama-French asset pricing factors already being carefully selected by domain experts. From an investment perspective, the analysis of individual principal component loadings indicates that factors such as investment-grade (BAA), high-yield below investment grade (BBB), and 5-year and 10-year constant maturity rates have a significant impact on most strategies. This is also expected, as these are key drivers of performance across various industries and sectors.

Furthermore, the empirical results are used to address main research questions. The prediction results of HFs return series confirm that dimensionality reduction, both linear and nonlinear, in most cases, positively affects the predictive capacity of ML forecasting models. However, nonlinear DR and nonlinear ML predictors together potentially generate more noise in the data e.g. combination of t-SNE/UMAP with NN increases error.

In general, linear PCA provides equal or better prediction results compared to non-reduced input datasets. It was expected that adding nonlinear NN and XGB predictors to non-reduced and/or PCA-reduced data will significantly reduce error. However, that was not the case for most strategies, even though linear DR did contribute to reducing error in general. This indicates the potential presence of nonlinear dependence in the original data which required analysis of more complex DR algorithms.

Among the tested nonlinear DR methods, t-SNE and UMAP resulted in higher prediction errors across strategies

(e.g., GM and FIA), indicating its limitations for this forecasting task. On the other hand, autoencoders are proven to contribute to predictive power to most ML models, and for all analyzed HF strategies. For all HF strategies, the best performance is achieved with two nonlinear DR techniques, KPCA and autoencoders, combined with NN forecasting model.

When considering algorithm characteristics, KPCA is computationally intensive and sensitive to high dimensionality, while autoencoders are better suited for processing larger datasets. From the perspective of HF managers, improved forecasting helps reduce performance uncertainty to some extent, supporting more informed decision-making when selecting among diverse hedge fund strategies. However, both approaches lack explainability, making it challenging for managers to justify their decisions.

V. Conclusion

This paper extends the research initiated in [12] on identifying and extracting key features in financial time series forecasting. In this study, the influence of various nonlinear DR methods was analyzed for HF performance forecasting. An evaluation of effectiveness of KPCA, t-SNE, UMAP and autoencoders was examined on real-world data. Reduced data serves as inputs to SVM with linear and nonlinear kernel, NN and XGB as predominant ML predictors for financial time series. To provide credible conclusions, we utilized HF returns data that represent different investment styles like CTA, ELS, EMN, FIA, and GM [12]. The four group of factors (15 features in total) covering interest rate, credit rating, trend and Fama-French model were included into analysis, over 25 years period.

The empirical findings address the primary research questions. The analysis shows that both linear and nonlinear DR contribute to ML forecasting results for diverse HF strategies. Linear PCA was not effective enough, even when combined with nonlinear ML predictors. The best performance was achieved with nonlinear DR, KPCA and autoencoders when paired with neural networks. Other critical DR characteristics were discussed for the most effective combinations. From the point of view of HF managers, the results provide better forecasting accuracy and contribute to more informed investment decision making. Besides the necessity for domain ML knowledge (e.g. hyper-parameters), the lack of explainability was identified as the main drawback, as expected.

Our future work will be oriented towards the development and application of investment-based DR methods that offer explainability as a baseline for effective decision-making (e.g. [12]). Also, investment metrics will be included to validate investment performance.

Encouraging Sustainable Fashion Choices Through a Mobile Application

Bianka Šimková

***Abstract*—This work presents the design and implementation of a mobile application for home wardrobe management, aimed at promoting sustainability in fashion by encouraging more conscious clothing choices. The theoretical part of the article deals with the concept of "fast fashion" and its impact on different areas of the fashion industry and defines the problem with existing apps in this field. The practical section includes the design of an information system based on a user preferences survey, and includes a visualization of the system architecture. This section also describes the implementation process of two parts of the system, namely the creation of a clothing classification application using the CRISP-DM methodology and the development of a mobile app for the Android operating system, as well as the testing process. The conclusion evaluates the outcomes of the project and outlines potential directions for future enhancements.**

I. Introduction

THE motivation for writing this article is the ever-growing fashion industry, which offers us an overabundance of clothes at very low prices. This results in a excessive number of garments in the wardrobe of an average individual and clutter in the wardrobe. Therefore, the aim of this article is to design and implement a home wardrobe management information system that will contribute to sustainability in fashion.

Consumerism still dominates the world today, and much of this is influenced by the fashion industry. The term "fast fashion" emerged in the 1990s, when retailers began offering clothes to the masses at low prices, but at the expense of quality, in order to keep up with the pace of changing trends and emulate more luxurious garments [1]. However, the large volumes of clothing produced lead to increased resources for disposal and consequently high levels of waste, which has a negative impact on the environment [2]. Extending the lifetime of products is one of the most effective environmental strategies as it has a great potential to prevent waste and reduce production, consumption (both in sourcing and disposal) and transportation. This has been conceptually known, documented, and recognised for a long time - for example, in the waste management hierarchy, where prevention is the highest priority [3]. This is also why terms such as sustainability and "slow fashion" have been frequently mentioned in recent years.

A recent study based on a sample of 2,000 respondents found that the average individual owns approximately 136 items of clothing, indicating a relatively high volume of wardrobe content [4]. Often, we may not have an overview of individual items of clothing, nor how many times a piece of clothing has been used and how long it has been in our wardrobe. This factor, combined with the ongoing marketing strategies employed by retailers, can result in impulsive purchases of clothing items that are redundant, seldom worn, or do not fit properly. This inspired the idea of developing a mobile application — a wardrobe database — that can categorize garments based on photos and assess whether similar items are already present in the wardrobe or were owned in the past, along with data on their frequency of use. This feature can assist during shopping by discouraging unnecessary purchases, helping to keep the closet more organized and less cluttered.

II. Related Work

According to Klepp et al. [3], the lifetime of garments can be described in a way that makes them comparable, using the following categories:

- Number of wears;
- Years (Duration of use);
- Number of users (owners);
- Number of cleaning cycles.

Another important aspect in the care of garments is the way they are cleaned, which in addition to having an impact on the lifetime of the garment, also has an impact on the environment. It has been shown that the correct washing machine setting for garments made of polyester will reduce the release of microplastics by 12 to 16% [6]. Accordingly, effective garment care also requires attention to the material's origin, particularly the fibre composition of the fabric, such as:

- Synthetic fibres - such as polyester, nylon or acrylic.
- Natural fibres - such as cotton, linen or wool.

Also, washing synthetic materials with hard surfaces, such as jeans, increases the risk of damaging the material. When washing synthetic fabrics, it is also advisable to use less detergent and avoid bleach. Finally, it is recommended not to use a tumble dryer to dry synthetic materials, as heat and mechanical forces can cause the release of microplastic fibres. Last but not least, a person's preferences in choosing and wearing clothes, including on the basis of hair colour, complexion, eyes and body type, are also a major factor.

As Acerbi et al. [5] argue, fashion is not shaped by random decisions; rather, individuals exhibit strong preferences for

specific cultural traits and tend to emulate certain styles and patterns. Fast fashion capitalizes on this behavior by employing innovative production and distribution strategies to drastically reduce the time required to bring garments from design to retail — often within weeks rather than months. As a result, the number of fashion seasons has expanded from the traditional two per year (spring/summer and autumn/winter) to as many as 50 to 100 micro-seasons annually [9]. This acceleration contributes to the continual shortening of the fashion cycle — the lifespan of a fashion trend — which is typically divided into five phases: introduction, rise, peak, decline, and obsolescence [10].

Many authors consider the rise of social media as the main cause of shorter and less predictable fashion cycles, as "trend drivers" [7]. A 2015 study confirmed that there is a direct and significant relationship between social media and the fashion industry [8]. There are some existing apps that focus on creating personal virtual wardrobe, such as Open-Wardrobe Outfit Planner ++[1], Acloset - AI Fashion Assistant[2], Whering:Digital Closet Stylist[3], or Style DNA: Fashion AI Stylist [4]. However, the applications are rather commercially tuned, i.e. built on the basis of recommendations of similar products that the user already owns. This consequently leads to unconsidered purchases and an excessive volume of clothing items, as mentioned in the introduction. Therefore, it would be advisable for the application to be able to assess, based on a photography of the garment, whether or not the user already owns a similar item and its frequency of use. Furthermore, existing apps either lack garment usage statistics or provide them in a rather superficial manner.

III. Proposed App Design

Initially, the requirements for the app were derived from survey responses published across various platforms. The survey was created with the intent to give us an insight into people's attitudes and behaviours related to fashion and clothes shopping. It consisted of 7 questions on demographic data, 8 statements related to personal preferences that respondents rated based on a Likert scale, and 1 question to select from the options of the preferred requirements of the wardrobe database application.[5] In total, 18 functional requirements were implemented in the app, namely: adding garments to your wardrobe; filtering and sorting garments by type, colour, pattern, material, recommended care, colour, number of wears, purchase price and date of purchase; adding care information to garments; recording garment washes; creating and saving an outfit; viewing saved outfits; planning an outfit; filtering saved outfits based on occasion and season; viewing wardrobe usage statistics; viewing usage statistics for a specific garment; automatic classification of garments by photo into type and colour; offering and accepting an outfit for exchange; adding personal preferences for style of clothing; estimating whether an outfit fits in the wardrobe. From the functional requirements, a list of ten use cases was created and made along with a UML diagram of the relationships between them to visualize more complex functionalities of the system that users expect and are of value to them.

Furthermore, four non-functional requirements were defined, focusing on security, performance, and usability. These included: mobile app response time of less than two seconds; support for at least 100 users in the database; encryption of stored data; and a simple, user-friendly graphical user interface (GUI).

The application consists of a 3-tier architecture as shown in Fig.1. The presentation layer consists of a user interface in the form of a xml layout and fragments. The business layer consists of an application core written in the Java programming language and a clothing classification API written in the Python programming language and deployed on Microsoft Azure. The data tier is managed by the Firebase platform. Attributes of garments and outfits, as well as the user's personal preferences, are stored in the Cloud Firestore database, and photos of garments and outfits are stored in Cloud Storage.

IV. Implementation

A. Methodology

The development took approximately 6 months. In the first part of the implementation, we worked on creating an API for clothing classification using the Python programming language. In the second part, we programmed an Android application in Java programming language and integrated the developed API into it. In modelling the SVM classifier, we followed the steps of the CRISP-DM methodology, which consists of understanding the objective, understanding the data, data preparation, modelling, evaluation and deployment.

B. Clothing Classifier

For training the SVM classifier we utilized the dataset *Clothing dataset (full, high resolution),*[6] which contains over 5,000 photos of clothing items in both original and reduced quality. An analysis of the image orientations — portrait versus landscape — revealed a significantly higher frequency of portrait-format photos, suggesting that the average user tends to capture clothing images in portrait mode. The standard for the aspect ratio of photos taken with a smartphone is 4:3, so we resized all these photos to 160x120 pixels, and converted them to an array of RGB pixel codes. There are 20 categories of clothing, but the number of categories varied considerably, which would have caused us problems in modelling, so we reduced these categories to 8 main ones: short-sleeved top, long-sleeved top, pants, dress, outerwear, shorts, skirt and shoes. After merging and reducing the categories, the frequencies are more balanced.

We used 80% of our preprocessed category and pixel dataset to train the model and 20% to test the model, maintaining the ratio of category frequencies. For training the SVM classifier, we chose the Gaussian Radial Basis Function (RBF) kernel function and the decision function shape One vs. One. We evaluated the model with the metrics of accuracy, precision recall and F1 score. The classification accuracy is 0.74, which provides a good basis for deploying the model in practice. Precision, recall, and F1 score are above 0.7 for most classes. For categorizing and calculating similarity between colours, we used the webcolours library.[7]

C. API Containerization

The SVM classifier was incorporated in an application to process clothing photography using FastAPI, a modern web framework for creating APIs using Python. The application provides two main endpoints that process prediction and classification requests and return JSON responses:

- classify - takes as the image of the garment as an input parameter and outputs the type and colour of the garment;
- predict - takes as the image of the garment, and the name of the user's colour palette, as an input parameters and outputs the type and colour of the garment, and a boolean value that tells whether the colour is in the user's predefined colour palette.

We containerized the application using Docker, with Gunicorn serving the FastAPI app through Uvicorn workers. The resulting Docker image was uploaded to Docker Hub and deployed to Microsoft Azure as a continuously running container.

D. Mobile App

The mobile app was developed in Android Studio in the Java programming language. The frontend of the final version of the mobile application consists of 23 fragments. The bottom of the screen features a navigation menu that is used to switch between the five main modules of the application.

1) Closet: This module can be accessed by the middle button in the bottom menu and will show us the wardrobe contents with options to filter, add new garments, view statistics, and view garments marked for washing. In the process of adding a garment by the "+" button, the aforementioned classifier is also used, which classifies the garment into type and colour. After adding a garment, the detail of the stored garment is displayed, which also contains the statistics of the particular garment (Fig. 2), which are automatically recalculated based on the planning of outfits - sets of garments. Additionally, the user can also access the aggregated statistics for the whole closet (Fig. 3). The "Filter" button will show the options to filter and sort the garments, and after confirming the selection, it will show us the closet with only the garments that meet the required characteristics.

2) Outfits: The first button in the bottom menu will launch the module related to storing, viewing, filtering, and planning outfits. The ability to filter and sort outfits works the same way as for clothing. When adding, all the outfits stored in the wardrobe are displayed, and the user selects the garments that make up the outfit. Scheduled outfits can be viewed by the user in the "OOTD" (Outfit Of The Day) section.

3) Settings: This module is accessed by the far-right button of the bottom menu and displays the login screen or, if the user is logged in, the option to log out and set personal preferences.

4) DoesItFit: The fourth button in the bottom menu gives us the ability to view the saved preferences and also the ability to estimate the fit to the wardrobe, where the user uploads a photo of the garment and the application here uses the classifier to classify the garment into type and colour, verifying that the colour of the garment is within the user's chosen colour palette and displaying similar garments in the wardrobe, i.e. of the same type and colour (Fig. 4).

5) Swap: By clicking on the second button in the bottom menu, we can see the garments offered for exchange. Clicking on a particular garment will show the details and the option to request the garment. Then the user who provided the garment for exchange can see in the details of their garment the email addresses of the users who requested the garment, and after selecting and confirming the selection of one of the email addresses, the garment will be reassigned to that user.

The backend of the application is written in the Java programming language and consists of 53 classes, which

[6]https://www.kaggle.com/datasets/agrigorev/clothing-dataset-full/code
[7]https://webcolours.readthedocs.io/en/latest/

Fig. 2. Clothing item detail.

are divided into five packages: `activities` (as mentioned previously in this section); `api` (classes associated with linking the application to the classifier); `entities` (constructors and methods of `ClothingItem`, `Outfit`, `SwapItem` and `Webcolours` objects); `recycler-view` (classes that modify the view of entities); `tools` (methods for working with the database, data visualization, image editing, calculating statistics, etc.). The remaining two classes are subclasses of the `Activity` class: `WelcomeActivity` and `MainActivity` that runs throughout the application and is responsible for controlling the bottom menu to change fragments.

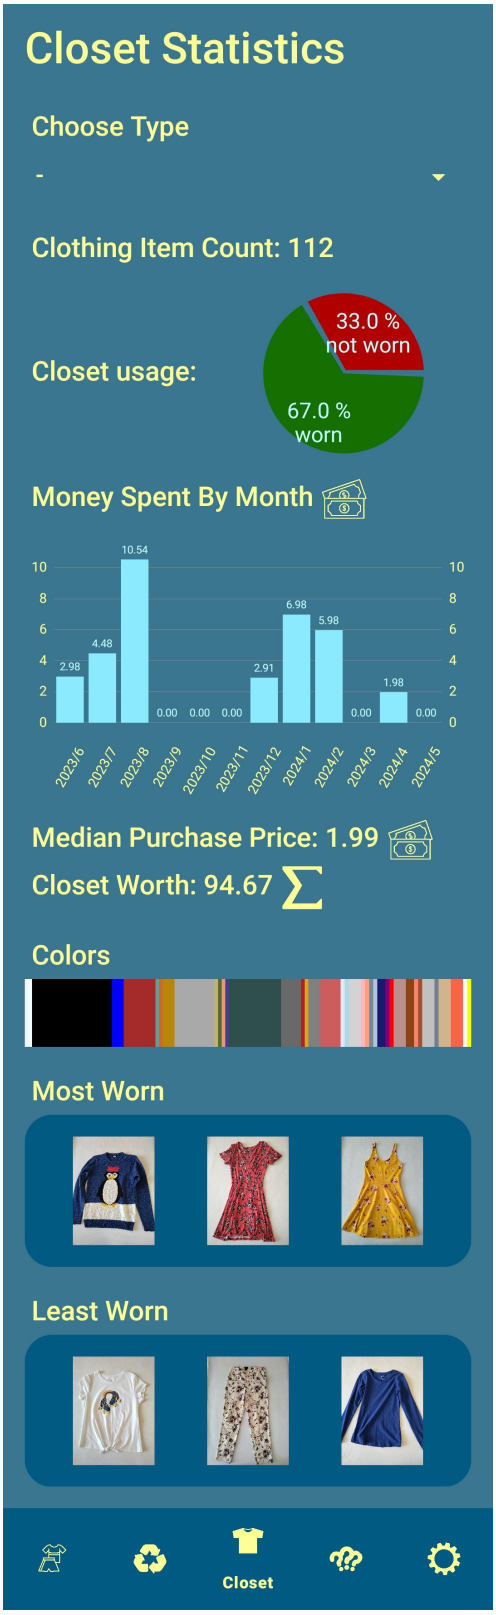

Fig. 3. Closet statistics.

Fig. 4. Application output on finding similar garments based on photo.

E. Database

We used the Firebase Firestore database to store attributes related to clothing items and outfits. The "user_clothes" collection contains documents named according to the unique user ID (UID) generated during registration via Firebase Authentication. Each of these documents includes two subcollections: "clothes" and "outfits", which contain documents named according to the IDs of the outfits. Each document captures 16 features of the corresponding item, including statistical attributes such as `timesWorn`, `timesWashed` and `wearPercentile`. The methods used for calculating statistics are contained in the `StatisticsCalculator` class, which includes, for example, a method to calculate garment usage frequency based on percentiles as shown in Algorithm 1 and 2. The underlying logic for these statistical measures is inspired by the concepts discussed in the article by Klepp et al. [3], as referenced in the introduction.

Algorithm 1 Calculate wear percentiles of clothing items

Require: List of clothing items with `timesWorn`
Ensure: List of wear percentiles (as integers from 0 to 100)

Initialize empty list $percentiles$
for all $calculatedItem \in clothingItems$ **do**
  $countLessOrEqual \leftarrow 0$
  for all $item \in clothingItems$ **do**
    if $item \neq calculatedItem$ **and** $item.timesWorn \leq calculatedItem.timesWorn$ **then**
      $countLessOrEqual \leftarrow countLessOrEqual + 1$
    end if
  end for
  Append $countLessOrEqual$ to $percentiles$
end for
$countAll \leftarrow$ size of $clothingItems - 1$
for $i = 0$ to $percentiles.size() - 1$ **do**
  $percentileFloat \leftarrow \frac{percentiles[i]}{countAll} \times 100$
  $percentiles[i] \leftarrow \lfloor percentileFloat \rfloor$
end for
return $percentiles$

Algorithm 2 Get wear frequency label

Require: A clothing item with computed percentile
Ensure: A frequency label (string)

$percentile \leftarrow clothingItem.getWearPercentile()$
if $percentile \leq 25$ **then**
  return "very low"
else if $percentile \leq 50$ **then**
  return "low"
else if $percentile \leq 75$ **then**
  return "medium"
else if $percentile \leq 100$ **then**
  return "high"
else
  return null
end if

V. Evaluation

Functional and integration testing of the application was also carried out in the implementation phase. At the end of the implementation, we evaluated the app using Firebase Test Lab. After evaluation by the Test Lab, we took the results of this testing into account and patched the version. We conducted acceptance testing in person with five target users who were asked to complete 13 tasks such as: use the app to add a garment to the wardrobe; use the app to create an outfit; use the app to view statistics about your wardrobe usage; use the app to check if the garment fits into your wardrobe. Immediately after testing, we had each participant complete a System Usability Scale (SUS) survey. All users rated the application rather positively, which resulted in the SUS score of 93.5. In addition, the survey included a question about which functionalities users found most or least useful. The most useful features were rated by users as the garment care record, viewing statistics, filtering garments, saving outfits, and estimating whether a garment fits them.

Among all features, testers found the clothing swap option to be the least beneficial.

In order to validate the non-functional requirement "mobile app response time of less than two seconds", we created a `StartupAndFrameBenchmark` class in the Android Studio environment, in which we defined tests to detect the duration of the app launch and the duration of the screen rendering after some action, i.e. the app response time. The results of this testing show that 99% of the measured responses were less than or equal to 205.0 milliseconds, which is approximately 0.2 seconds. The remaining non-functional requirements related to the database. Since we store data in Firestore database, we have fulfilled these requirements, since the capacity of Firestore database is 50 000 active users per month, Firebase automatically encrypts data in database. We also enhanced security by setting the Firebase rules so that each logged in user can only read and write data under the document that is identical to their UID or under the "swap" collection as mentioned before.

VI. Conclusion and future work

The aim of this work was to discuss the influence of different factors on fashion and propose a design and implementation of a mobile application with the intent of promoting sustainability in fashion. The implemented app lays the groundwork for encouraging more conscious consumption habits by helping users manage their wardrobes more efficiently and make sustainable fashion choices. The app also allows for possible future extensions, primarily focused on improving the user experience, such as: adding wardrobe sharing; adding automatic outfit suggestion; automatic background removal on photos of clothes; improving the accuracy of the classifier, or using neural networks in classification. The App and API are available on github.[8]

Thematic Sessions

PARTS 4 and 5 of FedCSIS 2025 Proceedings contain contributions originating from the Thematic Sections. Let us briefly introduce each one of them (in alphabetical order).

I. AI in Agriculture

Artificial Intelligence (AI) is increasingly used in agriculture for a variety of uses, from plant disease detection to weeding automation, soil status monitoring, crop prediction, irrigation management, and decreased use of resources for improving quality and productivity. This Thematic Session welcomes contributions related to a wide variety of interdisciplinary research and applications related to the application of intelligence systems in agriculture. AI can, in fact, provide highly positive effects on precision agriculture by optimizing, automating, and forecasting several aspects of farming and revolutionizing the sector, providing helpful information and driving decisions using multiple sources of data and different sensors.

Moreover, in the climate change era, AI can improve sustainability by optimizing resources such as water and soil management as well as fostering novel methods and approaches. We welcome innovative contributions, early results, and position papers addressing one or more of the topics listed below. We intend to foster informal discussions and bring together researchers, practitioners, and industry experts to explore the challenges and opportunities of intelligence systems and agriculture.

This Thematic Session was organized by:

- Charvat, Karel, Czech Center for Science and Society, Czech Republic
- Martinelli, Massimo, Institute of Information Science and Technologies, National Research Council of Italy, Italy
- Moroni, Davide, Institute of Information Science and Technologies, National Research Council of Italy, Italy
- Procházka, Ales, University of Chemistry and Technology and Czech Technical University CIIRC, Czech Republic

II. AI in Digital Humanities, Computational Social Sciences and Economics Research

This thematic session is dedicated to the computational study of Social Sciences, Economics and Humanities, including all subjects like, for example, education, labour market, history, religious studies, theology, cultural heritage, and informative predictions for decision–making and behavioural-science perspectives. While digital methods, intelligence systems, and AI have been emerging topics in these fields for several decades, this thematic session is not only limited to discoveries in these domains, but also dedicated to the reflections of these methods and results within the field of computer science. Thus, we are in particular interested in interdisciplinary exchange and dissemination with a clear focus on computational and AI methods for intelligence systems.

Since there is a clear methodological overlap between these three domains and often similar algorithms and AI approaches are considered, we see this thematic session as place for interdisciplinary learning, discussing a joint toolbox as a support for scholars from these field with human and context-aware agents. The aim of this thematic session is thus to bridge the gap between scientific domains, foster interdisciplinary exchange and discuss how research questions from other domains challenge current computer science. In particular, we are interested in communications between researchers from different fields of computer science, social sciences, economics, humanities, and practitioners from different fields

This Thematic Session was organized by:

- Cooper, Anthony-Paul, Durham University, United Kingdom and University of Turku, Finland
- Dörpinghaus, Jens, BIBB and University of Koblenz, Germany
- Helmrich, Robert, BIBB and University of Bonn, Germany
- Speckesser, Stefan, Brighton University, United Kingdom
- Tiemann, Michael, BIBB and University of Koblenz, Germany

III. Advances in Programming Languages

Programming languages are the most fundamental tools for programmers. With the right programming languages, one can significantly reduce the cost of building new applications and maintaining existing ones. Over the last few decades, there have been substantial advances in programming language technology within traditional paradigms such as functional, logic, object-oriented, and aspect-oriented programming. Today the growing influence of artificial intelligence on programming paradigms and the development of software systems is rapidly reshaping the field. Above all, programming tools based on generative artificial intelligence have become a standard, transforming programming practices in both academia and industry. The methods and approaches for selecting, adapting, and evaluating AI techniques for programming language design and implementation have become a critical area of research. Within this context, new advances in programming language research are also contributing to the design and implementation of autonomous and intelligent systems, such as those developed under the umbrella of agent-oriented programming. The primary motivation has always been, and will continue to be, to enable a more effective formulation of programmers' ideas. As a result, research in programming languages remains a perpetual activity and lies at the core of computer science. Hence, new language features and programming paradigms—particularly those enhanced by AI techniques—as well as improved compile-time and run-time mechanisms, can be anticipated in the near future.

This Thematic Session was organized by:

- Janousek, Jan, Czech Technical University, Czech Republic
- Rangel Henriques, Pedro, Universidade do Minho, Portugal
- Slivnik, Boštjan, University of Ljubljana, Slovenia
- Varanda Pereira, Maria Joao, Instituto Politecnico de Braganca, Portugal

IV. Computer Aspects of Numerical Algorithms

Numerical algorithms are widely used by scientists engaged in various areas. There is a special need of highly efficient and easy–to–use scalable tools for solving large scale problems. This Thematic Session is devoted to numerical algorithms with the particular attention to the latest scientific trends in this area and to problems related to implementation and utilization of libraries of efficient numerical algorithms. The goal is the meeting of researchers from various institutes and exchanging of their experience, and integrations of scientific centers.

This Thematic Session was organized by:

- Bylina, Beata, Maria Curie-Skłodowska University, Poland
- Bylina, Jarosław, Maria Curie-Skłodowska University, Poland
- Cyganek, Bogusław, AGH University of Kraków, Poland
- Lirkov, Ivan, Institute of Information and Communication Technologies, Bulgarian Academy of Sciences, Bulgaria
- Stpiczyński, Przemysław, Maria Curie-Skłodowska University, Poland

V. Challenges for Natural Language Processing

Natural Language Processing technologies enable Intelligence Systems to analyze, interpret, and generate human language, enhancing their capabilities to communicate and make informed decisions. This Thematic Session is dedicated to natural language processing methods that address challenging, non–obvious problems with the goal of advancing human language technologies. Special attention is given to tools that approach multilingual tasks, utilize cross–lingual learning and process natural languages that are not widely represented in other events.

This Thematic Session was organized by:

- Kobyliński, Łukasz, Institute of Computer Science, Polish Academy of Sciences, Poland
- Kubis, Marek, Adam Mickiewicz University, Poland

VI. Computational Optimization

In the real world, Intelligence Systems address numerous problems in the fields of engineering, economics, medicine, and other domains. Many of these problems can be formulated as optimization tasks, in particular, we may consider challenges that are frequently characterized by non–convex, non–differentiable, discontinuous, noisy, or dynamic objective functions and constraints that ask for adequate computational methods.

The aim of this Thematic Session is to stimulate communication between researchers working on different fields of optimization and practitioners who need reliable and efficient computational optimization methods.

This Thematic Session was organized by:

- Fidanova, Stefka, Institute of Information and Communication Technologies at Bulgarian Academy of Sciences, Bulgaria
- Mucherino, Antonio, IRISA, University of Rennes, France
- Zaharie, Daniela, West University of Timisoara, Romania

VII. Data Science in Health, Ecology and Commerce

Data Science in Health, Ecology and Commerce is a thematic session on the intersections of data analysis, data economics, information systems and data-based research. The workshop is explicitly focusing on the interaction of those four fields and interdisciplinary research. Here, data–driven solutions can be generated by understanding complex real–world (e.g. smart health services, interaction of ecological factors on wellbeing or the economic effects of sustainable infrastructures) related problems, critical thinking and analytics to derive knowledge from (big) data. The past years have shown a forthcoming interest in innovative data technology and analytics solutions that link and utilize large amounts of data across individual digital ecosystems. Innovative applications scenarios in the field of health, smart cities or sustainable value systems merge data from various IoT devices, social media or application systems and demonstrate the great potential for gaining new insights, supporting decisions or providing smarter services. Together with inexpensive sensors and computing power we are ahead of a world that bases its decisions on data. However, we are only at the beginning of this journey, and we need to further explore the required methods and technologies as well as the potential application fields and the impact on society and economy. This endeavor needs the knowledge of researchers from different fields applying diverse perspectives and using different methodological directions to find a way to grasp and fully understand the power and opportunities of data science.

This Thematic Session was organized by:

- Bumberger, Jan, Helmholtz Centre for Environmental Research, Germany
- Fernandes De Muylder, Cristiana, Universidade FUMEC, Brazil
- Franczyk, Bogdan, Wrocław University of Economics, Poland and Leipzig University, Germany
- Häckl, Dennis, Leipzig University, Germany
- Militzer-Horstmann, Carsta, Leipzig University, Germany
- Reinhold, Olaf, Cooperative State University Saxony, Germany

VIII. Education & AI systems

Etymologically, the word “school” originally meant “leisure,” or from the ancient Greek σχολή (scholē). Today, this foundational sense of leisure has often been lost as modern education focuses heavily on efficiency and structure. However, recent advances in AI technology, particularly generative AI (G–AI), have opened doors to newly creative ways of transmitting and sharing knowledge. This thematic session seeks to explore the transformative potential of AI-driven tools, especially chatbots and conversational agents, in education.

This session welcomes perspectives ranging from critical assessments to enthusiastic endorsements of AI's role in education. Questions include:

- What is now possible in education with the massive advent of new AI technologies?
- How can educational approaches be transformed to meet contemporary needs?
- What standards and best practices should be developed?
- What are the positive aspects, threats, and challenges of AI implementation?
- How can AI tools make education more creative, high–quality, and accessible, especially for underprivileged groups?
- How can G–AI enhance informed decision-making while addressing potential threats and security issues?

This Thematic Session was organized by:

- Dan, Daniel, MODUL University, Austria
- Nakayama, Minoru, Institute of Science Tokyo, Japan
- Wróblewska, Warsaw University of Technology, Poland

IX. Information Systems Management

This thematic session is a forum for the exchange of ideas for practitioners and theoreticians working in the broad area of information systems management in organizations. We invite you to submit papers from three complementary directions: information systems management in organizations, the use of information systems to strengthen the position of managers, and management information systems in the context of sustainable development. We are particularly interested in aspects of the adaptation of modern technologies in management information systems, i.e. the possibilities of using artificial intelligence, robotic process automation, and business intelligence in supporting the work of managers, decision–making, and setting directions for the strategic development of organizations. We also we expect papers on the impact of information systems on sustainable development and the assessment of this process.

This Thematic Session was organized by:

- Bicevska, Zane, University of Latvia, Latvia
- Chmielarz, Witold, University of Warsaw, Poland
- Leyh, Christian, Technische Hochschule Mittelhessen, Germany
- Sołtysik-Piorunkiewicz, Anna, University of Economics in Katowice, Poland

X. Model Driven Approaches in System Development

For many years, various approaches in system design and implementation differentiate between the specification of the system and its implementation on a particular platform. People in software industry have been using models for a precise description of systems at the appropriate abstraction level without unnecessary details. Model–Driven (MD) approaches to the system development increase the importance and power of models by shifting the focus from programming to modeling activities. Models may be used as primary artifacts in constructing software, which means that software components are generated from models.

In the AI era, MD approaches provide a structured framework for the design, development and optimization of complex systems by creating models that represent different system components, learning algorithms, neural networks and/or other components of a system. At the same time, adaptability is increased as the entire system can be updated quickly without having to rewrite large parts of the code, making it easier to integrate new functions or intelligent components.

A goal of the proposed workshop is to bring together people working on MD approaches, techniques and tools as well as domain–specific modeling (DSM) and domain–specific languages (DSL) and applying them in all aspects of intelligent or other information systems, in order to share their experiences, develop new ideas, evaluate and improve MD approaches, and disseminate their application. The intent is to strive for an interdisciplinary nature of MD approaches in software development, as well as research topics expressed by, but not limited to, acronyms such as Model Driven Software Engineering (MDSE), Model Driven Development (MDD), Domain Specific Modeling (DSM), and OMG's Model Driven Architecture (MDA). Apart from analyzing application perspectives of MD approaches in intelligent systems, another important aspect nowadays that MDASD intends to cover is how to deploy modern AI/ML based approaches in the software process based on a wide spectrum of MD approaches.

This Thematic Session was organized by:

- Milašinović, Boris, University of Zagreb, Croatia
- Ristić, Sonja, University of Novi Sad, Serbia
- Tolvanen, Juha-Pekka, MetaCase, Finland

XI. International Forum on Cyber Security, Privacy, and Trust

In today's digital age, information security serves as a backbone for protecting both user data and electronic transactions. Safeguarding communications and data infrastructures in an increasingly interconnected world has become more critical than ever. Security evolved into a vital scientific discipline, encompassing multifaceted complexities that require the collaboration of experts from computer science, engineering, information systems, and intelligence systems communities. Information security continues to advance through well–established technical research directions, including access control (user authentication and authorization), protocol security, software security, and data cryptography. Furthermore, emerging topics in organizational and intelligence–driven security have gained prominence alongside these traditional research areas.

The International Forum on Cyber Security, Privacy, and Trust thematic session emphasizes the diverse developments and deployments in cyber information security. It aims to highlight current challenges and present the latest research contributions. The forum serves as a platform to explore technical aspects of cyber security, innovative user privacy techniques, and trust mechanisms. Additionally, it broadens

its scope to address emerging topics, such as social, organizational, and intelligence system–driven security research directions. NEMESIS'25 provides an inclusive forum for presenting theoretical and applied research papers, case studies, implementation experiences, and work–in–progress results in cyber security.

This Thematic Session was organized by:

- Debar, Hervé, Télécom SudParis, Institut Mines-Télécom, France
- Felkner, Anna, NASK—National Research Institute, Poland
- Ioannidis, Sotirios, Technical University of Crete, Greece
- Kadobayashi, Youki, Nara Institute of Science and Technology, Japan
- Świątkowska, Joanna, European Cyber Security Organisation, Belgium

XII. Self Learning and Self Adaptive Systems

The proposed thematic session is focused on advanced Artificial Intelligence (AI) techniques and their applications in various fields. One of the advanced forms of AI methods is the Reinforcement Learning (RL) algorithms. RL or Self-learning systems are AI agents able to acquire and renew knowledge over time without hard coding. These are adaptive systems whose functions improve by a learning process based—typically—on the method of trial and error. A self-learning system initially interacts with its users or surrounding environment by attempting and observing the changes produced by its actions. This session will focus on the design, implementation, and exploitation of self-learning features within an Intelligent Environment or some of its components. The thematic session will represent an opportunity for academia and industry to debate the state–of-the-art challenges and open issues.

Multi-level Optimization-based Ensemble Machine Learning for Efficient Crop Yield Prediction in Saudi Arabia

Raya Aldawoud*, Zohra Sbaï*†
*Department of Computer Science, Prince Sattam bin Abdulaziz University, Al Kharj, Saudi Arabia
†National Engineering School of Tunis, Tunis El Manar University, Tunis, Tunisia

z.sbai@psau.edu.sa

***Abstract*—Accurate crop yield prediction is essential for enhancing food security, optimizing resource use, and supporting smart farming initiatives. Traditional statistical models often fail to capture the nonlinear interactions between environmental, climatic, and agronomic variables. To address these challenges, this research evaluated seven ensemble machine learning models: Random Forest, Bagged Decision Tree, AdaBoost, Gradient Boosting, Stochastic Gradient Boosting, eXtreme Gradient Boosting, and CatBoost. Being interested in the region of Saudi Arabia, we collected and integrated multi-source data that resulted in meteorological factors (temperature, humidity, precipitation), vegetation indices, pesticide usage, and historical yield records of thirty eight crop categories. While selecting only eight crops to study in the optimization phase, each model was assessed under four experimental configurations: baseline models, hyperparameter tuning, outliers' removal, and Bayesian optimization. Results showed that the optimized models performed up to 47% better than the default models. More precisely, hyperparameter tuning showed marginal gains, and Bayesian optimization and outliers' removal led to noticeable performance improvements. However, the effectiveness of each strategy was crop-specific.**

***Index Terms*—Crop Piield Prediction, Ensemble Machine Learning, Bagging, Boosting, Hyperparameter Tuning, Bayesian Optimization**

I. Introduction

ENSURING sustainable food production is a global challenge, especially in arid regions like Saudi Arabia, where agriculture is constrained by extreme climate, water scarcity, and limited arable land. Crop yield prediction has emerged as a critical tool to enhance agricultural planning, reduce resource waste, and support national food security strategies. Accurate forecasting allows for informed decisions in land management, irrigation scheduling, and fertilizer application, while also aiding in mitigating the risks of climate variability and supply chain disruptions.

Despite the advances in machine learning (ML) and deep learning (DL) methods for yield prediction, many existing studies are either based on synthetic or global datasets and rarely reflect the local agro-climatic and environmental realities of the Gulf region in general. Moreover, predictive models are often developed for major cereal crops like wheat and maize, with limited attention to a broader range of fruits and vegetables that are vital to the regional diet and agricultural economy. The present study addresses these gaps by developing an ensemble learning-based framework to forecast the yield of several crops grown in Saudi Arabia.

We propose a framework that leverages multiple ensemble learning techniques including Random Forest, Bagging Decision Trees, Gradient Boosting, Stochastic Gradient Boosting, XGBoost, AdaBoost, and CatBoost to exploit the strengths of individual models while enhancing robustness and accuracy. For each crop, the models are trained and evaluated using historical yield data alongside environmental variables such as temperature, precipitation, humidity, NDVI, VCI, WDRVI, and pesticide application rates.

In our research, we seek to develop predictive models specifically tailored to key crops grown in Saudi Arabia by utilizing real, localized agricultural data. The study aims to systematically compare the performance of various ensemble learning algorithms across multiple crop types to determine their relative strengths and limitations. Also, it seeks to identify the most effective model for each crop by evaluating their performance using standard regression metrics such as the coefficient of determination (R^2), Mean Absolute Error (MAE),Root Mean Squared Error (RMSE), and Mean Absolute Percentage Error (MAPE). Ultimately, the research aims to provide a scalable and reliable modeling framework that supports yield forecasting, enhances strategic food security planning, and promotes the adoption of smart agriculture practices in arid and data-constrained environments.

By combining local data with advanced ensemble learning strategies, this research contributes to the growing body of precision agriculture literature and offers practical insights for decision-makers aiming to modernize agriculture in Saudi Arabia. More precisely, the contributions of the present research are the following:

- Unified ensemble-based prediction framework tailored to the Saudi agro-environmental context.
- Comprehensive comparative analysis of seven ensemble machine learning models across multiple crop categories, revealing insights into their relative performance under different optimization conditions.

- Multi-stage optimization pipeline to enhance models' accuracy and stability; including direct optimization techniques such as hyperparameter tuning and Bayesian search and methods of enhancing performance like outliers' removal.

The remainder of the paper is organized as follows. Section 2 recalls the works existing in the literature for crop yield forecasting. Section 3 details the methodology adopted to realize the aforementioned contributions. The main results are discussed in section 4. Finally, section 5 concludes the paper.

II. Related work

Crop yield prediction has emerged as a critical area of research in agriculture [32], especially in the face of climate change, population growth, and food security challenges. Accurate prediction of agricultural production enables farmers, and agribusiness stakeholders to make decisions about resource allocation, land management, and market planning. It also plays a role in supporting food sustainability and reducing risks in agricultural investment and planning [11], [18].

In recent years, artificial intelligence (AI) and machine learning (ML) have been increasingly adopted for crop yield forecasting due to their capacity to model complex, nonlinear relationships among environmental, soil, and agronomic variables [12], [18]. These technologies have shown results compared to traditional statistical methods, especially when dealing with large datasets.

Palanivel and Surianarayanan [13] reviewed ML methods for crop yield prediction, highlighting ANN and SVM for handling nonlinear agricultural data. Studies from India, China, and South Africa covered wheat, maize, rice, cotton, and potatoes. Key features: climate (rainfall, temperature, humidity) and soil. ANN showed high accuracy—e.g., $\pm 9\%$ error in wheat yield. A big data framework was proposed to improve prediction via distributed processing.

Ashfaq et al. [1] proposed an ML framework for winter wheat yield prediction in Multan, Pakistan (2017–2022), integrating meteorological, NDVI, soil, and spatial data. Three models—SVM, RF, and LASSO—were evaluated using NDVI (Landsat 8), climate, and soil features. RF outperformed others with $R^2 = 0.88$, 97% accuracy, and RMSE of 0.056 t/ha. NDVI and climate data boosted accuracy, with water-related features more impactful. The study also produced spatial yield maps and highlighted RF's suitability for heterogeneous, data-scarce regions.

Ilyas et al. [4] proposed an AI-based framework for automated crop classification and yield prediction using remote sensing and ensemble learning. A fuzzy hybrid ensembled model was developed, combining spatial filtering and data augmentation with a bagging ensemble classifier. Yield prediction used GB, RF, DT, and linear regression trained on FAO and World Bank data (2017–2021) for flaxseed, lentils, rice, sugarcane, and wheat. The ensemble classifier improved accuracy by +13% over GB and +24% over DT. GB regressor achieved the best performance with lowest MSE and highest accuracy.

Yewlea et al. [2] proposed RicEns-Net, a deep ensemble model for rice yield prediction in Vietnam's An Giang province using multi-modal data: Sentinel-1 (SAR), Sentinel-2 (MSI), Sentinel-3 (meteorology), NASA rainfall, and field data. From 557 observations, 15 features were selected via statistical filtering. RicEns-Net combines CNN, MLP, DenseNet, and AE, weighted by validation error. It outperformed all tested models, achieving MAE = 341.13 kg/ha, RMSE = 436.26 kg/ha, and adjusted R^2 = 0.589, with minimal train-test variance (ΔR^2 = 0.063).

Wang et al. [6] reviewed DL models for yield prediction across crops: corn, soybean, rice, wheat, tomato, and lettuce. They evaluated LSTM, CNN, CNN-RNN, BO-LSTM, ConvLSTM, DNN, and GRU against ML models (RF, SVR, GBR, KNN), using meteorological, soil, remote sensing, and management data. Notable results: BO-LSTM ($R^2 = 0.82$ for wheat), GRU ($R^2 = 0.98$ for corn), CNN-RNN ($R^2 = 0.9995$ for tomato). DL outperformed ML on large datasets but at higher computational cost and lower interpretability.

Morales and Villalobos [15] evaluated ML models for wheat and sunflower yield prediction using synthetic data from DSSAT models across five Spanish regions. Features included weather, soil, cultivar, and management practices. Models tested: Lasso, Ridge, RF, and ANN (ANN-2 to ANN-12). RF achieved best test results for both crops (e.g., wheat: RMSE = 5%, R^2 = 0.99 train; sunflower: RMSE = 12%, R^2 = 0.97). ANN models showed overfitting risks. Chronological validation confirmed RF's robustness over random splits, supporting its use in real-world forecasting.

El-Kenawy et al. [21] evaluated ML and DL models for potato yield prediction using a Kaggle dataset with agro-climatic, temporal, and spatial variables. Models included KNN, GB, XGBoost, MLP (ML), and GNN, GRU, LSTM (DL). GNN outperformed all, achieving $R^2 = 0.5172$ and MSE=0.0236. LSTM and GRU followed with $R^2 = 0.4474$ and 0.3872. DL models better captured spatial-temporal dependencies. The study applied extensive preprocessing, hyperparameter tuning, and emphasized DL's value for sustainable agriculture and food security.

Joshi et al. [3] explored deep transfer learning for winter wheat yield prediction in U.S. climate zones using satellite time-series and climate data (2008–2020). A BiLSTM replaced MLP to better model spatiotemporal features. Four transfer techniques were tested: TrAdaBoost.R2, Two-stage TrAdaBoost.R2, DANN, and Fine-tuning. Two-stage TrAdaBoost.R2 + BiLSTM yielded top results (MAE = 0.41/0.42; R^2 = 0.51/0.53). DANN underperformed due to domain mismatch. The study highlights BiLSTM's and domain similarity's roles in enhancing transfer learning efficacy.

Brandt et al. [5] developed an ensemble learning framework for predicting yields of winter wheat, barley, and rapeseed in Germany using data from 140,000–155,000 parcels (2019–2022). Features included Sentinel-2 imagery, meteorological data, and soil properties. Two ensemble strategies—stacking (PLSR, RF, SVR, CTB, LGB, XGBoost with Elastic Net meta-learner) and majority voting—were tested.

The voting ensemble achieved the best parcel-level R^2 scores: wheat (0.74), barley (0.68), rapeseed (0.66). High-resolution EO and agro-climatic fusion enhanced accuracy and scalability.

Rao et al. [11] proposed a supervised ML model to guide crop selection based on soil nutrients (N, P, K), temperature, humidity, pH, and rainfall, using a dataset of 2200 samples across 22 crops. Evaluated models included KNN, DT, and RF classifiers. RF achieved top test accuracy (99.32%) with both Gini and Entropy. DT reached up to 98.86%, while KNN scored 97.04%. Regression analysis (ENet, Lasso, Kernel Ridge) and stacking were also used for yield approximation. A mobile app with GPS/rainfall tracking was suggested for practical deployment.

In Saudi Arabia, multiple research papers have studied crop yield prediction. For instance, Assous et al. [12] developed a neural network model for yield prediction across Gulf countries using some features such as temperature, rainfall, nitrogen, and pesticide use, achieved a determination coefficient (R^2) of 0.93. Likewise, Al-Adhaileh and Aldhyani [9] explained that pesticide, temperature, and rainfall were among the most effective predictors for major crops in Saudi Arabia like wheat and sorghum, achieved 0.96 of R^2 and 0.0449 of root mean square error (RMSE) using a multilayer perceptron (MLP) model.

Another recent research by Islam et al. [14] used XGBoost for yield prediction like wheat, maize, sorghum, potatoes and rice in the Saudi Arabia and obtained an R^2 score of 0.97 and RSME of 15803.15. Their research focused on the role of data in promoting climate-resilient agriculture in the region.

Al-Gaadi et al. [25] developed a precision agriculture framework to predict potato yield in Eastern Saudi Arabia using multispectral imagery (Landsat-8, Sentinel-2). Vegetation indices (NDVI, SAVI, CNDVI, CSAVI) were correlated with field yield data from 30-ha plots. Linear regression models showed Sentinel-2 performed best ($R^2 = 0.65$, RMSE = 4.96%), with optimal prediction 60–70 days post-planting. The study highlights the effectiveness of high-resolution satellite monitoring for yield estimation in arid regions.

Al-Gaadi et al. [26] assessed the water footprint (WF) and productivity of carrots and onions in arid Saudi conditions using Sentinel-2, Landsat-8, and the SSEB model. Spectral indices (NDVI, SAVI, RDVI, EVI) and LST were used to predict yield and evapotranspiration. Linear regression with NIR band achieved $R^2 = 0.77$ (carrots) and 0.68 (onions). Estimated WF was 312 m^3/t (carrots) and 230 m^3/t (onions), confirming the value of satellite-based monitoring for yield and water use efficiency.

Li et al. [27] performed a national-scale analysis of Saudi agriculture (1990–2021) using a hybrid ML framework combining DBSCAN, CNNs, and spectral clustering to map 28,000+ center-pivot fields via Landsat NDVI composites. Delineation accuracy was high ($R^2 > 0.97$; producer's: 83.7–94.8%, user's: 90.2–97.9%). Results showed expansion (2010–2015) and post-2016 contraction tied to water policy. The study offers high-resolution field data for future yield, WF, and crop type studies in arid regions.

Ahmed [28] proposed a maize yield prediction framework for Saudi Arabia using a modified MLP optimized by Spider Monkey Optimization (SMO). Trained on FAO and World Bank data (rainfall, temperature, yield), the MLP-SMO model outperformed LASSO, XGBoost, LightGBM, RF, SVM, GRNN, and LSTM, achieving $R^2 = 0.98$ and RMSE = 0.11 Mg/Ha. Statistical tests (MAE, MBE, Wilcoxon) confirmed its robustness. The study highlights the potential of hybrid neural-metaheuristic models for accurate yield forecasting in arid regions.

Jabbari et al. [29] studied IoT adoption for crop monitoring and yield prediction among 550 farmers in Jizan, Saudi Arabia. Statistical analysis showed a strong correlation between awareness and perceived benefits ($r = 0.835$, $p < 0.001$). Perceived benefits explained 21% of adoption variance ($R^2 = 0.210$), while access to information and government support were also significant predictors ($R^2 = 0.191$). The study highlights the need for targeted training and institutional backing to boost IoT adoption in precision agriculture.

A summary of the approaches for crop yield prediction in Saudi Arabia is given in table I.

TABLE I
EXISTING WORKS OF CROP YIELD PREDICTION IN SAUDI ARABIA

Ref, Year	Crop	Model	R^2	Data Source
[14], 2024	Maize, Potatoes, Sorghum, Soybean, Wheat	Bagging RF XGBoost	$\geq$0.91	FAO + World Bank Open Data

Despite advances in ML/DL for crop yield prediction, significant gaps exist in the literature, particularly in terms of regional adaptability to arid climates, full ensemble model evaluation, and holistic data fusion methodologies. Existing models frequently lack calibration for regions such as Saudi

Arabia, and therefore struggle with generalizable, scalable architecture. While specific ensemble strategies have been verified, few studies have systematically compared a wide range of ensemble methods across many crops and regions, a gap that this work fills by evaluating seven algorithms for Saudi crops. Furthermore, many implementations miss critical data fusion, particularly the combined influence of environmental, temporal, remote sensing, and management variables, whereas this study distinguishes the varied importance of components such as NDVI versus precipitation in the Saudi context. Also, we claim that the suggested approach has great generalizability, allowing for unlimited use across many situations, provided the necessary data is available.

III. Methodology

Sustainable food production in arid regions like Saudi Arabia faces significant challenges due to extreme climate, limited water resources, and constrained arable land. Crop yield prediction serves as a crucial tool to improve agricultural planning, optimize resources use, and support national food security. While ML and DL methods have shown promise in this domain, most prior studies rely on global datasets and focus primarily on few crops. These approaches often fail to generalize to local conditions and underrepresent crops vital to the Saudi agricultural economy, such as fruits and dates.

This research proposes a framework based on ensemble machine learning tailored to the agro-climatic context of Saudi Arabia. By leveraging multi-source datasets and a range of ensemble models including Random Forest, Bagging Decision Trees, Gradient Boosting, Stochastic Gradient Boosting, XGBoost, AdaBoost, and CatBoost, this study aims to deliver accurate and scalable yield predictions.

As illustrated in figure 1, the methodology is structured as follows: data collection and preprocessing, model training using historical and environmental variables (e.g., temperature, precipitation, NDVI, pesticide usage), performance evaluation using standard regression metrics (R^2, MAE, RMSE, MAPE), and different optimization experiments. This structured approach ensures robust, context-aware model development that supports smart agriculture in arid environments.

A. Data collection

To develop an effective crop yield prediction framework tailored to Saudi Arabia, a diverse set of datasets was compiled from reputable global platforms. The features were selected to reflect environmental, agronomic, and remote sensing variables that have been shown to impact crop productivity in prior studies.

- Crop type and yield: Crop-specific production and yield data were obtained from the the Food and Agriculture Organization (FAO) [30]. The data included total yield values (in kg per hectare) for several crops cultivated in Saudi Arabia like wheat, maize, tomatoes, potatoes, barley, sorghum, and dates.
- Pesticide use: Annual pesticide usage was collected from FAO databases. This variable represents the total quantity of pesticides applied in agricultural operations per year.
- Weather data: Meteorological data, including average annual temperature, total precipitation, and average humidity, were extracted from the World Bank Climate Data API [31]. The data were aggregated on a yearly basis for the studied country.
- Vegetation indices: The Normalized Difference Vegetation Index (NDVI) is a widely used spectral index that quantifies vegetation health and density by measuring the difference between near-infrared (NIR) and red (RED) reflectance captured by satellite sensors [1]. NDVI is calculated using the formula:

$$\text{NDVI} = \frac{\text{NIR} - \text{RED}}{\text{NIR} + \text{RED}}$$

This formula exploits the fact that healthy vegetation reflects more NIR light and absorbs more red light, while sparse or unhealthy vegetation shows the opposite pattern. NDVI values range from -1 to $+1$, where higher positive values typically indicate dense, healthy vegetation, and values near zero or negative indicate barren areas, water bodies, or built-up land.
In this study, NDVI images were extracted and processed using the Google Earth Engine (GEE) platform, which provides cloud-based access to satellite imagery and enables large-scale geospatial analysis. Landsat 5, 7, and 8 Surface Reflectance (SR) collections were utilized to ensure temporal continuity from 1990 to 2022. The satellite images were first filtered for cloud-free conditions and spatially clipped to specific agricultural regions in Saudi Arabia. For each image, NDVI was computed using GEE's built-in `normalizedDifference()` function, which efficiently implements the NDVI formula.

A summary of the data sources is given in Table II.

TABLE II
SUMMARY OF DATA SOURCES USED IN THE STUDY

Source	Type of Data	Time Range
FAO	Crop yield, pesticide use	1990–2022
GEE	Vegetation indices (NDVI)	1990–2023
World Bank Climate Data	Temperature, humidity, precipitation	1990–2022

B. Data pre-processing

Following the collection of raw datasets from various sources, basic pre-processing steps were applied to prepare the data for ML modeling. These steps were essential to ensure the consistency, completeness, and relevance of the input features.

- Vegetation indices computation:
To obtain a comprehensive overview of the crop condition, NDVI is used along with VCI (Vegetation Condition Index) and WDRVI (Wide Dynamic Range Vegetation Index). The three indices give complementary vegetation

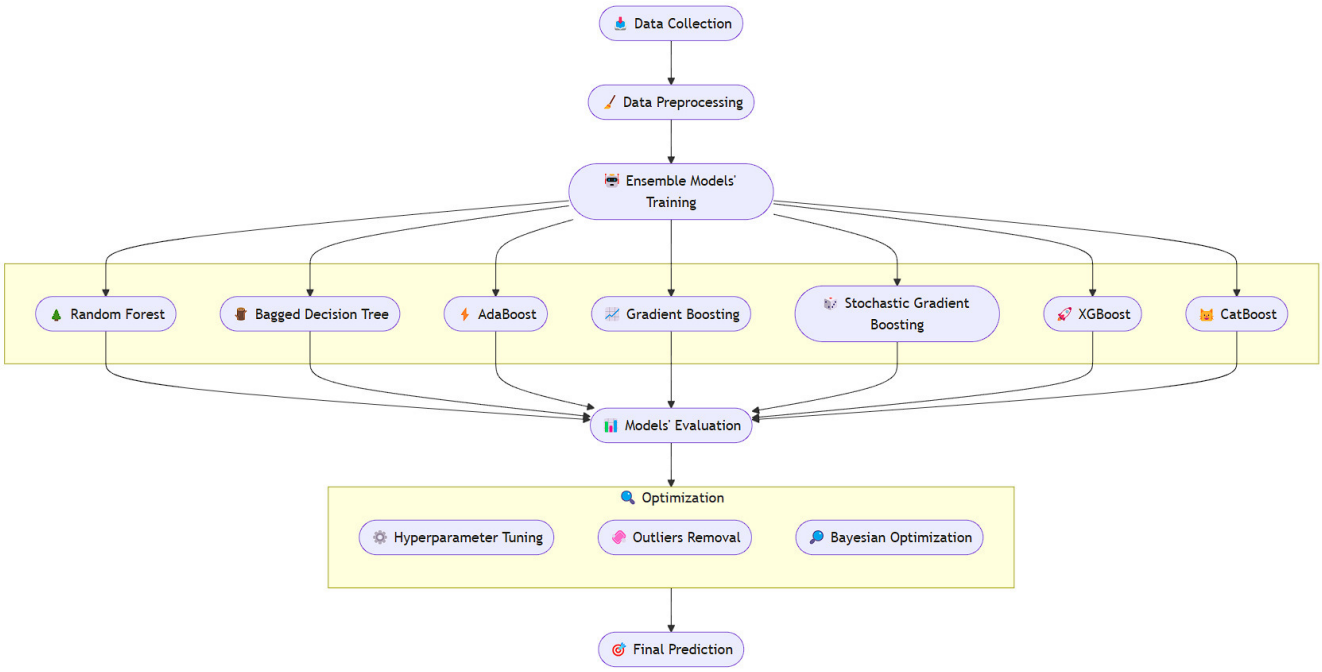

Fig. 1. Proposed framework

information, which is notably significant in agricultural surveillance and crop yield forecasting.

- VCI was calculated using the standard formula [4]:

$$VCI = \frac{NDVI - NDVI_{min}}{NDVI_{max} - NDVI_{min}} \times 100$$

- WDRVI was derived from red and near-infrared reflectance bands using:

$$WDRVI = \frac{(0.1 \cdot NIR) - RED}{(0.1 \cdot NIR) + RED}$$

where NIR and RED are the near-infrared and red reflectance values from MODIS [4].

- Data aggregation: All variables were aggregated at the annual level to align crop yield values with climate, pesticide, and remote sensing data.
- Missing data handling: Records with missing values were dropped or imputed using mean imputation where appropriate. This was particularly relevant in the early years with sparse pesticide data.
- Categorical encoding: The crop name (such as Wheat, Sorghum, Dates) was converted into numeric labels using label encoding to allow its use as a categorical feature in selected models. This is a critical step since machine learning models need numerical data. For presentation and evaluation, the original harvest names are kept in distinct variables or extracted using inverse_transform.

All datasets were harmonized to a common temporal resolution (annual), cleaned to remove missing values, and merged into a unified data frame containing 1117 records across all crop types and years. Descriptive data statistics are illustrated in figure 2.

C. Ensemble models

This research proposes a multi-stage ML pipeline to predict crop yields in various types of crop cultivated in Saudi Arabia. The methodology is centered on ensemble techniques, given that ensemble machine learning takes advantage of the complementary characteristics of many models to improve predictive accuracy, minimize variation and bias, and achieve improved generalization in complicated tasks. We implemented seven from the famous bagging and boosting models and proposed different optimizations based on regularization and hyperparameter tuning applied to the seven models. The analysis involved the evaluation of each model across all crops in the dataset, then the selection of the top-performing crops on which the optimization techniques were tested, and finally the in-depth training, tuning, and evaluation of all models per selected crop. The seven applied ensemble learning models fall in the bagging and boosting ensemble categories:

- Bagging models: Bagging models increase the accuracy of predictions by training several base learners simultaneously on random portions of the data.
  - Random Forest (RF) is an ensemble method that constructs multiple decision trees on bootstrapped samples of the data and averages their outputs. For regression, the prediction is given by:

$$\hat{y} = \frac{1}{K} \sum_{i=1}^{K} T_i(x)$$

	Year	Yield_Value	Temperature	Precipitation	Humidity	NDVI_Mean
count	1117.00	1117.00	1117.00	1117.00	1117.00	1117.00
mean	2006.93	12690.34	25.59	60.67	31.16	0.05

max	100.00	0.03	10495.54

Fig. 2. Collected Data Statistics

where $T_i(x)$ is the prediction from the i-th DT and K is the total number of trees [14].

– Bagged Decision Tree (Bagged DT) is similar to RF but without feature randomness; trees are trained on bootstrapped datasets only.

- Boosting models: Boosting models construct ensembles in stages, with each model focusing on rectifying the faults of the previous ones.
  – Gradient Boosting (GB) iteratively minimizes a loss function via gradient descent:

$$F_m(x) = F_{m-1}(x) + \gamma_m h_m(x)$$

  – Stochastic Gradient Boosting (Stochastic GB) is a variant of GB that introduces randomness by sampling the training set at each iteration [20].
  – eXtreme Gradient Boosting (XGBoost) is an optimized version of GB with regularization:

$$\text{Obj} = \sum_i l(y_i, \hat{y}_i) + \sum_t \Omega(f_t)$$

  where $\Omega(f_t)$ is a complexity penalty for tree f_t [20].
  – AdaBoost sequentially trains weak learners and combines them with weights:

$$F(x) = \sum_{m=1}^{M} \alpha_m h_m(x)$$

  where h_m is the m-th weak learner and α_m is its weight.
  – CatBoost uses ordered boosting and handles categorical features natively to reduce prediction shift and overfitting [20].

This ensemble learning-based framework proposed for crop yield prediction was inspired by the work of Zhou [20], which details the theoretical underpinnings and practical successes of such models in various domains.

All seven models were trained and evaluated in their baseline definition (called baseline models in the sequel), then three optimizations were proposed for each model resulting in 21 other models named respectively OR, Hypertuned, and BayesSearchCV for models optimized using Outliers Removal, Hyperparameters tuning, and Bayesian optimization.

D. Model's optimization

To enhance the accuracy and generalizability of the ensemble models, a structured optimization pipeline was implemented. This process consisted of three sequential steps: hyperparameter tuning, outlier removal, and Bayesian optimization. Each step was selected to address specific challenges in predictive modeling and improve the models' robustness.

1) Hyperparameter tuning: The optimization phase began with hyperparameter tuning using GridSearchCV, a technique that systematically explores combinations of predefined hyperparameter values. This approach enables the selection of optimal configurations for each model, such as the number of estimators, tree depth, and learning rate, by evaluating model performance across cross-validated folds.

Hyperparameter tuning plays a crucial role in reducing underfitting or overfitting, and ensures that models are well-calibrated for the underlying data distribution. Its effectiveness is well-documented in the ML literature [22].

In this study, a distinct set of parameter grids was defined for each ensemble model to account for their structural and functional differences. The search space proposed for each model, the best parameters obtained, and the crop for which the best values are achieved are summarized in table III.

2) Outliers' removal: As an *indirect* optimization method, we relied on the outliers' removal method to clean the data by removing anomalies, which identifies and excludes data points that differ considerably from the dataset's anticipated trends or distribution. This may lead to better generalization and lower error metrics (e.g., RMSE and MAE).

TABLE III
SELECTED HYPERPARAMETERS FOR TUNING THE DEVELOPED ENSEMBLE MODELS

Model	Search Space	Best Parameters	Crop

	min_samples_leaf: [1,3]	3	

Once the models were tuned, Isolation Forest was applied to remove outliers from the data. This unsupervised anomaly detection technique isolates unusual observations by randomly partitioning the feature space. Its strength lies in its scalability and independence from the data distribution assumptions.

To maintain consistency, the cleaned dataset was passed into retrained versions of the same ensemble models, each with fixed hyperparameters tailored for robust generalization. For instance, RF and Bagged DT were retrained using 100 estimators, while AdaBoost used 100 weak learners. GB and SGB were configured with 200 and 100 estimators respectively, with subsampling enabled to enhance robustness. XGBoost was applied with additional regularization (`reg_alpha` = 0.1, `reg_lambda` = 1.0) and feature subsampling (`colsample_bytree` = 0.8), aiming to mitigate overfitting on reduced data. CatBoost was configured with 200 iterations, a moderate learning rate (0.05), and a regularization term (`l2_leaf_reg` = 3.0), while disabling verbose output for computational efficiency.

All models used a consistent random seed to ensure reproducibility across experimental runs. Outliers' removal helped to mitigate the impact of noise and extreme values, which can distort model learning and inflate error metrics. This is particularly beneficial in agricultural datasets where variability is high [23].

3) Bayesian optimization: In the final step, Bayesian Optimization was conducted using `BayesSearchCV`. Unlike grid search, which exhaustively tests all combinations, Bayesian optimization models the objective function and iteratively selects hyperparameters that are likely to yield the best results. This method improves the search efficiency, particularly in high-dimensional spaces, and has been shown to outperform traditional tuning methods in many ML applications [24].

For this study, specific search spaces for each model were designed to reflect their structural characteristics and known sensitivities. The parameters used in these spaces are defined in table IV. In the same table, we report the best values obtained and the crop for which the model performs better.

These customized search spaces allowed for targeted exploration of the hyperparameter landscape while maintaining computational efficiency. All models were optimized with a fixed random seed for reproducibility, and verbosity was disabled for resource-controlled environments.

IV. RESULTS AND DISCUSSION

Rigorous assessment of the developed models is critical for verifying the efficacy of models, ensuring repeatability, and quantifying predicted reliability, which helps to enable accurate choices and trustworthy real-world deployment.

Our objective was to develop and evaluate seven ensemble machine learning models in their base configuration in addition

to the application of three techniques to study the models' performance enhancement. This resulted in the evaluation of 28 models resulting from the seven ensemble models discussed earlier multiplied by the four possible configurations. For this, we chose to assess these models on selected crops instead of studying all the crops obtained in the collected data. This choice is made on the basis of training the seven baseline models on each crop in the dataset and selecting the eight crops with best results according to the following metrics:

- R^2: Measures the proportion of variance in the dependent variable that is predictable from the independent variables. Values range from 0 to 1, with higher values indicating better model fit:

$$R^2 = 1 - \frac{\sum(y_i - \hat{y}_i)^2}{\sum(y_i - \bar{y})^2}$$

- Root Mean Squared Error (RMSE): is a fundamental evaluation metric widely used in regression problems, including crop yield prediction. It quantifies the square root of the average of the squared differences between predicted values $\hat{y}_i$ and actual values y_i, and is formally defined as:

$$RMSE = \sqrt{\frac{1}{n}\sum_{i=1}^{n}(y_i - \hat{y}_i)^2}$$

where n denotes the number of observations. The squaring of errors penalizes larger deviations more than smaller ones, making MSE particularly sensitive to outliers. This sensitivity allows it to highlight substantial prediction errors that may impact agricultural decision making.

- Mean Absolute Error (MAE): Represents the average magnitude of the prediction errors, without considering their direction:

$$MAE = \frac{1}{n}\sum_{i=1}^{n}|y_i - \hat{y}_i|$$

- Mean Absolute Percentage Error (MAPE): is a regression metric that measures the average absolute percentage difference between predicted and actual values, making it useful for determining the accuracy of the model

$$\text{MAPE} = \frac{100\%}{n}\sum_{i=1}^{n}\left|\frac{y_i - \hat{y}_i}{y_i}\right|$$

The crops selected for further investigation and the metrics obtained for the best model for each crop are summarized in table V.

A. Baseline models' Performance

As mentioned in the previous section, to establish a benchmark for model performance, all ensemble models were initially evaluated using default (untuned) configurations. The evaluation was carried out across eight diverse crop categories using standard regression metrics: MAE, RMSE, R^2, and MAPE (table V). We aim here to provide more insights about the training of the seven ensemble models (with default configurations) on the selected crops.

TABLE V
BEST MODEL AND ITS EVALUATION METRICS FOR EACH CROP

Crop	Best Model	MAE	RMSE	R^2	MAPE
Cereals, primary	AdaBoost (Baseline)	0.015	0.019	0.829	0.042
Dates	Gradient Boosting (Baseline)	0.022	0.034	0.861	0.299
Fruit Primary	Stochastic Gradient Boosting (Baseline)	0.026	0.035	0.918	0.890
Other fruits, n.e.c.	Stochastic Gradient Boosting (Baseline)	0.075	0.103	0.923	0.252
Pulses, Total	AdaBoost (Baseline)	0.003	0.005	0.976	0.007
Sorghum	Stochastic Gradient Boosting (Baseline)	0.008	0.013	0.894	0.016
Wheat	Stochastic Gradient Boosting (Baseline)	0.014	0.019	0.864	0.051
Pumpkins, squash and gourds	Random Forest (Baseline)	0.088	0.119	0.880	0.534

To visualize the overall model performance across crops, figure 3 presents a heatmap of R^2 scores, capturing the comparative behavior of all base models.

The heatmap confirms that CatBoost and Stochastic GB seem to be strong performers overall, consistently showing high R^2 scores. AdaBoost and Gradient Boosting show very good performance across most crops. Random Forest generally performs well achieving 97% for Pulses crop. On the other hand, Bagged DT and XGBoost appear to have lower R^2 scores, particularly for Dates and Other fruits, which supposes that they might not be suitable for these crop types compared to the other models.

From the lens of crops, Pulses, Fruit, and Sorghum seem to be relatively well-predicted across most models, with many R^2 scores greater than 0.80 and a score ranging between 0.91 and 0.98 for Pulses crop. Whereas, Dates and Other fruits tend to have lower R^2 scores for several models, indicating that predicting the target variable for these crops might be more challenging.

Learning curves obtained by testing the models' effectiveness on progressively bigger subsets of the input data through cross-validation were studied to identify probable variance and bias concerns. To understand how the seven models learn and generalize from data, we visualize the learning curves for "Pulses, Total" and "Dates". For Pulses crop, figure 4 shows that the models are capable of extremely quick learning. Despite limited training instances (e.g., 5-10), most models get strong R^2 values (typically greater than 0.80) on both training and cross-validated data. The curves increase rapidly and converge soon. However, figure 5 shows that for Dates, the models demonstrate slower and less efficient learning. Low training instances (e.g., up to 15-20) show a significant disparity between training R^2 (typically 1.0) and CV R^2 (near 0 or even negative), indicating early overfitting.

B. Performance of the optimized Models

For direct and indirect optimization of the developed models across the selected crops, we performed the following tasks as explained in the methodology section.

- Hyperparameter tuning
- Outliers' removal
- Bayesian optimization

The R^2 scores for all models are summarized in table VI. Accoding to the table, the proposed optimizations have significantly improved the models' performance across the studied crops, particularly for formerly underperforming predictions. For Dates crop for example, the XGBoost model showed an increase in R^2 score by $\tilde{4}7\%$ after hyperparameter tuning. Also, Bayesian optimization enhances dramatically the prediction of Dates by Bagged Decision Tree (R^2 scores passes from 0.67 to 0.92). It is indeed clear from the table that almost all the optimizated models perform better than the default models.

We also highlighted in gray the cell showing the best R^2 score for each crop for model selection. For example, the best predictor for Fruits is the hypertuned Stochastic GB model with a score R^2 of 0.98.

The capacity to accomplish such consistent generalization over a broader range of crop varieties demonstrates the success of our optimization method and establishes these models as dependable tools for the forecasting of crop yields.

V. CONCLUSION

In this research, we developed and evaluated seven ensemble-based machine learning models to predict eight crop yields in Saudi Arabia. In order to enhance the baseline models' performance, three optimization methods were developed: direct optimization via hyperparameter tuning and Bayesian optimization and indirect optimization through outliers' removal.

The results demonstrated that Stochastic Gradient Boosting and XGBoost are the best performers, each model achieving the highest R^2 values for three different crops. Then, CatBoost and AdaBoost were champions in predicting Other fruits and Cereals, resp. However, bagging models (RF and Bagged DT), and the GB model did not outperform the developed models in any of the selected crops.

It should be noted that the optimization strategies had varied effects. Hyperparameter tuning showed marginal gains, while Bayesian optimization and outlier removal (via Isolation Forest) led to noticeable performance improvements. However, the effectiveness of each strategy was dependent on the crop.

In summary, the proposed framework provided a scalable and interpretable approach to smart agriculture in Saudi Arabia. Its crop-level insights support data-driven decision-making for farmers and policymakers.

For future investigations, it is promising to expand the dataset to include soil characteristics, crop management practices, and economic indicators to improve model generalization. Also, it is propitious to explore deep learning architec-

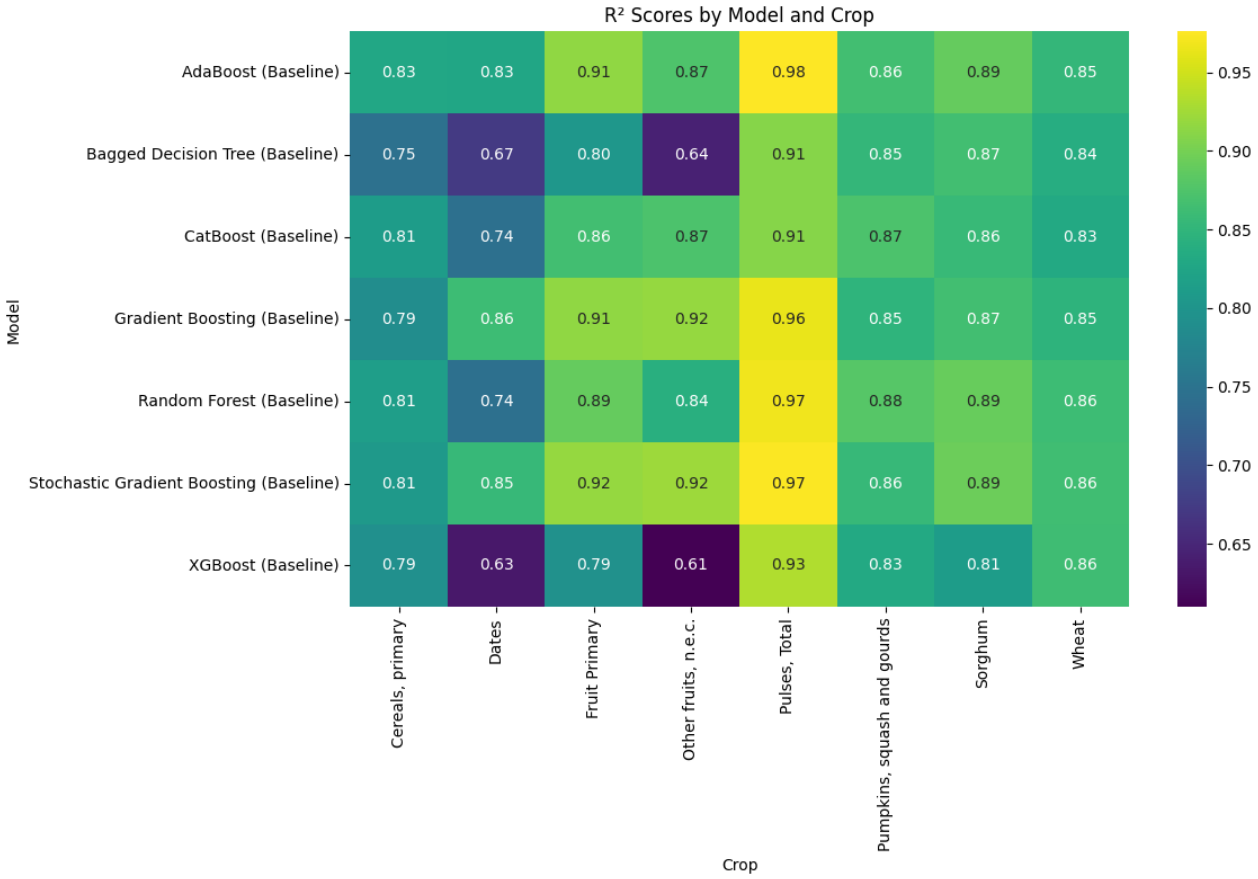

Fig. 3. Heatmap of R^2 values for baseline models across crops

tures such as LSTM or CNN to capture temporal dynamics more effectively where larger amount of data is available. Finally, exploring the performance of deep ensemble learning on the studied crops appears promising, given the encouraging results reported in [33].

***Abstract*—Export control (EC) compliance is a critical yet labour-intensive process within research institutions, where the classification of sensitive technologies and cross-border disclosures often depends on expert interpretation of complex legal frameworks. This paper investigates the potential of large language models (LLMs), specifically in this study ChatGPT-4o and LLaMA-3.3, to support EC screening through a multi-stage, expert-in-the-loop framework. The methodology includes prompt variation, regulatory conditioning, reflective reasoning, and expert-informed evaluation to simulate real-world compliance workflows. Using a curated dataset of UK research project descriptions and the UK Strategic Export Control List, we assess model performance across over 1,400 outputs. Results show that while both models benefit from domain-specific grounding, ChatGPT-4o consistently produces more stable and interpretable classifications. Prompt sensitivity, bias behaviour, and ambiguity handling are also examined to highlight model limitations. The findings suggest that LLMs can support early stage EC assessment but require structured prompting and human oversight to ensure regulatory alignment.**

***Index Terms*—Export control, large language models, regulatory compliance, prompt engineering, dual-use research, natural language processing, legal AI.**

I. Introduction

EXPORT CONTROL (EC) regulations play a critical role in governing the dissemination of sensitive technologies, intellectual property, and research outputs. While this study focuses specifically on the UK's export control regime—including mechanisms such as the Open General Export Licence (OGEL)[1], Standard Individual Export Licence (SIEL)[2], and the SPIRE application system [3], we reference international frameworks such as the Export Administration Regulations (EAR)[4] and the International Traffic in Arms Regulations (ITAR)[5] to provide broader regulatory context. These frameworks aim to mitigate national security and foreign policy risks by restricting unauthorised access to dual-use or controlled items. Dual-use items include those with both civilian and military applications, such as advanced materials, sensors, and encryption technologies, which are particularly sensitive in academic research contexts. Relevant legal instruments include the UK Export Control Order 2008 [6], the EU Dual-Use Regulation (EU) 2021/821 [7], the US EAR [4], and the UK Strategic Export Control List [8].

Within the academic sector, ensuring compliance with these frameworks is increasingly complex due to international collaboration, evolving research domains (e.g., quantum computing, artificial intelligence), and growing scrutiny from government bodies.

Despite their significance, export control processes remain predominantly manual and highly dependent on expert interpretation. Compliance officers are often required to assess project descriptions against regulatory texts that are both voluminous and legally dense. This results in considerable administrative burden and interpretive inconsistency, especially in institutions managing large volumes of research proposals or operating across multiple jurisdictions.

Recent developments in natural language processing (NLP), particularly through the advent of LLMs, offer new avenues for supporting regulatory compliance. Models such as GPT-4 and LLaMA have demonstrated potential in legal classification, policy reasoning, and context-aware document analysis [9], [10], [11]. However, several limitations remain. Prior work highlights that existing LLM pipelines often fail to generalise across domains, lack grounding in domain-specific legal contexts, and exhibit limited capacity for justification or error correction [12], [13], [14]. As noted by Hussain et al. [9], automated compliance in sensitive areas such as export control demands a level of interpretability and consistency that many current approaches have yet to achieve.

This paper introduces a multi-stage, expert-in-the-loop framework for evaluating the capability of LLMs to assess research disclosures under export control criteria. The framework is designed to emulate key components of institutional compliance workflows, allowing for iterative refinement through prompt variation, domain-specific grounding, reflective reasoning, and expert-informed logic. Rather than

relying on retraining or symbolic transformation, the proposed approach evaluates whether LLMs can reason effectively over full regulatory documents and project metadata.

The contributions of this paper are threefold. First, we propose a structured methodology for assessing LLM performance across different stages of reasoning, incorporating domain knowledge and expert feedback. Second, we conduct a comprehensive evaluation of ChatGPT-4o and LLaMA-3.3 across 1400 outputs using varied prompts, conditions, and error correction procedures. Third, we analyse model behaviour under ambiguity and potential bias, offering practical insights into reliability and risk in compliance decision-making.

The remainder of the paper is structured as follows: Section II reviews related work on automated legal compliance and the application of LLMs in regulatory domains. Section III outlines our proposed five-stage framework and design rationale. Section IV details the experimental setup, data sources, and evaluation procedures. Section V presents empirical findings on model performance across prompts, stages, and error correction conditions. Section VI contextualises these findings with respect to model generalisability, domain adaptation, and deployment feasibility. Finally, Section VII concludes with key insights and directions for future work.

II. Background and Related Work

Automating regulatory compliance has long posed a significant challenge for organisations operating within heavily regulated sectors such as finance, healthcare, and export control. The automation of regulatory compliance has traditionally relied on symbolic and rule-based approaches, including formal logic, ontologies, and information retrieval methods. These methods often apply sentence-level analysis and handcrafted rules to extract obligations or classify provisions. Traditional ML-based compliance checking in this area has relied on manually curated datasets and conceptual models, [15], [16]. While rule-based and symbolic methods offer transparency, many ML techniques particularly deep learning models require additional strategies to ensure interpretability and alignment with legal reasoning [9]. These methods typically focus on completeness and semantic coverage but struggle with ambiguity and cross-paragraph consistency [17]. This limitation becomes particularly pronounced in domains where legal language is dense and referential.

The emergence of large language models has prompted a shift in how regulatory artefacts are analysed. Unlike their symbolic predecessors, models such as ChatGPT-4o and LLaMA-3.3 are capable of interpreting language at the paragraph or document level, capturing contextual relationships and legal nuance in a way that more traditional techniques cannot [18]. Recent work by Hassani et al. [9] illustrates that LLMs outperform both keyword-based systems and fine-tuned BERT variants in legal classification tasks, particularly in domains like General Data Protection Regulation (GDPR) and food safety. An extension of this work [12] further examines paragraph-level grounding and contextual relevance. Similarly, [19] evaluated ChatGPT and LLaMA in the interpretation of clinical guidelines, highlighting their ability to follow structured protocols. Recent benchmarks by Yin et al. [20] also demonstrate LLM performance in semantic mapping of Sustainable Development Goals (SDGs), reinforcing their applicability in policy-oriented contexts.

LLMs have also shown potential for detecting inconsistencies in legal and technical requirements. In [21], they demonstrated that ChatGPT can be used to flag contradictions in natural language software specifications, highlighting broader utility for regulatory oversight. Similarly, Zhang et al. [11] showed that hallucination risks persist in extractive clinical NLP tasks, emphasising the need for cautious deployment in compliance settings.

Recent implementations have integrated LLMs into structured compliance systems. For example, the Gracenote platform [10] uses GPT-4 and prompt engineering to generate obligations registers, support consultation tools, and perform regulatory horizon scanning. LangChain pipelines have further enhanced LLM performance through document embeddings and retrieval-augmented generation (RAG). Al-Turki et al. [22] developed a human-in-the-loop LLM architecture for building regulation compliance, translating legal texts into structured YAML formats using GPT-4 with iterative expert feedback. Complementary work by Chen et al. [13] integrates deep learning and ontologies to check BIM (Building Information Modelling) compliance, combining LLMs with symbolic representation. These advances illustrate the growing role of LLMs as context-aware, domain-adaptable engines for compliance support.

This emphasis on context-aware interpretability and structured reasoning is echoed in recent work on legal NLP and compliance-oriented modelling. For example, a Bi-LSTM-based architecture has been used to detect explicit cause-and-effect relationships in court judgments, using labelled sentence structures to support traceable and explainable inference over legal arguments [23].

A risk-based quality control framework for legally regulated software further demonstrates how domain-specific structural representations can enhance traceability, regulatory robustness, and the auditability of automated compliance workflows [24].

The translation of natural language requirements into access control policies using LLMs has also been explored in the context of policy automation, offering insights relevant to export screening and classification workflows [25].

However, despite these developments, the use of LLMs in export control compliance remains largely underexplored. This domain involves a particularly challenging regulatory landscape governed by overlapping national and international regimes such as the UK Export Control Order, the EU Dual-Use Regulation, and the US EAR. In [14], the authors demonstrated a similar application in financial auditing, highlighting LLMs' potential to support layered and context-sensitive regulatory checks. The complexity of export classifications ranging from technical specification alignment to licensing decisions which requires a level of interpretive reasoning that

few systems currently offer.

Based on the literature, this paper highlights three key limitations:(1) the lack of annotated export control datasets for training or benchmarking; (2) minimal evaluation of LLMs across different legal jurisdictions; and (3) limited deployment of LLMs for core export tasks such as EC classification, red-flag screening, or licensing eligibility.

In this context, this paper explores a framework to evaluate whether ChatGPT-4o and LLaMA-3.3 can directly assess the applicability of export control regulations based on full-text legal documents and project descriptions. Unlike approaches that rely on intermediate representations or symbolic transformation, our framework ingests unstructured regulatory texts and infers, from context, whether export restrictions apply to a given scenario. This mirrors how compliance officers perform early-stage screening and allows us to evaluate the practical value of LLMs in complex classification tasks, particularly in domains like export control where project-specific variables and legal precision are critical.

III. Methodology

This work proposes a five-stage, expert-in-the-loop framework to evaluate and iteratively improve the ability of LLMs to classify research outputs under export control regulations. The methodology simulates regulatory decision-making by combining baseline reasoning, regulatory conditioning, error analysis, reflective prompting, and expert-guided optimisation. Each stage builds upon the previous to promote contextual learning and alignment with expert judgement.

The framework is summarised in Fig. 1 and includes the following stages:

1) **Baseline Inference (Stage 1)**: In this stage, the language model is prompted to classify domain-specific research descriptions without prior instruction. This establishes a baseline for the model's default reasoning capabilities. The model also generates a natural language justification for each prediction
2) **Domain Conditioning (Stage 2)**: The UK Strategic Export Control List is introduced to the model as context. Models are then re-evaluated on the same dataset to assess domain knowledge integration.
3) **Disagreement Analysis (Stage 3)**: Model predictions are compared with expert annotations. Disagreements are categorised to identify systematic reasoning issues.
4) **Model Reflection (Stage 4)**: In this stage, disagreement examples are reprocessed using self-prompting techniques that guide the model to reflect on its earlier decision. Prompts are crafted to encourage regulatory reasoning, contextualization, and consistency with prior outputs. The goal is to assess whether reflective prompting improves alignment without additional training
5) **Expert-in-the-Loop Optimisation (Stage 5)**: Model outputs from the reflection stage are reviewed again by the expert, who provides feedback on both classification decisions and explanations. This feedback is used to refine prompts and adjust reasoning templates, forming a closed loop for improving the model's interpretability and regulatory conformity.

This iterative process promotes improved regulatory alignment and explanation quality without the need for model retraining.

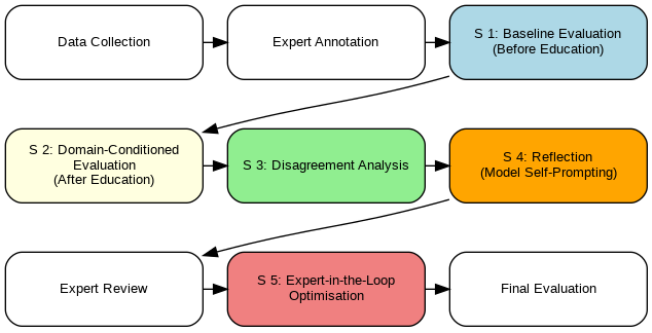

Fig. 1. Five-Stage Expert-Enhanced Framework for Export Control Classification.

IV. Experimental Setup

To evaluate the proposed methodology, a series of experiments were conducted using ChatGPT-4o and LLaMA-3.3. The setup includes data sources, model prompting, evaluation metrics, and bias analysis.

A. Data Collection

Two primary sources were used:

- **Regulatory Document:** The UK Strategic Export Control List was retrieved from official UK government publications.[1], [2], [8].
- **Project Dataset:** 50 research project descriptions were collected from the UKRI EPSRC funding portal[1]. Each entry included the fields: Title, Abstract, Project Partners, Organisation, and Department.

Each project description was independently annotated by a compliance officer from the University of Liverpool. Labels were binary, indicating whether the project should be subject to export control. These expert annotations were treated as ground truth across all experiments. Seven additional cases were marked as ambiguous for later bias and uncertainty evaluation.

B. Prompt Design and Evolution

Prompt engineering was central to model evaluation. Each stage involved a different prompting strategy:

1) Initial Prompt:

> I will give you a description of many grant projects from EPSRC in the UK. The description includes Title, Abstract, Project Partners, Organisation, and Department. I need you to tell me whether the owner of this project should apply for export control items or not and give me an explanation for your answer.

[1]https://www.ukri.org/councils/epsrc/

2) Prompt Diversity: To evaluate model robustness and sensitivity to prompt phrasing, five semantically similar variants of the initial prompt were generated per model. These new prompts were then used to rerun both the Stage 1 and Stage 2 evaluations, producing six runs per model (original + 5 variants), resulting in 24 experimental conditions and 1200 model outputs in total.

3) Reflective Prompting: Incorrect predictions were re-evaluated using prompts designed to promote self-correction:

> You previously answered that export control applies. Re-assess this decision considering the regulation provided. Identify any mistakes in your previous reasoning and provide a revised classification and justification.

4) Final Structured Prompt: A compliance-driven decision flow was embedded into a structured Yes/No prompt:

> I will describe a research or teaching project. Follow this step-by-step Yes/No flow to assess whether export controls apply:
>
> 1) Is the project exporting materials, technology, software, or information outside the UK? (Consider collaborators, overseas travel, or postgraduate students overseas.)
> → If NO, export controls do not apply. If YES, continue.
> 2) Do you know or suspect that any participant (staff, student, collaborator, or end user) intends to use the materials for military or WMD purposes?
> → If YES, export controls apply — recommend contacting `exportcontrol@liverpool.ac.uk`. If NO, continue.
> 3) Are any items subject to US export controls?
> → If YES, flag as potentially restricted and recommend further review. If NO, continue.
> 4) Are any items on the UK Strategic Export Control List, or is the project working with sanctioned entities?
> → If NO, export controls do not apply. If YES, continue.
> 5) Does the project fall under any exemptions (public domain, basic scientific research, or patent filing)?
> → If YES, export controls may not apply. If NO, export controls apply — recommend contacting `exportcontrol@liverpool.ac.uk`.
>
> Always reference UK Government and University of Liverpool guidance in your reasoning [2], [26].

C. Model Configurations

Two LLMs were tested: ChatGPT-4o, accessed via the OpenAI API, and LLaMA-3.3, accessed via the Hugging Face Inference API.

D. Evaluation Metrics

The following metrics were used: Accuracy, Precision, Recall, F1-score, and confidence scores on incorrect predictions. Confidence scores were obtained by instructing the model to label each decision with one of three categories: Low (0–40%), Medium (41–70%), or High (71–100%), based on how confident it was in its prediction. Prompt variance was measured as the standard deviation in accuracy across prompt variants.

E. Ambiguity and Bias Evaluation

Ambiguous cases were used to test confidence stability across prompts. Additionally, a bias test was conducted by modifying the institutional affiliation of partners (e.g., replacing EU with non-EU universities) to observe if geopolitical factors affected model judgement.

While this multi-stage design may appear complex, it is intended to emulate the layered decision-making practices of institutional export control review. Compliance officers often rely on contextual interpretation, iterative clarification, and expert oversight—requirements that cannot be captured by one-shot classification alone. The staged approach allows the model to integrate domain knowledge, reflect on prior outputs, and adapt to expert feedback, thereby aligning more closely with real-world compliance workflows.

V. Results

A. Initial Prompt Performance

Initial classification performance was evaluated using the original prompt, which produced three output labels: `YES`, `NO`, and `MAYBE`. In Stage 1, ChatGPT-4o tended to produce confident binary classifications (40% YES, 60% NO, 0% MAYBE), whereas LLaMA-3.3 showed greater uncertainty, assigning 30% YES, 15% NO, and 55% MAYBE. Following domain-specific conditioning in Stage 2, both models showed improved calibration. ChatGPT-4o's MAYBE rate increased slightly to 2%, while LLaMA-3.3 reduced its MAYBE usage to 8%, achieving better balance across output categories. These shifts indicate a positive effect of domain exposure in aligning outputs with regulatory expectations.

B. Prompt Sensitivity and Variance

To complement the overall classification performance analysis, we examined the extent to which prompt phrasing influences model reliability. Each model was evaluated using five semantically equivalent prompt variants differing in structure and wording. Although this introduced some fluctuation, the overall impact on classification metrics was relatively minor, particularly for ChatGPT-4o.

As illustrated in Fig. 3 and Fig. 2, ChatGPT-4o maintained stable F1-scores across all five prompts in Stage 1, ranging from 60.61% to 70.59%, with a standard deviation of 4.33 percentage points. In Stage 2, the F1-score range expanded to 64.52%–75.29%, with a standard deviation of 4.24 percentage points, reflecting slightly greater variability under conditioning. Similarly, its accuracy fluctuated by only 6.97 percentage points between the best- and worst-performing prompt.

In contrast, LLaMA-3.3 exhibited greater prompt sensitivity in Stage 1, with F1-scores ranging from 63.41% to 72.22% and an accuracy spread of 11.62 percentage points. In Stage 2, the accuracy range narrowed to 4.65 percentage points, though F1-score variability remained comparable (62.86%–70.27%, standard deviation of 3.36 percentage points). This suggests modest gains in output consistency, but not a clear improvement in classification performance.

Prompt paraphrasing thus introduced measurable variation in classification performance across both models. Structured prompts that incorporated regulatory keywords or decision templates tended to elicit more consistent and context-aware outputs, whereas open-ended variants were more sensitive to ambiguity. ChatGPT-4o also exhibited lower overall variance in prediction confidence, suggesting more stable calibration under prompt variation.

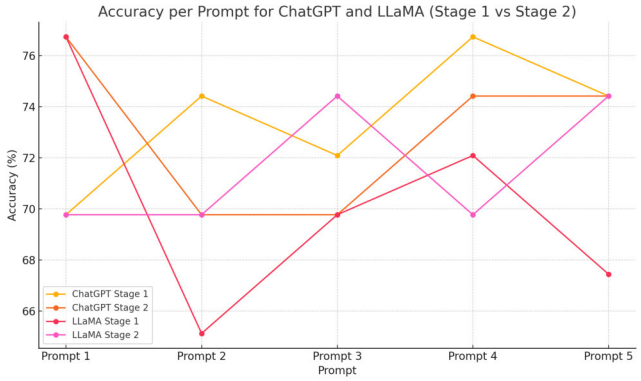

Fig. 2. Accuracy per prompt across ChatGPT-4o and LLaMA-3.3 in Stage 1 and Stage 2.

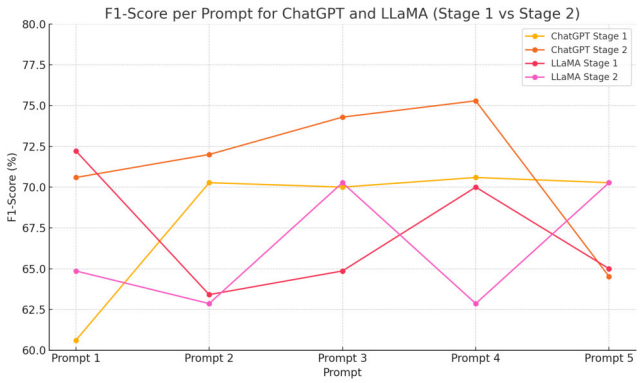

Fig. 3. F1-score per prompt for ChatGPT-4o and LLaMA-3.3 in Stage 1 and Stage 2.

C. Effect of Domain Conditioning

To evaluate the effect of domain-specific education, we compared model performance across all five prompt variants in Stage 1 (pre-conditioning) and Stage 2 (post-conditioning). This setup reflects how each model generalises its export control reasoning before and after exposure to the UK Strategic Export Control List.

Across all five prompt variants, ChatGPT-4o maintained a strong baseline with an average accuracy of 73.49% in Stage 1, and a comparable 73.02% in Stage 2. While the difference in accuracy was negligible, the model exhibited slightly improved calibration through more consistent outputs and reduced variance in confidence scores. LLaMA, by contrast, demonstrated more visible changes in response to domain conditioning. Its average accuracy improved from 70.23% to 71.63%. More notably, LLaMA-3.3's confidence in incorrect predictions decreased by approximately 8.8 percentage points which indicating better uncertainty management after incorporating regulatory context.

D. Reflective Inference Impact

Stage 4 introduced reflective prompting to evaluate whether large language models could revise incorrect classifications when explicitly asked to reassess their prior outputs. ChatGPT-4o corrected 4 out of 11 previous errors, resulting in a 36.36% resolution rate and an F1-score increase from 64.52% to 78.79%. In contrast, LLaMA-3.3 corrected none of its 11 prior misclassifications, and its F1-score declined due to additional false negatives.

A representative example illustrates this dynamic: ChatGPT-4o initially classified a cybersecurity research project with UK defence partners (e.g., RAF, Rolls-Royce) as controlled due to perceived dual-use concerns. After reflection, it revised the label to "not controlled," noting that the project lacked direct transfers or controlled components, and instead recommended internal review. This revision aligned with the expert's nuanced judgment and indicates improved reasoning alignment through structured metacognitive intervention.

These findings suggest that reflective prompting can enhance decision quality in models with sufficient contextual comprehension, such as ChatGPT-4o, but may be ineffective for models like LLaMA-3.3, which lack adequate task adaptation capacity or grounding.

E. Final Prompt Effectiveness

Stage 5 evaluated an expert-informed prompt based on institutional decision logic. As shown in Table I, this prompt led to the highest F1-scores for both models: 82.40% for ChatGPT-4o and 81.08% for LLaMA-3.3. ChatGPT-4o achieved balanced improvements in both precision and recall, while LLaMA-3.3's performance was driven by a substantial increase in recall 93.75%

TABLE I
PERFORMANCE USING EXPERT-INFORMED FINAL PROMPT (STAGE 5)

Model	Accuracy (%)	Precision (%)	Recall (%)	F1-Score (%)
ChatGPT-4o (Stage 1)	73.49	58.58	82.67	68.35
ChatGPT-4o (Stage 5)	86.00	77.80	87.50	82.40
LLaMA-3.3 (Stage 1)	70.23	54.89	86.67	67.10
LLaMA-3.3 (Stage 5)	83.72	71.43	93.75	81.08

The table and figure demonstrate that the expert-informed prompt (Stage 5) led to the best overall performance. ChatGPT-4o reached 82.40% with balanced precision and recall, while LLaMA-3.3 attained its highest F1-score 81.08% primarily through a notable increase in recall 93.75%.

F. Ambiguity Handling and Bias Evaluation

Model behaviour on ambiguous export control cases was assessed using five prompts with uncertain control status. ChatGPT-4o maintained high and stable average confidence

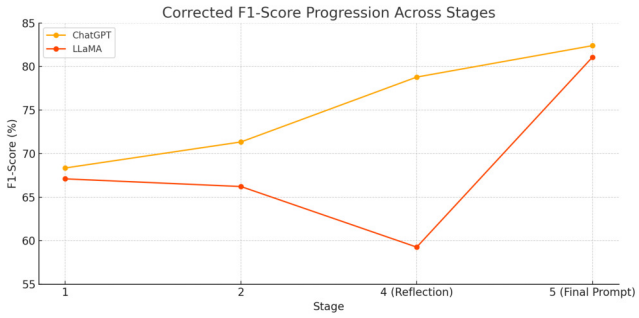

Fig. 4. F1-score progression across stages for both models. Stage 5 shows peak performance, with ChatGPT-4o reaching 82.40% and LLaMA-3.3 achieving 81.08%, driven by improved precision and recall.

levels across all prompts in Stage 1 85–92% and Stage 2 82–91%, as shown in figures 5 and 6. In contrast, LLaMA-3.3 exhibited broader fluctuations, with confidence levels ranging from 65% to 80%.

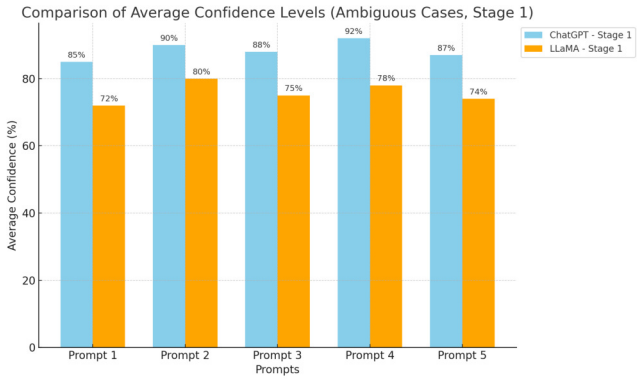

Fig. 5. Average confidence levels for ambiguous cases Stage 1. ChatGPT-4o shows higher and more consistent confidence than LLaMA-3.3 across all prompts.

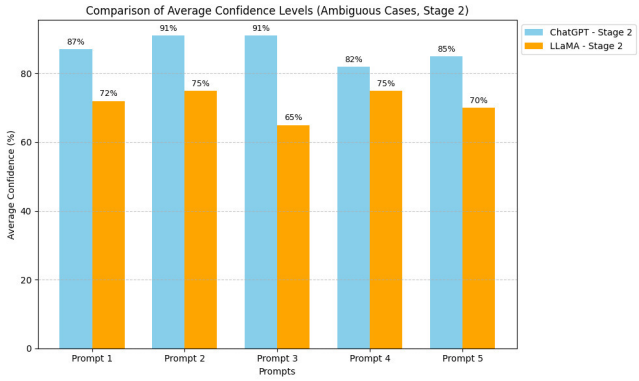

Fig. 6. Average confidence levels for ambiguous cases Stage 2. ChatGPT-4o maintains stable high confidence; LLaMA-3.3 remains more variable and generally lower.

Figure 7 illustrates the variance in confidence across stages. ChatGPT-4o's variance remained low and stable, at 43.7 in Stage 1 and 44.6 in Stage 2, whereas LLaMA-3.3's was substantially higher, at 180.3 in Stage 1 and 173.4 in Stage 2, indicating persistent volatility.

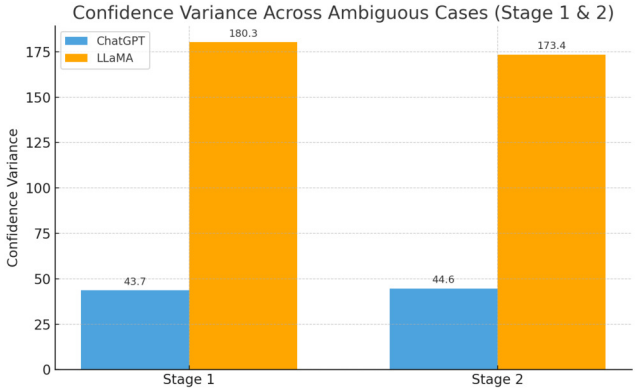

Fig. 7. Confidence variance on ambiguous cases. ChatGPT-4o shows stable variance across stages, while LLaMA-3.3's variance remains significantly higher, despite domain conditioning.

These findings suggest that ChatGPT-4o is better calibrated under uncertainty, whereas LLaMA-3.3 continues to exhibit erratic confidence distributions, reducing reliability in ambiguous classifications.

G. Bias in Partner Attribution

To evaluate the influence of institutional affiliation on compliance classification, we tested models on paired inputs with identical technical descriptions but different international partners. As shown in Table II, the inclusion of a non-EU collaborator (King Saud University) resulted in a classification change from "not controlled" to "controlled" for both ChatGPT-4o and LLaMA-3.3, despite no changes in project content, scope, or end-use.

The shift in decision was reflected in the model's generated justifications, which included references to U.S. export control frameworks (e.g., ITAR/EAR), reclassification of the technology as dual-use, and heightened concern over sensitive or military end-use. By contrast, substitution with a European partner (University of Amsterdam) produced no change in classification or in the model's accompanying rationale.

These findings indicate a model-level inclination to infer elevated risk based on geopolitical affiliation. These results suggest that models may be over-weighting partner nationality or geopolitical affiliation, even when the technical content of the project remains unchanged. This raises concerns about fairness and legal validity in automated screening, highlighting the need for explicit bias mitigation strategies in export control applications.

VI. Discussion

This study aimed to critically evaluate the capacity of large language models to reason about export control classifications using a staged framework. The experimental objectives focused on four dimensions of model behaviour: (1) prompt variation sensitivity, (2) the effect of domain-specific conditioning

TABLE II
IMPACT OF ADDING FOREIGN PARTNERS ON EXPORT CONTROL COMPLIANCE DECISIONS

Title	Project Partners	Organisation	ChatGPT-4o	LLaMA-3.3
XXXXXX	BT, Intel, Open Networking Foundation, Ori Industries 1 Ltd, Yale University, King Saud University (Saudi Arabia)	Univ. of Oxford	YES	YES
XXXXXX	BT, Intel, Open Networking Foundation, Ori Industries 1 Ltd, Yale University, University of Amsterdam	Univ. of Oxford	NO	NO

Note: For both examples shown above, the LLMs' original classification decisions (before the addition of new partners) were "NO."

("education"), (3) the impact of reflective prompting for error correction, and (4) the value of expert-informed structured prompts. In addition, model responses to ambiguous cases and bias-inducing input modifications were assessed to explore practical risks in regulatory deployment.

Prompt variation tests revealed that both models were somewhat sensitive to surface-level differences in input phrasing, though this effect was less pronounced than expected. ChatGPT-4o demonstrated stronger robustness to linguistic variation across all stages, aligning with findings by Bogireddy and Dasari [18], who observed consistent performance from ChatGPT-4o across diverse tasks. LLaMA-3.3, on the other hand, showed substantial variance in Stage 1, with up to 11.6 percentage points difference in accuracy across prompts. This instability improved notably post-conditioning. These results suggest that while prompt phrasing can influence model responses, its effect is comparatively modest in classification contexts, particularly for better calibrated models like ChatGPT-4o. Nevertheless, this sensitivity may still pose risks in high-stakes regulatory settings if users craft prompts inconsistently.

Domain-specific conditioning through the provision of the UK Strategic Export Control List was introduced in Stage 2 to simulate regulatory education. ChatGPT-4o's accuracy rose by just 0.1%, while LLaMA-3.3 improved by 0.6%. The more significant impact was observed in confidence calibration: LLaMA's confidence on incorrect predictions dropped by nearly 9 percentage points, indicating improved uncertainty management. More sophisticated grounding techniques, such as retrieval-augmented generation (RAG), may be required to meaningfully shift classification outcomes, as RAG models have been shown to improve factual accuracy, specificity, and task performance by combining pre-trained parametric memory with non-parametric knowledge sources [27].

Stage 4 explored whether models could improve their decisions through structured reflection. ChatGPT-4o successfully revised 36.4% of its prior errors, demonstrating an ability to align with regulatory expectations after self-assessment. This supports research by Lawal et al. [25], who found that prompting LLMs to reflect on prior outputs can lead to more policy aligned decisions. In contrast, LLaMA-3.3 failed to correct any outputs, reinforcing concerns around the model's adaptability and interpretive reasoning under pressure. The divergent performance highlights the need for models to not only generate initial outputs reliably but also to re-engage critically when prompted, particularly in domains that require explainability and self-consistency.

Stage 5 incorporated an expert-designed prompt that mirrored institutional export control procedures. This structured, decision-flow-based format led to the highest performance for both models, especially in recall. LLaMA-3.3's recall increased to 93.75%, a substantial leap from earlier stages. These results mirror findings from Al-Turki et al. [22], who showed that expert-guided input schemas can compensate for model instability. Unlike earlier stages, which tested the models' inherent flexibility, this final configuration emphasised alignment with operational logic. The results underscore the importance of designing prompts that do not merely inform the model but actively shape its reasoning observable in the generated outputs in a way that mirrors human expert processes. This strategy loosely aligns with principles of chain-of-thought prompting, where structured input sequences encourage more consistent and interpretable decision-making.

The final experimental tasks evaluated model behaviour in ambiguous or politically sensitive cases. ChatGPT-4o exhibited stable confidence across all uncertainty cases, while LLaMA-3.3 continued to show high variance. Bias testing further revealed problematic behaviours: both models flagged higher regulatory risk when international collaborators were from non-EU regions, despite identical technical content. This highlights the urgent need for robust bias mitigation strategies if LLMs are to be deployed in real-world compliance workflows.

In summary, the results suggest that while domain-specific input and expert-informed prompts can improve regulatory alignment, gains from prompt variation and naive domain conditioning remain modest. Models like ChatGPT-4o show stronger baseline reliability, while LLaMA-3.3 benefits more from external structure. Ultimately, consistent improvements were achieved only when expert logic was embedded directly into the input format, pointing toward the value of hybrid frameworks that combine human expertise with adaptable LLM reasoning.

Although Stage 5 achieved the highest performance metrics, it also required the most expert intervention and prompt engineering effort. In contrast, Stage 2 produced modest

but reliable gains with minimal human oversight, offering a more scalable compromise between accuracy and automation. Future deployment strategies may adopt a hybrid model, where expert input is reserved for edge cases flagged by lower-confidence outputs.

VII. Conclusion and Future Work

This study investigated the use of LLMs for export control classification of research disclosures, proposing a multi-stage, expert-in-the-loop framework. Through prompt variation, domain-specific conditioning, reflective prompting, and expert-informed refinement, we evaluated the classification performance and behavioural consistency of ChatGPT-4o and LLaMA-3.3. Our findings suggest that structured prompting and regulatory context can meaningfully enhance model reliability, with ChatGPT-4o demonstrating more consistent and interpretable outputs. However, challenges remain, particularly in handling ambiguous phrasing, edge cases, and politically sensitive affiliations.

Future work will address several areas. First, we plan to significantly expand the dataset, incorporating a broader range of research descriptions and licensing scenarios. This will enable more rigorous statistical analysis and improve generalisability. Second, we aim to evaluate additional LLM architectures, including newer open-source models and multilingual variants to assess comparative strengths across regulatory regimes. Third, we intend to explore the integration of automated outputs into institutional review processes, to assess whether human-machine collaboration improves both decision accuracy and accountability. Finally, we will extend this approach to adjacent compliance domains, such as sanctions screening and dual-use research oversight, where similar regulatory reasoning is required.

We also intend to experiment with retrieval-augmented generation (RAG) architectures to assess whether real-time document retrieval can enhance legal grounding and factual consistency, while monitoring for risks such as retrieval drift or hallucinated justifications.

***Abstract*—In recent years, plagiarism detection systems have evolved from basic lexical matching and n-gram overlap methods to Deep Learning (DL) models capable of capturing semantic relationships between texts. While these DL-based approaches have achieved notable success across various languages, their effectiveness in Arabic remains limited due to inherent linguistic ambiguities, particularly the omission of diacritical marks. This absence hinders accurate semantic interpretation and limits the ability of models to detect paraphrased or semantically obfuscated content in Arabic texts. This paper presents an evaluation of Arabic Text Diacritization (ATD) tools as the initial phase of a plagiarism detection framework designed for Arabic–English cross-lingual model text analysis (AraXLM). It describes the first stage of the framework, which focuses on assessing the performance of state-of-the-art ATD tools. An empirical analysis was conducted on six ATD models using Word Error Rate (WER), Diacritic Error Rate (DER), both with and without case endings (CE), and Bilingual Evaluation Understudy (BLEU) metrics. The results show that tools such as Shakkelha produced lower DER and high BLEU values, indicating high accuracy in diacritic restoration, while Fine-Tashkeel demonstrates the lowest WER and highest BLEU, reflecting best word-level performance. In contrast, CAMeL Tools and Mishkal display comparatively higher error rates across both metrics. These findings suggest that incorporating accurate diacritization models into Arabic NLP tasks, such as Machine Translation (MT) and Plagiarism Detection (PD), improves text normalisation and the quality of semantic embeddings. Thus, the AraXLM framework, supported by effective diacritization pre-processing, enhances linguistically aware detection of plagiarism involving Arabic text, where precise semantic alignment between languages is essential.**

***Index Terms*—Deep Learning (DL), Arabic Text Diacritization (ATD), Word Error Rate (WER), Diacritic Error Rate (DER), Case Ending (CE), Machine Translation (MT), Plagiarism Detection (PD), Bilingual Evaluation Understudy (BLEU).**

I. Introduction

DIACRITIC marks are a fundamental characteristic of the Arabic language. These symbols, placed above or below letters, indicate pronunciation and disambiguate meaning [1], [2]. Each mark has a specific position, Unicode representation, and functional role, influenced by syntactic and phonetic context. Diacritics are essential for accurate word interpretation, enhancing reading fluency, improving speech recognition systems, and facilitating natural language understanding. However, most Arabic texts omit these marks, which introduces semantic ambiguity and creates homographic conflicts [3].

A. Problem Statement

Recently, NLP techniques have started to include diacritical marks in their approaches to enhance language processing performance [4]. Most techniques used in plagiarism detection for the Arabic language preprocess the source document by removing the diacritic marks [5],[6]. The performance of these tests has still not improved due to pre-processing the document and not using semantic-based algorithms. The absence of diacritical marks in Arabic text introduces ambiguity that negatively impacts NLP tasks such as machine translation and plagiarism detection. Despite advances in deep learning and NLP, many systems either ignore diacritics or preprocess them away, limiting semantic accuracy and cross-lingual performance [7], [8]. Therefore, linguistic knowledge, such as vowel marks in Arabic language, needs to be addressed and evaluated in NLP tasks for enhancing semantic alignment across languages.

B. Research Questions

In order to address the issues that have been identified of applying and evaluating the ATD models, we will commence with these research sub-questions:

1) what is the most effective ATD tool for integrating into our proposed framework (AraXLM).
2) What issues are identified when conducting our experimental study, particularly for Arabic language?

The main research question is: given 2 sentences in different language, S1(English) and S2(Arabic), is S2 plagiarized from S1?

In order to answer this broad question, we defined the sub-questions that help to provide a complete answers to the overall research question. Our previous proposed framework was designed and presented for cross-language Plagiarism Detection (PD), including ATD as a linguistic feature [9]. The aim of our research contributes to detect the similarity between Arabic and English sentence pairs, including the diacritization process for Arabic sentences (see Figure 1). Diacritization is the process of adding diacritical marks (such as fatḥah, ḍammah, kasrah, shaddah, tanwīn, and sukūn) to unvowelled Arabic letters in order to indicate correct pronunciation and clarify meaning. This process is essential for various Natural Language Processing (NLP) tasks, such as MT, as it reduces the ambiguity caused by the absence of these marks. This paper presents the results of evaluating several tools concerning the accuracy of ATD.

In summary, our experimental design evaluates six Arabic diacritization tools using publicly available corpora. This study aims to identify the most effective Arabic ATD models to integrate into our proposed framework [9]. The evaluation employs three standard metrics: Word Error Rate (WER), Diacritic Error Rate (DER), and Bilingual Evaluation Understudy (BLEU). This multi-metric analysis provides a comprehensive comparison and deeper insight into the types of errors produced by each tool, with enhancing semantic accuracy in ML-based models. The results indicate that ML-based approaches achieve lower DER and higher BLEU scores, reflecting improved diacritic restoration and closer alignment with reference texts. However, these models produced higher WER, highlighting challenges associated with word-level tokenisation in Arabic, despite their character-level and semantic accuracy strengths.

II. Background

Arabic diacritization is a task in Arabic natural language processing (ANLP). These diacritics ensure correct pronunciation, disambiguation, and improved MT. However, the complex morphology of Arabic and the high level of ambiguity in unvowelled text make diacritization challenging task [10]. Over the years, researchers have developed various approaches to address this task, which can be categorized into three main types: rule-based, machine learning-based, and hybrid-based methods. Each approach employs different methodologies to overcome the challenges and develop accuracy in this field.

A. Rule-Based Diacritization Tools

Rule-based approaches apply diacritic marks based on predefined linguistic features (e.g., morphology, syntax, lexicon) [11]. In these tools, sequences of Arabic letters are mapped to specific diacritic categories through encoded rules derived from morphological analysers, syntactic parsers, and lexicon lookup tables [12]. However, pure rule based systems can fail with out of vocabulary (OOV) words and ambiguous contexts where multiple diacritic patterns may be valid. Moreover, validating the hundreds of rules and large lexicons required for comprehensive coverage can be time-consuming, error prone, and challenging to scale as the language evolves [12]. In contrast, rule-based diacritization tools achieve good result on words or structures explicitly defined within their linguistic frameworks, by applying deterministic rules derived from formal Arabic grammar.

B. Machine Learning Based Diacritization Tools

ML-based approaches for Arabic diacritization leverage neural networks (NNs) to learn and predict diacritic marks from text patterns. These approaches require datasets for training the model on diacritizing text pattern. ML algorithms can be categories to different types of Neural Networks (NNs): Artificial Neural Networks (ANNs), Convolution Neural Network (CNNs), Recurrent Neural Network (RNNs), and Transformer Neural Network (TNNs). Each type is used to process specific data and extract features that are relevant to the task.

FNNs are the simplest form of neural networks, consisting of input, interconnected hidden layers, and output layers. They process input data in a forward direction without cycles or loops [13]. FNNs have been used as baseline models for Arabic diacritization for capturing local patterns without requiring morphological pre-processing [14]. In ANNs types, back-propagation concept adjusts each weight in the layers. This step is done to eliminate the error (Loss) between the predicted output and the true target [15]. Thus, FNN is a subclass of ANN because the data flows on forward propagation only. However, there is no feedback loop in each node as outputs to inputs during inference. There-

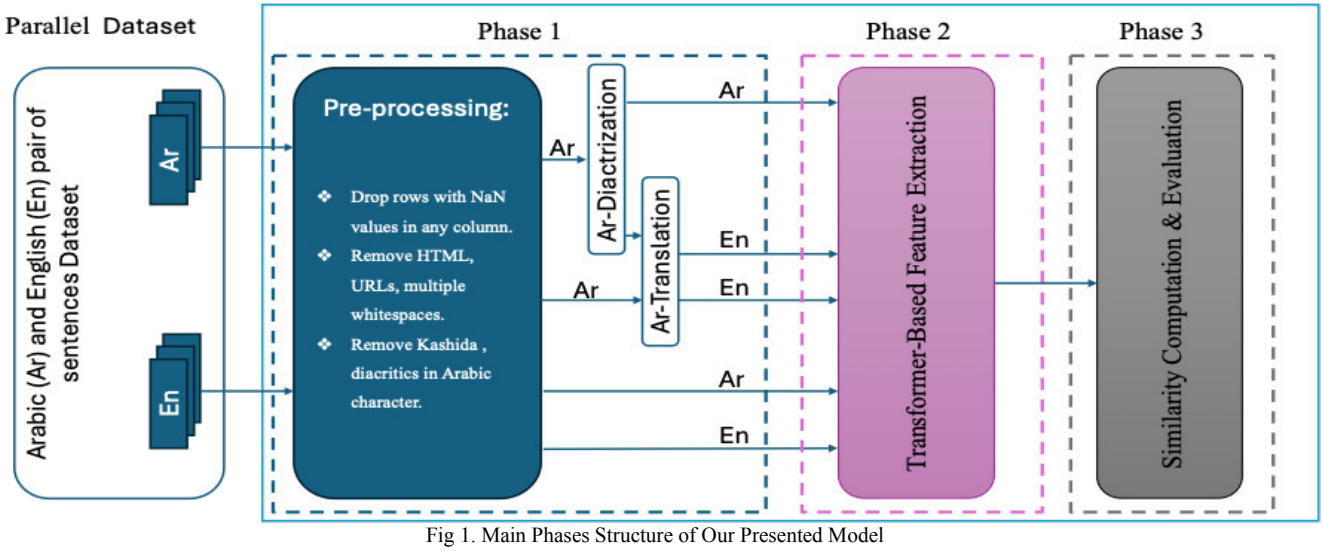

Fig 1. Main Phases Structure of Our Presented Model

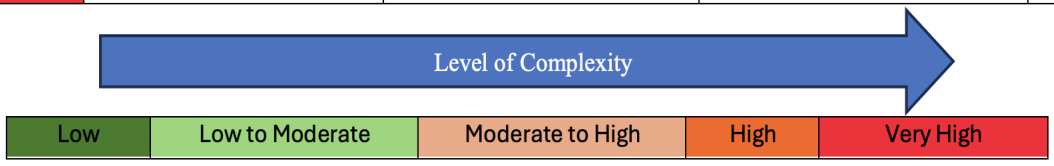
fore, their ability to capture syntactic diacritization, such as case endings, is limited.

CNNs apply convolutional filters over embedding vectors to detect local patterns and have been used in image and text processing tasks [16]. In Arabic diacritization, CNNs have been employed to recognize diacritic marks in images of Arabic text, such as in Optical Character Recognition (OCR) systems, rather than for direct sequence labelling of plain text.

RNNs enable each hidden unit to receive inputs from both the current and previous time steps, thereby allowing the network to capture temporal dependencies within sequential data [17]. By combining the current input with the previous hidden state, the network updates the current hidden state, which is then used to generate the output. This sequential modelling allows RNNs to predict diacritics for each character in context [18]. However, RNNs encounter difficulties when processing long sequences due to the gradient problem. The gradient represents the scale of change used to update the network during training. Over extended sequences, gradients can either vanish (become very small) or explode (grow very large), depending on the activation functions employed [19]. This occurrence causes the network to forget earlier information in the sequence, thereby limiting its ability to learn long-range dependencies.



The Transformer architecture was introduced to process data in parallel by replacing recurrence and convolution with positional encoding and self-attention mechanisms [20]. In this architecture, the encoder generates contextualized representations of the input sequence, which are used by attention mechanisms in the decoder to focus on relevant parts of the input during output generation. The transformer architecture can consist of encoder and/or decoder layers. Recently, TNNs have been employed in ATD models to capture both local and global contextual information in parallel [21]. As a result, TNNs models have transformed NLP by introducing attention mechanisms that address key limitations of earlier approaches [22]. TABLE I shows the main differences between neural network approaches types. For example, TNN leverage attention mechanism for tasks requiring long sequence dependency, such as NLP task. The emergence of NN types with ATD have driven the advancement of structure models.

C. *Hybrid Based Diacritization Tools*

Hybrid-based diacritization approaches combine rule-based and machine learning (ML) methods to leverage both linguistic knowledge and contextual information in text. These tools apply ML components to handle lexical disambiguation and rule-based frameworks for syntactic case endings, capitalizing on the strengths of both paradigms. [23]. Recent research has adopted hybrid approaches for Arabic diacritization, combining rule-based linguistic knowledge with ML techniques to enhance accuracy and address the

TABLE I.
OVERVIEW OF NEURAL NETWORKS AND THEIR FEATURES

NN Type	Complexity	Data Type	Task	Feature	Authors
FNN		Structured, tabular data	Traditional ML (Classification, Regression)	One Directional (forward) Connected Layer	[13], [14]
ANN		Structured, tabular data	Traditional ML (Classification, Regression)	Fully Connected Layer	[15]
CNN		Spatial Data (Image, Videos)	Object Detection, Image recognition, Image Processing Computer Vision	Convolution Layer, Pool Layer, Flattening Layer and Fully Connected Layer.	[16]
RNN		Sequential Data (Text, Time Series)	Weather (time series) Forecasting, Speech Recognition	Recurrent Layers with hidden states that maintain a memory of previous inputs	[17], [18]
TNN		Parallelized Data (Text, image, Audio)	NLP, Text Summarization, Question Answering, Translation, PD	Attention Mechanism	[19], [20]

complexities inherent in the language [24], [25]. However, these systems, incorporating ML components, remain under development for requirement of large and good quality annotated corpora for effective training [26], [27]. Therefore, integrating rule-based and ML models require alignment and coordination to ensure consistency and resolve conflicts between these components when deployed together in hybrid tools.

III. Experimental Setup

In ATD, several studies have established systematic benchmarks frameworks, based on manually curated and expertly validated datasets, as the gold-standard for evaluating Arabic diacritization tools [28], [29]. To determine the most effective ATD tools for Phase 1 of the proposed framework [9], we conducted experiment on six diacritization tools. This experiment focused on evaluating their ability to restore diacritic marks on Arabic sentences for subsequent processing. We employed a repeated measures (within-subjects) design [30], in which each sentence (experimental unit) was processed by every diacritization tool (treatment) in the same order. This setup was designed to test the hypothesis that diacritization enhances the semantic clarity of Arabic text and aligns it more closely with its English counterparts for the next Phase.

A. Experiment Design

The dataset used in this experiment was designed by Alasmary in 2024 and consists of 742 sentences collected from internet sources covering various topics such as science, art, sport, and culture [28]. The author introduced this benchmark, known as the Character-based Arabic Tashkeel Transformer (CATT) dataset, to evaluate different ATD tools. All sentences were manually diacritized by native Arabic speakers and subsequently validated by experts to establish a gold-standard reference.

Preparation of the Arabic dataset for assessment involved several steps to ensure data quality. For example, text normalization was performed to eliminate noise caused by foreign symbols (non-Arabic characters). Second, numerical digits were converted from their digital (numeric) form into textual form, thereby ensuring the dataset is fully normalized and ready for use without additional pre-processing. This conversion is used during preparation, because Arabic numbers are represented in different numeral systems depending on regional preferences and historical influences [31]. TABLE II shows three Arabic numeral systems may appear in Arabic texts. These pre-processing steps ensure the dataset is standardised and ready for direct use without extra modification.

TABLE II.
NUMERL SYSTEMS IN ARABIC LANGUAGE [30]

System	Digit
1-Arabic numerals-European	0 1 2 3 4 5 6 7 8 9
2-Arabic-Indic	٩ ٨ ٧ ٦ ٥ ٤ ٣ ٢ ١ ٠
3-Eastern Arabic-Indic	۰ ۱ ۲ ۳ ۴ ۵ ۶ ۷ ۸ ۹

B. Evaluation Metrics

We conducted our experiment using six Arabic diacritization tools and evaluated their performance by calculating the WER and the DER metrics. However, Arabic grammar requires different evaluation rules for diacritics on the final letter of words [32] as follow:

- Full Diacritization, including case endings (CE).
- Core-Word Diacritization, excluding CE.

Therefore, WER and DER can be reported with and without case endings. Each rule is used to provide distinct insights into performance measurements. For example, error rates with CE measures overall performance, including syntactic case endings that influence sentence meaning. Whereas error rates without CE measures the model's ability to restore word-internal morphology.

The `diacritization_evaluation`[1] Python package is used to calculate DER and WER metrics, relying on a predefined set of Arabic characters stored in its configuration files. The DER is computed by the file `der.py` as the percentage of mismatched diacritics-those that differ from the reference gold-standard text file over the total number of diacritic comparisons (matches and mismatches), rounded to two decimal places (see Equation 1). Similarly, the WER is calculated by the file `wer.py` as the percentage of mismatched words-those that differ from the reference gold-standard text file over the total number of word comparisons (matches and mismatches) (see Equation 2).

$$DER = \frac{Number\ of\ mismatched\ diacritics}{matched + mismatched} \quad (1)$$

$$WER = \frac{Number\ of\ mismatched\ words}{matched + mismatched} \quad (2)$$

Moreover, the BLEU (Bilingual Evaluation Understudy) metric is used to evaluate the quality of ATD models alongside WER and DER, providing a comprehensive assessment of diacritization performance. BLUE metric developed for machine translation (MT) evaluation, but it can be applied to measure the output of Arabic diacritization tools [33]. There are two types of BLEU metrics: word-level and character-level. In word-level BLEU, n-gram overlaps (default n=4) between the gold-standard dataset and the output file from the ATD models are computed, with mismatched diacritic marks counted as errors. Character-level BLEU, on the other hand, treats each Unicode code-point as a separate token for comparison.

C. Tools Performance

The following diacritization tools were compared in the experiment: CAMel Tools [34], Farasa [27], Mishkal [35], i2Text[2] online tool, Fine-Tashkeel [29] and Shakkelha [36]. These tools and their associated Python packages were implemented using the NVIDIA A100 GPU runtime on Google

[1] https://pypi.org/project/diacritization-evaluation/#files
[2] https://www.i2text.com/diacritize-arabic-text

Colab Pro. Since the experimental setup relies on multiple packages and modules written in Python, the scripts and files used in our tests were modified to suit our needs. The modifications are detailed as follows:

- Farasa Tool: The `diacritization_evaluation` package DER and WER using a predefined set of Arabic characters. However, the output generated by Farasa included a combined diacritic not originally present in the package's character file. To ensure accurate error rate calculation, we added this new diacritic mark to the set. Notably, this mark results from the combination of Shaddah and Sukun into a single diacritic, which is not standard in Arabic but appeared during the diacritization process by the Farasa tool.
- Mishkal tool, The output text file from the Mishkal tool represents the Tanween vowel as a combination double vowel (e.g., `Fatha+Fatha`). However, Tanween and Fatha have different Unicode representations when processed as diacritic marks. To handle this, we updated the diacritization_evaluation pack-age to recognize `Fatha + Fatha` as Tanween. During testing, Mishkal produced other compinged marks, such as `Fatha + Kasra`, `Kasra + Kasra`, and `Sukun + Sukun`, which we similarly added to the package's set of recognized diacritic characters.
- Fine-Tashkeel, We tokenised the input file and set the parameter `max_new_tokens=512` when invoking `model.generate` to process texts longer than the model's default context window of 128 tokens. This tool took long time (e.g., 5 hours) to diacritize the text file.

IV. Results of The Experiment

The results obtained from applying the selected ATD models using CATT benchmark are presented below:

A. WER and DER Evaluation

TABLE III and Figure 2 presents the evaluation results using WER and DER, both with and without case endings (CE). In the context of Arabic diacritization, lower WER and DER values indicate fewer errors and therefore better tool performance.

TABLE III.
WER AND DER IN % OF EVALUATED ATD TOOLS

Diacritization Tool	Case Ending %		No Case Ending %	
	WER	DER	WER	DER
CAMeL Tools	75.85	71.71	56.84	69.86
Farasa	65.79	18.04	59.99	18.47
Mishkal	60.92	74.59	39.33	73.16
Fine-Tashkeel	35.70	67.73	30.24	67.28
i2text	61.04	21.14	39.30	17.39
Shakkelha	47.45	13.22	37.76	12.0

The results show that Shakkelha and i2text yield the lowest DER values, particularly when case endings are excluded, reflecting their effectiveness in diacritic restoration at the character level. In contrast, the generation of merged and non-standard diacritic combinations during the diacritization process affected the performance and the output quality of tools such as Mishkal and Farasa. These irregular patterns introduced inconsistencies in the evaluation and interpretation of the diacritized output, which is reflected in their elevated DER scores despite achieving moderate WER. This indicates that while token-level segmentation can be acceptable, the character-level precision required for reliable diacritic restoration remains insufficient in these tools.

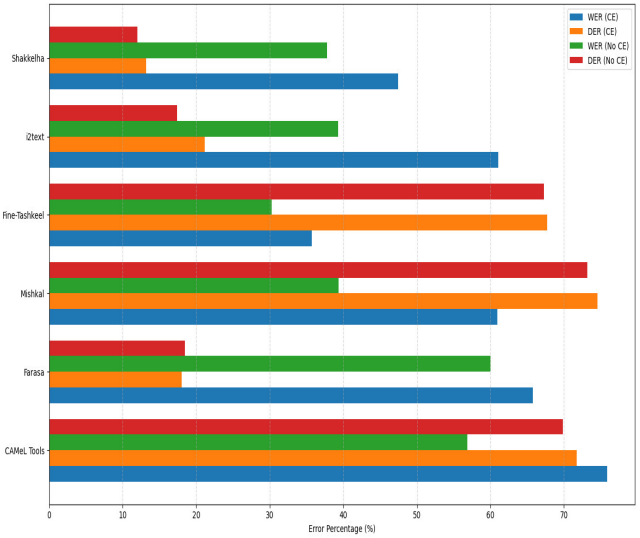


Fig 2. WER and DER by Arabic Diacritization Tool (with/without Case Endings)

Fine-Tashkeel, which leverages a fine-tuned multilingual transformer model (ByT5) with integrated tokenisation, generates fully diacritized text by assigning a diacritic to every character and applying multiple diacritic marks to some characters. This approach results in a lower WER, as words are correctly segmented. However, it leads to a higher DER, since the model introduces unnecessary or additional diacritics, increasing character-level errors. During the rendering of diacritic marks, several issues were introduced (see TABLE IV), including incorrect diacritic substitutions (e.g., fatḥah replaced with kasrah), and the addition of unintended punctuation such as parentheses or colons. These errors highlight the need for enhanced morphological awareness and post-processing techniques to improve the accuracy of diacritic restoration and ensure better alignment with gold-standard references.

TABLE IV.
IDENTIFIED ISSUES IN FINE-TASHKEEL' ATD TOOL

Gold-Standard Reference	Fine-Tashkeel Prediction
اِنْتَقَلَتْ إِلَى رَحْمَةِ اللهِ تَعَالَى	انْتَقَلَتْ إِلَى رَحْمَةِ اللَّهِ تَعَالَى
فَعَالِيَّتَها فِي تَقْلِيلِ نِسَبِ الْإِصابَةِ وَلَيْسَ مَنْعُها بِالْكامِلِ	فَعَالِيَّتَهَا فِي تَقْلِيلِ نَسَبِ الْإِصَابَةِ وَلَيْسَ مَنْعُهَا بِالْكَامِلِ)
النَّجْرِبَةِ مَرَّةً أُخْرَى	النَّجْرِبَةِ مَرَّةً أُخْرَى:

On the other hand, CAMeL Tools tokenises each word independently and applies diacritics using the `mle.disambiguate` function. However, it introduces additional diacritical marks, such as maddah and hamza, that were not present in the original undiacritized input. TABLE V compares the output of CAMeL Tools with the gold-standard diacritized reference. Each row shows a separate sentence from the dataset, highlighting the performance of the tool in restoring Arabic diacritics. It demonstrates inconsistent performance when handling morphological structures and complex verb forms. The model shows orthographic overcorrections, including the unnecessary insertion of the dagger alif, duplication of shaddah, and frequent mismatches in grammatical case endings. As a result, both its WER and DER are high due to the inclusion of these extraneous diacritics, which negatively impact alignment with the reference text.

TABLE V.
IDENTIFIED ISSUES IN CAMEL TOOLS' ATD

Gold-Standard Reference	CAMeLTools Prediction
نَجَحَ مُسْتَشْفَى الْمَلِكِ سَلْمانَ عُضْوٌ تَجَمُّع الرِّياضِ الصِحِّيّ الْأَوَّلِ فِي تَثْبِيتِ كَسْرِ مُضاعَفٍ وَمُهَشَّمٍ لِعَضُدٍ مُصابَةٌ إِثْرَ تَعَرُّضِها لِلسُّقُوطِ	نَجَحَ مُسْتَشْفَى المَلِكُ سَلْمان عُضْوٌ تَجْمَع الرياضِ الصِحِّيّ الأَوَّل فِي تَثْبِيتُ كَسْرِ مُضاعَف وَمُهَشَّم لِعَضُد مُصابَةٌ أَثْرَ تَعَرُّضِها لِلسُّقُوطِ
وَاخْتُتِمَ الْمِرانُ بِمُناوَرَةٍ عَلَى جُزْءٍ مِنَ الْمَلْعَبِ	وَاخْتَتَمَ المَرْآن بِمُناوَرَة عَلَى جُزْء مِن المَلْعَبِ
إِذا طَلَعَتِ الْجَوْزاءُ فَامْلَأِ الْحَوزاءَ	إِذا طَلَعَتْ الجَوْزاء فَأَمْلا الحوزاء

غَفَرَ اللهُ لَها وَرَحِمَها	غَفَرَ اللهُ لَها وَرَحِمَها

B. BLEU-Based Evaluation

To provide a more comprehensive evaluation of diacritization quality, beside WER and DER, this study incorporates the Bilingual Evaluation Understudy (BLEU) metric. BLEU offers a corresponding perspective by measuring the degree of n-gram overlap between the predicted and reference outputs.

As represented in TABLE VI and Figure 3, BLEU scores were calculated at both the word level and character level to capture accuracy across different linguistic features. In addition, we employed `camel_tools.tokenizers` to reflect token-based alignment accuracy in Arabic text. This BLEU metrics evaluation enables a more understanding of how effectively each tool restores diacritics in ways that are compatible with downstream token-based NLP tasks. The word-level BLEU scores remain low across all tools, reveal-ing penalties for tokenisation mismatches and sensitivity to n-gram overlap. In contrast, character-level BLEU scores are higher, as this metric treats each Unicode character as a token, making it more suitable for assessing diacritic placement precision at the subword level. Shakkelha performs well in character-level and tokeniser-based BLEU, suggesting good subword precision and compatibility with token-based Arabic NLP frameworks. In contrast, CAMeL Tools shows the lowest scores across all BLEU metrics, consistent with its poor performance in WER/DER due to added and misaligned diacritics within sentence structure.

TABLE VI.
BLEU IN % OF EVALUATION ATD TOOLS

Tool	Diacritized %		Diacritized with camel_tools.tokenizers
	Word-level BLEU	Char-level BLEU	
CAMeL Tools	2.97	66.95	2.94
Farasa	7.94	71.55	7.87
Mishkal	13.01	78.44	13.27
Fine-Tashkeel	39.36	86.80	38.74
i2text	12.98	78.32	13.24
Shakkelha	25.07	81.72	24.69

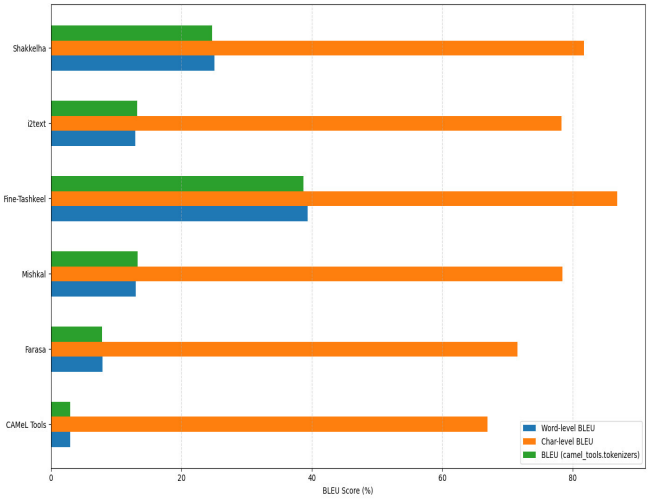

Fig 3. Comparison of BLEU Scores for Arabic Diacritization Tools

We conducted a Unicode-level analysis comparing the predicted outputs against the gold-standard references. As illustrated in TABLE VII. For instance, this is one diacritized pair:

Original no-Diacritic Marks:
"وأكدت الحوسني في إفادتها أن اللقاحات المضادة لفيروس كورونا أثبتت فعاليتها في تقليل نسب الإصابة وليس منعها بالكامل"

Gold-Standard Reference:
"وَأَكَّدَتِ الْحُوسَنِي فِي إِفَادَتِهَا أَنَّ اللِّقَاحَاتِ الْمُضَادَّةَ لِفَيْرُوسِ كُورُونَا أَثْبَتَتْ فَعَالِيَّتَهَا فِي تَقْلِيلِ نِسَبِ الإِصَابَةِ وَلَيْسَ مَنْعُهَا بِالْكَامِلِ"

Predicted by Fine-Tashkeel:
"وَأَكَّدَتِ الْحَوْسَنِيُّ فِي إِفَادَتِهَا أَنَّ اللِّقَاحَاتِ الْمُضَادَّةَ لِفَيْرُوسِ كُورُونَا أَثْبَتَتْ فَعَالِيَّتَهَا فِي تَقْلِيلِ نَسَبِ الإِصَابَةِ وَلَيْسَ مَنْعُهَا بِالْكَامِلِ"

The results showed several differences were identified at the character encoding level that impact the accuracy and evaluability of the tool's output. These irrelevant characters are introduced during token reconstruction and text formatting, and they do not reflect linguistic features. Their presence negatively affects character-level and word-level metrics. Furthermore, the predicted output included duplicated diacritics (e.g., double fathah, parenthesis, dot) and altered character spacing that increased the total Unicode code point count, which was not present in the original input or reference.

In summary, the Pearson correlation coefficient was used to calculate the correlation for understanding the linear relationship between different error rates across Arabic diacritization tools (see Figure 4). The results indicated that WER and DER measure different aspects of model performance and do not strongly correlate with each other. WER is relevant to downstream tasks such as MT and text-to-speech, where word-level accuracy is critical, while DER provides assessment of diacritization quality, making it suitable for evaluating ATD models.These findings highlight the importance of evaluating both WER and DER separately, and demonstrate how correlation analysis can guide the selection or improvement of diacritization models.

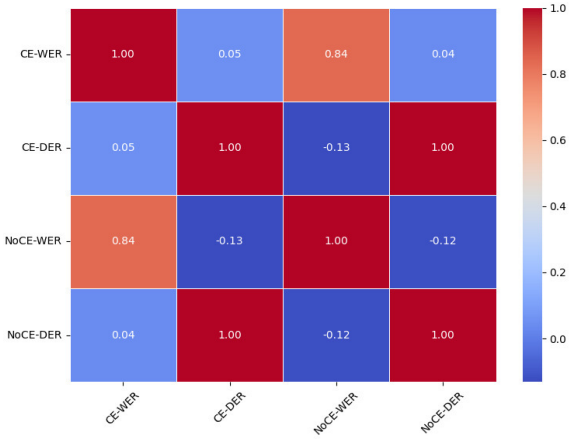

Fig 4. Pearson Correlation Matrix between WER and DER of ATD

V. EMPIRICAL EVALUATION OF FINE-TUNED TRANSFORMER MODELS FOR DIACRITIZED ARABIC-ENGLISH STS

In our proposed framework, a transformer-based approach is employed to effectively address the challenges of cross-lingual STS, with a particular focus on Arabic-English sentence pairs. The Arabic input is diacritized by Shakkelha prior to training, enabling the model to better disambiguate meanings and improve alignment with corresponding English texts. By incorporating fine-tuning into our approach, the transformer encoder is adapted to the specific semantic and linguistic characteristics of the dataset. In order to select the appropriate XLM-R variant for our model, we conducted a comparative evaluation of three XLMR-based transformer encoders by empirical experimentation. The chosen models were tested on an Arabic-English STS dataset, STS-Benchmark has 250 pairs and introduced in 2017, with Arabic sentences diacritized before and after training the models. This STS benchmark contains a variety of semantic similarity levels showing moderate similarity label balance. Then, the score in this dataset was normalized from [0 – 5] to [0 – 1] for fine-tuning. Normalizing STS scores to the [0 – 1] range is standard preparation in sentence embedding models with STS task and is fundamental for correct training and

evaluation. The dataset was randomly divided using the train_test_split function from scikit-learn, with 80% of the sentence pairs used for training and the remaining 20% reserved for development (dev) validation. This split was applied to the pre-processed and normalized STS-labelled CSV data to ensure a clear separation between training and evaluation samples. The results are summarised in TABLE VIII, which presents the Pearson correlation coefficients computed on the development (dev) set before and after fine-tuning. It shows the effect of fine-tuning five different multilingual sentence encoders on a SemEval Semantic Textual Similarity task using Arabic text that has diacritization by ATD tool. The metric used to evaluate the effectiveness of fine-tuning is the Pearson correlation coefficient (r) between the predicted similarity scores and the gold standard labels, along with p-values to test statistical significance. Pearson correlation measures the degree of linear association between the similarity scores produced by the model and the human-annotated gold-standard similarity scores. Evaluation on the dev set, rather than the training set, ensures an unbiased estimation of the model's generalization performance on unseen data and avoid the risk of overfitting or performance inflation due to exposure to training data. In addition to the correlation coefficients, corresponding p-values are reported to assess the statistical significance of the observed correlations. A low p-value (significant if $p < 0.05$) indicates that the correlation is unlikely to have arisen by random chance under the null hypothesis of no association, thereby supporting the reliability and validity of the model's semantic alignment with human judgments. Based on these results, model 1 & 2 are statistically significant because the null hypothesis (Fine-tuning the encoder on diacritized Arabic text does not affect performance on the STS benchmark) is rejected. Therefore, the paraphrase-xlm-r-multilingual-v1 model that achieved the highest Pearson correlation scores both before and after fine-tuning was selected for use in AraXLM. Fine-tuning this encoder model on diacritized Arabic text enhances semantic similarity detection, particularly when applied to paraphrase pretrained multilingual encoder variant.

TABLE VIII.
EXPERIMENTAL RESULTS OF PEARSON CORRELATION PRE- AND POST-FINE-TUNING ON DEV ATD SET

#	Model	Pearson Correlation (Before)	P-Value	Pearson Correlation (After)	P-Value

5	xlm-roberta-large	-24.32%	0.088	5.94%	0.68

VI. COMPARISON WITH OTHER APPROACHES IN STS TRACK2

The SemEval-2017 STS Cross-lingual Arabic-English task provided benchmark reference systems against which new approaches can be evaluated [37]. The ECNU [38] and BIT [39] systems reported Pearson correlation scores of 0.74 and 0.69 , respectively, on the official test set[3]. In comparison, the fine-tuned variant incorporating diacritized Arabic text demonstrated competitive performance. The evaluated textual inputs included:

- The original English sentence from STS (En)
- The original Arabic sentence from STS (Ar)
- The Arabic-to-English translation of Ar (Ar-TrE)
- The diacritized Arabic sentence (ArATD)
- The translation of ArATD into English (ArATD-TrE)

ArATD_TrE_CosineSimilarity and FAISS IP (Inner Product) achieved the highest Pearson correlation scores of 0.78 and 0.77, respectively, outperformed both ECNU and BIT baselines (see TABLE IX). Additionally, Ar_TrE_CosSim exhibited strong performance (Spearman: 0.80, Pearson: 0.77), closely aligning with the top-performing metrics. These results confirm that leveraging translated and diacritized Arabic variants significantly enhances cross-lingual semantic similarity detection.

TABLE IX.
COMPARATIVE EVALUATION BASED ON STS DATASET

Metric	Spearman Correlation	Pearson Correlation
ECNU	NA	0.74
BIT	NA	0.69
IP_Score_FAISS	0.81	0.77
ArabicSentence_CosSim	0.75	0.72
Ar_TrE_CosSim	0.8	0.77
ArATD_CosSim	0.35	0.33
ArATD_TrE_CosSim	0.81	0.78

VII. DISCUSSION OF THE RESULTS AND CONCLUSION

This study aimed to evaluate the performance of six ATD tools for Arabic using established metrics, WER, DER, and BLEU. In response to research sub-question 1: What is the most effective ATD tool for integration into our proposed framework (AraXLM)?

Our experiments demonstrated that Shakkelha, a deep learning-based tool designed for Modern Standard Arabic, outperformed other models across key evaluation metrics. It achieved high character-level BLEU scores and low DER when case endings were excluded, making it the most effective candidate for integration into the AraXLM framework.

In response to research sub-question 2: What issues are identified when conducting our experimental study, particularly for Arabic?

Several challenges were noted, including:

- A significant increase in WER (up to 16 percentage points) when syntactic case endings (CE) were restored.

[3] https://docs.google.com/spreadsheets/d/1a5ZNg5IqKnBLaNKHMyVvmAn2_xc79FqwbXLL5z4ABAk/edit?gid=0#gid=0

- Difficulties in tokenising diacritized Arabic, due to non-standard outputs (e.g., merged diacritics like shaddah with sukun, or irregular representations of tanwīn).
- Variability in how tools apply full diacritization, sometimes leading to redundant or incorrect diacritic marks.

These issues highlight both linguistic and technical limitations in current ATD models when applied to Arabic morphology and syntax.

The results highlight that fully diacritizing every character is not always good and may introduce noise or errors, thereby skewing evaluation metrics and negatively impacting downstream NLP applications. The merging of diacritics (e.g., shaddah with sukun) and inconsistent representations (e.g., tanwīn as repeated fatha) complicate tokenization and evaluation.

These findings emphasize the requirement of standardised evaluation methodologies and tokenization practices that are sensitive to Arabic's unique linguistic structure. The implementation of robust ATD models is vital not only for accurate diacritization but also as a foundational layer in advanced NLP tasks such as semantic search and plagiarism detection across languages. The study also supports the integration of linguistic knowledge with deep learning models, showing the way for adaptable and accurate transformer-based systems in low-resource languages, such as Arabic.

Despite the insights gained from the results, it was limited by the lack of gold-standard diacritized datasets and the narrow range of tools, many of which were trained on specific text domains. Additionally, integrating these tools into Python required adjustments due to the complexity of Arabic script and morphology.

In conclusion, this study highlights the importance of accurate ATD for improving ANLP,and supports the integration of Shakkelha as the most effective tool within the proposed AraXLM framework. The results demonstrate its consistent performance across key evaluation metrics, while exposing limitations in current tokenisation and evaluation methods. These findings underscore the need for linguistically informed, standardised pre and post-processing approaches tailored to the structural complexity of the Arabic language.

In future work, the next phase investigate how diacritization affects cross-lingual semantic similarity in AraXLM. We plan to integrate ATD outputs within our proposed AraXLM framework to enhance performance in cross-lingual semantic similarity tasks with FAISS vector-based. This integration aims to improve accuracy, contextual adaptability, and the robustness of transfer learning systems in Arabic-English applications.

***Abstract*—Pneumonia is a disease that impacts millions of people worldwide, and X-ray image detection is one of the primary diagnostic tools used. This study presents a hybrid diagnostic approach combining Convolutional Neural Networks (CNNs) with traditional classifiers, namely Random Forest (RF) and Support Vector Machine (SVM), to detect pneumonia from chest X-ray images. Features were extracted from MobileNetV2, VGG16, and EfficientNetB0 and used to train RF and SVM models with hyperparameter tuning via GridSearchCV. Ensemble models were also explored: (i) CNNs + RF, (ii) CNNs + SVM, and (iii) RF + SVM. Experiments were conducted using a public pediatric dataset (5.856 X-rays) with stratified k-fold cross-validation and data augmentation. CNNs + RF achieved the highest 0.977 AUC and 91.9% accuracy, while individual models like VGG16 showed competitive performance (91.8% accuracy, 0.969 AUC). Results were statistically validated and showed strong potential for clinical support, particularly in settings with limited resources. In future work, we propose extending the approach to multiclass classification and refining model optimization strategies.**

***Index Terms*—Deep Learning, Ensemble Learning, Medical Imaging**

I. Introduction

PNEUMONIA is one of the leading causes of death globally. According to the World Health Organization (WHO)[1], over 808,000 children under the age of five died from pneumonia in 2017, which accounted for 15% of all deaths in that age group. Additionally, data from the 2024 Global Burden of Disease study conducted by the Institute for Health Metrics and Evaluation[2] revealed that the highest mortality rates from pneumonia in 2019 were among individuals aged 70 and older. In Brazil, prolonged droughts and recent Amazon wildfires have worsened air quality and increased respiratory illnesses, especially among children, highlighting the need for urgent public health action, as confirmed by a 2024 UNICEF report[3] [1].

X-ray imaging has become a standard method for detecting pneumonia. However, manual interpretation of these images requires time and expertise from health professionals [2]. In addition, there has been a significant increase in the costs associated with diagnostic imaging, especially in universal healthcare systems such as the Brazilian or the British ones, where resources are often limited and unevenly distributed [3]. In this context, deep learning methods have shown potential for optimizing the diagnostic process, reducing costs, and increasing efficiency and accessibility [4].

Sharma et al. [4] systematically review pneumonia detection studies using chest X-ray images, presenting models based on Convolutional Neural Networks (CNNs), pre-trained, and Ensemble models. The latter, which combines the predictions of different architectures, has outperformed individual models in metrics such as accuracy, sensitivity, and specificity. Each implementation has advantages and disadvantages, depending on the data characteristics and the number of samples. Models based on CNNs can extract relevant features directly from X-ray images, but face challenges related to the need for large volumes of data to avoid overfitting [5]. Pre-trained models have shown high efficiency due to transfer learning, reducing training time, and using prior knowledge. Ensemble models excelled, achieving an accuracy of up to 99.61% in some studies [6], due to the integration of complementary architectures [4], [7].

Despite these advances, few studies have explored how traditional classifiers, such as Random Forest (RF) or Support

[1]https://www.who.int/health-topics/pneumonia
[2]https://ourworldindata.org/pneumonia
[3]https://bit.ly/4jzNPXy

Vector Machines (SVM), perform with features extracted from modern CNNs. This combination may offer benefits in scenarios with limited data or noisy inputs [8], [9]. Moreover, many works do not assess the statistical significance of model comparisons or provide publicly available code to support reproducibility, issues increasingly emphasized in recent reviews [10].

Inspired by recent advances in deep learning and hybrid modeling, this study proposes a classification pipeline that combines CNN-based feature extraction (*e.g.*, MobileNetV2, EfficientNetB0, and VGG16) with traditional machine learning classifiers, namely RF and SVM. Additionally, ensemble models that aggregate predictions from multiple classifiers are evaluated. The objective is to assess whether conventional classifiers can outperform end-to-end deep models when leveraging CNN-derived features and whether combining predictions improves diagnostic accuracy. The approach is applied to the publicly available pneumonia X-ray dataset by [11], with experiments incorporating hyperparameter tuning, data augmentation, and statistical validation to ensure reproducibility.

The results demonstrate the potential of hybrid pipelines in improving diagnostic performance, particularly their applicability in low-resource clinical settings. By integrating deep learning with lightweight classifiers, the approach seeks to balance diagnostic efficacy with computational efficiency, contributing to scalable and affordable diagnostic tools for real-world healthcare settings.

The remainder of this paper is organized as follows: The related works are discussed in Section II. The proposed method is described in Section III, and results are presented in Section IV. Finally, conclusions, limitations, and directions for future work are given in Section V.

II. Related Works

General studies in the field of medical diagnostics show that image analysis, such as X-rays, is one of the main tools for detecting diseases, including pneumonia [12], [6], [7], [13], [9]. According to [4], the early diagnosis of pneumonia via chest images is widely studied, with approaches ranging from CNNs created from scratch to pre-trained models (*e.g.*, VGG16, VGG19, DenseNet, ResNet, and Inception) and ensemble techniques. The study highlights the benefits of deep learning for feature extraction and classification, emphasizing the relevance of combining deep feature extractors with traditional machine learning classifiers such as SVM, KNN, and RF. Additionally, the authors discuss challenges such as limited datasets, the need for data augmentation, the absence of standardized comparisons across models, and insufficient studies on hyperparameter tuning. Although the reviewed models have shown promising results, they suggest that further improvements are possible, primarily through more diverse datasets and integrating multiple architectures and classification strategies.

Diniz et al. [12] describes a novel algorithm for diagnosing breast cancer in ultrasound images, called EfficientNet Ensemble, evaluating many image preprocessing methods and data augmentation. The proposed method can extract Regions of Interest (ROIs), apply guided and median filters, and train three EfficientNet variants (B0, B1, B2) combined in an ensemble with majority voting. After adjusting the hyperparameters (learning rate, batch size, and epochs), the method achieved 96.67% accuracy, outperforming the individual EfficientNetB0 (86.57%) and several other related studies. The architecture demonstrated the benefits of integrating preprocessing with CNN ensembles.

Munzlinger, Yepes, and Rieder [14] presented a detector of COVID-19, pneumonia, and tuberculosis in chest X-rays. The system is based on the ResNet-50 architecture, employing transfer learning. After model adjustments, custom dense layers were added, and the last five layers were trained while retaining the pre-trained weights. The model was trained on a dataset of 7,097 images collected from multiple open repositories (Kaggle, Vindr-CXR, FIPS), achieving an accuracy of 89%, slightly below the predefined goal of 90%, due to computational constraints (Google Colab limit of 100 epochs).

Toğaçar et al. [6] proposed a hybrid classification model combining CNN feature extraction (VGG16, VGG19, and AlexNet) with traditional machine learning classifiers such as SVM and LDA. The features extracted from the final fully connected layers were reduced using the mRMR (minimum Redundancy Maximum Relevance) method to 100 per model, and then concatenated. Their approach achieved an accuracy of up to 99.41%, showing that combining CNN-derived features with classical classifiers can yield highly competitive results. This highlights the potential of hybrid pipelines and reinforces the motivation for exploring CNN + ML classifier combinations in this study.

Varshni et al. [9], pre-trained CNN models such as DenseNet-169 are evaluated for diagnosing pneumonia in chest X-rays, using feature extraction and supervised classifiers, especially SVM (kernel RBF). The ChestX-ray14 database contained 2,862 images balanced between normal and pneumonia. The method included image resizing and feature extraction with DenseNet-169, which showed superior performance with an AUC of 0.8002 after hyperparameter optimization. The proposed model outperforms previous studies, demonstrating the effectiveness of DenseNet-169 combined with SVM for accurate and efficient diagnosis in medical images.

Akgundogdu [8], the model based on combining the 2D Discrete Wavelet Transform (2D DWT) for extracting features from chest X-ray images and using RF as a classifier for detecting pneumonia, is introduced. The dataset contained 5,856 images (4,273 with pneumonia and 1,583 normal). The method uses 24 features extracted from the wavelet sub-bands (LL, LH, HL, HH), including minimum, maximum, mean, standard deviation, variance, and third-order moment values. Their results showed that the model achieved an accuracy of 97.11%, sensitivity of 91.79%, and specificity of 99.09%, with an area under the curve (AUC) of 0.99. The study highlights the efficiency of the proposed model in terms of speed and accuracy, making it a promising and less complex alternative

to deep learning methods for diagnosing pneumonia. In future work, the authors mentioned that deep learning methods should be incorporated for comparison and improvement.

Mabrouk and Dias Redondo [7] proposed an Ensemble Learning (EL) model, combining DenseNet169, MobileNetV2, and Vision Transformer (VIT), adjusted with transfer learning on the ImageNet database and trained on pneumonia chest X-rays. The method outperformed the state-of-the-art, achieving 93.91% accuracy and 93.88% F1-score. The approach combines the features extracted by the models with pooling, normalization, and regularization techniques, reducing the risk of overfitting. In addition, the integration of Vision Transformer stands out for its ability to capture relationships between image patches, complementing the limitations of traditional CNNs. Despite the success, challenges such as the hyperparameter tuning and more significant variation in the data are mentioned. Moreover, strategies for weight assignments are interesting to investigate.

Recent advances in deep learning for medical images have also explored the integration of attention mechanisms and Transformer-based architectures. These approaches, by allowing models to focus on the most salient regions of an image, have shown promising results in tasks such as chest X-ray classification with improved interpretability and performance by dynamically weighting the importance of features. For example, [15] proposed an attention-based deep learning model for medical image classification, demonstrating its effectiveness on various medical datasets. [16] presented an attention-driven Spatial Transformer Network (STERN) for abnormality detection in chest X-ray images, highlighting its ability to dynamically scale and align images to maximize classifier performance by selecting the thorax and eliminating artifacts, achieving a mean AUC of 85.67% on the CheXpert dataset. Similarly, [17] introduced ResfEANet, a novel architecture combining ResNet with an external attention mechanism for tuberculosis diagnosis from chest X-rays, achieving high accuracy (97.59%) and sensitivity (100%) even without pre-training on a multi-source TB dataset. While this study focuses on established CNN backbones and hybrid classifiers, the evolving landscape of deep learning presents further avenues for investigation.

The reviewed literature demonstrates that combining CNN-based models [9], [14], traditional classifiers such as RF and SVM [8], [6], and ensemble strategies [7] can enhance pneumonia detection from chest X-rays. Despite high reported accuracies, many studies rely on limited datasets, lack external validation, underexplored hyperparameter tuning, and often restrict classification to single-view X-rays. Additionally, some works are constrained by limited computational resources, which affects model complexity and training duration. While DWT + RF [8] offer simplicity and high accuracy (97.11%), they depend on handcrafted features and lack scalability. This motivates exploring deep feature extractors such as VGG16, widely used in medical imaging tasks due to its simplicity and effectiveness [11], alongside more modern CNNs like MobileNetV2 and EfficientNet. A systematic hyperparameter search (GridSearchCV), k-fold cross-validation, and data augmentation techniques are employed to improve robustness and generalization. Similar strategies have proven valuable in other domains, such as image captioning, where the effectiveness of visual representation is highly dependent on the backbone CNN used [18]. In line with open science practices, the experimental framework and results are publicly available to support reproducibility and enable adaptation to other medical imaging modalities.

III. Material and Methods

This work proposes a systematic approach for diagnosing pneumonia in chest X-rays using different machine-learning models selected from existing literature. The experimental framework includes the definition of a computational environment for the experiments, the use of a dataset widely referenced in the literature, the application of pre-processing techniques to improve data quality, the implementation of a classifier architecture based on deep and ensemble learning models, and a validation process using K-Fold Cross-Validation. The following subsections detail the experimental framework, the dataset used, the pre-processing procedures applied, the model architectures, and the training and evaluation strategies.

A. Setup

The experiments used Google Colab Pro+, leveraging a Google Compute Engine backend with an NVIDIA T4 GPU. The system had 51 GB of RAM and 15 GB of GPU memory and ran Python scripts in version 3. This cloud-based environment provided efficient computational resources, enabling faster training and experimentation.

The main libraries and tools used include: `TensorFlow`, `NumPy`, `Scikit-learn`, `Matplotlib`, `Seaborn` and `Pandas`. The pre-trained CNNs were tuned using the TensorFlow framework, while the RF and SVM model was implemented with Scikit-learn. In addition, data augmentation techniques were applied using `ImageDataGenerator` from TensorFlow/Keras, and `EarlyStopping` callbacks were employed to prevent overfitting during CNN training [19], [4]. The corresponding subsections detail the hyperparameter tuning, including specific configurations for the CNN networks, classifiers, and the ensemble methods.

B. Dataset

The dataset used in this work consists of chest X-ray images, made publicly available[4] and presented initially by [11], [20]. This dataset is widely used in research to detect pneumonia [4]. It contains 5,857 images, which are distributed into two main sets: a training set with 5,233 images (1,349 Normal and 3,884 Pneumonia), and a fixed test set with 624 images (234 Normal and 390 Pneumonia). Figure 1 illustrates representative examples of both classes. A chest X-ray of a healthy patient shows clear lungs with no areas of abnormal opacification. In contrast, pneumonia usually shows focal lobar

[4]https://data.mendeley.com/datasets/rscbjbr9sj/3

consolidation (bacterial pneumonia) or manifests with a more diffuse "interstitial" pattern in both lungs (viral pneumonia), as described for [11].

The images are in JPEG format and have a resolution suitable for analysis by deep learning models. All X-rays were selected from retrospective cohorts of pediatric patients aged between one and five years from the Guangzhou Women and Children's Medical Center in Guangzhou, China. The X-ray examinations were performed as part of routine clinical care, and the image diagnoses were evaluated by two medical specialists, with the test set evaluation subsequently reviewed by a third specialist to mitigate possible classification errors [11].

C. Pre-Processing

To ensure the reliability of the experiments and improve model generalization, a 5-fold Stratified Cross-Validation was used. This technique preserves the class distribution across folds, allowing each sample to be used for training and validation in different iterations while maintaining a consistent proportion of `NORMAL` and `PNEUMONIA` cases [8]. The test set, comprising 624 images (234 Normal and 390 Pneumonia), was held out from the total dataset and remained fixed throughout the process to enable standardized performance evaluation across models. [4].

All images were resized to 224x224 pixels, a standard input format for pre-trained architectures like MobileNetV2, EfficientNetB0, and VGG16. This resolution balances computational efficiency and preserves key visual patterns critical for diagnosis. Pixel values were normalized to the range [0,1] to facilitate training convergence.

For the training set, *data augmentation* techniques were applied to mitigate overfitting, increase data diversity, and improve the generalization capacity of the models [19]. These augmentations simulate real-world variations observed in X-ray images, such as patient positioning, lighting, and equipment differences. These transformations help models generalize better to opacities or consolidations located in various lung regions [21], [13], [6]. The selected augmentations are summarized in Table I and follow recommendations from recent literature [6], [13], [4].

TABLE I
DATA AUGMENTATION TECHNIQUES APPLIED TO THE TRAINING SET

Transformation	**Values**
Rotations (`rotation_range`)	30°
Horizontal Shifts (`width_shift_range`)	30%
Vertical Shifts (`height_shift_range`)	30%
Zoom (`zoom_range`)	20%
Brightness Adjustments (`brightness_range`)	[0.8, 1.2]
Shear (`shear_range`)	20°
Horizontal Flip (`horizontal_flip`)	`True`

As presented in Table I, these transformations which include rotation, shear, displacement, brightness adjustments, and horizontal flipping, are clinically relevant because they improve the model's ability to detect pneumonia manifestations that may appear in different lung zones or vary due to patient orientation or image quality [4].

D. Model Architecture and Training

This study proposes a hybrid architecture that combines deep feature extraction using CNNs with traditional machine learning classifiers, represented by the state-of-the-art discussed in Section II. The overall architecture of the proposed method is summarized in Figure 2.

Six classification strategies were tested: three end-to-end CNNs (MobileNetV2, EfficientNetB0, VGG16), two traditional classifiers (RF, SVM) trained on CNN-derived features, and ensemble configurations. The goal is to evaluate whether classical classifiers can outperform deep models when provided with expressive representations and whether combining several models yields additional performance gains, considering computational limitations.The CNNs were implemented using *transfer learning*, a technique shown to be efficient in medical image classification tasks [4].

MobileNetV2: The first model is an efficient architecture for devices with limited resources. It employs separable convolutions (*depthwise* and *pointwise*) to reduce computational cost and model size, as described by [22]. The MobileNetV2 is optimized with layers of batch normalization (*ReLU*), activation (*ReLU*), and global pooling (*pooling global*) before the fully connected layer, which makes it suitable for *transfer learning* in specific tasks [4], [7].

EfficientNetB0: This model features a scalable *design*, combining efficiency and superior performance by automatically adjusting the network's depth, width, and resolution [23]. It uses transfer learning techniques and is designed to maximize accuracy while reducing the computational resources required, as suggested by [13].

VGG16: Developed by the *Visual Geometry Group* in partnership with DeepMind, expands the AlexNet architecture by using smaller convolutional layers (3x3) and *pooling* layers (2x2) to increase the network's depth [20]. This allows for more detailed feature extraction, excelling in visual classification and transfer learning tasks [4].

The parameter settings for the CNNs were primarily based on the literature reviewed in the previous sections. All models were initialized with ImageNet weights and personalized using transfer learning. The last 20 layers of each base CNN were unfrozen and fine-tuned on the dataset to allow the networks to specialize in domain-specific features. They share the same general training settings, so the architecture was extended with a global average pooling layer, followed by batch normalization, a dense layer with 128 neurons (with *ReLU activation*), and a 50% dropout layer to deal with overfitting. Then, a second dense layer with 64 neurons and *ReLU activation* (called *"feature_dense"*) was added for feature extraction, which feeds into a final sigmoid output neuron for binary classification. This 64-dimensional output was chosen as a balanced representation that retains important information while significantly reducing dimensionality for classical classifiers, thereby managing computational complexity and mitigating

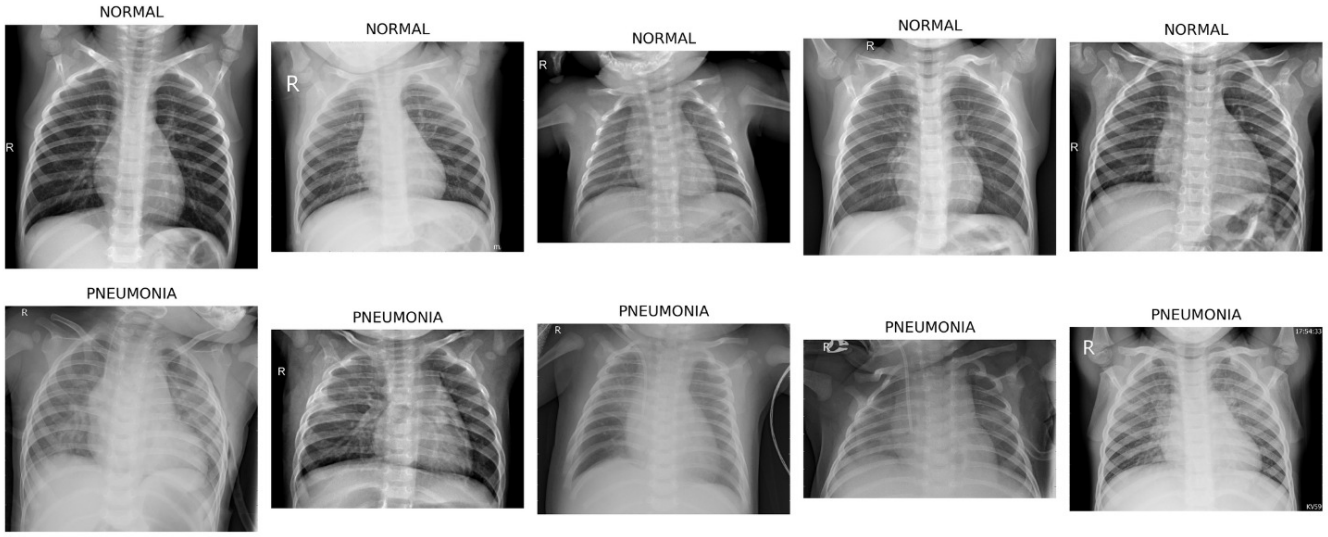

Fig. 1. Examples of chest X-ray images, including normal cases and patients diagnosed with pneumonia

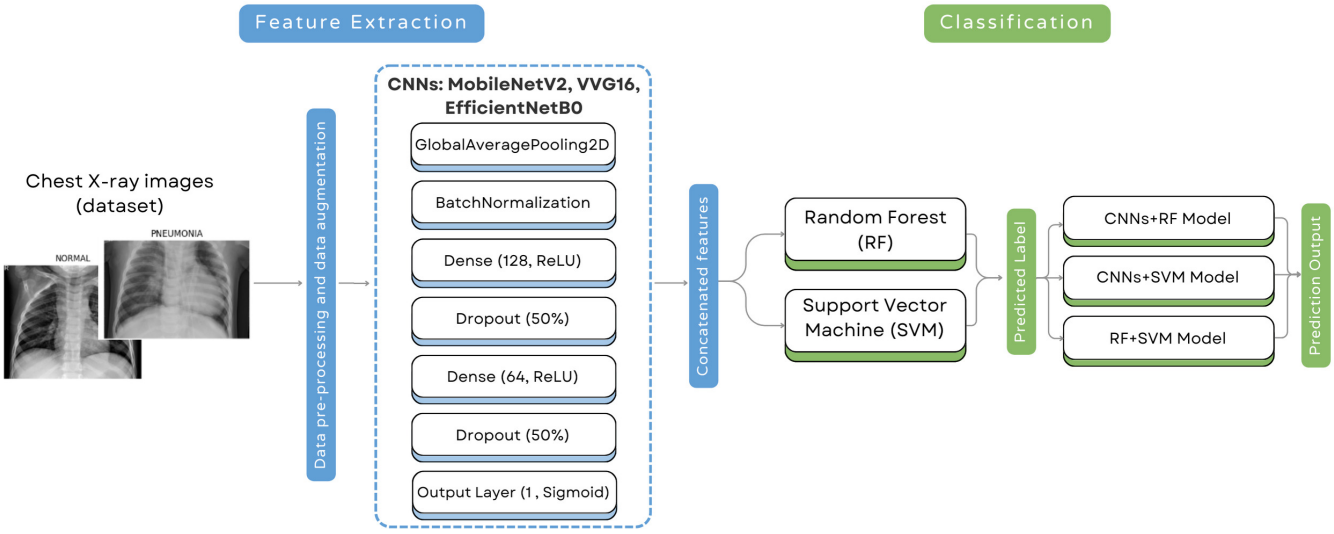

Fig. 2. Proposed hybrid architecture. Features extracted from MobileNetV2, VGG16, and EfficientNetB0 are concatenated and used to train classical classifiers (RF and SVM). The predicted labels are combined into ensemble models: CNNs+RF, CNNs+SVM, and RF+SVM.

the risks of overfitting for subsequent tasks [9], [6]. The models were trained using the Adam optimizer with a learning rate of 1×10^{-5} and the loss function *binary crossentropy*.

The 64-dimensional outputs from the *"feature_dense"* layer were extracted for all images in the training and test sets. These features were concatenated across the CNNs to form comprehensive input vectors for the classical classifiers. This hybrid approach combines the expressive power of deep neural networks with the interpretability and efficiency of traditional machine learning algorithms. The extracted features were subsequently used to train the classifiers described below.

RF: was selected due to its robustness to noise, ability to handle redundant features, and relatively low computational cost. According to previous studies, it can be trained and show significant results using features extracted from the CNNs [8], [4], [9]. This study was implemented with 200 trees (`n_estimators=100`), a maximum depth of 15, and class balancing enabled. It was also evaluated using 5-fold cross-validation with ROC AUC as the scoring function. The importance of the features was also extracted and analyzed.

SVM: is a well-established algorithm known for its strong performance in high-dimensional spaces, especially when dealing with limited data samples [9], [13], [4]. Its hyperparameters were optimized using a GridSearch strategy, and the kernel types were tested, including linear and Radial Basis Functions (RBF). Key parameters such as the regularization term (C) and kernel coefficient (γ) were tuned based on AUC performance, with the following search space:

$C \in \{0.1, 1, 10, 100\}$ and $\gamma \in \{\texttt{scale}, \texttt{auto}, 0.01, 0.1\}$. The best parameters were `kernel=poly`, `C=1`, `gamma=scale`, which were evaluated using 5-fold cross-validation, using metrics such as accuracy, balanced accuracy, F1-score (macro and weighted), and AUC were computed per fold.

The ensemble prediction was generated by averaging the predicted probabilities from the individual models. This method aligns with prior studies emphasizing the benefits of combining heterogeneous architectures to increase robustness and compensate for weaknesses of individual models [7], [6]. It is worth mentioning that four test scenarios were conducted during the experiments: two Ensemble CNNs + RF/SVM, created by combining the three proposed CNNs using either RF or SVM; and Ensemble RF + SVM; finally, Ensemble MN + VGG + RF generated by combining MobileNetV2, VGG16, and RF, only for testing due to the performance of EfficientNetB0.

E. Evaluation

For model evaluation, multiple metrics were considered to know: i) *accuracy* - represents the overall proportion of correct predictions and serves as a general indicator of model effectiveness. However, in clinical settings with imbalanced datasets, it may be misleading; ii) *precision* - quantifies the proportion of predicted positive cases that are truly positive. Clinically, a high precision reduces the risk of incorrectly diagnosing healthy individuals with pneumonia; iii) *recall* (also known as sensitivity)- represents the model's ability to identify all true positives correctly. This metric is particularly critical in the medical context, as a low recall could lead to undiagnosed pneumonia cases, potentially resulting in delayed or missed treatment; iv) *F1-score* - the harmonic mean between precision and recall, providing a balanced metric handy for imbalanced data, handy when both false positives and false negatives carry significant clinical implications; and v) the *Area Under the ROC Curve (AUC-ROC)*, which assesses the model's ability to distinguish between positive and negative classes across different decision thresholds - indicates strong discriminative capacity, essential when defining clinically appropriate cut-off points. [24].

The CNNs were evaluated using 5-fold cross-validation. The resulting models were consolidated by averaging their weights, and final predictions were made on the test set. Classical classifiers (RF and SVM) and their ensembles were evaluated using the same metrics on the test set.

The Kruskal–Wallis test was applied to statistically compare model performances. This non-parametric test evaluates whether significant differences exist between multiple classifiers across different folds by analyzing the mean ranks of different groups [25]. It quantifies the dissimilarities using a single metric (the p-value), testing the null hypothesis (H_0) that the observed differences between group medians can be attributed to random sampling, meaning the groups may originate from the same population [26], [27].

If the Kruskal–Wallis test indicated statistically significant differences ($p < 0.05$), post-hoc pairwise comparisons were conducted using Dunn's test to determine which models presented significantly different performances [28]. This test is widely used in diagnostic and fault detection studies where normality and homoscedasticity assumptions do not hold [29], [10]. Applying these statistical tests ensures a more reliable model performance evaluation by minimizing biases arising from single-test comparisons.

IV. Results

This section discusses the comparative performance of all tested classification models, including individual CNNs, ensemble strategies, and baseline approaches from the literature. All metrics reported consider class imbalance, following recommendations by [4]. Table II presents the performance evaluated through multiple metrics.

Among the individual CNN architectures, VGG16 achieved the highest performance, with an accuracy of 91.8% and an AUC of 0.969. These results are consistent with prior findings from [11], who reported competitive accuracy using the same architecture for pediatric pneumonia detection. The stability and convergence behavior of VGG16, despite its relative architectural simplicity, support its continued use in medical imaging tasks where model transparency and reliability are valued.

MobileNetV2 obtained 88.9% accuracy, making it a viable candidate for low-resource applications. EfficientNetB0, though theoretically promising, underperformed slightly (89.6% accuracy and 0.896 F1-score), suggesting potential sensitivity to hyperparameters or training instability, as previously noted in [13].

When applied to CNN-extracted features, Random Forest achieved 87.8% accuracy, validating the idea of combining handcrafted or statistical features with decision tree-based models, as done by [8].

Ensemble models outperformed individual classifiers across most metrics. The CNNs + RF ensemble achieved the highest overall accuracy (91.9%) and F1-score (0.918), demonstrating a balanced and consistent prediction capability. The CNNs + SVM ensemble yielded the best recall (0.979), a critical factor in clinical diagnosis scenarios where false negatives must be minimized. Despite lower precision (0.862), its F1-score (0.917) and AUC (0.963) confirm its practical effectiveness, aligning with results from [13] using hybrid CNN-SVM methods.

In contrast, the RF + SVM ensemble presented the weakest performance (accuracy = 72.4%, F1 = 0.703), indicating that naïve classifier fusion strategies may not effectively capture model complementarity. Despite being from different families, both classifiers operated on identical CNN-extracted features, which may have limited their diversity and led to overlapping decision boundaries, since the effectiveness of the ensemble depends not only on accuracy but also on the diversity among the basic learners [30].

Compared to the literature, the proposed ensembles generalize well over the same *Kermany dataset* [20]. The CNNs + SVM ensemble, for example, achieved recall comparable to

TABLE II
PERFORMANCE METRICS FOR INDIVIDUAL AND ENSEMBLE MODELS (PROPOSED AND LITERATURE)

Model	Accuracy	Precision	Recall (Sens.)	F1-score	F1-macro	AUC
Literature Models						
[6] – VGG16 + SVM	0.967	0.966	**0.968**	0.967	–	–
[8] – 2D DWT + RF	**0.971**	0.990	0.917	**0.980**	**0.926**	**0.990**
[8] – 2D DWT + SVM	0.934	0.946	0.852	0.875	0.830	0.908
[13] – Hybrid (EffNetB0 + SVM)	0.970	**1.000**	0.958	0.979	–	0.980
[13] – EfficientNetB0 (sigmoid)	0.967	0.999	0.956	0.977	–	0.976
[11] – InceptionV3 + TL	0.928	0.901	0.932	0.928	–	0.968
Proposed Models						
MobileNetV2	0.889	0.893	0.889	0.887	0.877	0.954
VGG16	0.918	0.921	0.918	0.917	0.911	0.969
EfficientNetB0	0.896	0.898	0.896	0.896	0.890	0.963
Random Forest	0.878	0.882	0.878	0.875	0.864	0.945
Ensemble CNNs + RF	**0.919**	**0.921**	**0.919**	**0.918**	**0.911**	**0.977**
Ensemble MN + VGG + RF	0.911	0.915	0.911	0.909	0.901	0.974
Ensemble CNNs + SVM	0.897	0.862	0.979	0.917	0.889	0.963
Ensemble RF + SVM	0.724	0.725	0.724	0.703	0.670	0.802

the *EffNetB0 + SVM* hybrid from [13] (0.979 vs. 0.958), while offering better balance in precision (0.862 vs. 1.000). Additionally, the proposed methods rival traditional pipelines such as *2D DWT + RF* and *2D DWT + SVM* [8], despite relying on raw image features rather than handcrafted descriptors.

This balance is also reflected in the confusion matrices (Figure 3), where ensemble models, particularly CNNs + SVM and CNNs + RF, demonstrate reduced false negatives and improved sensitivity in detecting pneumonia cases, confirming their clinical relevance.

Figure 3 presents the confusion matrices obtained from the best-performing fold of each model. The results indicate model efficacy in distinguishing Normal and Pneumonia cases, with ensembles achieving more balanced predictions. Ensemble methods, especially CNNs + SVM and CNNs + RF, resulted in fewer false negatives, confirming their higher recall and F1-scores. CNNs + SVM had the lowest number of missed pneumonia cases (only 8), while CNNs + RF maintained a strong balance across both classes (only 15 false negatives and 29 false positives). Among individual models, VGG16 demonstrated strong overall performance with low false positive and false negative counts (18 and 27, respectively), outperforming EfficientNetB0 and MobileNetV2, which had higher error rates. Random Forest showed the highest number of false positives (48), suggesting a tendency to over-predict the Pneumonia class, which aligns with its slightly lower precision.

To assess the statistical significance of performance differences across models, the Kruskal-Wallis test was applied to all metrics. As shown in Table III the test revealed significant differences ($p < 0.05$) for all metrics, including accuracy, precision, recall, F1-score, and AUC (only statistically significant pairwise comparisons - Accuracy, are shown).

Dunn's post-hoc test confirmed that Random Forest was significantly outperformed by VGG16 and the CNNs + RF ensemble, with p-values of 0.0078 and 0.0068, respectively. No statistically significant differences were observed between the remaining models, suggesting comparable performance among top classifiers.

TABLE III
KRUSKAL-WALLIS AND DUNN'S TEST RESULTS COMPARING MODELS USING 5-FOLD CROSS-VALIDATION.

Kruskal-Wallis test results		
Metric	**H-statistic**	**p-Value**
Accuracy	22.3256	0.0005
Balanced Accuracy	18.2603	0.0026
Precision	23.0593	0.0003
Recall	22.3256	0.0005
F1-score	22.1094	0.0005
F1-macro	20.7827	0.0009
AUC	25.6245	0.0001
Dunn's Post-Hoc test results (Accuracy)		
Comparison		**p-Value**
Ensemble CNNs + RF *vs* Random Forest		**0.0068**
Random Forest *vs* VGG16		**0.0078**

These findings confirm that ensemble approaches, especially those integrating multiple CNNs with RF or SVM, are practical for pneumonia classification. The models achieved results comparable to or better than prior studies while maintaining practical implementation advantages through lightweight, image-only pipelines.

V. CONCLUSION

This study investigated hybrid and ensemble strategies for detecting pneumonia in chest X-ray images, combining CNN-based feature extraction with classical machine learning classifiers. The results confirm that ensemble models, especially

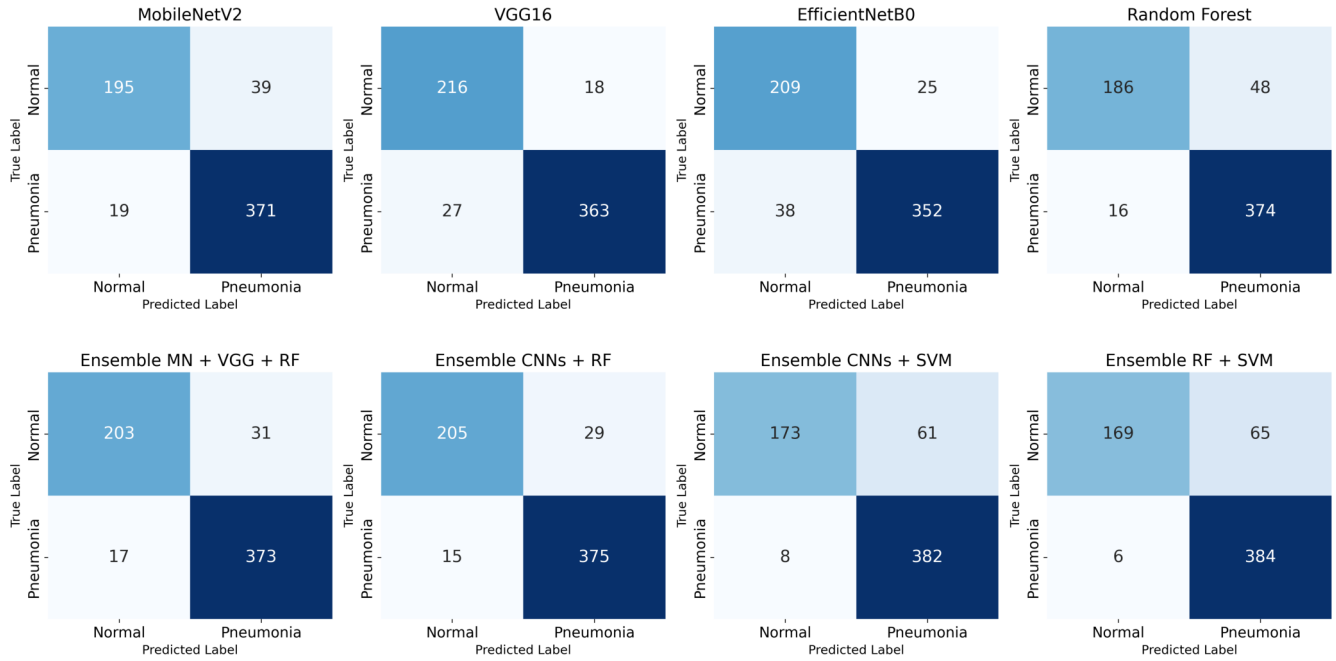

Fig. 3. Confusion matrices representative of the best fold's performance for each individual and ensemble model, evaluated on the fixed test set (624 samples). Each matrix displays (top-left) True Negatives, (top-right) False Positives, (bottom-left) False Negatives, and (bottom-right) True Positives.

those integrating CNNs with RF or SVM, are promising approaches compared to individual models in several evaluation metrics. In particular, the CNNs + RF ensemble obtained the highest accuracy (91.9%) and AUC (0.977), while CNNs + SVM maximized recovery (0.979), an essential metric for minimizing false negatives in clinical diagnosis. Nevertheless, indicator models such as VGG16 also showed significant individual performance (91.8% accuracy), reinforcing their continued relevance in medical imaging tasks, as seen in other studies.

The RF performance suggests that traditional classifiers combined with deep feature extraction remain competitive in medical applications, especially in data-limited scenarios. This can be attributed to RF's tolerance of redundant features and outliers, an aspect worth exploring in future feature importance analyses. In contrast, naive fusion models such as RF + SVM underperformed, highlighting the need for more ensemble strategies and further investigation.

In addition to reinforcing the utility of ensemble strategies, this study offers a refined pipeline for pneumonia detection in X-ray images. The proposed methodology is generalizable to other imaging modalities, such as ultrasound, computed tomography (CT), and magnetic resonance imaging (MRI), particularly when datasets are limited or noisy. A key contribution is the full public release of the experimental code and data pipeline, adhering to open science principles to support reproducibility and community-driven development [31], [32].

In addition to empirical performance, the results also present relevant theoretical and practical implications. Theoretically, this work corroborates the growing evidence that deep feature extractors combined with classical classifiers can be a viable alternative to purely end-to-end models, particularly when training data is limited, noisy, or imbalanced. The practical implications of this study are significant, especially for low-resource healthcare environments where access to specialized radiologists or advanced computational infrastructure may be limited. The hybrid approach provides a cost-effective and computationally efficient solution for automated pneumonia screening, potentially facilitating rapid diagnosis and early intervention by offering scalable and affordable diagnostic tools for real-world healthcare settings. Using lightweight CNNs and interpretable classifiers, such as RF and SVM, allows for deployment in real-world scenarios with constrained computational resources. These characteristics are especially relevant for diagnostic support in underserved healthcare settings, where scalable and efficient solutions must be considered.

Some limitations of this study include computational constraints, the exclusive focus on a pediatric dataset (aged between one and five years), which limits direct generalizability to adult populations, and the focus on binary classification. Although clinically justified for early pneumonia screening, the expansion to multiclass scenarios should be evaluated and applied for future work, particularly in the differential diagnosis of conditions such as tuberculosis, COVID-19, and other lung diseases with larger classes.

Given this, future directions include hyperparameter optimization for underperforming models such as EfficientNetB0, experimentation with advanced ensemble fusion strategies, such as weighted averaging schemes, stacking, or boosting

techniques that can leverage the complementary strengths of diverse hybrid models, and incorporation of explainability techniques to support clinical decision-making and model transparency. Furthermore, exploring more advanced architectures, such as those integrating attention mechanisms or Transformer-based models, as demonstrated by recent studies like [17], [16] and [15], could yield further performance improvements and enhance interpretability for critical clinical tasks. Broader validation on external datasets is also recommended to assess generalizability in real-world clinical scenarios, especially across diverse age groups and multi-institutional cohorts to enhance clinical translatability.

The code developed is available publicly[5], promoting the reproduction and extension of the experiments carried out.

***Abstract*—Optical Character Recognition (OCR) systems are frequently used to digitise text, but often produce noisy results, especially with historical, poor-quality or multilingual data. Despite advances in OCR technology, post-processing remains a significant bottleneck. We propose TOOL (Treating OCR Output as a Language), a new approach that understands OCR correction as a machine translation task. By treating noisy OCR text as a language in its own right, TOOL employs sequence-to-sequence models like Marian to translate it into clean, standardised text. This method is scalable, model-independent and language-flexible. We demonstrate this approach by translating "OCR German" to Standard German from around 1871 to the present day, improving accuracy at the token level by using matched training pairs of OCR output and base text.**

I. Introduction

OCR (**O**ptical **C**haracter **R**ecognition) systems are widely used to digitise printed and handwritten documents. However, their output is often noisy, particularly when dealing with low-quality scans, historical materials or multilingual content. While recent advancements in computer vision and language modelling have enhanced OCR (**O**ptical **C**haracter **R**ecognition) accuracy, post-processing remains a critical bottleneck, especially in error-prone scenarios. OCR text recognition errors tend to follow systematic, learnable patterns, similar to those found in low-resource language translation or noisy text correction.

TOOL (**T**reating **O**CR **O**utput as a **L**anguage) introduces a novel paradigm: treating OCR output as a textual language that can be translated into clean text (free from errors) using Seq2Seq (**Seq**uence-**to**-**Seq**uence) models. By leveraging translation models such as BART (**B**idirectional and **A**uto-**R**egressive **T**ransformers) [14], Marian [13] or other LLMs (**L**arge **L**anguage **M**odels), TOOL frames OCR correction as a machine translation task. This enables robust, model-agnostic and domain-adaptable post-processing. The approach offers a scalable and language-independent framework for improving OCR results without requiring any modifications to the OCR engine itself.

The research was funded by the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation) under Germany´s Excellence Strategy – EXC 2176 'Understanding Written Artefacts: Material, Interaction and Transmission in Manuscript Cultures', project no. 390893796.

There is a need for such a flexible, general-purpose solution that can learn to correct OCR errors in a data-driven manner. This approach addresses the problem by training Seq2Seq models on aligned pairs of noisy OCR output and the corresponding GT (**G**round **T**ruth) text. In this paper, we specifically address the task of translating from "OCR German" to standard German from 1871 to the present day to improve token accuracy.

II. Related Work

Seq2Seq modelling plays a foundational role in tasks such as machine translation, text summarisation, and now, OCR post-correction. The original Seq2Seq framework was introduced by Sutskever et al. (2014) [24], who proposed using RNs (**R**ecurrent **N**etwork**s**) with LSTM (**L**ong **S**hort-**T**erm **M**emory) units to encode an input sequence into a fixed-length vector and decode it into an output sequence. This approach demonstrated promising results for translations but had difficulties with long sequences due to information bottlenecks in the fixed-size context vector. To address this limitation, Bahdanau et al. (2015) [3] introduced the *attention mechanism*, allowing the decoder to access different parts of the input sequence dynamically. This innovation significantly improved translation quality and became a core component of subsequent Seq2Seq models.

The Transformer architecture by Vaswani et al. (2017) [26] replaced recurrence entirely with self-attention mechanisms, enabling more efficient training and better performance on long sequences. Transformers rapidly became the standard architecture for Seq2Seq tasks. Building on the Transformer, Lewis et al. (2020) [14] introduced BART, a denoising autoencoder for Seq2Seq generation. BART combines a bidirectional encoder (similar to BERT (**B**idirectional **E**ncoder **R**epresentations from **T**ransformers) [9]) with an autoregressive decoder (similar to GPT (**G**enerative **P**re-trained **T**ransformer) [21]), making it well-suited for text generation, correction and translation tasks; particularly when input text is noisy, such as in OCR outputs.

Around the same time, Marian [13] was developed as a highly efficient, production-grade translation system optimised for multilingual environments. As shown by Junczys-

Dowmunt et al. (2018) [12], Marian is particularly effective in low-resource settings, making it a strong candidate for OCR correction across diverse languages.

III. Use Case

This section begins by outlining the background of education, followed by an examination of the data availability concerning VET (**V**ocational **E**ducation and **T**raining), which serves as the primary data source and use case for the proposed TOOL approach.

A. Education Stages

Education comprises a sequence of structured stages, each contributing uniquely to an individual's personal and intellectual development [19]. The stages usually begin with ECEC (**E**arly **C**hildhood **E**ducation and **C**are), which includes programmes and services for children from birth to five years of age. This period is vital for the development of foundational cognitive, social and emotional skills. Evidence suggests that high-quality ECEC programs can have long-term positive effects on academic performance and social integration [17], [25].

Following ECEC, school education is generally categorised into primary and secondary levels. Primary education lays the groundwork for essential academic skills such as reading, writing, mathematics and science while fostering critical thinking and communication. Secondary education expands on this base, introducing more complex subjects and sometimes offering specialised or vocational tracks to prepare students for higher education or employment [10].

Higher education encompasses academic institutions like universities and colleges that confer undergraduate and postgraduate qualifications. These institutions provide in-depth disciplinary expertise and facilitate the development of research, innovation and professional competencies. Higher education is thus a significant driver of socio-economic growth and individual career advancement [1].

VET is a parallel pathway focusing on practical and occupational skills, tailored to specific sectors such as healthcare, manufacturing, hospitality and technology. VET programs often involve work-based learning, such as apprenticeships, to ensure graduates meet industry needs. These programs also support lifelong learning by offering reskilling and upskilling opportunities, thereby enhancing workforce adaptability [7], [8].

CVET (**C**ontinuing **V**ocational **E**ducation and **T**raining) plays a crucial role in supporting ongoing employability and national competitiveness. Many European countries, including Germany, have implemented policies to support lifelong learning and professional development through national strategies [22]. The German system differentiates between initial vocational training (German: *Ausbildung*), retraining (German: *Umschulung*), advanced continuing training (German: *Weiterbildung*) and upgrading training (German: *Fortbildung*). Upgrading training is often governed by federal regulations such as the Vocational Training Act (German: *Berufsbildungsgesetz*, BBiG) [6] and the Crafts Code (German: *Handwerksordnung*, HwO) [5]. In contrast, other forms of CVET are typically more decentralised and less regulated, though equally important for continuous skill development.

B. OCR Processing of Documents for VET

Fig. 1 shows a document which is part of a collection of historical VET. It is just one example of many similar materials that outline training regulations, exam requirements and pedagogical standards for skilled trades in early 20th-century Germany. These documents were typically issued or supervised by state institutions such as the Imperial Institute for Vocational Training in Trade and Industry (German: *Reichsinstitut für Berufsausbildung in Handel und Gewerbe*), which played a central role in standardising vocational training across the German Reich. The aim is to process such

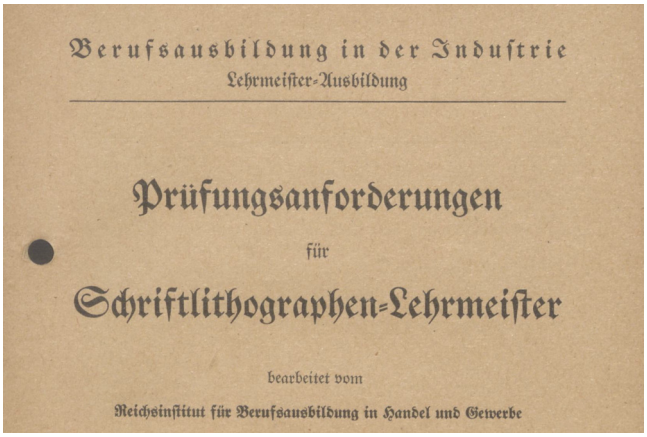

Fig. 1. Exam requirements for a type lithographer teacher (orig. in German: *Prüfungsanforderungen für Schriftlithographen-Lehrmeister*).

documents using OCR to make them digitally searchable and analysable. By converting these historical printed documents into machine-readable text, we aim to simplify research into the development of vocational training systems, qualification frameworks and occupation-specific pedagogical methods. However, processing these materials presents significant technical challenges.

An important problem is the typographical style of the original prints: Many documents from the early 20th century use Fraktur or broken Antiqua fonts, which are very different from modern Latin script. These fonts have unusual letter forms (e.g., long s "ſ" versus short s "s") and dense ligatures that are poorly recognised by standard OCR engines. The result is a high rate of recognition errors, such as character confusion, word fragmentation or misreadings that distort key terms (e.g., the German words: *Lehrmeister*, *Prüfungsanforderung*, etc.). In addition, the print quality of many originals contributes to noisy OCR output with smudges, uneven contrast and marginal notes that are interpreted as content. Therefore, in the following, we show a new approach to dealing with these problems without having to change the OCR process itself.

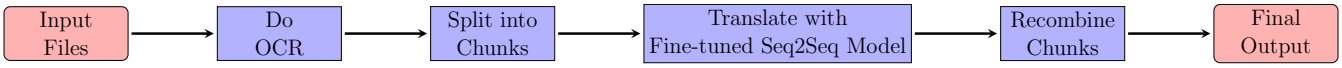

Fig. 2. Process flow for the TOOL-based OCR translation pipeline. *Input files* are first passed through the *Do OCR* process. Then the following processes are executed: *Split into Chunks*, *Translate with Fine-tuned Seq2Seq Model*, and *Recombine Chunks*. Together, these steps produce the *Final Output*.

IV. Method

To introduce TOOL, we begin by analysing the broader context. Specifically, we consider a comprehensive dataset comprising scans of VET documents, which is a collection of image files representing a set of text-based records. The primary objective is to generate high-quality transcriptions of these documents in a manner that is as automated as possible. Additionally, a limited set of manually transcribed documents is available, which can be used for training purposes. Generally, this situation is a common use case for OCR, but as stated before, the OCR results do not fulfil our needs. Furthermore, the available set of transcribed documents is too small to be used for training of a full custom OCR model. However, we recognise that the not-satisfying OCR output follows its own characteristics. Typical and recurring errors are, e.g., (i) the Umlaut "ü" in a scanned document often results in the sequence "ii" in the recognized text or (ii) the long s "ſ" is recognized as "f".

We observe that the OCR output is not correct German, but some type of inherent *language*. Hence, the output can be treated as a language, which leads us to the approach of TOOL: Translating from the OCR output *language* to a correct natural language, German in our case. Thus, TOOL consists of two steps: the OCR step and the *translate* step.

The OCR step does not require any further training of models and generalises well for different OCR models and languages. Even though the *translate* step still requires an individually trained model, this training requires only a small amount of training data and resources.

State-of-the-art translation models are based on LLMs, just like the translation step of TOOL. There are many different methods for solving the OCR problem described above, several of which we briefly outline here. These include a) Encoder, b) Instruction LLM, and c) Seq2Seq.

a) Encoder: One potential approach involves the use of an encoder-only model such as BERT. BERT processes an input sequence of words and outputs a corresponding sequence of contextualised embedding vectors. The idea is to utilise the vector space of the embedding vectors of a default BERT and train a custom BERT in a way that it generates for the OCR output embeddings in the same vector space as a default BERT. The big advantage over the instruction LLMs, such as Llama and GPT, is that in contrast only a small BERT needs to be fine-tuned for TOOL and a shared embedding vector space is used, i.e., techniques like RAG (**R**etrieval **A**ugmented **G**eneration) for retrieving documents from a collection can be applied directly. However, there is also a need for the correct German transcriptions of the scans and text generation from BERT embeddings is not straightforward. Additionally, there is no GT for the vector embeddings as our training data contains transcribed documents and not embeddings.

b) Instruction LLM: Another possibility is to apply an instruction LLM, like Llama or GPT, similar to [2]. Instead of training a model for TOOL's translation step, the instruction LLM gets the OCR output and is prompted to *correct* it. This approach works well, but there are disadvantages. While requiring no training is an advantage, the downside is that the process does not speed up once training is complete. An instruction LLM is a pretty large model, and running it requires special hardware and a lot of resources.

c) Seq2Seq: After all, TOOL's translation step should use a small transformer based LLM, i.e., a model taking a sequence of words as input and returning a transformed, e.g., translated, version of the words. A popular choice for such Seq2Seq models is Marian [13]. Using Marian for TOOL's translation step solves both issues stated before: First, there is no need for sharing an embedding vector space as required when using BERT. Second, Marian is a comparatively small model and can be fine-tuned in a reasonable amount of time. Additionally, after fine-tuning, the model can be used with standard hardware. Following a thorough evaluation, we selected the Seq2Seq model Marian, or more specifically, its Python implementation called MarianMT[1], to perform the translation step within TOOL.

The full TOOL pipeline is shown in Fig. 2. On the left-hand side, the red box depicts the input files, i.e., the scanned VET documents. The first two purple boxes depict TOOL's first step, i.e., the OCR. The remaining three purple boxes represent TOOL's second step, the translation using a custom fine-tuned MarianMT. As the input length of MarianMT is limited, the OCR output is split into chunks before it is translated by MarianMT. Finally, the translated chunks are concatenated, and the results are ready to be stored (the red box on the right-hand side).

Overall, the big advantages of the TOOL approach are:

- Any OCR tool can be used in the first step.
- For the second step, a pre-trained Seq2Seq LLM for translation, like variants of MarianMT, can be used.
- It does not require much training in terms of fine-tuning.
- The resulting pipeline, OCR and translation, is quite fast and resource efficient, especially compared to applying an instruction LLM [2].

Next, we describe the technical details of TOOL, our evaluation and present the results.

V. Experiments and Results

In order to verify the method described in this paper, experiments were conducted using the texts described in Section III. First, the process of fine-tuning with its subprocesses a) OCR, b) Preprocessing for Fine-Tuning, and c) Fine-Tuning is described.

A. Preprocessing and Fine-Tuning

A process flow diagram for fine-tuning the model can be seen in Fig. 3. The experimentation setup does not serve as a mean to find out the best possible models and parameters to use but rather it aims to show that the method works in practical scenarios.

a) OCR: As a first step, OCR is performed on all files from our dataset. We have decided to use Tesseract [23] as our OCR engine of choice as it is open source and widely adopted, with libraries available for many programming languages like Python[2].

b) Preprocessing for Fine-Tuning: The files are randomly split into a dataset for training and validation, and another dataset for testing after training. The second testing dataset is not used during the training phase, but to compute the metrics later on to verify how well the model generalises. For this experiment, we have split the dataset to have around 50% of the text files in the training and validation dataset and the other 50% in the testing dataset. Thus, each dataset has around 145 text files in total.

As a next step, the texts in each file are split into separate sentences using the NLTK (**N**atural **L**anguage **T**ool**k**it) [16] punkt tokeniser. This is done for the texts from OCR and the GT texts to have texts that can be used for fine-tuning the MarianMT model.

For the final preprocessing step, the corresponding sentences from the GT (see Fig. 2) and after the OCR process need to be aligned in order to have the corresponding sentence pairs. To do so, we have used a LaBSE (**L**anguage-**a**gnostic **B**ERT **S**entence **E**mbedding) model [11] which is based on the BERT architecture. This language-agnostic model allows us to encode texts from different languages into the same vector space. Using a distance measure, like the cosine similarity, we can pair sentences that are close in this vector space. The cosine similarity, as used, is defined as

$$\text{cosine similarity}(\mathbf{A}, \mathbf{B}) = \frac{\mathbf{A} \cdot \mathbf{B}}{\|\mathbf{A}\|\|\mathbf{B}\|}, \text{ where} \tag{1}$$

- $\mathbf{A}$ and $\mathbf{B}$ are two n-dimensional vectors, $n \in \mathbb{N}$,
- $\mathbf{A} \cdot \mathbf{B}$ is the dot product between two vectors $\mathbf{A}$ and $\mathbf{B}$ and
- $\|\mathbf{A}\|$ and $\|\mathbf{B}\|$ being the Euclidean norms of $\mathbf{A}$ and $\mathbf{B}$.

The vectors $\mathbf{A}$ and $\mathbf{B}$ are the embeddings of the GT texts and after the OCR process. The resulting value is in the range of $[-1, 1]$, with -1 denoting exactly opposite vectors, 0 denoting orthogonal vectors and 1 denoting exactly the same vectors.

[2]https://pypi.org/project/pytesseract/

Since our goal is to have sentence pairs that are highly likely to correspond, yet they may differ in a few aspects, we have set a minimum cosine similarity between the pairs to 0.7. In the end, we obtained approximately 10000 sentence pairs for training and verification during training and 8000 sentence pairs for testing afterwards.

c) Fine-Tuning: After generating the sentence pairs, fine-tuning is possible. We have chosen to use a MarianMT model [13] because this class of models is relatively small and lightweight. This not only ensures that fine-tuning is possible on moderate hardware but also makes inference possible on modern consumer computers.

Based on the specific language(s) needed, the user must choose the appropriate base model. Since we are dealing with texts written in German, we have used the "Helsinki-NLP/opus-mt-de-de"[3] model as our basis for fine-tuning. This model was pre-trained to translate from German into German, with our goal after fine-tuning being to translate from "OCR German" into correct German. For the experiments here, the following hyperparameters have been used:

- number of epochs: 30,
- learning rate: 5×10^{-5} and
- weight decay: 0.05.

The hyperparameters were chosen based on past experiences and are thus not necessarily the ones that provide the best results. Instead, the goal is to show that the method does work in general. Based on the specific use case, the hyperparameters need to be found, e.g., using Optuna[4]. For the fine-tuning, 90% of the training dataset has been used for training while the remaining 10% has been used for validation.

Fine-tuning was performed on a single Nvidia DGX A100 with 80GB of video RAM[5]. After around 1.5 hours, fine-tuning was finished, and the resulting model was stored to be used in the translation pipeline.

B. Translation

The translation pipeline follows the same process flow described in Fig. 2. In the first step, standard OCR needs to be performed on the text corpus. This output then needs to be split up into chunks of appropriate length. The reason behind splitting up is that most Seq2Seq models are only able to process a certain number of tokens. This value needs to be researched by the user and is set to 512 tokens for MarianMT. One possible way to generate these chunks is to split the input into sentences. Since the experiments performed for this article already did both steps for the pipeline presented prior, OCR and splitting up were not done in the translation pipeline, where it would have been typically done in a real-world scenario. The next step is then the translation, which is done with the fine-tuned MarianMT model. Additionally, for comparison in this work, translation was also done using the base MarianMT that is pre-trained for translating German into

[3]https://huggingface.co/Helsinki-NLP/opus-mt-de-de

[4]https://optuna.org/

[5]The datasheet can be found here: https://images.nvidia.com/aem-dam/Solutions/Data-Center/nvidia-dgx-a100-datasheet.pdf

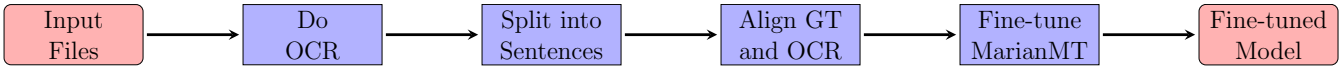

Fig. 3. Process flow for OCR to MarianMT fine-tuning pipeline. *Input files* are first passed through the *Do OCR* process. Then the following processes are executed: *Split into Sentences*, *Align GT and OCR*, and *Fine-tune MarianMT*. Together, these steps produce the *Fine-tuned Model*.

German, but not with the special cases we have in our corpus, like the ſ. After translating the text sentence by sentence, the results need to be recombined to get the full text back again.

This translation step was performed on a standard MacBook Pro 14 inch with M3 processor and 16GB of RAM[6]. For all the examples from the testing dataset, translation took around 1.5 hours.

C. Performance Metrics

Before discussing the results of our experiments, a brief introduction to the performance metrics used is given.

a) Hunspell Errors: One of the goals of TOOL is to have valid German afterwards. Thus, we have used Hunspell to verify that. Hunspell is an open-source spell checker and morphological analyser that is used in a few popular open-source tools like LibreOffice or the Firefox web browser, among others [18]. In order for Hunspell to do its work, a dictionary needs to be used. For our task, we have used a German dictionary called "German (de-De frami)"[7]. The number of errors given by Hunspell based on this dictionary are counted. To have a value that then also accounts for the length of the text, as longer texts are more likely to have a higher number of errors produced, the resulting value is then divided by the total number of words in the GT text.

$$\text{Hunspell value (text)} = \frac{E}{N}, \quad \text{where} \tag{2}$$

- E is the number of Hunspell-detected spelling errors and
- N is the number of words in the GT text.

b) (Normalised) Levenshtein Distance: The Levenshtein distance is a measure used to calculate the distance between two sequences. In our case, we calculate the distance between two sequences of characters. To calculate the Levenshtein distance, the minimum number of single-character edits to transform a provided sequence A, e.g., the texts after the TOOL pipeline, into the other sequence B, here the GT texts, is counted. These single-character edits can be insertions, deletions or substitutions. Similar to the case with the Hunspell errors, a longer text will more likely need more edits to be transformed into the other text, and thus, we have normalised the Levenshtein distance by dividing the results by the number of characters in the GT text.

c) Word Error Rate (WER): The WER (**W**ord **E**rror and **R**ate) is calculated in a similar way to the Levenshtein distance. In contrast to the Levenshtein distance, though, the WER counts the minimum number of words needed to change a text A into another text B. As an example, "I like a sandwich" and "I like this sandwich" have three character errors but only one word error, which is viewed at for the WER. For computing the WER, the number of word substitutions, deletions and insertions is counted. The resulting value is then divided by the total number of words in the GT text.

$$WER = \frac{S + D + I}{N}, \text{where} \tag{3}$$

- S being the number of substitutions,
- D being the number of deletions,
- I being the number of insertions and
- N being the total number of words in the GT text.

d) Jaccard Similarity: The Jaccard similarity is a set-based similarity measure between two sets A and B. Because sets do not have an order, the similarity measure does not take the order of the words in the text into account. However, this measure can still provide interesting insights into how well a user searching for a specific term may find this term in the results. Formally, it is defined as:

$$\text{Jaccard}(A, B) = \left| \frac{A \cap B}{A \cup B} \right|. \tag{4}$$

The resulting value will be between 0 and 1, with 1 denoting identical sets and 0 meaning no overlaps at all. In order to still preserve some form of ordering, we have measured the Jaccard similarity with regards to word bigrams, i.e., the sets consist of combinations of two words as entries. This takes immediate context into account and makes the measure stricter.

e) BLEU(-4): The BLEU (**Bil**ingual **E**valuation **U**nderstudy) score is a value between 0 and 1, and it evaluates the quality of one text compared to another. If the resulting value is getting closer to one, both texts are getting more similar. Initially, it was designed for machine translation tasks, but it can also be applied to other similar tasks. In essence, BLEU calculates how many words or n-grams in the candidate text, i.e., the text after TOOL, match those of the reference text. Detailed information can be found in its original paper by Papineni et al. [20].

We have decided to use the BLEU-4 score version that considers n-grams up to 4-grams, i.e., sequences of one up to four words in length. The precision for each n-gram is calculated, and then the geometric mean over all scores is taken.

$$\text{BLEU-4} = \text{BP} \cdot \exp\left(\sum_{n=1}^{4} w_n \log p_n \right), \text{where} \tag{5}$$

- BP is the brevity penalty,
- p_n the precision for n-gram of size $n \in \mathbb{N}$ and

[6]For technical specifications, visit https://web.archive.org/web/20250518115318/https://support.apple.com/en-gb/117735

[7]https://extensions.openoffice.org/en/project/german-de-de-frami-dictionaries

- w_n the weight for each n-gram precision (in our case, we have set it uniformly to $\frac{1}{4}$).

The brevity penalty is used to penalise translations that are too short when compared to the reference.

$$\text{BP} = \begin{cases} 1 & \text{if } t > g \\ \exp\left(1 - \frac{g}{t}\right) & \text{if } t \leq g \end{cases}, \text{where} \tag{6}$$

- t is the total word length of the translation and
- g is the total word length of the GT text.

Thus, if the translation is longer than the GT text, nothing happens, but if the translation is shorter, the BLEU score gets penalised exponentially.

f) METEOR: Unlike BLEU, the METEOR (**M**etric for **E**valuation of **T**ranslation with **E**xplicit **Or**dering) score is not only looking at exact matches, but it is extended to also include stem matching (e.g., "read" and "reading") and synonym matching (e.g., "bike" and "bicycle"). More details can be found in its original paper by Banerjee and Lavie [4]. It is calculated as follows:

$$\text{METEOR} = F_{mean} \cdot (1 - Penalty). \tag{7}$$

The individual components of this equation are given as:

$$Precision = \frac{m}{w_t}, \quad Recall = \frac{m}{w_{gt}}, \text{where} \tag{8}$$

- m is the number of matched unigrams,
- w_t the number of words in the translation and
- w_{gt} the number of words in the GT texts.

Using precision and recall, the F_{mean} score can be calculated.

$$F_{mean} = \frac{(1+\alpha) \cdot Precision \cdot Recall}{\alpha \cdot Precision + Recall}, \text{where} \tag{9}$$

- $\alpha \in (0, 1)$ being a parameter giving weight to recall over precision.

By default, α is set to 0.9, meaning that recall is weighted slightly above precision.

Finally, the penalty term is computed as:

$$Penalty = \gamma \cdot \left(\frac{ch}{m}\right)^{\beta}, \text{where} \tag{10}$$

- ch is the number of chunks,
- m the number of matches and
- β and γ being tuning parameters.

Also for the penalty term, the parameters β and γ have been kept their default values ($\beta = 3$, $\gamma = 0.5$).

g) ROUGE(-2): The ROUGE (**R**ecall-**O**riented **U**nderstudy for **G**isting **E**valuation) score was first described by Lin [15] in 2004. In contrast to BLEU, ROUGE is generally a measure of recall. However, it can also be F1-score based, which is the version we have used in our evaluation. Additionally, we have calculated the score using text bigrams to capture more of the context of the words. This F1-score version using bigrams is calculated as follows:

$$\text{ROUGE-F1} = \frac{2 \cdot \text{Precision} \cdot \text{Recall}}{\text{Precision} + \text{Recall}}. \tag{11}$$

Precision and recall are as defined in Equation 8 but with word bigrams instead of unigrams.

D. Results

The evaluation for TOOL was performed on the previously held-back testing dataset. This dataset contains around 8000 sentence pairs consisting of the texts after OCR, base MarianMT or TOOL respectively, and the corresponding GT sentences. All the text used for this dataset was chosen at random from our text corpus. Using that dataset, eight performance metrics were calculated. First, they were calculated for each sentence individually and then combined using both the mean and the median. Table I shows all the metrics for all the test datasets, all eight performance metrics and both the mean and median. Row "Tesseract only" shows the performances for only using the Tesseract OCR engine. In row "Base MarianMT" are the results shown for using the base MarianMT German into German translation model after the Tesseract OCR. This is done to compare the performance of the pre-trained MarianMT with both Tesseract alone and also TOOL. Finally, the row "TOOL" contains the performances for the approach presented in this article. The best values for both mean and median for each performance metric are highlighted in boldface.

Figure 4 shows the same data also in bar chart form. Orange bars are for the experiments with Tesseract alone, blue bars are the experiments after using the pre-trained MarianMT, and magenta bars are for TOOL. Solid bars are used for the mean, while hatched bars are for the median.

The performance metrics are calculated as described in Subsection V-C. For the columns "Hunspell Errors", "Normalised Levenshtein Distance" (abbreviated to "Norm. Lev. Dist."), and the "Word Error Rate" ("WER" in the table), a smaller value denotes a better performance. In contrast, for the "Jaccard Bigrams", "BLEU-4", "METEOR" and "ROUGE-2", a higher value denotes a better performance. For brevity, in this section we will refer to the BLEU-4 score as just BLEU and the ROUGE-2 score as just ROUGE.

At first, we look at the mean of each performance metric. Overall, it can be seen that the TOOL pipeline improves performance for all performance metrics. The number of errors identified using Hunspell was, on average, almost halved. Also, the Jaccard similarity for word bigrams as well as the BLEU and ROUGE scores doubled compared to the baseline Tesseract only. The normalised Levenshtein distance also got reduced. All of this indicates that the resulting text after TOOL gets closer to the GT, showing that the pipeline works.

Comparing the results after Tesseract alone and TOOL to the base pre-trained MarianMT was done in order to judge how much of the ability to correct the OCR errors is already inherent to the base model and how much was added via fine-tuning. Additionally, this serves as a baseline to judge whether the still relatively small dataset for fine-tuning has an impact on performance or not.

The MarianMT base model is consistently outperformed by our TOOL pipeline, demonstrating that fine-tuning sig-

TABLE I
EVALUATION METRICS FOR DIFFERENT MODELS (MEAN, MEDIAN).

Metric / Model	Hunspell Errors		Norm. Lev. Dist.		WER		Jaccard Bigrams		BLEU-4		METEOR		ROUGE-2	
	Mean	Median	Mean	Median	Mean	Median	Mean	Median	Mean	Median	Mean	Median	Mean	Median
Tesseract only	0.3670	0.4568	0.2275	0.1834	0.5357	0.5347	0.2079	0.1435	0.3047	0.2559	0.5977	0.5710	0.2913	0.2270
Base MarianMT	0.3455	0.4311	0.3387	0.3090	0.6252	0.5975	0.1975	0.1383	0.2338	0.1749	0.5083	0.4737	0.2755	0.2150
TOOL	**0.1963**	**0.1925**	**0.2175**	**0.1587**	**0.3626**	**0.2716**	**0.4723**	**0.4954**	**0.5695**	**0.6211**	**0.7761**	**0.8052**	**0.5781**	**0.6053**

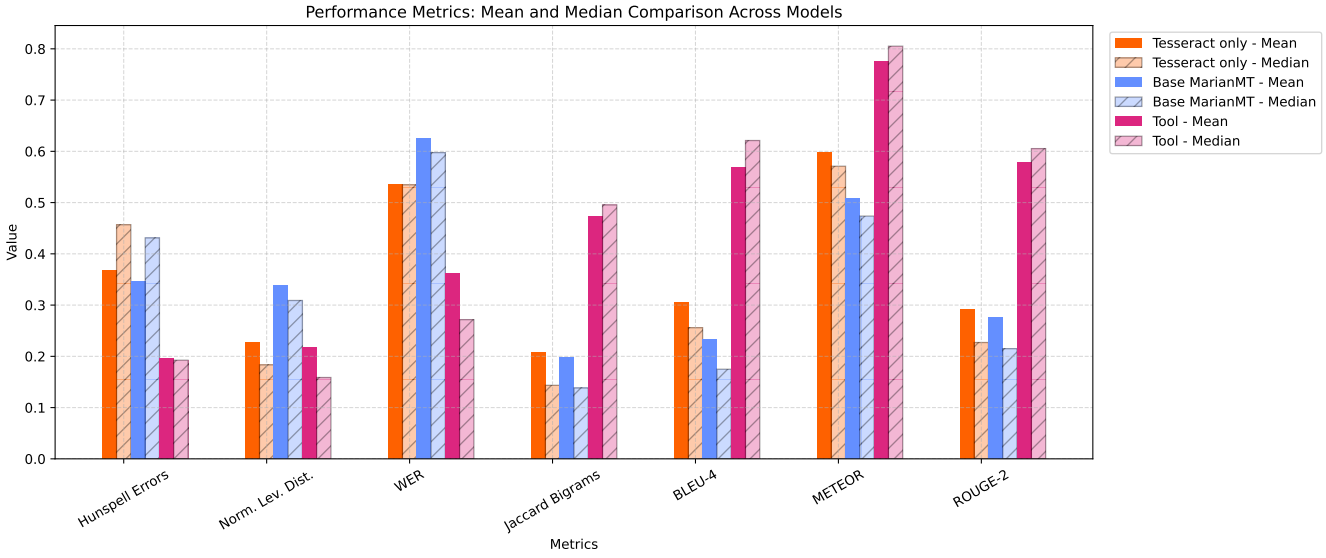

Fig. 4. Evaluation metrics shown as bar charts. Solid bars indicate the mean, while hatched bars are the median.

nificantly improves the results, even with a relatively small dataset. Moreover, the base MarianMT is also almost always worse than just Tesseract alone. It only outperforms Tesseract alone in the number of Hunspell errors, which is an indicator that the language produced after the translation is closer to German than the result after OCR alone. However, in correcting these mistakes, the results diverge from the GT leading to overall worse performance. Thus, using the base MarianMT without first fine-tuning to this specific OCR task is not helpful and even degrades results.

In addition to the mean, we also calculated the median value of each performance metric over all results. This was done in order to judge whether a few examples are skewing the results in one or the other direction. Looking at all performance metrics, the median is mostly worse than the mean for Tesseract only, but also for the base MarianMT model. The two exceptions are the normalised Levenshtein distance and the word error rate, where the results are getting slightly better. This is an indicator that there are a few outliers skewing the results slightly in a mostly worse direction. For our TOOL pipeline, the value is, however, almost always very close in both mean and median. The trend here is the same, with base MarianMT producing the worst results, while Tesseract alone performs slightly better, apart from the Hunspell errors, as already described in the mean value, and TOOL is the best.

VI. CONCLUSION AND OUTLOOK

In this article, we introduced TOOL, a novel method that reconceptualises OCR correction as a translation task from noisy to clean text. We demonstrated TOOL, which uses the Seq2Seq model MarianMT to translate the "OCR German" output into Standard German from around 1871 to the present day. We implemented TOOL with this lightweight model that runs efficiently on consumer-grade hardware. While the results are promising and show performance improvements, the current study relies on a relatively small dataset and serves as a proof of concept.

Future work will focus on scaling to larger datasets, which is expected to enhance performance and robustness. Extending this approach to other languages also represents a promising direction for future research.

***Abstract*—The work is dedicated to the study of drone use in horticulture, focusing on an example of blackcurrant cultivation. The research aims to use drones to monitor vegetation in plantations and to maintain the technological environment of plants, using traditional agrotechnical field care methods. The concept offers mapping and instance segmentation followed by multi-label classification operations, taking into account the specifics of blackcurrant plantations. The mapping operation creates blackcurrant plantation maps from images taken by drones at low altitudes. This ensures the acquisition of high-quality maps of large areas with the help of simple image photography cameras. Instance segmentation is intended for extracting singular leaf instances from mapped images, which are analyzed using classification methods to detect blackcurrant diseases, pest spread, nutrient and moisture deficiencies, and other plant vegetation-related parameters. Classification employs machine learning techniques and is specific to the cultivation of a particular plants – blackcurrants. The proposed technology, with appropriate adjustments, can also be applied to the vegetation monitoring of other horticultural plants.**

I. Introduction

TODAY, drone manufacturing costs and production volumes have reached a level that allows their application in various fields, including precision agriculture. The scientific reviews available in the literature analyze the latest advances in drone technology used in precision farming. For example, [1] compiles 184 publications using Google Scholar and SCOPUS data, while [2] reviews 164 articles focusing on the application of AI methods in agriculture.

The authors of these studies unanimously conclude that drones can be used effectively to monitor plant vegetation, while agricultural operations should be carried out using ground-based equipment. During a flight, a drone can capture images of designated field areas and transmit them to computers for further analysis. Using machine learning methods, this enables the detection of vegetation conditions and issues that determine necessary agronomic actions. Thus, drones allow for rapid inspection of large agricultural areas and the collection of crucial data on crop health and required maintenance tasks.

This study adopts a practical approach with the primary objective of developing a technology that integrates drones and artificial intelligence techniques to monitor plant vegetation. The system is designed to provide early warnings to farmers regarding plant diseases, pest infestations, nutrient deficiencies, and other agronomic issues. A key contribution of this work is the development of a robust image analysis system capable of processing leaf images to reliably detect plant (particularly blackcurrant) diseases, thereby enhancing the system's applicability in real-world agricultural settings.

The following chapters provide a description of the technology designed to support blackcurrant cultivation using basic drones and imaging cameras. The proposed technology was tested on a blackcurrant farm in Latvia, confirming the validity of the chosen approach.

The structure of this study is as follows: Chapter 1 provides an overview of drone usage in precision agriculture worldwide. Chapter 2 focuses specifically on drone applications in horticulture. Chapter 3 presents the authors' proposed methodology for assessing blackcurrant plantations. Chapter 4 offers a visualization of blackcurrant plantation conditions. Chapter 5 discusses the results obtained and presents the conclusions.

II. Drone Application in Horticulture

To feed the rapidly growing global population, agricultural enterprises must produce more food without increasing the areas of cultivated land. This can be achieved by applying advanced farming technologies. Some of these technologies are still in development, while others are already offered by commercial companies. Today, farms can utilize a variety of advanced tools, such as satellite data, drones, autonomous platforms for agricultural operations, sensors, and robots, to obtain detailed information about crop and soil conditions and to perform specific agronomic tasks. However, in many countries, including Latvia, the adoption of drone technology in agriculture is still in its early stages. Among the various scientific and technological challenges that are being addressed to achieve the goals of sustainable development, the use of new technologies and methodologies in agriculture has attracted the interest of the engineering research community ([3]). The objective is to develop technologies suitable for precision agriculture that improve the long-term profitability and efficiency of agricultural production ([4]).

A. General Overview of Drone Applications

According to [1] and [2], data from the Food and Agriculture Organization (FAO) indicate that global food production

must increase by 70% by 2050 to support the growing world population. However, in the European Union, the number of people employed in agriculture has decreased by 35% over the past decade, and the expansion of agricultural land is largely unfeasible.

These factors have driven an increase in interest in advanced agricultural technologies, including sensors, robots, drones, digitalization, and artificial intelligence (AI). AI and machine learning are considered highly promising for detecting agricultural problems, monitoring crop health, forecasting yields and prices, mapping harvests, and optimizing pesticide and fertilizer use.

There are various research directions that discuss the use of modern technologies in agriculture: Internet of Things (IoT) technologies in agriculture ([5]), bibliometric analysis of drone use in agriculture ([6]), deep learning methods for controlled environment agriculture ([7]), robotic harvesting technologies (Mail et al., 2023), machine vision applications in agricultural robot navigation ([8]), AI in agriculture ([9]), Agriculture 4.0 ([10], [11]).

Depending on the specific task, drones can offer similar capabilities to satellite image analysis but with higher precision and flexibility. They can perform tasks such as soil analysis ([12], [13], [14]), monitoring sowing density and crop development ([15], [16]), weed and pest detection and classification ([17], [18], [19]) and yield prediction and maturity assessment ([20], [21], [22]).

In rare cases, drones can also be used for harvesting, precision fertilization ([23], [24], [25]), pesticide spraying ([26], [27], [28]) and even mechanical pest eradication. IoT and sensor technologies provide farmers with real-time data on soil parameters, temperature, atmospheric gases, weather conditions, and many other variables, often processed in cloud-based IT infrastructures for further analysis and forecasting ([29], [30], [31]).

B. Scope of Drone Applications

The use of artificial intelligence and cloud technology in drones has brought significant improvements to smart agriculture. These new technologies can capture high-resolution images, aerial maps, and thermal images, which can be utilized in various agricultural applications, including:

- Soil analysis: Drones can be used for soil sampling, analyzing soil moisture levels, and assessing soil quality, helping farmers optimize fertilization and irrigation processes,
- Planting: Drones can be used for precise seed sowing and/or seedling planting, reducing labour and planting material costs,
- Crop spraying: Drones equipped with spraying systems can be used for the precise distribution of pesticides, herbicides, and fertilizers, minimizing environmental impact while saving time and financial resources,
- Irrigation management: Drones equipped with thermal sensors and infrared cameras can identify areas needing irrigation, helping to optimize water use and reduce waste,
- Yield mapping: Drones can generate yield maps, assisting farmers in optimizing crop management and increasing overall production,
- Livestock monitoring: Drones equipped with cameras can be used to monitor livestock health and behaviour, as well as track animal locations,
- Crop monitoring: Drones equipped with sensors and cameras can collect real-time data on crop health, growth, and yield, creating crop health maps,
- Field mapping: Drones can create high-resolution field maps, providing data on soil structure, topography, and plant populations, which can be used for informed decision-making regarding planting, fertilization, and other crop management practices,
- Pest and disease control: Drones can help detect and map the spread of pests and diseases in crops, helping farmers take timely action.

These drone applications have gained significant research attention over the past five years. Studies provide evidence of the potential of drones in agriculture. However, these results remain a future vision that is not yet accessible to practitioners. Implementing such technologies requires the involvement of highly qualified specialists and the establishment of modern infrastructure.

III. Applications of Machine Learning in Plant Disease Diagnosis

A. Overview and Summary of Existing Solutions

The authors have reviewed several solutions for diagnosing plant diseases using images of plant leaves. The works discussed in this subsection will not be described individually, but rather grouped according to the nature of the solutions reviewed, and common features will be highlighted to indicate current trends in addressing such problems.

The solutions include methods such as the use of convolutional neural networks, the application of transfer learning, the use of traditional classification methods, the application of segmentation, object detection, and data augmentation.

Convolutional neural networks dominate plant leaf image classification in the context of the reviewed studies. In most of the research reviewed by the authors, convolutional neural networks are either trained from scratch on specific plant data or used as part of transfer learning. For example, in the work by Khalid M. Hosny and co-authors titled **"Multi-Class Classification of Plant Leaf Diseases Using Feature Fusion of Deep Convolutional Neural Network and Local Binary Pattern"** [32], several examples of convolutional neural network architectures - AlexNet, VGG16, and GoogLeNet - are analyzed. These are trained on the PlantVillage dataset [**datasetPlantVillage**] and enhanced with the use of local binary patterns to incorporate texture information. Another good example of convolutional neural network use is described in the work by Prabhjot Kaur and co-authors titled

"A novel hybrid CNN methodology for automated leaf disease detection and classification" [33], where a convolutional neural network (ResNet50) is combined with a support vector machine (replacing the fully connected layers of the convolutional neural network). An interesting application of convolutional neural networks is found in the publication by Rasika Gajendra Patil and Ajit More titled **" Grape Leaf Disease Diagnosis System Using Fused Deep Learning Features Based System"** [34], where the proposed method fuses the results obtained from the deep feature layers of two selected convolutional neural networks.

Similar to convolutional neural networks, transfer learning approaches are also commonly found in the reviewed solutions. They are widely used because they allow the utilization of pre-trained networks. An example is the study developed by Vinay Gautam and co-authors titled **A Transfer Learning-Based Artificial Intelligence Model for Leaf Disease Assessment** [35], where transfer learning is applied to models such as: AlexNet, VGG16, VGG19, InceptionV4, SqueezeNet, and Xception. The use of transfer learning is particularly important in situations where data collection is expensive or limited, such as in the case of rare diseases. A similar situation is observed in the study by Yan Guo, Jin Zhang, and co-authors titled **" Plant Disease Identification Based on Deep Learning Algorithm in Smart Farming"** [36], where the solution is based on pre-trained VGG16 and ResNet101 models. These models were fine-tuned for specific plant recognition using a dataset of 1000 images from the China Plant Image Bank.

Although deep learning models dominate the reviewed solutions, some of them still employ classical supervised learning methods. Techniques such as support vector machines, the k-nearest neighbors algorithm, and the random forest classifier are often used in combination with traditional feature extraction—such as histogram analysis, color moments, and shape descriptors [37],[38]. For example, in the previously mentioned work by Rasika Gajendra Patil and Ajit More [34], a convolutional neural network was initially applied to the dataset items, but the final classification was determined using a support vector machine classifier. Such methods are often easier to interpret and less demanding in terms of computational resources.

Similar to the use of convolutional neural networks and transfer learning, a commonly observed trend in solutions is the use of semantic or instance segmentation prior to classification in order to achieve better results. In the publication by Gangadevi Ganesan and Jayakumar Chinnappan titled **"Hybridization of ResNet with YOLO classifier for automated paddy leaf disease recognition: An optimized model"** [39], segmentation of diseased leaf regions was performed using K-means clustering. Similarly, in the publications by Muhammad Sharif and co-authors and by Vinay Gautam and co-authors [40], [35], semantic segmentation of the diseased regions was applied. This indicates that, in plant leaf disease diagnosis, it is valuable to use only the regions showing anomalies for classification, rather than the entire leaf instance. However, such an approach is effective only in solutions where the processed dataset contains images in which each image depicts only a single leaf instance. In the solution described in the publication by Marcelo Vassallo-Barco and co-authors titled **"Automatic Detection of Nutritional Deficiencies In Coffee Tree Leaves Through Shape And Texture Descriptors"** [41], the Otsu thresholding method was used for instance segmentation, however, the publication does not specify the exact accuracy achieved by the proposed method, making it difficult to draw significant conclusions from this study. Instance segmentation is also found in the solution mentioned in the publication by F. Khan and co-authors titled **"A mobile-based system for maize plant leaf disease detection and classification using deep learning"** [37], where the YOLO model family is used. In this context, instance segmentation is applied to identify and classify leaf instances, including their masks, since the dataset images depict multiple leaves. This approach provides high data granularity and allows for the analysis of individual leaves.

Additionally, it should be noted that the analyzed solutions also include image preprocessing methods and various data augmentation techniques. Given the frequent lack of data, different data augmentation methods are used - such as image rotation, zooming, cropping, and others. These methods help reduce the risk of overfitting and improve the generalization ability of the models.[36], [41]

B. Conclusions for the Selection of a Practical Solution

After analyzing and comparing various existing solutions, the author chose to apply convolutional neural networks (CNN) for leaf classification and instance segmentation to separate leaf instances prior to classification in the development of a practical solution. Since the previously mentioned work using YOLO models demonstrated high precision [37], the author selected the YOLO model family for the instance segmentation task and, based on the strong performance of ResNet models [34], chose ResNet models for the classification task. At the same time, it can be concluded that for each plant species, a specifically trained model must be developed because plants differ visually and various diseases may manifest differently. Therefore, the prototype of the study's solution focuses on only one plant species - blackcurrants - on which the proposed solution is tested.

IV. Proposed Solution of Technology

This section presents the authors' proposed technology for monitoring blackcurrant vegetation using simple drones and artificial intelligence methods. The proposed solution is applied in a blackcurrant farming operation in Latvia.

A. Informal Description of Solution

The technology is offered to blackcurrant growers to monitor plantations using drones, allowing detection of healthy blackcurrant plants, fungal diseases, and nutritional deficiencies. The system consists of two main functions:

- Mapping: Prepares maps of blackcurrant plantations with the required precision (scale), links them to GPS (Global

Fig. 1. Blackcurrant plantation photo from 5 meters height (row spacing – 4 meters).

Positioning System) coordinates, records drone flight routes, and specifies operations/photography to be performed during flights.

- Analyze and classification: Uses trained neural networks to extract blackcurrant leaf clusters from the mapped images. The instance segmentation then identifies individual blackcurrant leaves, which are passed to the classification stage for further analysis. As a result, three types of leaves are identified: healthy leaves, leaves affected by fungal diseases, and leaves indicating nutrient deficiencies. As a result, the study provides a blackcurrant plantation analysis solution that gathers information on plantation conditions and visualizes it for growers, aiding decision-making on necessary interventions.

B. Mapping and Planning of Image Capturing Routes for of Horticultural Areas

The area captured by drones for image analysis is usually significantly smaller than the cultivated field area in horticulture. This is determined by the technical parameters of the drone camera and the scale of the captured images Fig. (1). To obtain complete information about the field, the authors took multiple photographs every 10 meters. Although the images do not fully cover the entire field (each image captures an area of approximately 8×5 meters), they still provide a sufficient overview of the field as a whole, which typically ranges in size from 2 to 20 hectares.

To obtain the necessary images, a drone flight route with a photography plan must be created for each monitored field. The route can be created using the Mission Planner program (web-03). The overall image route is calculated on the basis of the drone's flight altitude and camera parameters (e.g., the angle the camera captures). As a result, a route will be obtained for the drone to follow, an example of which can be seen in the image prepared by the authors in Fig. 2.

The automatic flight is provided by the Litchi program. It is available on both the computer's website (web-04) to create the route and on mobile phones (web-05) to fly the route.

During the experiments, *Dji Mavic Air 2S* with a 4k camera was used. All pictures were taken from a height of 5m. To

Fig. 2. Drone mission plan: route and photography points

carry out the mission plan shown in Fig. 2 (which covered 2.5 hectares), approximately 15 minutes were required (time may be affected by wind speed), and one drone battery was used (i.e., the flight was continuous).

C. Image Analyzes and Classification

For the analysis of blackcurrant leaf images, the authors have chosen a solution that combines instance segmentation and multi-label classification. Instance segmentation ensures the separation of leaf instances from the background, while multi-label classification assigns each leaf instance to one or more of the predefined classes. For instance segmentation, the authors trained two models from the YOLO family — YOLOv8n-seg and YOLOv9c-seg. For multi-label classification, the authors trained three models from the ResNet family — ResNet-50, ResNet-101, and ResNet-152. Based on the training results, the authors selected one model for each task (instance segmentation, multi-label classification) and integrated the segmentation and classification models to form a unified solution for blackcurrant leaf analysis.

1) Image Acquisition: The authors independently performed the acquisition of specific images used to train the models applied in the proposed solution. All the images used in the training, validation, and test datasets, as described in subsection IV-C3, were captured using a *Nikon D3300 DSLR* camera equipped with a 24.2 MP DX-format CMOS sensor. The images (sample image in Fig. 3) were taken from the same blackcurrant field, capturing photographs from various angles and under different lighting conditions to ensure dataset diversity. This diversity can enhance model training results and improve the robustness of the trained models in non-standard scenarios.

2) Image Annotation: Image annotation for instance segmentation and multi-class classification was performed using

Fig. 3. Image of blackcurrant leaves

various methods to support the formats required by the specific machine learning models.

For the instance segmentation datasets, each image was manually annotated by outlining the contour of each individual blackcurrant leaf instance. Annotation was performed using the open source image and video annotation tool *Computer Vision Annotation Tool (CVAT)*, developed by *Intel*. The annotations were then exported as point coordinates in the *YOLOv8 segmentation 1.0* format. This type of data annotation is time-consuming as images of blackcurrant bushes contain a large number of leaf instances that must be precisely annotated. Such accuracy is essential for the model to correctly detect and isolate leaves from the background and overlapping objects, which is critical for accurate instance segmentation. One of resulting images is available in Fig. 4)

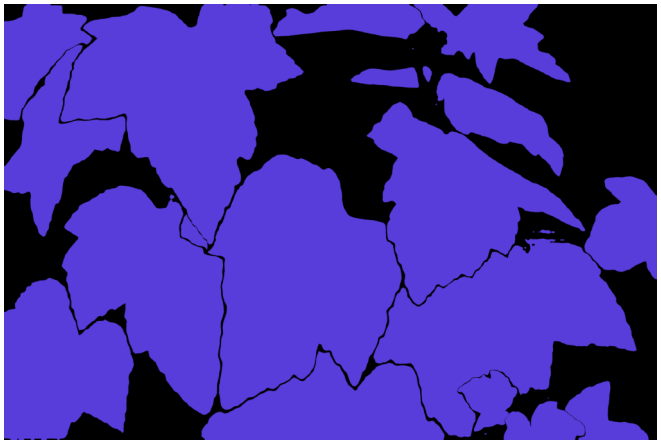

Fig. 4. Instance segmentation annotation example

For multi-label classification, annotation was performed by isolating individual instances from blackcurrant leaf images using the *Adobe Photoshop* graphic editing software, creating images where each blackcurrant leaf instance was placed against a black background (sample Fig. 5). Each resulting image was then assigned a label indicating its correspondence to one or more of the predefined blackcurrant health condition classes. The specific classification scheme — which includes the classes: healthy leaves (HL), leaves with nutrient deficiency (NDL), and leaves affected by *Mycosphaerella ribis* (MRL) — was developed in collaboration with an industry expert, based on an assessment of the blackcurrant field available to the author. A more detailed overview of the classes can be found in subsection IV-C3. All image labels were compiled into a structured file containing the image names and their corresponding class assignments.

Fig. 5. Multi-label classification dataset example: leaf with nutrient deficiency

3) Datasets overview: This work utilizes two main datasets to support different stages of the proposed method: one for multi-label classification and another for instance segmentation. The multi-label classification dataset contains 287 images, each featuring a single blackcurrant leaf against a black background. These images are divided into training (229), validation (49), and test (49) subsets. Each leaf is labeled according to a classification scheme developed in collaboration with an industry expert, categorizing them as healthy leaves (HL), leaves with nutrient deficiency (NDL), or leaves affected by Mycosphaerella ribis (MRL). Since a single leaf may exhibit symptoms of multiple classes, a multi-label classification approach is used. The class distribution is provided in a Table I, showing that the total number of labeled instances exceeds the number of images due to overlapping class characteristics.

The instance segmentation dataset comprises 87 images, split into 71 for training and 16 for validation. Each image includes only blackcurrant leaves, and each leaf has been manually annotated with precise contours. This detailed annotation process is resource-intensive but essential, as it enables the

TABLE I
DISTRIBUTION OF CLASS OCCURRENCES ACROSS TRAINING, VALIDATION, AND TEST SETS

Class	Training (229 images)	Validation (49 images)	Test (49 images)
HL	92	21	19
NDL	85	19	16
MRL	80	14	18
Total Labels	257	54	53

segmentation model to accurately detect and isolate individual leaves from complex backgrounds.

4) Model training overview: For the instance segmentation training process, the following models were used: YOLOv8n-seg and YOLOv9c-seg [42]. These were trained using the open-source Ultralytics package in Python [43], which provides an efficient workflow for YOLO models, including automated hyperparameter configuration such as learning rate adjustment based on gradient changes, default use of the Adam optimizer, and automatic batch size selection based on available GPU memory — set to 8 in this case. Each model was trained with three different image resolutions: 256x256, 512x512, and 1024x1024. This approach allowed the author to evaluate model behavior across varying resolutions and assess the impact of image size on instance segmentation accuracy. Based on the training loss analysis, 70 epochs were chosen for the final training.

For the multiclass classification training process, the following models were used: ResNet-50, ResNet-101, and ResNet-152. These models were implemented using the PyTorch machine learning library in Python and initialized with default pretrained weights to leverage feature representations learned from large-scale datasets. The final fully connected layer of each ResNet model was replaced to enable prediction of three target classes, making them suitable for the classification of disease instances on blackcurrant leaves. Input images were resized to 256×256 pixels and transformed into tensors for model processing. The models were trained using the BCEWithLogitsLoss loss function, combining Sigmoid activation with binary cross-entropy for numerical stability in multiclass tasks. The Adam optimizer was chosen for its ability to dynamically adjust learning rates and incorporate momentum. To identify optimal hyperparameters, a grid search was conducted over the number of epochs, learning rate, and batch size for each ResNet variant. The best-performing configurations were: 70 epochs, a learning rate of 0.0001, and batch sizes of 16 (ResNet-50 and ResNet-152) or 8 (ResNet-101).

5) Model training results: The training results of the instance segmentation models YOLOv8n-seg and YOLOv9c-seg are summarized in Tables II and III, showing their performance across different image resolutions (256×256, 512×512, 1024×1024). Both box (B) and mask (M) performance metrics were evaluated, including mAP50, mAP50–95, and precision (Pre), which together assess the models' ability to localize and delineate object instances at the pixel level. The results indicate that YOLOv9c-seg consistently outperformed YOLOv8n-seg.

across all tested resolutions and metrics. The highest performance was observed at the highest resolution (1024×1024), where YOLOv9c-seg achieved mAP50 values of 0.72130 for boxes and 0.69930 for masks. Additionally, an increase in input image resolution correlates with improved model performance for both architectures, emphasizing the significance of higher resolution imagery in enhancing segmentation precision. This is particularly important within the context of this study, where precise delineation of blackcurrant leaf instances from the background is essential for subsequent classification tasks. Nonetheless, the results are not without limitations, likely attributable to the relatively small size of the training dataset employed.

TABLE II
YOLOV8N INSTANCE SEGMENTATION RESULTS

Model	YOLOv8n-seg		
Image size	256x256	512x512	1024x1024
mAP50 (B)	0.59164	0.65656	0.67211

mAP50-95 (B)	0.46194	0.54670	**0.68643**
Pre (B)	0.74662	0.87470	**0.88182**
mAP50 (M)	0.65124	0.69849	**0.69930**
mAP50-95 (M)	0.47340	0.51147	**0.53121**
Pre (M)	0.72102	0.79023	**0.81230**

Table IV summarizes the training performance of three ResNet architectures (ResNet-50, ResNet-101, and ResNet-152) on a multi-label classification task. Among the evaluated models, *ResNet-152* achieved the highest overall performance, with accuracy, sensitivity, specificity, and precision reaching 94.0%, 96.7%, 98.8%, and 98.2% respectively. *ResNet-101* also demonstrated strong results, attaining 93.1% accuracy and 96.5% precision, while *ResNet-50* showed slightly lower accuracy (89.6%) but competitive sensitivity and precision,

and even outperformed *ResNet-101* in specificity. The results suggest that increasing model complexity yields diminishing returns, as the simpler *ResNet-50* architecture delivered satisfactory performance. The similar metric values across architectures imply that dataset characteristics, such as size and class distribution, may exert greater influence on model efficacy than network depth. Consequently, *ResNet-50* offers a favorable balance between accuracy and computational efficiency, making it a practical choice for this classification task.

TABLE IV
MULTI-LABEL CLASSIFICATION RESULTS TABLE

Model	ResNet-50	ResNet-101	ResNet-152
Acc (%)	89.6	93.1	94.0
Sen (%)	91.3	94.8	96.7
Spe (%)	98.2	98.1	98.8
Pre (%)	91.3	96.5	98.2
Epochs	70	70	70
Batch size	16	8	16
Lr	0.0001	0.0001	0.0001

Summarizing the instance segmentation and multilabel classification model training results, the authors selected YOLOv9c-seg for instance segmentation and ResNet-50 for multilabel classification as the final practical solution.

V. HISTORY OF FIELDS

For every farm, it is beneficial to maintain a field record journal that logs all activities within a specific agricultural area, including completed horticultural operations, the use of crop materials, and plant protection products. Several information systems already exist to support such functionalities.

However, this study focuses on collecting field images, offering a different perspective on historical data, both visually and through insights derived from image analysis. The goal of our research is to develop a solution that allows visual tracking of field changes over time while also providing timely detection of plant health issues identified through image analysis.

To ensure field history tracking:

- identify the surveyed fields (this information is used to plan drone flight and photography routes),
- conduct field surveys using drones to capture images and link them to specific geolocations,
- analyze the images to identify plant health issues,
- visualize the extracted information on a map for better interpretation and decision-making.

The results of the image analysis conducted on a single day are presented in Fig. 6. As shown, within the selected location, 6.51% of the identified leaves were classified as diseased, 0.38% exhibited signs of nutrient deficiency, and 93.10% were determined to be healthy.

This type of solution is designed for horticulturists. Their main interest is tracking long-term changes in fields, especially in crop cultivation involving perennial plants such as

Fig. 6. Blackcurrant field condition analysis result

blackcurrants. In such cases, even historical images taken from the same vantage point can provide valuable insights into field conditions, moisture levels, pest infestations, disease development, and more.

Although the functionalities may seem simple, this type of solution comes with certain technical challenges. Even if the captured images do not cover the entire field area, their number is sufficiently large, and storing historical images can be space-intensive, considering that blackcurrant plantations typically cover between 2 to 20 hectares. Moreover, analyzing such a vast number of images is time-consuming as it involves identifying and classifying thousands of leaves.

The problem can be partially solved by increasing the decreasing of the image capture grid, e.g., from 10 to 20 meters. A similar approach is used in the evaluation of soil fertility, where the sampling is carried out systematically at predetermined intervals. In this case of 20 meters, evaluating one hectare would require only 36 images, significantly reducing storage and analysis demands. This approach would still provide sufficiently representative information about the field's condition and the spread of potential issues.

VI. DISCUSSION

The study results demonstrate new technologies for monitoring blackcurrant vegetation. Instead of traditional visual assessments by horticulturists, an automated system is proposed, offering several advantages: precise plant evaluation using AI methods, applicability to large blackcurrant plantations, economic efficiency, and ease of implementation.

However, these achievements should be considered a first step toward precision agriculture in blackcurrant cultivation, requiring further development. The proposed approach relies on blackcurrant leaf analysis, which means it can only detect diseases affecting leaves, while issues affecting roots and stems - such as blackcurrant clearwing moth (*Synanthedon tipuliformis*) and blackcurrant bud mite (*Eriophyes ribis*) - remain undetected. Similarly, yield prediction requires an

alternative approach, possibly analyzing entire blackcurrant bushes rather than just leaves. Pest infestations can also only be partially identified through leaf analysis. Nevertheless, other blackcurrant cultivation challenges, such as crown rust, can be identified using similar methods by analyzing different plant parts, segmenting them in images, and classifying them based on the specific problem being addressed.

A. Additional Applications of the Method

A diligent horticulturist monitors not only the spread of blackcurrant diseases but also frost damage, flowering progress, yield ripening time and volume predictions, and other vegetation-related events. Although these aspects were not the primary focus of this study, they could be addressed by modifying the proposed method—for example, by segmenting and classifying flower buds and berry clusters accordingly.

Beyond plant vegetation monitoring, the method can also be applied to optimizing agricultural operations. By identifying disease-affected field areas, maintenance tasks such as targeted spraying can be carried out only in infected regions. This would lead to significant savings in materials and labor resources.

A promising direction for further development is integrating the method into dynamic robotic management. By transferring real-time data from the blackcurrant plant analysis module to an agricultural operations execution robot, it would be possible to perform precise interventions only where necessary, further increasing efficiency and sustainability.

B. Limitations of the Method's Application

When analyzing the benefits of the proposed method, it is also important to highlight its limitations.

One key limitation is the lack of precision in determining nutrient deficiencies. While the method can detect a deficiency, it cannot specify which particular nutrient — potassium, phosphorus, or nitrogen — is lacking. Currently, this type of analysis is performed using soil and plant agrochemical testing, which involves manually collecting soil and leaf samples. This process requires significant labor resources.

A more advanced approach involves spectral analysis of plants, which can provide more precise diagnosis of nutrient deficiency. However, this requires more complex imaging cameras.

In addition, leaves are only one indicator of plant health, but they do not reveal all potential problems. For example, pest infestations, such as the blackcurrant clearwing moth, which primarily affects the stems rather than the leaves, cannot be detected using this method.

VII. Conclusions

Key conclusions of the conducted research and its application results:

1) Blackcurrant plantation monitoring is recommended to be carried out in two stages: (1) field mapping – capturing plantation field images with the required precision; (2) image instance segmentation and multi-label classification – an instance segmentation model extracts individual leaf instances from the mapped images, and a multi-label classification model employs a trained neural network to identify fungal diseases and nutrient deficiencies by assigning one or more class labels to each leaf.
2) Mapping functions can be implemented using standard solutions available in commercial drone systems or by adapting open source solutions for blackcurrant cultivation. Segmentation solutions must be developed individually in collaboration with industry experts, in the case of this project, blackcurrant growers. This includes training a neural network for leaf recognition and transmitting the identified leaf information for classification. The classification task involves training a neural network to recognize specific characteristics of blackcurrant leaves, which is the final goal of the project and is of interest to horticulturists.
3) The final result consists of blackcurrant field images that visually distinguish between healthy areas, fungal disease-affected zones, and nutrient-deficient regions. The field history application provides horticulturists with an intuitive tool to monitor blackcurrant crop development over time
4) Scientific literature and practical experience confirm that drone-based plant condition monitoring is effective. Collected crop image datasets have significant potential for machine learning applications.

Following the identification of fungal diseases and nutrient deficiencies, future potential applications include prediction of yield, detection of pests, and identification of other plant diseases. A key challenge remains in improving the speed of image analysis, as computational demands can exceed the capabilities of simple and inexpensive hardware.

***Abstract*—Educational video games have demonstrated significant potential as a modern complement to traditional e-learning in higher education. However, the scarcity of free tools and platforms for creating and customizing educational games impedes their widespread adoption in teaching. This paper introduces an educational video game focused on entrepreneurship, developed using a custom-designed software platform for generating and personalizing learning-based video games through 3D mazes. This platform empowers educators to effortlessly construct hierarchical, personalized 3D mazes for interactive presentation of multimedia educational content. Learners engage with new ideas, concepts, and theories while navigating the 3D maze, and can participate in various embedded mini-games designed to enhance visual and spatial reasoning, psychomotor skills, and context-based reasoning—all of which are vital for successful entrepreneurship. The results obtained from the study are highly promising, particularly regarding the usability and effectiveness of the created 3D video game.**

***Index Terms*—serious game, maze, entrepreneurship, strategic management, GEQ.**

I. Introduction

SINCE the 1970s, computer games have continued to grow, evolving from simple text-based formats into complex, visually rich experiences. Modern computer games make extensive use of two-dimensional (2D) and three-dimensional (3D) video technologies, along with embedded multimedia content, to create immersive and interactive environments. Various genres of video games can now be identified [1], all falling into two main categories: entertainment and serious games. Entertainment games are designed primarily to entertain players [2]. In contrast, serious games (also known as applied games) are created with goals beyond entertainment, integrating entertainment with education, business, healthcare, public order, culture, and other areas [3]. These games have been successfully implemented as educational tools [4], learning environments for social reintegration of marginalized youth [5], rehabilitation platforms for different patient groups [6], and systems for improving cognitive and social activities in the elderly, as well as for telerehabilitation and prevention [7]. The increasing sophistication of serious games demonstrates their potential to engage users in meaningful ways, making learning more interactive, accessible, and effective across disciplines. This sophistication is supported by advanced research in areas such as game AI [8], underlying game theory [9], and even security considerations in game design [10].

This study focuses on innovative approaches to game-based learning in higher education, especially in entrepreneurship education. The target group was chosen due to the growing importance of entrepreneurship education as a key driver of economic growth and social progress [11]. Despite the importance of entrepreneurship education, the availability of educational games in this area remains limited. Furthermore, there is a lack of free software platforms that allow educators without technical expertise to create engaging educational games. This problem is why it is difficult to integrate game-based learning into entrepreneurship courses, as developing such games requires specialized IT knowledge.

If this challenge is met, game-based learning can enhance entrepreneurship courses by helping students develop domain-specific skills, such as critical thinking, problem solving, and innovation. This paper presents STRAMAG, an innovative educational video game designed to bridge this gap. Developed using an open-source, adaptive platform, STRAMAG uses 3D mazes to deliver personalized and hierarchical strategic management training within an entrepreneurship curriculum. Unlike generic educational games, STRAMAG focuses on developing specific skills necessary for entrepreneurial success. Learners navigate the 3D maze, engaging with multimedia content and participating in embedded mini-games designed to improve visual-spatial thinking, psychomotor skills, and context-based decision-making skills directly applicable to real-world entrepreneurial challenges.

The STRAMAG game was created as a customizable video maze using Brainstorm eStudio & API[1] and enabling educators with no IT skills to create engaging, hands-on learning experiences. An experiment with this game was conducted,

[1] https://www.brainstorm3d.com/products/estudio/

and the preliminary results of this study demonstrate the potential of this platform and game.

This paper has two primary objectives:

1. To introduce and describe STRAMAG, a novel adaptive 3D educational game designed specifically for entrepreneurship education;
2. To evaluate the game experience of students playing different mini-games with style-based adaptation of learning content inside a maze using the Game Experience Questionnaire (GEQ).

These objectives lead to the following research question: *How do different video mini-games that adapt educational content to learning styles affect student engagement*?

The paper is organized as follows: Section II reviews relevant literature on serious games, 3D maze games, entrepreneurship education, and game experience evaluation. Section III details the STRAMAG game's design, structure, and content. Section IV describes the experimental setup. Section V presents the results from the game experience evaluation. Section VI discusses the implications of these findings, and Section VII concludes with limitations and directions for future research.

II. Background

A. Serious games for education

Serious games are defined as tools that add entertainment elements to learning. These games are considered an alternative to entertainment games, although there is evidence supporting the acquisition of various skills and abilities through the latter, such as spatial thinking, strategic skills, and memory development [12]. Recent meta-analyses indicate that serious games can increase knowledge retention compared to traditional instructional methods [13], with particularly strong effects in applied fields like business and management [14].

The scenarios of serious video games involve problem-solving and decision-making activities, usually through content presented in three-dimensional form. One of the most intriguing challenges in designing serious learning games is how the player can make meaningful and beneficial choices in a serious context. One key approach to address this is through adaptation in these games. Adaptation in serious games operates at multiple levels: content adaptation (adjusting material based on prior knowledge), difficulty adaptation (modifying challenge levels based on performance), and path adaptation (altering the sequence of learning activities [15]. However, Mayer et al. [16] identified significant limitations in current adaptation mechanisms, noting that different player types cannot fully utilize their qualification levels, playing styles, and cognitive abilities when making key decisions. This limitation is particularly relevant to entrepreneurship education, where individual differences in risk tolerance, creativity, and decision-making styles significantly impact learning outcomes [17]. In other words, the personalization and adaptation of games remains an unresolved problem.

A key advantage of serious games in educational contexts is their ability to track a wide range of performance metrics beyond traditional assessments. As Rahimi and Shute [18] observe, these games not only test current knowledge and practical skills but also assess preparation for future learning by tracking collaboration, innovation, design thinking, and entrepreneurial abilities. Recent advances in learning analytics have enhanced this capability, allowing for more sophisticated assessment of complex competencies [19].

B. Adaptive 3D Maze Games for Learning

Many of the latest approaches to learning through games rely on the use of serious maze games for educational purposes [20]. Mazes are widely used in entertainment games and can be represented by graphs, making them very suitable for interactive content presentation, where the player chooses one of several possible actions. Typically, a maze presents part of a course or module, where each position (i.e., a node in the maze's graph) contains information about a concept or situation. For a given position, there are several possible choices (actions) through which the player can continue in the maze. After selecting the desired action, the player moves to the next position (node) of the transition graph and explores the information in that node to decide how to proceed further. In this way, he/she can navigate the entire maze, following his/her strategy for choosing nodes in the transition graph and familiarizing himself/herself with the learning material presented in it. In this way, mazes enhance engagement and promote active learning are a useful tool for educational games.

The 3D virtual environments offer significant potential for engaging and immersive learning, and this extends to maze-based educational tools. While platforms like EcoMUVE [21], which allows students to explore complex ecological systems, and Second Life [22] have demonstrated the capacity of 3D environments for experiential learning, challenges remain in adapting these tools for specific pedagogical needs. Specifically, the authoring and modification of 3D learning content often demand considerable technical expertise from educators, hindering widespread adoption in mainstream education [23]. In contrast, simpler 2D maze creation tools, such as those created with Scratch [24] for basic navigation skills, provide greater accessibility but typically lack the immersive qualities and capacity for sophisticated, scenario-based decision-making that more complex 3D environments can offer [25].

The primary limitations of current maze-based learning tools include:

1. Limited educator control over content without programming knowledge
2. Insufficient adaptation to different learning styles and paces
3. Weak connection between maze structure and pedagogical objectives
4. Inadequate assessment mechanisms for complex competencies.

These limitations are particularly problematic for entrepreneurship education, where rapidly evolving business landscapes require frequent content updates, and diverse student backgrounds necessitate personalized learning paths [17].

C. Teaching technological entrepreneurship through serious games

The application of games in strategic education has a rich history, tracing back to 17th-century war games that simulated complex military decisions [26]. Contemporary computer-based simulations have become increasingly prevalent in entrepreneurship education, with numerous studies demonstrating their effectiveness in developing specific entrepreneurial competencies [27]. The competencies targeted with these games include opportunity recognition and evaluation, resource acquisition and allocation, risk assessment and management [13], business model development and pivoting, and market analysis and competitive positioning. These competencies are crucial parts of all stages of the strategic management process, and their proper implementation increases the chances of success of strategic management.

Neck and Greene [11] argue that entrepreneurship is best taught as a method rather than a process, requiring active practice of entrepreneurial thinking rather than passive learning of concepts. Serious games align perfectly with this pedagogical approach by allowing students to experiment with entrepreneurial decisions in low-risk environments [28].

Several initiatives have emerged to support the development and implementation of serious games in entrepreneurship education:

- The Serious Games Initiative [29] focuses on addressing management and leadership challenges through game-based learning
- The eSG Project [30] aims to stimulate innovation and entrepreneurial mindsets through tailored video games
- ENTRExplorer [31] emphasizes entrepreneurial motivation and risk-taking through gamified learning experiences.

A diverse array of techniques and methodologies for applying serious games in technology entrepreneurship exists [32], including the use of customizable video mazes to teach effectuation through specialized software platforms [33]. However, the potential of style-based adaptive video games remains largely unexplored [12]. Preliminary research among master's students in entrepreneurship indicates a positive reception to these games, particularly regarding their ability to capture student interest [12]. Further investigation, incorporating student interest indicators and adaptive game implementation, alongside detailed student feedback, is essential to comprehensively understand the motivational impact of style-based adaptive video games.

D. The Game Experience Questionnaire (GEQ)

The Game Experience Questionnaire (GEQ) [34] is a widely validated and standardized instrument specifically designed to assess the multifaceted subjective experience of players during gameplay. Beyond simply measuring enjoyment, the GEQ delves into key aspects of engagement that are particularly relevant to the effectiveness of serious games for learning. These aspects include:

- Immersion - the degree to which players feel absorbed in and connected to the game world, a crucial factor in maintaining attention and facilitating engagement with learning content.
- Flow - a state of optimal experience characterized by deep concentration, a sense of control, and intrinsic enjoyment, which can significantly enhance learning and motivation.
- Competence - the player's feeling of mastery and effectiveness within the game, which can positively impact self-efficacy and the willingness to tackle challenging learning tasks.
- Tension/Challenge - The level of pressure and difficulty experienced, which, when appropriately balanced, can drive engagement and critical thinking.
- Negative Affect - feelings such as frustration, boredom, or anxiety, which can hinder learning and should be minimized in effective educational games.
- Positive Affect - emotions like enjoyment, fun, and satisfaction, which can foster a more positive learning attitude and improve retention.

The GEQ provides valuable insights into how players interact with and perceive a game, highlighting elements that contribute to engagement and overall experience. Understanding these aspects is crucial in the context of serious games, as a positive and engaging experience can enhance learning outcomes. By quantifying these subjective dimensions, the GEQ allows researchers to gain a deeper understanding of how game design choices impact player engagement and overall experience, providing essential data for the design and evaluation of serious games aimed at achieving specific learning outcomes.

E. Synthesis and Research Gap

According to the literature review, each of the domains - 3D maze serious games, entrepreneurship education and motivational design - contributes to effective entrepreneurship education. 3D maze serious games provide opportunities for engagement and assessment and offer solution-based learning pathways. Entrepreneurship education defines critical competencies. Understanding the game experience, as measured by instruments like the GEQ, provides a framework for evaluating the effectiveness of these games in engaging learners.

However, significant gaps remain in the effective integration of these elements:

- Most existing entrepreneurship games lack sophisticated adaptation mechanisms to suit individual learning styles and entrepreneurial orientations
- Current 3D learning environments require technical expertise to be modified, which limits their usefulness for entrepreneurship educators
- Few platforms combine immersive 3D environments with teacher-friendly content management systems

The STRAMAG game addresses these gaps by providing an accessible system for creating adaptive 3D maze learning

environments specifically designed for entrepreneurship education. Unlike previous approaches that prioritize either technical complexity or ease of use, STRAMAG offers both and enables non-technical educators to create serious games. By focusing on creating an engaging game experience (assessed using the GEQ) and mapping maze structures to entrepreneurial decision-making processes, STRAMAG represents a new synthesis of the research areas discussed above.

III. THE STRAMAG GAME

A recent research of game-based learning indicated that most serious game studies focus on learning conceptually, with concepts such as general reasoning, creativity, system understanding, and decision making, which do not demand special knowledge of subject areas [2]. This study, however, investigates the use of style-based adaptive video games to enhance learning motivation within a strategic management module of an entrepreneurship program.

The game design and learning content were developed adhering to the Essential Design Criteria for Educational Games [32], which emphasize:

1. Winning should be based on knowledge or skills, not random factors.
2. The game should focus on core curriculum content, not trivial information.
3. The dynamics of the game should be easy to understand and interesting for the players but not obstruct or distort learning.
4. Students should not lose points for wrong answers.
5. Games should not be zero-sum exercises.

One of the biggest challenges in developing learning content for games is the risk that the content in these games is too general and inappropriate for fulfilling existing curricula [3], which leads to an inability to accurately evaluate the applicability of serious games in education. The learning content of this experiment was developed following the educational curricula of the “Strategic management” course within the master's degree program “Technology Entrepreneurship and Innovations in IT” at Sofia University “St. Kliment Ohridski” (Bulgaria). More precisely, the didactic content in the maze game is based on the first two modules of this course, namely “Introduction to Strategic Management” and “Strategic Management Analysis”.

A. Structuring of the learning content

The implementation of a style-based adaptive video game in the educational process of Strategic management required preparation of a specific learning content for the game. This content was designed to:

- Encompass all key syllabus elements;
- Offer well-structured and precise information for each of the elements in the syllabus;
- Offer textual and graphic learning content in format and size, which is supported by the game's design;
- Include learning content suitable for the learning styles of all four basic types - theorists, reflectors, pragmatists, and activists.

The learning content was structured into learning units [11] based on the strategic management process [31], covering the initial stages: Strategic Philosophical Values and Strategic Analysis. An overview of the overall strategic management process is also included at the beginning of the learning content, as it is included in the educational curricula.

The learning content in the game incorporated the following elements:

- Overview of the Strategic Management Process and Stages;
- Strategic Philosophical Values (company values, vision, mission, strategic goals);
- Strategic Analysis (SWOT Analysis, PEST Analysis, Porter’s Five Forces Analysis, VRIO Analysis, USP Analysis).

The learning units, included in the 3D serious educational game STRAMAG, cover the introduction to the Strategic Management Stages. Following the initial structural knowledge on the process stages, a thorough view of the strategic philosophical basics is introduced. These include Strategic Philosophical Values of the company, Vision, Mission, and Strategic goals. These competencies are of crucial importance for the stable strategic management of the company. After introducing the competencies for forming the foundation of strategic management of the company, an introduction to Strategic Analysis is performed. The Strategic Analysis tools included in the game start with SWOT Analysis. This basic micro-environment analysis on the internal strengths and weaknesses, and external opportunities and threats is focused on analyzing all specific factors for the company impacting its strategic choices. This is done through dividing the factors by two scale dimensions – source type (internal/external) and impact type (positive/negative). This tool is applicable in every occasion of changes in the micro-environment and is one of the most widely used strategic management tools. The second Strategic Analysis Tool implemented in the game is PEST Analysis. It is evaluating external political, economic, social, and technological macro-environment factors influencing the company, and it is of very high importance for strategic management when changing the external macro-environment, starting operations in a new market for the company, or facing large changes in the current market. [35] The third Strategic Analysis Tool included in the game is Porter’s Five Forces Analysis. Its goal is to analyze the competitive intensity and attractiveness of an industry, and it is achieving its goal through analyzing the forces that shape them – Competitive Rivals, Potential for New Entrants in an Industry, Supplier Power, Customer Power, and Threat of Substitutes. The fourth Strategic Analysis Tool, which is included in the game, is VRIO Analysis. It is focused on evaluating the availability, type and strength of the company’s competitive advantage. The fifth Strategic Analysis Tool included in the STRAMAG game is USP Analysis. The Unique

Selling Proposition Analysis is a detailed approach to identifying the specific competitive advantages in the company's offers. USP Analysis is a crucial step in defining a strategic advantage for the company's products on the market. It is supporting the development of products and services with higher value for the customers with great precision due to the evaluation of each feature and its level of importance for the customers. [36]

Each learning unit developed in STRAMAG game includes: (1) textual learning content, (2) graphical learning content, (3) additional information (video, textual, graphical, etc.), (4) additional learning tasks and homework. The learning tasks and homework were grouped based on their appropriateness for a specific learning style of Honey and Mumford [37]. Therefore, four groups of tasks were created, appropriate for the learning style of activists, reflectors, theorists, and pragmatists as follows:

- Activists' tasks – include implementation of different activities, aiming to increase the learning motivation of activist players
- Reflectors' tasks – include materials, tasks and puzzles, giving them opportunity for commenting, overviewing and reflecting on the educational materials and practices
- Theorists' tasks – include reading texts and further materials, creating structures and solving logically complex problems
- Pragmatists' tasks – include directions for direct application of the learned theoretic materials, best practices and examples.

B. Game design and structure

Effective implementation methodologies are crucial for the success of serious games in education [5, 6]. Recent applications have demonstrated the efficacy of maze structures for presenting learning material [7], which are also employed in the "STRAMAG" 3D educational game. Students navigate between learning units situated within "rooms" (nodes) by selecting from connecting "tunnels" (pathways).

Each learning unit is situated within a distinct "room." The "tunnels" connecting these "rooms" incorporate tasks and mini-games tailored to individual student learning styles. Figure 1 illustrates the organization of learning units and their placement within these "rooms," with numerical identifiers (0-9) indicated in red circles.

Both "rooms" and "tunnels" contain learning materials and tasks designed for different learning styles. The game's adaptive algorithm ensures students are presented only with content relevant to their specific style.

The primary objective is to address the unique learning needs of each student and enhance their motivation through the use of a style-based adaptive video game. To illustrate the specific learning content delivered through this maze structure, the following section details the content within each of the ten rooms (or halls) of the maze representing the "STRAMAG" game.

C. Description of the maze rooms with learning content

The maze contains ten rooms (interconnected via tunnels), as follows below.

Room 1: "Strategic Management - Basic stages" – includes information about the basic stages in the strategic management process: Philosophical values - Strategic Analysis - Strategy Formulation - Strategy Implementation - Strategy Execution - Strategy Control and Evaluation. It includes textual material, graphics and diagrams clarifying the concepts, as well as links for further reading.

Room 2: "Strategic Management – Vision" – provides the textual learning content connected with company's vision - definition, basic elements, major directions when formulating the vision and most important questions, which the vision should answer. The learning content also includes practical examples of visions from real companies and links for further reading on the topic.

Room 3: "Strategic Management – Mission" – contains textual content on company mission: definition, differentiation from vision, key questions, examples, video materials, and links for further reading.

Room 4: "Strategic Management - Strategic goals" – focuses on strategic goals and requirements, explaining SMART goals, key questions, graphics, and links for further reading.

Room 5: "Strategic Management - Strategic analysis introduction" – covers the importance and place of strategic analysis in the strategic management process, basic analysis directions, the distinction between strategic analysis in the internal and external environment, basic tools of strategic analysis, examples, and links for further reading.

Room 6: "Strategic Management -Strategic analysis - SWOT Analysis" – focuses on SWOT analysis. It includes textual and graphical learning content describing the tool, all of its elements, the basic questions, and the direction for analysis in each of its sectors, as well as providing a thorough step-by-step guide for implementing the analysis, suitable also for pragmatists and activist learners.

Room 7: "Strategic Management – Strategic analysis - PEST Analysis" – dedicated to PEST analysis. The learning content includes textual and graphical information about the analysis, its application, elements, basic questions, and directions in the implementation of each element of the analysis, as well as an explanation of the other variations of the PEST analysis - PESTLE/PESTEL/PESTLED/STEEPLE/etc.

Room 8: "Strategic Management - Strategic analysis - P5F Analysis" – covers Porter's Five Forces Analysis, its definition, application, content, directions in implementation, and application. It describes all the basic powers in the analysis, their specifics, and influence on the others, as well as information on the key practical points in applying the P5F Analysis in the Strategic Management Process.

Room 9: "Strategic Management - Strategic analysis - VRIO Analysis" – covers VRIO analysis, its definition, textual and graphical presentation, its importance, and a graphical presentation of the methodology of evaluating the type

and durability of the competitive advantage of a company by providing a step-by-step evaluation model for practical application of the analysis.

Room 10: “Strategic Management - Strategic analysis - USP Analysis” – focuses on USP analysis and its importance in the strategic management process for entrepreneurial companies. The room contains the definition of the analysis, its application, and a practical graphical and textual presentation of an example in the application of the analysis.

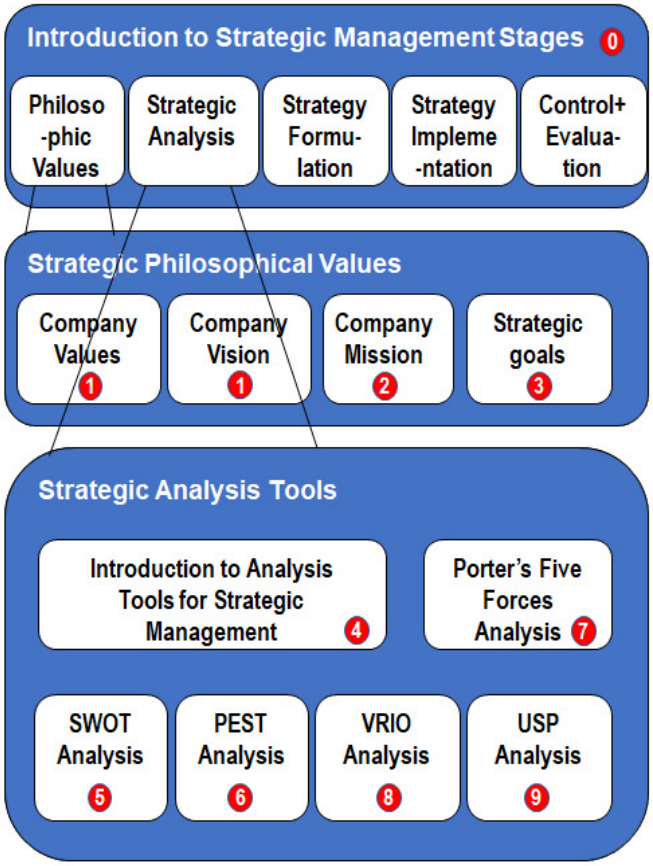

Fig 1. Content distribution across learning units and game rooms

Each room is accessible by "tunnels" and contains tasks and puzzles tailored to individual learning styles, determined during initial gameplay. The "tunnels" feature tasks and activities designed for activist, reflector, theorist, and pragmatist learning styles.

The learning content in every room and the tunnels includes materials and tasks suitable for all learning styles, but all players are shown only the elements suitable for them, according to the learning-style adaptation of the game. The goal is for the learning content to respond to the learning needs of every student in the game, about his/her learning style, and to foster learning motivation during the educational process by using a style-based adaptive video game.

Other mini-games include arranging contextually related images and assembling 3D geometric bodies, which develop associative thinking and spatial imagination. Teachers can customize both the quiz questions and the content of the other mini-games.

Fig. 2. Start screen of the STRAMAG game

The educational content presented in the maze rooms (Fig. 2) encompasses the theory of effectuation, developed by Dr. Saras Sarasvathy [38]. This theory, which has become popular in the last decade, focuses on strategies for achieving entrepreneurial goals under conditions of uncertainty [39].

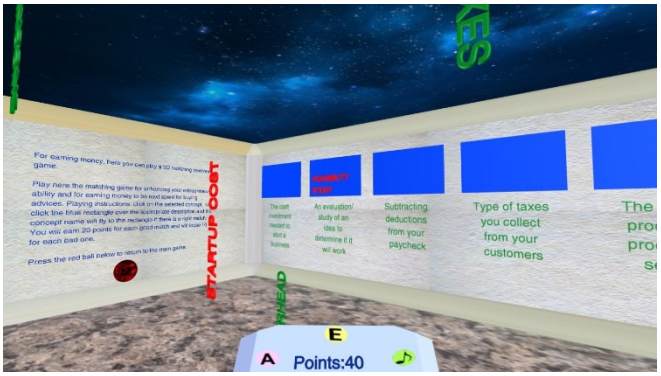

Fig. 3. Inside one of the matching games in the quiz room

Each tunnel passage requires students to use a certain number of points, which adds an element of strategy and planning. To increase their points, students must complete additional tasks integrated into the game.

Fig. 4. Screen of the 3D Zoom game

To prevent monotony and increase the effectiveness of learning, a variety of mini-games are included in the maze. These mini-games are designed to develop fine motor skills, visual-spatial thinking, and context-based decision-making abilities, encouraging entrepreneurial activity and creativity. The mini-games range from entertaining to those with a clear didactic purpose, such as 3D quizzes and games with goal-oriented tasks. For example, a dynamic 3D quiz (Fig. 3) requires students to select from moving text objects containing answers to questions. The speed of movement and rotation of the objects can be adjusted to vary the difficulty. Correct answers are awarded points, allowing the quiz to be used as an assessment tool.

IV. Experimental Setup

The 3D Maze game for entrepreneurship education described above was used in a practical experiment together with two included mini-games – a quiz (3D Quiz – Fig. 3) and an arrangement of scattered context-related images (3D Zoom – Fig. 4). The selection of the educational content and mini-games was coordinated with leading experts in the area of entrepreneurial education, who possess many years of experience in entrepreneurship education. The essence of the effectuation theory, its principles, their comparison with those of causal relationships, as well as the process and entrepreneurial method identified by Sarasvathy [39], were described on boards and interactive whiteboards in six rooms of the maze. The test questions in the 3D Quiz referred to both the educational content presented in the halls and to basic concepts in entrepreneurship, such as what a feasibility study is, net profit, initial and overhead costs, etc.

23 students from the master's program in Technological Entrepreneurship at the Faculty of Mathematics and Informatics of Sofia University "St. Kliment Ohridski" participated in the experiment. All participants had excellent computer skills and basic knowledge of entrepreneurship.

The practical experiment consisted of a presentation and demonstration of the 3D maze video game "STRAMAG", followed by individual game sessions, each lasting approximately 10 minutes. After the sessions, participants completed the GEQ [34], which assesses the level of engagement and experience during gameplay.

V. Results

A. Player profiles

23 students enrolled in the master's program in "Technology Entrepreneurship and Innovations in IT" at the Faculty of Mathematics and Informatics of Sofia University "St. Kliment Ohridski" participated in this study. The age of the participants ranged from 20 to 35 years. The mean age was approximately 26.3 years, with a standard deviation of approximately 3.8 years. The gender distribution of the participants was 15 males and 8 females. Before participation, all students self-assessed their computer skills on a 5-point scale (1 = lowest, 5 = highest). The distribution of self-assessments was as follows: 0 participants rated their skills as a 1, 2 as a 2, 2 as a 3, 15 as a 4, and 4 as a 5. This distribution indicates a generally high level of self-perceived computer proficiency within the participant group.

B. GEQ results

Figure 5 and Table I illustrate the responses to the GEQ questions. Overall, students reported a positive experience with the STRAMAG game. High mean scores were observed across several dimensions: Immersion, Positive Affect, Competence, and Flow. These results suggest that students found the game engaging, enjoyable, and provided a strong sense of mastery.

TABLE I.
MEAN VALUES OF GEQ DIMENSIONS AND ASSOCIATED QUESTIONS FOR DIFFERENT MINI-GAMES (3D MAZE, 3D QUIZ, 3D ZOOM)

Dimension	Questions	3D Maze	3D Quiz	3D Zoom
Competence	2, 10, 15, 17, 21	3.91	3.74	4.09
Immersion (sensory & imaginative)	3, 12, 18, 19, 27, 30	4.35	4.13	4.17
Flow	5, 13, 25, 28, 31	3.70	3.96	3.87
Tension/ Annoyance	22, 24, 29	2.32	2.04	2.17
Challenge	11, 23, 26, 32, 33	2.09	2.17	2.26
Negative Affect	7, 8, 9, 16	2.14	2.06	2.36
Positive Affect	1, 4, 6, 14, 20	3.96	3.74	4.09

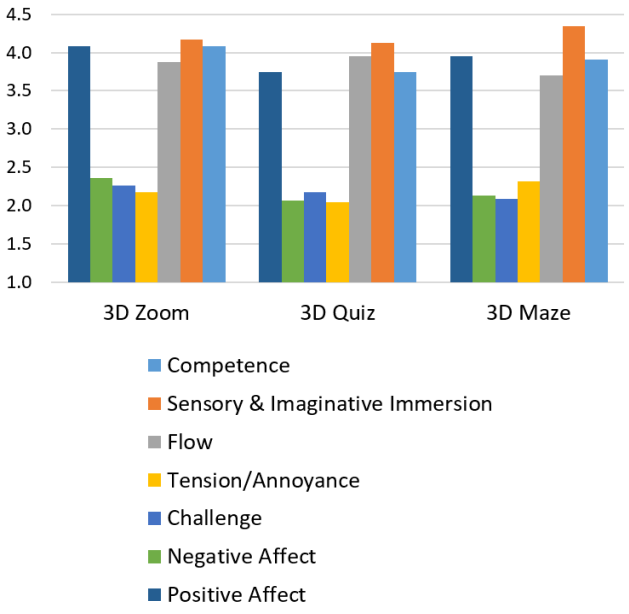

Fig. 5. Responses to the questions from the GEQ

The Negative Affect dimension showed consistently low scores across all game versions (3D Maze: 2.14, 3D Quiz: 2.06, 3D Zoom: 2.36), indicating minimal levels of frustration, boredom, or anxiety. Similarly, the Tension/Annoyance dimension yielded low scores (3D Maze: 2.32, 3D Quiz: 2.04, 3D Zoom: 2.17), suggesting that students experienced little discomfort. The Challenge dimension also showed moderate scores (3D Maze: 2.09, 3D Quiz: 2.17, 3D Zoom: 2.26), reflecting an optimal level of difficulty for maintaining engagement.

VI. Discussion

The findings of this study provide strong evidence for the usability and effectiveness of the STRAMAG game as an educational tool for entrepreneurship and strategic management. The game's 3D environment, combined with embedded mini-games, offers a dynamic and interactive learning experience that traditional methods often lack. Moreover, the novelty of the STRAMAG game consists in introducing an adaptation of learning content based on the learning style of the individual player. The results presented in Fig. 5 show that different video mini-games that adapt educational content to learning styles affect student engagement in a slightly different way.

The positive responses observed in the GEQ indicate that the game effectively engaged the students. The high scores for Immersion, positive effect, Flow, and Competence can be attributed to the design of the 3D maze environment and the integration of relevant entrepreneurial concepts within the maze structure and the embedded mini-games.

The Negative Affect dimension showed consistently low scores across all mini games (3D Maze: 2.14, 3D Quiz: 2.06, 3D Zoom: 2.36), indicating a minimal level of frustration, boredom, or anxiety. Similarly, the Tension/Annoyance dimension yielded low scores (3D Maze: 2.32, 3D Quiz: 2.04, 3D Zoom: 2.17), suggesting that students experienced little discomfort. The Challenge dimension also showed moderate scores (3D Maze: 2.09, 3D Quiz: 2.17, 3D Zoom: 2.26), reflecting an optimal level of difficulty for maintaining engagement.

It is important to acknowledge the limitations of this study. The sample size of 23 master's students, while sufficient for preliminary analysis, may limit the generalizability of the findings. Future research should aim to include larger and more diverse student populations. Additionally, longitudinal studies could investigate the long-term impact of the STRAMAG game on students' entrepreneurial skills and career trajectories. Further refinement of the game's adaptive mechanisms and exploration of additional game-based learning strategies are also warranted.

VII. Conclusions

The use of educational video games in higher education has the potential to significantly enhance the outcomes of traditional e-learning by making it more engaging and effective. Video games offer innovative ways to acquire knowledge and practical skills through informal and often implicit problem-solving.

This research was motivated by the existing lack of customizable and free video games for educating young people in entrepreneurship and strategic management [40]. The developed software system for declarative description, personalization, and generation of 3D video mazes, or such that offer a free solution for mass game-based learning, not only in entrepreneurship. It allows teachers to construct mazes presenting content from a given subject area in a personalized and interactive way, where the learner chooses how to continue navigating the maze. In addition to becoming acquainted with new ideas, concepts, and theories in a 3D maze, learners can play entertaining embedded mini-games with didactic value that develop motor skills, visual and spatial thinking, and context-based reasoning. The positive results from the Game Experience Questionnaire indicate that students found the STRAMAG game to be highly immersive and perceived the learning content as useful, suggesting the potential of this game for engaging and effective entrepreneurship education.

Future research and development should focus on several key areas. Firstly, expanding the learning content within STRAMAG to encompass a broader range of entrepreneurship topics would increase its applicability. Secondly, implementing more nuanced adaptive learning mechanisms that dynamically adjust difficulty and content based on individual student progress and learning styles could further enhance its effectiveness and foster a greater sense of competence. To further capture and maintain student attention, future iterations could explore incorporating more dynamic visual elements and unexpected challenges. Additionally, enhancing the perceived relevance of the content through personalized pathways and real-world scenarios, and integrating a more robust reward system to increase learner satisfaction, are important avenues for future development. The authors plan to compare the knowledge acquisition of students who played the game with those who did not by conducting a controlled experiment with a larger sample size, dividing participants into experimental and control groups. Finally, exploring the integration of collaborative gameplay features could foster social learning and engagement among students.

***Abstract*—The number of STEM camps and extracurricular initiatives has risen considerably in recent years, driven by the increasing emphasis on the workforce shortage in STEM fields. However, despite their growth, these programs often suffer from a lack of structured evaluation practices, a well-known issue that hinders a comprehensive understanding of their effectiveness. This work focuses specifically on outreach initiatives and proposes ELEVATE-AI, a standardized evaluation platform that includes data-cleaning procedures, Exploratory Factor Analysis (EFA), and regression analysis to measure impacts effectively. Furthermore, we discuss the potential integration of AI-based tools to support non-experts in interpreting the results of the proposed analysis flow. The platform aims to lower technical barriers, promote systematic assessment, and encourage the widespread adoption of data-driven practices in evaluating CS and STEM outreach activities. To facilitate adoption and reproducibility, the platform will be made available as an open-source tool.**

I. Introduction

IN RECENT years, particularly since the mid-2010s, there has been growing attention at all levels of society toward increasing the number of graduates in STEM fields, particularly in computer science (CS). Public institutions such as the European Union have highlighted the urgent need for more professionals in digital and technological sectors, citing projected shortages of ICT specialists and the importance of closing the gender gap in these domains [1]. Similarly, the OECD and national education authorities have acknowledged the underrepresentation of women in STEM careers and the need for inclusive educational strategies [2].

Among the most prominent approaches to address this challenge are extracurricular and outreach initiatives, activities not formally associated with standard curricula but aimed at introducing students to STEM topics through informal, hands-on learning. Particularly in the case of girls, experiential and mentorship-based learning environments have shown effectiveness in fostering self-efficacy and interest in STEM subjects [3]. Broader studies confirm that these benefits extend to students of all genders when appropriate pedagogical strategies are used [4].

Despite their increasing prevalence, many outreach initiatives lack systematic evaluation, limiting their scalability and long-term impact [4], [5]. Programs often shift focus to trending topics, such as artificial intelligence, without assessing the impact of each iteration, resulting in design decisions based more on intuition than evidence [6]. One of the reasons for this absence of evaluation is the informal nature of these activities: unlike curricular settings, where learning outcomes can be tested directly, outreach initiatives tend to rely on self-perception measures rooted in Bandura's theory of self-efficacy [7].

Nevertheless, recent research demonstrates that robust evaluation is feasible even in informal contexts [5]. In this paper, we propose an open-source, self-hostable platform that provides a standardized, literature-informed workflow for evaluating extracurricular STEM initiatives. The platform, intended to be accessible to both researchers and educators, automates the main key phases of the evaluation process: survey design and deployment, data collection and validation, Exploratory Factor Analysis (EFA), and regression-based impact evaluation. The platform is designed to promote broader adoption of data-driven evaluation practices and to support community-driven contributions to its development. A valuable additional contribution of this paper is that the platform will be publicly released as an open-source resource, to maximize its impact and facilitate rapid adoption by researchers and practitioners.

The remaining part of the paper is structured as follows. Sec. II discusses the motivational background of the proposal. Sec. III describes the methodology including the three main phases of survey design, data collection and validation, and data analysis and implementation. Sec. IV presents the platform architecture and Sec. V illustrates the user interaction workflow. Finally, Sec. VI provides some concluding remarks and depicts the future research directions.

II. Motivation and Background

The evaluation of STEM and CS outreach activities, particularly in extracurricular settings, presents methodological challenges not typically encountered in formal education. In such informal contexts, learners often engage voluntarily, and activities are less structured, with outcomes being more affective or motivational than knowledge-based.

In contrast, the curricular context benefits from the increasing automation of evaluation processes, which often extends to automatic analysis and feedback generation. Several examples

illustrate this trend, particularly in STEM education. Cipriano et al. [8] present Drop Project, a platform designed to automate test result analysis and feedback for programming assignments. Similarly, Web-CAT[9] offers an automated grading system that compiles, tests, and evaluates student code submissions, providing immediate feedback. Majerník [10] introduces an e-Assessment Management System aimed at comprehensively evaluating medical students' knowledge, while, more generally, Stanescu et al. [11] propose a solution for automatic assessment of narrative answers, further demonstrating how structured digital platforms can support rigorous assessment practices even in highly specialized domains. These platforms are just some examples of how it is not only feasible but also widely applied to automate evaluation systems when grading and formal tests are involved.

Another contribution to formal testing automation in STEM is *LASSO* [12], a tool designed to support instructors in the assessments of their courses. LASSO's primary purpose is to promote the implementation of research-based teaching practices; in fact, it guides the teacher through a rigorous process of pre-test and post-test analysis. The platform consists of a generalized version of the previously cited Web-CAT and Drop Project, providing a platform to facilitate rigorous formal evaluation in all STEM fields.

More broadly, in formal education, structured assessments such as knowledge tests allow for systematic and replicable evaluation. Notably, Hattie's Visible Learning synthesis [13] aggregated thousands of studies to quantify the effect size of nearly every measurable educational intervention. This kind of quantification is feasible mainly because of the controlled nature of formal instruction and the availability of consistent outcome measures.

Nevertheless, the principle behind Visible Learning, making instructional choices based on solid evidence rather than trends or intuition, is just as applicable in informal learning. Even in the absence of formal testing, it is possible to build robust evaluation models using survey-based self-perception data as long as those instruments are rigorously validated and analyzed. By supporting outreach practitioners in collecting and interpreting valid data, we argue that evidence-informed design is not only possible but necessary in extracurricular education.

While standardized questionnaires and evaluation frameworks developed for formal environments cannot be directly transplanted into outreach contexts without adaptation, several initiatives have attempted to improve evaluation in informal contexts, such as the CISE REU toolkit [5] and the survey repository curated by Decker and McGill [14]. Although these resources provide a helpful starting point, they require contextual refinement to be used effectively in pre-college or extracurricular settings.

Knekta et al. [15] indeed underline the issue of contextualization by arguing that validity is not a property of an instrument itself but of the inferences drawn from its use in a specific context. Their study, titled "One Size Doesn't Fit All," emphasizes the importance of context-specific validation using techniques such as Exploratory Factor Analysis (EFA). In their view, even well-designed instruments must be empirically validated with data from the actual population and learning setting in which they are used. This is particularly relevant for outreach initiatives targeting diverse, often underrepresented groups in non-standard learning environments.

In line with the need for contextualization, the *Towards s'more Connected Coding Camps* study [16] outlines the vision of the European OSCAR initiative, which seeks to integrate informal STEM learning experiences, such as coding camps, into students' broader educational and professional trajectories. The initiative focuses on the current fragmentation of the panorama of extracurricular activities. The proposal is to give continuity and align these activities with formal education, developing a coherent learning pathway in which informal learning is no longer treated as an isolated experience but contributes meaningfully to long-term educational outcomes.

TheFragebogen [17], a web-based, open-source questionnaire framework initially developed for Quality of Experience (QoE) research, provides a compelling model for digital instrument delivery. Its architecture is guided by three design principles: responsiveness to research needs (e.g., multimedia support, scalability), extensibility and flexibility (including serverless deployment), and a focus on robustness and reproducibility (e.g., long-term data archiving). While it originates outside the domain of education, TheFragebogen exemplifies how modular, browser-based systems can meet the needs of research-grade data collection. These principles are particularly relevant to the design of evaluation tools for outreach education, where technological robustness must be paired with usability and adaptability.

The evaluation platform proposed in this paper results from several years of iterative refinement grounded in field experience. Specifically, its development began in 2016 within the context of *Digital Girls* [18], [19], a long-running Italian initiative launched in 2013 to engage female students aged 16–18 and introduce them to computer science (CS). The project is recognized in the Observatory for Public Sector Innovation Case Study Library [1] and was cited in the European Commission's 2021 *She Figures* report[2].

Digital Girls evolved from a single-university summer camp into a regionally coordinated program supported by local universities, schools, and stakeholders. It combines site visits, guest lectures, and project-based learning in a female-only setting, addressing confidence gaps and gender stereotypes before university entry. The program spans two weeks and offers approximately 50 hours of immersive activities in university settings.

The iterative enhancement of this program and its evaluation methodology followed a design-based research model [20]. The research adopted an iterative and literature-informed de-

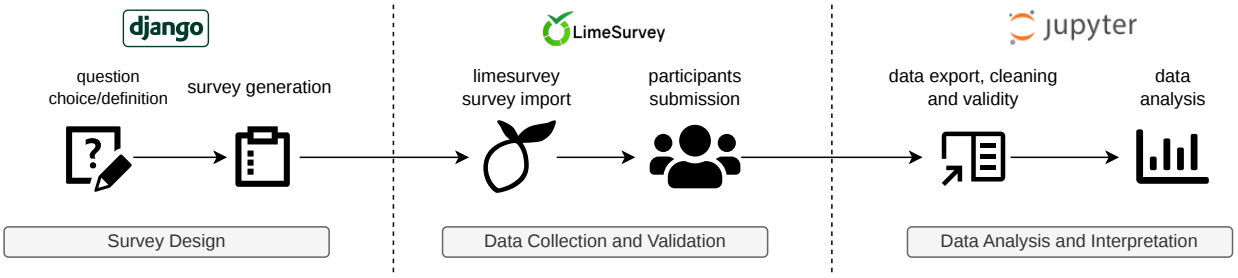

Fig. 1. Overall Platform Flow and Underlying Technologies

sign approach [21] involving cycles of instrument refinement, deployment, and validation. Survey instruments were informed by existing literature references but were adapted through feedback gathered via focus groups with past participants [22].

The resulting methodology includes two core survey phases, pre-camp, and post-camp, designed to capture changes in participants' perceptions, intentions, and confidence regarding CS. Several questions are repeated across both surveys to enable a longitudinal comparison of key indicators. Additional dimensions include background data (school type, video game experience, coding exposure), social influence (parental background), and affective constructs (motivation, stereotype perception), which align with Bandura's theory of self-efficacy [7] and Ajzen's theory of planned behavior [23].

Given the informal learning setting commonly associated with extracurricular initiatives, the evaluation strategy commonly deliberately excludes formal knowledge testing. Instead, it relies on participants' self-assessment to understand whether and how their attitudes have shifted as a result of the experience. A typical example is the measurement of self-efficacy in relation to the main topic of the camp, such as programming or algorithmic thinking. These constructs are typically evaluated through Likert-scale items, which provide a straightforward basis for statistical analysis. In some cases, free-text questions are added as they can provide meaningful additions or subtractions to the Likert items [24].

One of the main goals of STEM extracurricular initiatives is to engage participants and encourage them to consider future academic or professional paths in STEM fields. These programs are designed with the hope that, after the experience, participants will be more inclined to include STEM-related options among their future choices. In this context, Ajzen's theory of planned behavior [23] is particularly relevant, as it provides a framework for analyzing changes in intention. For instance, one of the main objectives of the *Digital Girls* initiative is to investigate whether the camp experience influences participants to reconsider their university plans, specifically, whether they become more likely to pursue a degree in computer science. To this end, the pre- and post-camp surveys are structured to detect shifts in intention, which can be analyzed as dependent variables in regression models to assess the impact of specific features of the camp.

III. Methodology

The multi-year experience derived from the organization of Digital Girls and other initiatives related to STEM disciplines led to the formalization of the platform presented in this paper. The platform is open-source, self-hostable, and modular, being written in Django, a Python framework for web platforms. It is structured, as shown in Figure 1, to assist both researchers and educators in evaluating CS outreach activities through three main phases: Survey Design, Data Collection and Validation, and Data Analysis and Interpretation.

A. Survey Design

One of the most critical components of any evaluation system is the design of the survey instrument, which essentially involves selecting appropriate questions for the context being evaluated.

Designing a proper survey is a complex activity, as it involves several steps that may be difficult to carry out without specific expertise. Some of the initial phases in survey development, such as literature reviews, interviews, or focus groups, require time and methodological competence [25].

The proposed platform supports this process by offering a curated set of questions, collected over time from relevant literature and organized according to the underlying constructs they aim to measure. Nonetheless, users can add new questions, provided with literature references, allowing more experienced users to expand and tailor the instrument to their specific needs.

Questions are grouped by thematic categories, more precisely referred to as *constructs*, defined in educational research as latent variables that represent abstract concepts measured through multiple related items [25]. Examples of such constructs include self-efficacy, motivation, or future academic intentions. Each construct can be measured at different levels of detail. For instance, satisfaction may be assessed through a single global item or through more granular questions addressing specific aspects such as satisfaction with the activity, teamwork, or instructor interaction. Similarly, future career intentions in STEM fields may be captured through a general yes/no item or a more detailed question listing potential academic or career paths.

While the platform provides a validated and structured base, it allows users to control the level of depth and complexity of their evaluation. Users can select only a minimal set of items for a lightweight assessment or opt for a more in-depth investigation depending on their goals and available resources.

This modular structure also supports the automatic generation of tailored analysis notebooks. When a construct is assessed through multiple items, the analysis notebook includes pre-configured aggregation options, such as mean scores, sum scores, or principal component analysis, based on the selected configuration.

B. Data Collection and Validation

The data collection phase occurs outside the platform itself. The platform provides an export functionality that generates a survey in a format compatible with LimeSurvey, an open-source and self-hostable tool for questionnaire administration. LimeSurvey enables the collection of responses in a way that allows pre- and post-survey data to be linked while still preserving respondent anonymity through the use of pseudonymized identifiers.

A crucial aspect of this phase, as emphasized by Knekta et al. [15], is the importance of validating the survey instrument in the specific context in which it is used. Even well-designed instruments must be empirically tested to ensure they measure the intended constructs within the target population. The platform facilitates this validation process by providing pre-configured scripts for performing Exploratory Factor Analysis (EFA) and reliability checks, such as Cronbach's alpha, based on the collected data.

However, the implementation of the validation process, including when and how it is conducted, remains the responsibility of the organizers. Depending on available resources, this may involve administering the generated surveys to a control group before the camp, or performing post-hoc validation using the responses from a single cohort at the end of the activity.

Furthermore, generating the questionnaire in LimeSurvey through the platform enables the seamless export of data that can be directly analyzed using the pre-configured notebooks. By assigning matching labels to the survey questions during the generation process, the platform ensures that the collected data can be automatically linked with the corresponding analysis.

C. Data Analysis and Interpretation

Data analysis and interpretation represent the most critical phase of the evaluation process, enabling organizers and stakeholders to derive meaningful insights about the impact of the activities undertaken. However, data analysis is rarely a linear or fully generalizable process. As emphasized in the literature on educational measurement and social science research (e.g., Maxwell's work on qualitative inquiry [26]), effective analysis depends heavily on the context, goals, and structure of the collected data. For non-expert users, this complexity can pose significant challenges.

To address these difficulties, the proposed platform supports a dual approach. On one hand, it provides a set of ready-to-use Jupyter notebooks tailored to the survey configuration chosen by the user. These notebooks guide the analyst through a basic data analysis pipeline, including data import, cleaning, outlier detection, and the application of standard techniques such as regression and multivariate analysis. While the notebooks are not meant to replace the role of a trained data scientist, they offer a transparent and extensible framework that reduces the technical burden on users.

On the other hand, to further support interpretation, the platform includes an optional notebook equipped with prompts and suggestions designed to work in conjunction with large language models (LLMs), aligning with a growing trend in educational research to adopt LLMs for supporting instructional tasks [27], [28]. This tool assists users, particularly those without a strong background in statistics, in understanding the meaning of key outputs and how they might inform future program design.

IV. Platform Architecture

The platform is built to be released free and open-source. Surveys in fields involving underage students often require strict privacy measures; as a consequence, the ability to self-host the platform allows for more control over the data being handled. The choice of technologies reflects these principles; in particular, the platform is divided into a central application and several integrated external tools, all open-source and self-hostable.

As shown in Figure 2, the central platform is responsible for managing the survey lifecycle, from creation to deployment, as well as integrating with external tools for data collection and analysis. The technology chosen for this part is Django [3], a Python framework widely used in open-source projects. Django was selected for its scalability, security, and extensibility. Its internal architecture is well-suited to handle complex workflows like survey management while also providing an admin interface that simplifies user interaction.

Once the user completes the survey definition, a Python package called Citric[4] is used to interact with the LimeSurvey platform[5], automating the transfer of the survey to LimeSurvey for deployment. LimeSurvey is a well-known, open-source, self-hosted tool for survey creation and data collection, which aligns with the platform's goals of maintaining control over survey data. While many survey platforms are not specifically designed for scientific research [17], LimeSurvey is a widely used and well-maintained solution that reduces both development time and maintenance burden.

The central platform also generates Jupyter Notebooks [6] for data analysis. The choice of Jupyter Notebooks is based on their widespread use in the research community and their ability to integrate code and text in a single, interactive

[3]https://www.djangoproject.com/
[4]https://github.com/edgarrmondragon/citric
[5]https://www.limesurvey.org/
[6]https://jupyter.org/

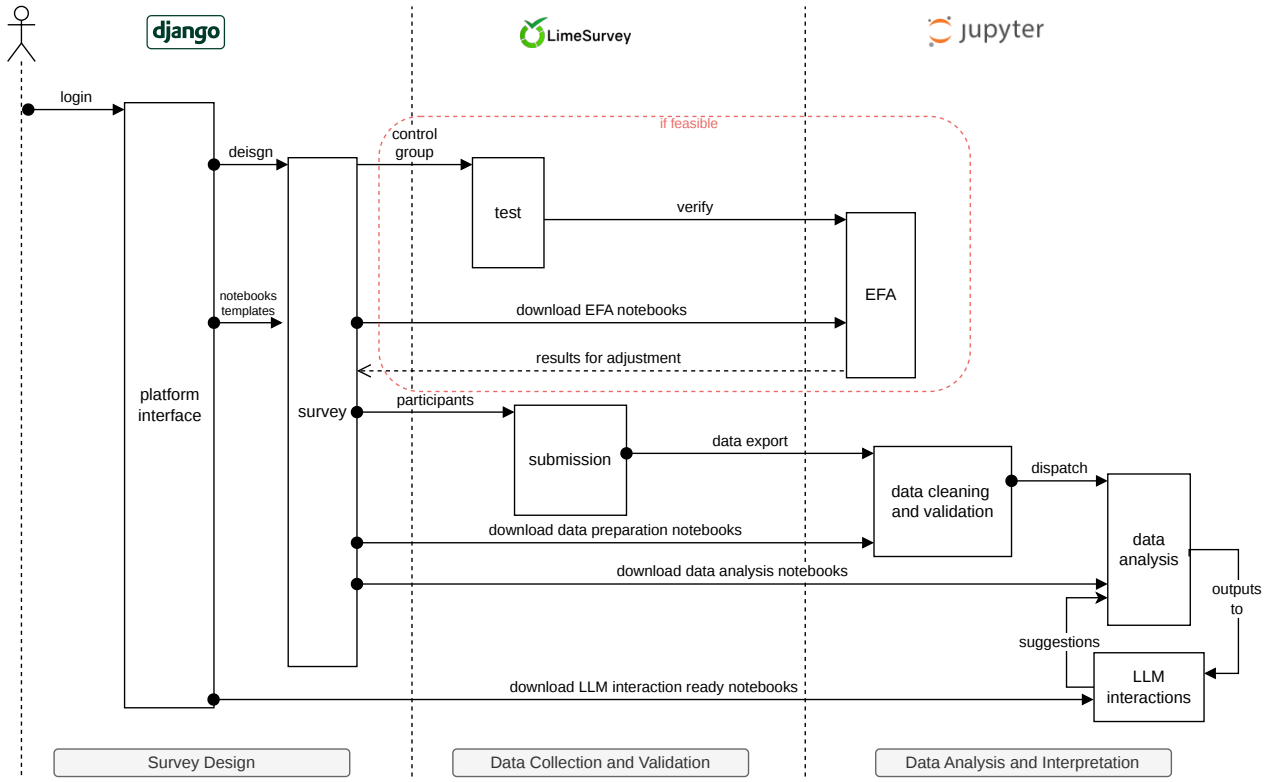

Fig. 2. User interaction flow

environment. This supports reproducibility in research [29], allowing users to document their analysis while performing it. Additionally, the Django template system enabled the customization of notebooks for each survey, allowing the creation of notebooks that fit research questions chosen in the design phase.

The generated notebooks integrate both explanatory text and executable code, allowing users to understand each step of the analysis and modify it as needed. The notebooks are divided into preparation and analysis notebooks. The formers are designed to verify the validity of the survey through Exploratory Factor Analysis (EFA), clean the data by removing any outliers, and assess consistency using Cronbach's alpha. Each step is accompanied by visualizations of the results, such as scree plots and factor loadings, to help users better understand the findings. The analysis notebooks assist users in performing further analysis; in addition to providing descriptive representations of the results, they offer templates for executing regression analysis on key variables and provide appropriate verifications and suggestions for improving the model fit.

Furthermore, the platform offers additional notebooks with the integration of Large Language Models (LLMs) to support users in interpreting their analysis. The main purpose is to provide contextualised suggestions and interpretations for users who do not have a strong background in data analysis. While it is well-known that LLMs cannot substitute for statisticians and that improper use of LLMs can even lead to mistakes that invalidate results, recent research by Zhu et al. [30] demonstrated that certain LLMs can perform reasonably well for relatively simple tasks, such as providing interpretations and suggestions for basic statistical analysis. This research helped guide the selection of an LLM that balances performance with the specific needs of our platform.

The final step in ensuring that the platform is truly self-hostable was the creation of a standardized deployment process that includes all the necessary components. Docker, and specifically Docker Compose, was selected for this task. A Docker Compose configuration[7] is provided, which encapsulates all the services required for the platform to function correctly. This configuration allows end users to launch the entire platform on their premises with minimal setup, requiring only a machine with Docker pre-installed. This approach greatly simplifies deployment, ensures consistency across different environments, and reduces the setup effort for users, allowing them to take full control of their data and platform infrastructure. All source code, configuration files, and usage instructions are openly available in the project repository at

https://gitlab.com/frfaenza/elevate-ai.

V. User Interaction Workflow

The platform's design prioritizes usability, allowing non-expert users, such as researchers and educators, to effortlessly deploy and analyze surveys for outreach programs. The interaction process is intuitive and modular, guiding users through the entire survey lifecycle, from design to data analysis. The proposed workflow reflects our own experience with outreach initiatives [31].

Following the flow presented in Figure 2, users begin by creating a new evaluation process. They define a title, a description, and optional metadata to help document the assessment process. Additionally, they specify a start and end date, which are used by the platform to automate the creation of surveys in LimeSurvey. The overall sequence of steps and system interactions is also graphically illustrated in Figure 3.

The next step is to select questions to include in the evaluation. To encourage adoption, a set of questions frequently used in the literature is already embedded in the Django migration system, ensuring the database is pre-populated at deployment. This does not prevent users from creating new, custom questions tailored to their specific needs. Each question is linked to a literature reference, making its origin traceable. Questions are also grouped under constructs (e.g., self-efficacy, motivation), a feature implemented in the model schema to facilitate notebook generation for subsequent analysis.

By default, the evaluation is structured as a pre-post comparison. During survey composition, the user can specify whether each question should appear in the pre-survey, the post-survey, or both. It is also possible to mark questions as mandatory or conditionally displayed based on prior responses. While these are just a subset of LimeSurvey's full capabilities, they cover the most commonly used options in educational research.

Once the questions, order, and pre/post assignment have been finalized, the user can invoke the function that uses Citric to generate and upload the surveys to the LimeSurvey instance.

An essential aspect of the process is survey validation via Exploratory Factor Analysis (EFA). As highlighted in Figure 2, this step is optional and marked in red, as its feasibility depends on the specific constraints of the organizers. A robust validation process ideally requires a control group to complete the survey, followed by EFA to verify that the constructs align with the collected data (see Knekta et al. [15]). The platform provides a notebook to perform EFA, allowing practitioners to make informed decisions about modifying or retaining the current questionnaire structure.

If validation with a control group is not feasible, the user can proceed directly to deployment using LimeSurvey's native interface and then validate with participants' data. The platform generates both a public link and a QR code for distribution, though direct interaction with LimeSurvey remains possible for users with advanced needs.

One factor that determines whether further interaction with the LimeSurvey platform is needed is the method used to connect pre- and post-surveys. The default approach allows for multiple options. The first and easiest way is to use participants' email addresses. In this case, the provided notebook will assign a pseudonym and remove the email for privacy reasons. Alternatives could be assigning random codes or letting users generate their own codes through a specific question.

Once data has been collected, the analysis phase begins. The deployment includes a Jupyter server, allowing users to launch pre-generated analysis notebooks directly. Based on the selected survey configuration, the following notebooks are provided:

- **data cleaning notebook**: Processes exported responses, cleans the dataset, and connects pre- and post-survey entries
- **outliers and validity notebook**: Identifies outliers (e.g., through response time [32] _) and performs validity checks using EFA and Cronbach's alpha
- **descriptive analysis notebook**: Provides summary statistics and visualizations based on survey constructs
- **regression notebook**: Offers pre-configured regression models with customization instructions

While the analysis notebooks include embedded explanations, statistical knowledge is still required. To support non-expert users, the platform offers an additional notebook that integrates with a Large Language Model (LLM). The user will be able to carry on the analysis while interacting with LLM for assistance.

Following Zhu et al. [30], who compared LLM performance in statistical reasoning, the platform incorporates LLM-generated prompts to help users interpret outputs and navigate the analysis steps. To preserve the open-source and self-hostable nature of the platform, we support integration with local models via the Hugging Face framework[8]. Although these models can run on modern laptops with longer response times, they may be too resource-intensive for some users. Therefore, we also provide a notebook that connects to the ChatGPT-4 API[9], accompanied by prompt templates similar to those used locally. In both cases, however, users must register on a platform, either Hugging Face or OpenAI (for ChatGPT), to obtain an API key, which must be inserted into the notebook for it to function correctly.

VI. Conclusions and Future Development

In this paper, we presented an open-source, self-hostable platform designed to support the evaluation of STEM and CS outreach initiatives. The platform aims to address the lack of appropriate assessment during extracurricular activities. By automating survey generation, facilitating data validation, and guiding users through standard analysis workflows, including support from integrated Large Language Models (LLMs), our platform lowers the technical barrier to performing robust evaluations in informal settings.

The platform's design is grounded in educational research and informed by practical field experience. It aligns with

[8]https://huggingface.co
[9]https://chatgpt.com/

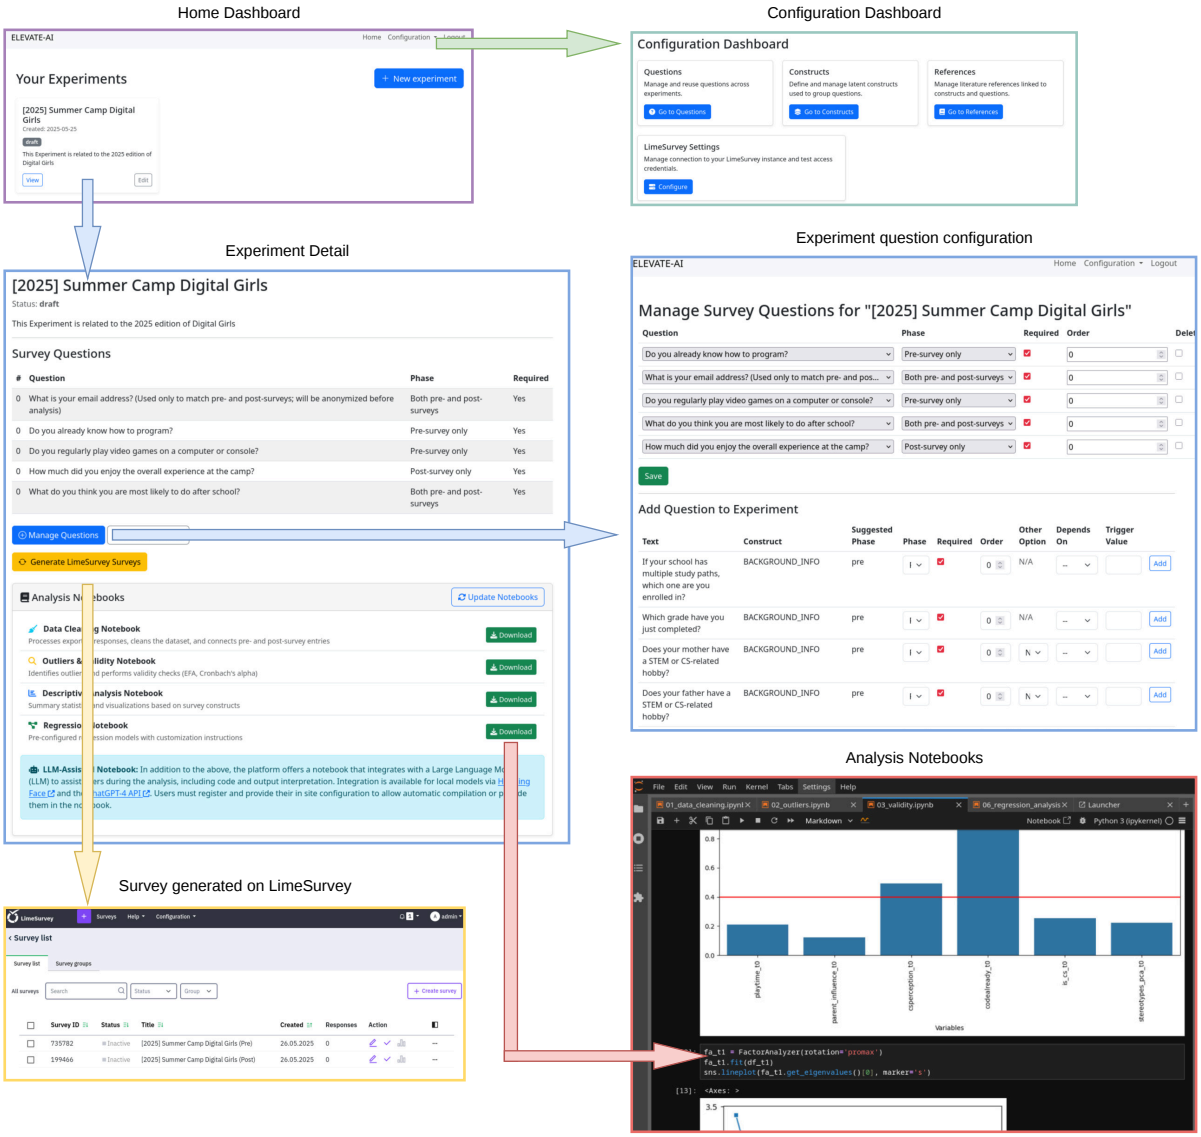

Fig. 3. Use case flow

widely adopted practices in survey validation and quantitative analysis. The tool builds upon several years of implementation in gender-focused STEM outreach, notably the Digital Girls initiative, and has been refined to meet the needs of organizers working in contexts where both methodological rigor and usability are essential.

The project's open-source nature is intended to foster a community of contributors who can collaboratively expand the platform by adding validated questions with corresponding literature references, sharing analysis templates, and suggesting feature improvements. All source code, deployment files, and usage documentation are freely available at https://gitlab.com/frfaenza/elevate-ai.

Looking ahead, several lines of development are planned. First, we aim to expand the LLM-assisted functionalities to support users not only during data analysis but also in survey design and validation. Furthermore, inspired by recent findings from Zhu et al. [30], we are exploring the possibility of integrating a fine-tuned model optimized explicitly for the types of evaluation workflows supported by the platform.

Finally, we plan to further simplify the user experience by streamlining access to the analysis tools. A step in this direction is the integration of Jupyter notebooks directly within the Django interface, removing the need for separate notebook deployment or configuration. Similar approaches have been adopted in prior research focused on improving the accessi-

bility of computational notebooks for non-technical users [33].

***Abstract*—Large Language Models (LLMs) excel at synthesising globally documented knowledge but lack the fine-grained, real-time awareness required for field-level agricultural and rural-planning decisions. This paper introduces JackDaw, a spatially enabled chat-agent architecture that couples foundation-model reasoning with multi-modal geospatial data streams and a retrieval-augmented generation (RAG) pipeline. JackDaw implements a tool-prefiltering mechanism that selects only those data connectors whose topical, temporal and spatial metadata match the current query, thereby mitigating the diminishing returns observed when LLMs are exposed to large, flat toolsets. Through LangChain-based orchestration the platform dynamically assembles workflows that range from lightweight natural-language processing models to domain-specific analytic kernels, while a value-engineering strategy allocates computationally intensive models (e.g., GPT-4-class) only to tasks that require broad contextual reasoning. Benchmark experiments on forestry-asset discovery and vineyard-site assessment demonstrate that JackDaw delivers location-specific, traceable answers that outperform a standalone proprietary LLM, which provides only generic or spatially misattributed responses. The results confirm that bridging global language models with local spatial intelligence markedly reduces hallucination rates and enhances the operational readiness of AI for sustainable agriculture and rural development.**

***Index Terms*—Large language models; geospatial AI; retrieval-augmented generation; context-aware agriculture; spatial decision support; tool prefiltering; JackDaw system; rural planning.**

I. Introduction

ARTIFICIAL intelligence (AI) has transitioned from a niche computational technique to a pervasive epistemic lens through which agriculture and rural development are increasingly interpreted. In agronomic contexts, AI is not merely a collection of algorithms but a socio-technical apparatus that converts raw environmental signals into actionable knowledge, thereby mediating the long-standing tension between global food-system efficiency and local stewardship of land, labour and biodiversity. By formalising inductive reasoning at unprecedented spatial and temporal scales, AI promises to reconcile high-frequency decision support for producers with broader rural-development directives, resilience, equity, sustainability, provided its deployment remains transparent, uncertainty-aware and ethically aligned [1], [2].

AI pipelines now ingest heterogeneous data streams from in-situ sensors (soil-moisture probes, automated weather stations), passive and active satellite constellations (multispectral Sentinel-2 MSI, C-band Sentinel-1 SAR, DESIS hyperspectral, LiDAR), low-altitude unmanned-aerial systems [3], and physics-based or statistical climate re-analyses (GFS, ERA-5-Land). Early studies relied on single-sensor inputs and shallow classifiers; contemporary frameworks fuse multi-temporal, multi-modal observations via machine-and deep-learning architectures optimized for high-dimensional spatiotemporal covariance structures. Sentinel-2 reflectance cubes harmonised with

Sentinel-1 back-scatter underpin continental land-use-intensification inventories [4] and sub-field crop-type delineation [5]. Binary classifiers trained on multi-season Sentinel mosaics further attain F1 $\geq$ 0.90 for key commodity classes [6]. Ensemble decision-tree learners, notably Random Forest, remain baseline regressors for temperate-cereal yield [7] and national wheat statistics [8], while deep neural networks gain traction where label density is sufficient: One study [9] stacked convolutional, gated-recurrent, and transformer encoders on fused Sentinel-1/2 sequences for pixel-level classification; The method proposed in [10] introduced the 3-D $\rightarrow$ 2-D HypsLiDNet that couples DESIS voxels with LiDAR-derived canopy structure; multi-site neural networks now invert hyperspectral reflectance directly to nitrogen and leaf-area traits with ≈10 % relative RMSE [11]. Research in [12] demonstrated multimodal convolutional fusion of Sentinel-2, edaphic layers and mesoscale meteorology for field-scale yield forecasting. Object-based learning exploiting explicit geostatistical segmentation persists for landscape stratification, findings from [13] combined Sentinel-2A, ALOS DSM, and PALSAR layers with Random Forest to derive agro-ecological strata lightweight transformer networks distilled from deep vision models extend the approach to UAV weed-mapping with reduced compute overhead [14], and temporal self-attention mechanisms have been applied to integrated crop-livestock delineation in the subtropics [15]. Wave-equation-informed convolutions also elevate spatio-temporal forest-monitoring accuracy, pointing to transferable architectures for land-cover dynamics [16].

Operational deployment is constrained by observation gaps (cloud cover, revisit frequency) and by aleatoric uncertainty in multi-sensor fusion. Research described in [17] mitigated these issues by embedding Sentinel-1 SAR into the UnCRtainTS cloud-removal network, lowering spectral MAE to ≈ 0.025 reflectance units, and enabling continuous NDVI trajectories across Central-European croplands. On the prognostic front, high-resolution climatic forcing has been advanced by up-scaling 0.25° GFS products to ERA-5-Land resolution via a U-Net super-resolution model, merging the output with HadISD station records, and applying CatBoost regression to reduce 24-h temperature MAE to ~1 °C [18]. Nevertheless, most agronomic AI studies still rely on internal cross-validation; spatially independent or inter-annual robustness tests remain rare; examples include paddock-out validation [19] and temporally stratified ten-fold splits [20]. Consequently, the methodological frontier is defined by scalable multi-sensor fusion, uncertainty-aware ensembles or transformers, and rigorous cross-region benchmarking to support operational use in dynamic agroecosystems.

Large-language-model (LLM) research entered agricultural informatics only recently, yet adoption is rapid. A systematic scan identified 26 geospatial-LLM papers up to early 2024, almost all post-November 2022, describing the field as “embryonic but rapidly accelerating” [21]; a parallel survey of multimodal ag-LLMs reached similar conclusions and noted rudimentary benchmarks [22]. Developments have progressed from demonstration chatbots to end-to-end systems: ChatGeoAI converts plain-language queries into PyQGIS code [23]; OmniGeo demonstrates zero-shot reasoning over satellite imagery, vector polygons, and free text using an instruction-tuned vision-language model [24]. Text-focused agronomic advisers include a retrieval-augmented fruit-and-vegetable system coupling Baichuan-2 with RAG to reduce hallucination rates by 10–40 % [25] and a cotton-soil engine where a fine-tuned GPT-2 outperforms LLaMA-2 for nutrient recommendations [26]. Synthetic data generation is exemplified by an LLM-driven agentic workflow that fabricates realistic fault patterns for smart-tractor telemetry, enabling predictive maintenance testing). Document intelligence pipelines empower domain-agnostic LLMs to extract structured pest information from agronomic literature in zero-shot mode [27]. Complementary graph-generation pipelines capture pest–symptom ontologies for tea production, easing structured decision-support [28].

Across these studies, shared hurdles are evident. High-quality labeled agri-text corpora and paired image–text datasets remain scarce, forcing reliance on generic foundation models or few-shot prompting [25] [22]. Factual reliability is fragile, motivating retrieval-augmented generation [21]. Multimodal grounding across satellite, drone, sensor, and text streams is largely heuristic, as shown in [22] [24], while the compute and energy costs of fine-tuning multi-billion-parameter models raise sustainability concerns. Explainability, data governance, and ethical compliance are critical yet under-explored prerequisites for commercial farm deployment [21].

Within two harvest seasons, the community has advanced from isolated demonstrations to retrieval-augmented, multimodal assistants addressing yield prediction, soil management, pest intelligence, and equipment maintenance. Consolidating open data resources, curbing hallucinations, mastering efficient geo-text fusion, and delivering transparent, farmer-oriented explanations now constitute the central agenda for AI-driven rural development.

II. MOTIVATION

Large Language Models (LLMs) have significantly impacted various domains by leveraging vast datasets to provide comprehensive responses on diverse topics. Their capability to process global and well-documented information allows them to efficiently recognize general trends, interpret historical data patterns, and detail well-known geographical areas. However, despite these substantial strengths, LLMs frequently exhibit limitations

concerning the provision of precise, real-time insights required for location-specific and dynamic contexts, such as agriculture and rural development.

In agricultural practices, where decisions rely heavily on real-time data about local environmental conditions, precise field-level analytics, and seasonal variability, the limitations of standalone LLMs become particularly pronounced. For instance, while an LLM may comprehensively discuss global agricultural trends or extensively documented practices, it may lack critical, timely insights into crop conditions in a less-documented rural area or the subtle seasonal variations affecting local agricultural productivity.

Integrating LLMs with geospatial data offers a robust solution to bridge these gaps. Real-time geospatial data, encompassing remote sensing imagery from satellites, drones, weather stations, and in-situ sensors, can complement the generalized insights of LLMs with detailed, actionable information at specific locations and moments in time. By coupling spatial analysis technologies (already established through remote sensing platforms such as Sentinel-1 and Sentinel-2, as well as advanced AI-driven methodologies) with the broad contextual knowledge offered by LLMs, systems like JackDaw have demonstrated the potential to significantly enhance rural-urban planning and agricultural decision-making.

The JackDaw prototype has underscored the value of this integrative approach by successfully combining the power of LLM reasoning with spatial analysis to provide context-aware insights critical for agriculture and rural management. Its approach exemplifies how synthesizing multi-modal data streams with deep-learning architectures can mitigate the limitations stemming from gaps in sensor observations or uncertainties in data fusion. Furthermore, JackDaw exemplifies the potential of multi-modal integration to improve practical agricultural outcomes by offering more precise yield forecasts, targeted resource management recommendations, and improved environmental monitoring.

Thus, developing an integrative platform that combines the strengths of LLMs with standard agricultural AI tools and GIS solutions represents a strategic opportunity. Such integration promises substantial advancements in rural agricultural practices, enabling more robust, evidence-based decision-making, enhancing sustainability, and ultimately improving rural livelihoods and economic development.

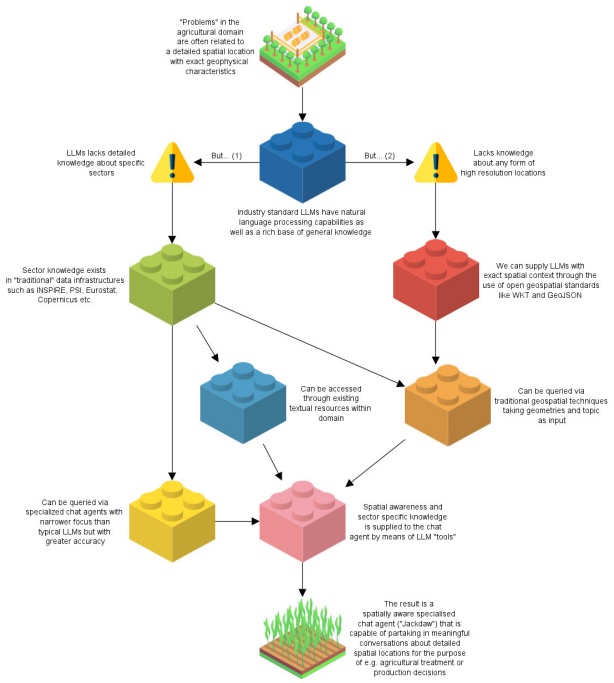

Fig 1. The motivation for developing the JackDaw chat agent

III. SOLUTION

The JackDaw solution is designed to enhance the functionality of LLMs by addressing their inherent limitations in accessing and interpreting localized, real-time data. This enhancement is significant in agricultural and rural planning professions, where precise localized knowledge is crucial. The gap between the global knowledge embedded in LLMs and the need for detailed local contextual information is significant. JackDaw attempts to bridge this gap by integrating advanced geospatial data analysis and specialised AI tools into conversational AI interfaces. This integration enables more accurate and contextually aware responses from LLMs than what is possible with the foundation models.

The conceptual solution underlying JackDaw is facilitating meaningful conversations about geographical locations through LLMs. To achieve this, it is essential for LLMs to be not only aware of the location being discussed but also to possess an understanding of what specific data is relevant to that place. Furthermore, to provide useful responses, JackDaw requires the model to discern which data sources should be utilised based on the topic, purpose, and spatial location of the conversation. These LLMs are expected to engage iteratively with various data sources to foster an incremental understanding of the context-specific to each inquiry.

Conceptual workflow of a conversation with the JackDaw chat agent

JackDaw operates using a systematic workflow that begins when a user initiates a query related to a specific geographic location through a user message to the agent.

The system interprets this query and tries to match it against a large number of available “tools” that connect the LLM to a wide range of relevant data sources. These sources include spatial datasets, such as those defined by the Infrastructure for Spatial Information in Europe (INSPIRE), public sector information (PSI), and specialised AI models optimised for agricultural analytics.

Upon identifying which “tools” may be relevant to answering the question, JackDaw proceeds to pass them to the language model, which collects both spatial and tabular data sets pertinent to the user's query. This includes sensor-derived field data, satellite imagery, current weather forecasts, soil properties, and agronomic statistics. Specialised AI models process these datasets to generate analytical insights, which are then contextualised and embedded into the chat interface.

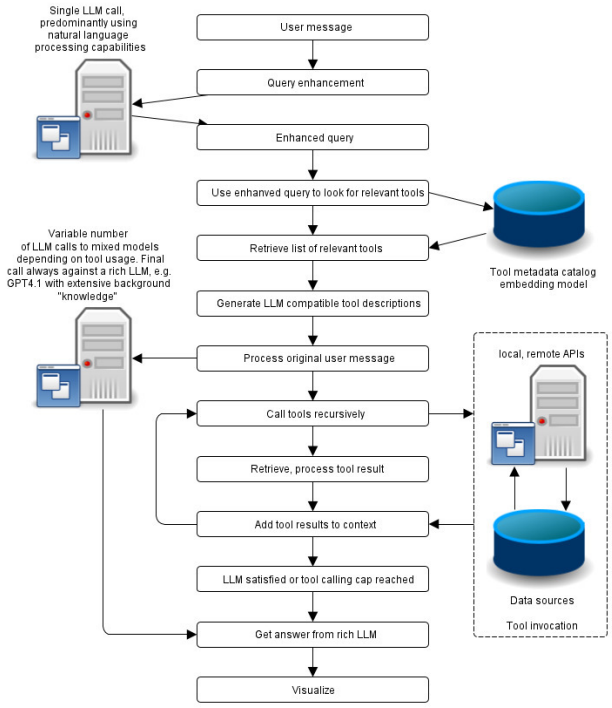

Fig 2. Conceptual flow of a conversation with the JackDaw spatial-enabled chat agent

Visualisations derived from the processed datasets are integrated into the user interface, providing graphical context to the inquiries. These visual representations facilitate clearer insights and more actionable decision-making. By embedding enriched data insights into the LLM's reasoning process, JackDaw effectively bridges the gap between general global knowledge and the need for localized, actionable information. This approach offers robust and informed answers to user inquiries, promoting enhanced decision-making processes tailored specifically to rural and agricultural contexts.

Through the innovative integration of geographic information systems (GIS) and advanced AI-driven data analytics, JackDaw capitalises on existing expertise within these domains. This harnessing of advanced technologies promotes a nuanced and effective decision-making process, significantly enhancing LLM capabilities in understanding and responding to location-specific questions. Consequently, JackDaw transforms the application of LLMs in agricultural planning and rural development, making them more responsive and accurate in addressing context-specific inquiries.

Enhancing Chat Conversations with Spatial Context

Integrating an area of interest into a chat query can significantly augment user interaction by providing spatial context to the conversation. This enhancement involves adding spatial features that encapsulate the geographical areas users wish to inquire about. The spatial data is represented using Well-Known Text (WKT) geometry features, a format allowing a detailed description of geometric shapes in a human-readable text string. By incorporating WKT geometry, users can define specific areas of interest directly within the chat interface.

Ways of Incorporating Spatial Features

Users can add spatial features to a chat query in two primary ways: through a client interface or via natural language processing (NLP). When utilising a client interface, users can directly draw the areas of interest onto a map. This method relies on graphical tools that allow precise selection and adjustment of shapes to represent the desired geographical space accurately. These shapes are then converted into WKT format, maintaining their geometric characteristics while enabling text-based communication in the chat. This method provides users with a tangible and intuitive way to specify areas of interest.

Alternatively, spatial features can be derived from NLP queries. In this approach, a tool or algorithm processes the user's natural language inputs to extract relevant geographical information and convert it into WKT geometry. This method leverages advances in NLP to interpret user intent and spatial references embedded within the chat. Such tools can identify place names, landmarks, or specific directions mentioned by users and translate them into spatial features. This capability allows users to describe their areas of interest using everyday language, simplifying the process and making it accessible to a broader range of users.

Facilitating Function and Tool Integration

Once the spatial features are integrated into the chat, they are encapsulated within code blocks. These code blocks are clearly delineated to distinguish them from other elements of the chat. This demarcation ensures that

the data is accurately identified and processed by subsequent tools or functions that the chat agent may call upon. Code blocks serve not only to organise information but also to maintain data integrity when transferring inputs across different operational environments.

Incorporating spatial features as part of chat queries empowers chat agents to utilise this data in subsequent interactions. The defined area of interest can be used as a parameter for various function or tool calls. For instance, a chat agent might access weather data, perform geographical analysis, or retrieve demographic information specific to the identified area. This capacity expands the functionality of chat agents, enabling more sophisticated queries and responses tailored to the user's spatial context.

Adding areas of interest to chat queries through WKT geometry represents a meaningful advancement in interactive technology. By allowing users to define spatial parameters using both graphical interfaces and natural language processing, the system becomes more flexible and user-centric. Furthermore, the encapsulation of data within distinct code blocks facilitates seamless integration with other tools and functions. Such enhancements lead to more effective and targeted interactions, bridging the gap between spatial awareness and conversational interfaces. This integration serves as a transformative enhancement in fields where geographical context is critical, such as urban planning, logistics, and environmental monitoring, thereby expanding the utility and applicability of chat-based systems in professional and research environments.

Connecting data sources to LLMs

Implementing knowledge acquisition in large language models (LLMs) involves equipping these models with an understanding of various "things," or categories of information, which can be used to improve the applicability and accuracy of chat agents. This methodology necessitates the development of versatile tools that connect LLMs with relevant data sources. LLM tools serve a crucial function in facilitating this connection, providing the necessary scaffolding to bridge the gap between an LLM's inherent language skills and its access to a structured knowledge base.

Versatility is a fundamental requirement when constructing these tools. They must be able to interlink effectively with multiple data sources, thereby expanding the functional capabilities of chat agents. To achieve this, tool prompt engineering is an essential process. This involves designing specific prompts that guide the retrieval and processing of data in a manner that aligns with the operational goals of the LLM. Making each tool available through a web service enhances accessibility and usability, allowing these tools to be integrated seamlessly into web-based applications.

Developing numerous specialised tools can significantly enhance the LLM's ability to handle complex inquiries. In the realm of geophysical information, for instance, tools can analyse terrain by examining landforms, elevation, aspect, slope, and surface roughness. This data provides essential context for applications ranging from environmental monitoring to urban planning. Similarly, climatic tools that gather information about temperature, wind patterns, cloud cover, precipitation, and solar radiation contribute to a comprehensive understanding of environmental conditions across different regions and times, enriching predictive models and research studies.

Demographic information represents another vital category, enabling insights into population characteristics and trends. Tools that analyse demographic data must consider population size, growth projections, historical trends, and the composition of populations based on gender and age. This data supports social dynamics, policy making, and economic forecast analyses. Economic tools can assess business demography and market sizes, offering valuable input for economic modeling, investment analysis, and strategic planning.

Temporal tools are indispensable for temporal analysis, which is critical in assessing real-time changes and zeitgeist trends. When coupled with historical data, a snapshot of current weather conditions enables detailed climatic assessments. Moreover, zeitgeist tools, such as those utilising the Global Database of Events, Language, and Tone (GDELT), are instrumental in capturing contemporary socio-political dynamics, offering insights into prevailing public sentiment and events affecting international relations and market behaviours.

Incorporating statistical data with georeferenced identifiers is instrumental for deriving meaningful insights based on location-specific features. By identifying Nomenclature of Territorial Units for Statistics (NUTS) identifiers for particular locations, it is possible to gather relevant demographic and business demography statistics. This georeferenced approach enables tailored analyses considering local variations, which is essential for targeted policymaking and regional development strategies.

The utilisation of raster and grid data complements this analysis by providing detailed spatial information. Sources such as the European Space Agency (ESA), the Group on Earth Observations (GEO), and Sentinel data offer high-resolution satellite imagery and derived raster datasets. These datasets are optimised for large-scale multidimensional queries, allowing users to extract information that spans multiple dimensions and scales. This capability is particularly useful in applications like precision agriculture, land use planning, and disaster management.

Vector data, on the other hand, involves using line and polygon data formats typical of traditional Geographic Information System (GIS) infrastructures. Adhering to standards such as those established by the Infrastructure for Spatial Information in the European Community (INSPIRE), vector data provides a detailed locational

context crucial for detailed mapping and spatial analysis. This infrastructure supports a wide array of applications, from infrastructure development to environmental conservation efforts.

Document data serves an integral role in the holistic use of LLM tools, particularly in contexts that require the retrieval of legal documents, plans, reports, and other contextual information. Access to such documents allows LLMs to provide informed responses that are grounded in the regulatory and historical framework of the area in question. For instance, in urban development scenarios, understanding zoning laws and historical city planning documents is essential to delivering relevant insights and recommendations.

Limiting the number of tools made available to the LLM for improved accuracy and efficiency

A significant aspect of working with these models involves the invocation of external tools to enhance their problem-solving capabilities. However, as the number of tools accessible to an LLM increases, the efficiency and effectiveness of these tool invocations tend to diminish. To address this issue, it is critical to develop a robust method for prefiltering tools based on the specific requirements of a query or question.

LLMs are inherently equipped with flat tool invocation capabilities. This means that they can be supplied with a limited set of tools to assist in fulfilling a task. However, as the array of available tools expands, the efficiency of the model's capacity to appropriately call upon these tools declines. This is mainly due to the overwhelming number of potential options, which can obscure the model's decision-making process and reduce its ability to select the most pertinent tools for a given task. Therefore, a prefiltering step becomes necessary to manage tool selection effectively.

Prefiltering tools is an essential process that relies on structural metadata to determine which tools should be considered by the model in relation to the question at hand. This step ensures that only relevant tools are available for use, thereby optimising the model's performance and reducing computational overhead. The prefiltering step can be executed by employing several criteria, each aimed at ensuring the model's proficiency in addressing the specific nuances of the question.

The initial criterion for filtering tools involves sorting by topic relevance. This means identifying tools that align with the subject matter of the inquiry. Questions often pertain to specific topics, and tools designed with an understanding of these subjects can offer more accurate and precise insights. For instance, if a question relates to environmental science, the prefiltering system would bypass tools irrelevant to this field and focus on those offering insights or functionality that complement environmental studies.

Another critical filtering criterion is temporal resolution. Questions may address events or data related to particular time periods, and not all tools possess the capability to handle temporal queries comprehensively. The prefiltering system must, therefore, identify and prioritise tools that are equipped to deal with the specified temporal context. For example, if a query involves historical climate data from the 1980s, the system should filter out tools that only provide contemporary data, ensuring the most temporally relevant tools are selected.

In addition to temporal relevance, the selection of tools may also hinge on determining the best source of information, especially in scenarios with overlapping data coverage. This means the system should favour tools that offer the most precise or contextually appropriate data. For example, if a model for Norway offers superior data specificity compared to a broader European model for a particular question, the prefiltering mechanism should select the Norwegian model. This ensures that the data used is both relevant and of the highest quality possible for the query.

Spatial resolution is another determinant in the prefiltering process. Many questions necessitate specific spatial data resolutions, and tools may vary greatly in the granularity of their data. It is essential to filter tools based on the spatial requirements specified in the question. If a question demands high-resolution spatial data, such as a 1-meter resolution for detailed topographic analysis, the prefiltering mechanism should prioritise those tools capable of fulfilling such needs. Conversely, for less detailed queries, tools offering broader, 100-meter resolution data may suffice.

The implementation of a structured prefiltering step enhances the ability of LLMs to select and utilise tools effectively, leading to more accurate and efficient outcomes. By categorising tools based on topic, temporal and spatial capabilities, and data quality, the system reduces the cognitive load on the model and ensures that only the most relevant tools are engaged. This not only improves the model's response time and accuracy but also conserves computational resources.

Agent implementation using Langchain for Python

The integration and orchestration of calls to various machine learning models constitute a key component in the efficient deployment and utilisation of these models in real-world applications. Among the technologies facilitating this process, Langchain emerges as a pivotal tool. It offers an interface designed specifically for dynamic interaction with language models, significantly enhancing applied solutions' flexibility and maintainability.

Langchain serves as an abstraction layer that simplifies the setup of client calls to large language models (LLMs). Through its design, Langchain provides a mechanism by

which these models can be interacted with seamlessly, ensuring that the underlying complexities of each model are effectively managed. The abstraction layer implemented by Langchain allows developers to perform model orchestration in a manner that separates the business logic from model-specific code. This, in turn, supports the ease of integration and modular development, facilitating a more structured approach to software development that incorporates these advanced models.

Further, the abstraction layer not only supports seamless communication with a single LLM but also allows for the straightforward replacement of one model with another. This feature is essential in today's rapidly evolving machine-learning landscape, where the rapid development of new models can often leave practitioners with outdated tools. By using Langchain, developers can efficiently swap out LLMs at any workflow stage to achieve improved performance, accuracy, or other desirable traits inherent in more advanced models.

The utility of this abstraction layer extends beyond the wholesale replacement of models. It also permits granular control over individual steps within the model workflow. This means that each component of the process can be optimised by integrating the most suitable model for that specific task. Such granular control is invaluable, as it provides the opportunity to tailor each step of the interaction with the LLM to align with specific requirements or constraints. Consequently, applications deploying these models become more robust and targeted in their outcomes.

Langchain's design enhances the portability and scalability of machine learning systems, allowing for simple expansion in scope and scale. Abstracting model interactions enables systems to cater to increased demand or incorporate complex functionalities without significantly reengineering existing systems. The ability to efficiently manage and organise various LLMs through Langchain allows developers to create more sophisticated applications that can handle a wider range of tasks and challenges.

Moreover, Langchain plays a significant role in encouraging best practices in software engineering and model deployment. Enforcing separation of concerns ensures that the model logic does not hinder the development of other software components. Developers are encouraged to engage in clean code practices and modular development, which enhances the maintainability and longevity of software systems. Using an abstraction layer thus aids in creating a more streamlined development process, where different teams can work on separate components without interference, leading to a more collaborative and efficient workflow.

In addition to improving development processes, Langchain may also contribute to the reduction of deployment risks. It allows testing new models within existing infrastructures without extensive overhauls, facilitating smoother transitions and updates. This capacity to swap models quickly and without significant downtime is especially critical in environments where continuous integration and deployment are essential requirements.

Fostering an ecosystem where evolving models can be integrated without friction is fundamental to maintaining a competitive edge in fields relying heavily on machine learning. Langchain thus acts as a linchpin in the operational management of these models, aligning technological capabilities with business objectives. Organisations are thereby empowered to harness the full potential of LLM advancements with minimal disruption to their existing systems.

Value engineering in the back-end solution

Back-end value engineering is a crucial aspect in the development of computational tools, particularly tools like JackDaw that involve complex model interactions. This discipline focuses on the optimal allocation of computational resources to enhance performance and reduce operational costs. Within the context of back-end value engineering, a nuanced approach to model selection and implementation can lead to substantial improvements in efficiency and effectiveness.

At its core, the process of back-end value engineering involves the strategic use of different models for varying steps within a computational sequence. By tailoring the choice of model to the specific requirements of each task, developers can achieve better resource allocation, ultimately enhancing the tool's performance.

For initial tasks requiring basic language processing capabilities, models possessing natural language processing (NLP) capacity are sufficient. Such tasks often involve identifying appropriate arguments to be passed to a function. NLP models excel in understanding linguistic input, making them ideal for these preliminary steps. Their use ensures that computational resources are not expended unnecessarily on more complex models when simpler ones suffice.

In contrast, certain steps necessitate the employment of a base model with a comprehensive understanding of diverse knowledge areas. Models like GPT-4po serve this purpose effectively. These models are designed to possess a wide-ranging repository of generic knowledge, thereby enabling them to tackle tasks that demand a broad understanding. Their utility lies in their ability to provide insights and execute functions that require a generalist perspective.

Moreover, some stages in a computational process necessitate the application of bespoke models with domain-specific expertise. An example might be a model engineered to handle species tolerance parameters. These custom models are tailored to address specialised tasks, offering insights and solutions that generic models might overlook. Their usage is particularly advantageous in niche

applications where precision and specialised knowledge are critical.

By implementing an optimised model selection strategy, the overall cost associated with complex tool-calling chains can be significantly mitigated. This approach entails identifying the most suitable model for any given task and deploying it accordingly. Such strategic allocation not only reduces computational expenses but also enhances the tool's efficacy in performing its designated functions.

The process of determining the optimal model for each step involves several considerations. These include the computational requirements of the task, the desired level of accuracy, and the potential impact on overall performance. By weighing these factors, developers can make informed choices that align with both technical objectives and budgetary constraints.

There is a crucial balance to be struck between leveraging the simplicity and efficiency of NLP models and harnessing the expansive capabilities of base models like GPT-4po. Additionally, the precision offered by customised models with specialised knowledge must be integrated judiciously to maximise effectiveness. Such decisions require careful assessment and strategic planning to ensure that the right model is deployed at the right stage.

In scenarios where tasks are relatively straightforward, deploying simpler models can free up computational resources, thereby allowing more complex models to be reserved for tasks that truly necessitate their capabilities. Conversely, when tasks demand a more in-depth understanding or specialised insight, more sophisticated models are utilised to achieve the desired outcomes.

Furthermore, this tiered approach to model selection also facilitates scalability. As computational demands evolve, new models can be integrated, or existing models can be updated to reflect the latest advancements and requirements. This adaptability ensures the system remains robust and responsive to changing needs without requiring complete overhauls or excessive expenditure.

Integrating diverse models in back-end processes also fosters innovation, as developers are encouraged to explore novel combinations and applications to enhance performance. By considering how different models can interact and complement one another, new solutions can be devised that push the boundaries of current capabilities, all while keeping resource use and costs in check.

Through careful analysis and planning, back-end value engineering plays an instrumental role in the development and deployment of computational tools. By strategically selecting and implementing models tailored to specific tasks, developers can transform their systems into more efficient and cost-effective solutions. This calculated approach not only optimises performance but also paves the way for ongoing innovation and refinement.

While of lesser scientific value, value engineering is critical to ensuring adoption and a realistic path to a real and tangible market.

RAG module

One of the key components that enables JackDaw to deliver more credible and less hallucination-prone responses is the Retrieval Augmented Generation (RAG) module, illustrated in Figure 3. This module enhances JackDaw's responses by grounding them in external references and supporting the ingestion of new data sources. The RAG module consists of three main components:

1. **Embedding Model** - Transforms input text into high-dimensional vector embeddings, enabling semantic search within a vector database.
2. **PDF-to-Markdown Conversion Tool** - Parses user-submitted PDF files and extracts both content and structure. It converts the documents into clean, structured Markdown, preserving key elements such as headings, paragraphs, tables, and lists to maintain readability and information integrity.
3. **RAG Application** - The core service that handles user queries, retrieves relevant content from the vector database, and compiles the results for response generation.

The module uses a microservices architecture to support scalability and simplify maintenance. At its core is the RAG Application, which orchestrates the query processing and retrieval workflow.

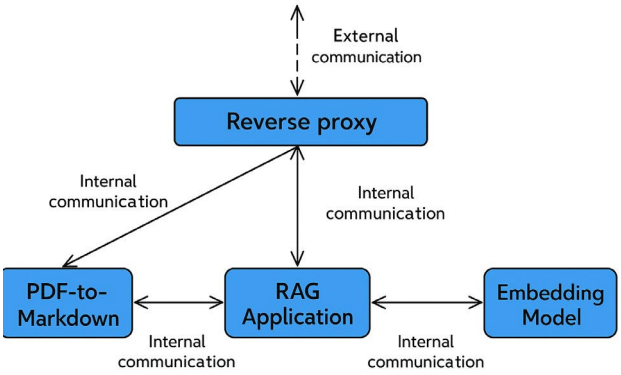

Fig 3. Overview of the RAG module architecture

The RAG module interfaces with the JackDaw system through a reverse proxy, facilitating secure external communication. Internally, the reverse proxy routes requests to two main components: the RAG Application and the PDF-to-Markdown Conversion tool. The RAG Application acts as the central component, orchestrating interactions with both the PDF-to-Markdown Conversion tool and the Embedding Model. All communication between these components occurs internally, ensuring efficient data flow within the system.

Before deployment, the system was seeded with trusted content - policy documents and scientific articles. These documents were processed using the same PDF-to-Markdown tool described above. This tool utilized Docling Library [29] to perform the parsing. The resulting Markdown files were segmented into smaller units of approximately 500 tokens, referred to as chunks.

Each chunk was embedded using the **Alibaba-NLP/gte-Qwen2-1.5B-instruct Model** [30], a high-performing multilingual language model. The resulting embeddings, along with their corresponding text chunks, were stored in **ChromaDB**, an open-source vector database optimized for similarity search.

At runtime, when a user submits a query, the RAG Application first generates an embedding of the query. This embedding is then used to retrieve semantically similar chunks from the vector database. These passages are returned to JackDaw along with metadata that includes source information, enabling more accurate responses and full traceability. This approach ensures that users can access the original documents from which answers are derived, promoting transparency and trust.

Currently, the PDF-to-Markdown tool is limited to processing individual PDF files and returning the parsed content directly to JackDaw. This setup is designed for scenarios where users want assistance understanding or extracting information from specific documents.

In the future, the tool will be expanded to support the creation of personalized knowledge bases. Users will be able to upload multiple PDF files, effectively building a private vector database similar to the existing global one. This personal database can then be used to enrich the responses generated by the language model, resulting in more context-aware, tailored, and useful interactions. Moreover, this setup will support the continuous growth of the data source, enabling users to expand and evolve their assistant's knowledge over time incrementally.

IV. Results

We tested the performance of JackDaw on various scenarios related to geospatial data tasks in agriculture and forestry and compared its solutions with standard proprietary LLMs to determine its benefits and limitations. For each user's query, our system invokes tools with information about the geographical area of interest and reasons over the retrieved content to provide a final answer. To make the comparison more balanced, we include the geographical area in the form of bounding box coordinates in the input query so that the standard LLM has some information about the location. Without this information, the standard LLM would have no way of providing relevant information. The following scenarios showcase that JackDaw is able to provide location-specific relevant information, whereas the standard LLM can only give general advice, sometimes not even related to the area of interest. We used GPT-4o-mini as the LLM.

Scenario 1

In this scenario, we asked about a partially forested area; the user query was: "Is this area forested, and are there any specific utilities regarding forestry?". Figure 4 shows responses from JackDaw and a standard LLM. It also contains the selected area of interest. GPT-4o-mini managed to offer general advice and derived the location from the coordinates as close to Pilsen, which is true, but it was unable to determine the real location. JackDaw retrieved data by utilizing tools and was able to list existing facilities related to forestry and also determine the distribution of land in the area.

Scenario 2

In this scenario, we asked whether an area in the Czech Republic is suitable for vineyards. The user query was: "Determine if this area is suitable for a vineyard and provide a concise answer." Figure 5 shows both responses together with the area of interest. This time, JackDaw provided a concise answer consisting of climate, land cover, and elevation analysis. The standard LLM wrongly determined the area to be in Austria, with a general recommendation for the area for vineyards without any backing data.

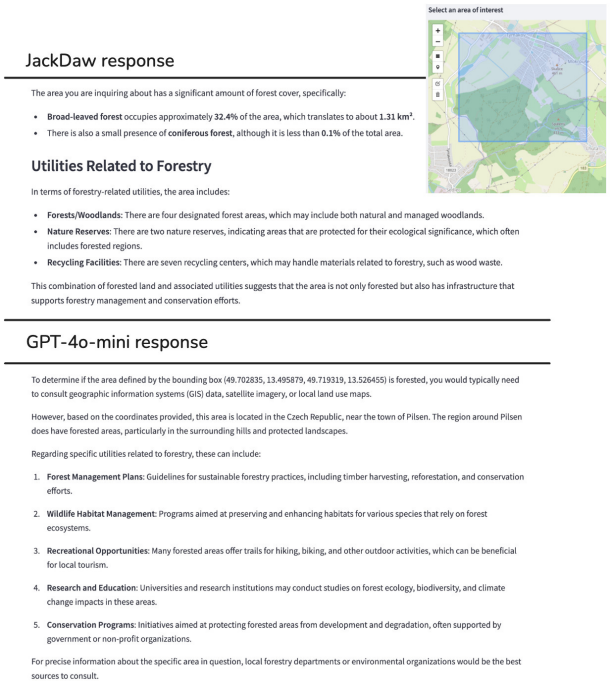

Fig 4. Comparison of responses regarding a query about forestry

Context and Visualisation Imperatives

In the years leading up to generative AI becoming "public property", the volume of text emerging from argumentative sources such as consultancy reports was already expanding noticeably. The increase was often

characterised by esoteric industry language and overcomplicated sentence structures, far beyond what was necessary for effective communication. Reports usually offered vague reasoning and inconclusive advice. Consequently, readers, typically non-scientific, technically oriented professionals had to develop new approaches to extract key ideas or recommendations from these wordy passages, which again led to altered reading habits and gave root to the scientifically unjustified and yet not entirely unfounded maxim that “nobody reads”.

Following the advent of the Language Model (LLM), the creation of well-structured text is now within reach of literally anyone, leading to a further accelerated growth in well-padded textual content, resulting in a situation where now not only “nobody reads” but neither does anyone write. While this is anecdotal and should not be considered a scientific finding, it does describe a situation where visualisation remains as important as ever to reveal and convey trends and exceptions in data in a manner that makes it more easily accessible to readers who may find a good-looking block of text deceptively attractive without taking into consideration what it actually says.

Effective visualisation in this context means applying the building blocks derived from the more traditional analytical tool suites, such as geoportals (maps, 2D, 3D) and business intelligence (charts, tables), as well as more advanced forms of visualisation.

LLMs generate text and often use the "markdown" language to include formatting. This includes the capability of outputting code blocks that can contain structured data intermixed with the text. A code block may contain any text-based or text-representable format, such as GeoJSON or GeoCSV, making rendering LLM output as any of the above visual indicators easy. JackDaw utilises custom markdown renderers to accomplish render tables, charts, and maps.

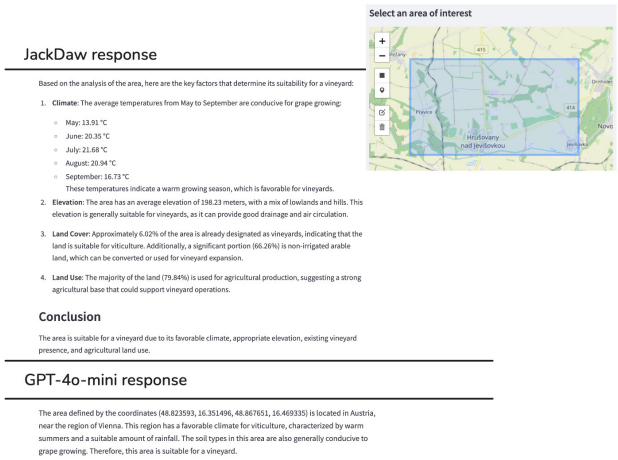

Fig 5. Comparison of responses to an area analysis query related to vineyards

V. Conclusion

This paper has demonstrated that a language-model agent can be made spatially competent by constraining its reasoning to a query-specific subset of geospatial tools and by grounding each answer in an external retrieval layer. The proposed JackDaw architecture contributes three principal advances:

1. Structured tool pre-filtering. Tools are surfaced to the LLM only when their topical, temporal and spatial metadata intersect the user’s query, avoiding the accuracy and latency penalties that arise from flat tool lists.

2. Value-engineered model orchestration. A LangChain abstraction allocates lightweight NLP models to syntactic steps, reserves foundation models for broad-context reasoning, and inserts domain-specific kernels where specialised knowledge is required.

3. Retrieval-augmented generation with transparent provenance. A micro-service RAG layer embeds trusted documents in a vector store and returns source passages with every response, enabling fact-checking and reducing hallucinations.

Benchmark experiments on forestry-asset discovery and vineyard-site assessment show that JackDaw delivers concise, location-specific answers, whereas a baseline proprietary LLM produces only generic or spatially misattributed guidance. These findings confirm that coupling global language understanding with local spatial intelligence materially improves decision support in agriculture and rural planning.

Limitations. The evaluation covered two use-cases within Central Europe and a single growing season; cross-regional transferability, additional thematic domains and longer temporal windows remain untested. The current RAG pipeline ingests individual PDF documents but does not yet support user-specific knowledge bases or large-scale cloud retrieval, and cost modelling excluded vector-query overheads.

Future work. Planned extensions include (i) adaptive ontology-driven tool selection to further shrink the action space, (ii) ingestion of multimodal sensor streams (e.g., hyperspectral cubes, IoT telemetry), (iii) private vector databases for institutional users, and (iv) benchmarking against emerging geospatial-LLM test suites. Governance requirements—explainability, bias auditing and energy accounting—will be addressed to ensure regulatory compliance and sustainable operation.

In summary, the results substantiate that an architecture which bridges foundation-scale language models with dynamically selected, high-resolution spatial data streams is a viable path toward reliable, context-aware AI services for agriculture and rural development.

***Abstract*—This paper introduces a novel technique for automatically synthesizing assertion-safe `while`-guards in imperative programs. Given a partial program (sketch) with missing `while`-guards, the proposed algorithm synthesizes complete Boolean expressions for the missing ones, such that the obtained complete program satisfies the given assertions. To solve this problem, our technique uses forward and backward abstract static analyses of programs to generate (logical) constraints with unknown predicates that are subsequently solved by employing the logical Constraint Horn Clause (CHC) solvers.**

We have implemented our synthesis algorithm in a proof-of-concept tool, and evaluated it on a set of C programs with missing `while`-guards. By experiments we prove the effectiveness of the proposed technique for synthesizing arbitrary Boolean expressions defined over program variables for some interesting program sketches written in C.

***Index Terms*—Program Synthesis, Abstract Static Analysis, Constraint Horn Clause (CHC) solving.**

I. Introduction

PROGRAM synthesis [1] is a process of automatically constructing a program from a given specification. Program sketches [2], [3] are partial programs with missing (arithmetic and Boolean) expressions called *holes* (`??`). They simplify the synthesis problem by limiting the search to programs of particular form. The earliest approaches to program sketching [2], [3], [4] can automatically synthesize only integer "constants" for the holes. In particular, given a sketch and an assertion, the synthesizer (e.g., `Sketcher` [2], [3]) automatically finds integer constants for the holes such that the synthesized complete program satisfies the assertion. Subsequently, the generalized program sketcher [5] is introduced, which uses abstract interpretation [6], [7], [8] and logical abduction [9] to infer arbitrary expressions, rather than only integer constants, for the holes in program sketches. The missing holes occur either as guards (Boolean expressions) in `if`-s and `while`-s or as right-hand sides (arithmetic expressions) in assignments. However, in the case of missing `while`-guards, this approach [5] is cumbersome due to the difficulty to infer precise inductive invariants for `while`-s, and so it often fails to generate satisfactory solutions.

In this paper, we explore the problem of inferring missing `while`-guards in program sketches by introducing a novel algorithm based on abstract static analysis of programs [6], [7], [8] and logical Constraint Horn Clause (CHC) solving [10], [11]. In particular, our synthesis algorithm consists of two phases: *constraint generation* and *constraint solving*. In *the first phase*, we employ forward and backward abstract static analyses of programs, whose aim is to determine dynamic program properties in a fully automatic manner. The forward abstract analysis [6], [7], which is similar to strongest postcondition inference [12], works by propagating the initial facts towards the final locations, thus computing the invariant postconditions before the holes. The backward abstract analysis [6], [7], which is similar to weakest precondition inference [12], works by propagating the final (assertion) facts towards the initial locations, thus computing the sufficient preconditions that ensure assertion validity after the holes. The numerical abstract domains, such as Intervals [6], Octagons [13], Polyhedra [14], are widely used in practice for static analyses to infer information about the possible values of program variables together with the possible relations between them. Thus, they are employed for computing invariant postconditions and sufficient preconditions in the form of linear integer constraints over program variables. Subsequently, in *the second phase*, we employ the logical constraints generated in the first phase by abstract static analyses as well as the logical CHC solving technique to synthesize the missing Boolean expressions. That is, the `while`-guard synthesis problem is encoded as a set of CHCs, which represent a class of first-order logical formulas modulo some background theories, like linear integer arithmetic (LIA). More specifically, a CHC is a logical implication formula containing unknown predicates. This way, all holes in the sketch as well as inductive invariants for the `while`-s are represented by unknown predicates in the CHCs. A solution to a set of CHCs assigns a logical formula to each unknown predicate in such a way that all CHCs become valid formulas, and moreover their validity guarantees the correctness of the resulting complete program. By solving the obtained CHCs with off-the-shelf CHC solvers, such as `Eldarica` [11], `Spacer` [10], `Duality` [15], and `FreqHorn` [16], we can synthesize complete Boolean expressions for the missing holes `??` in the program sketch, which will guarantee the assertion validity of the resulting complete program.

We have implemented the proposed algorithm in a proof-of-concept tool, called $\texttt{WhileSketching}_{\texttt{CHC}}$. For the constraint generation phase, we use the numerical abstract domains

```
void main() {
① int x = 10, y = 0;
② while ⓗ (??) do {
③   x = x-1;
④   y = y+1;}
⑤ assert (y==10);
//assert (y>x);
//assert (y==x);
//assert (x=10); }
//assert (x>15); }
```

Fig. 1. `while.c`.

(e.g., Polyhedra [14]) from the APRON library [17], while for the constraint solving phase, we use the `Eldarica` [11] and `Z3` [18] tools for CHC- and SMT-solving. We perform an experimental evaluation on a selected set of benchmarks written in C, which are taken from the SV-COMP (https://sv-comp.sosy-lab.org/) and the literature [19], [5]. The experiments demonstrate the practicality of our technique to successfully synthesize assertion-safe `while`-guards in some interesting C sketches.

This work brings the following contributions:

(1) We present the `while`-guard synthesis problem for automatically synthesizing arbitrary complete Boolean expressions for missing holes in sketches;
(2) We introduce a novel algorithm for solving this problem by interaction between the abstract static analysis and the logical CHC solving;
(3) We implement our algorithm and evaluate it on a set of interesting program sketches written in C.

This work is organized in the following way. Section II presents a small example illustrating how our algorithm infers missing `while`-guards. Section III defines a small imperative language that is used for the formal development as well as its concrete and abstract semantics. Moreover, the CHC problem is also defined here. Section IV presents the main `while`-guard synthesis algorithm. Section V briefly describes another existing approach for resolving program sketches based on logical abduction. Section VI presents an experimental evaluation of the introduced approach, comparing our tool with a program sketching tool based on logical abduction. Finally, Section VII and VIII discuss related work, summarize the introduced approach, and highlight future research direction.

II. Illustration

We now illustrate our approach through one motivating example taken from [5]. The program sketch given in Fig. 1, called `while.c`, contains one unknown hole `??` in the `while`-guard. Our aim is to replace the unknown hole at loc. ⓗ with a Boolean expression, such that the assertion at loc ⑤ is valid.

Our approach consists of two phases: constraint generation and constraint solving. In the first phase, our technique starts by performing forward and backward abstract static analyses based on the Polyhedra abstract domain [14]. The over-approximating forward static analysis starts with the initial fact $\top$ (i.e., true) at loc. ①, and by propagating it forwards it infers the invariants $(\texttt{x=10} \wedge \texttt{y=0})$ at loc. ② before the `while` as well as $(\texttt{x} \leq 10 \wedge \texttt{x+y=10})$ at loc. ⓗ. The under-approximating backward static analysis starts with the assertion fact $(\texttt{y=10})$ at loc. ⑤, and by propagating it backwards it infers the preconditions $(\texttt{y=10})$ at loc. ⑤ after the `while` as well as $\bot$ (i.e., false) at loc. ⓗ. The loc. ⓗ is reached upon entering the `while`-loop and after each `while`-iteration, so the facts inferred by both analyses at loc. ⓗ correspond to the *inductive `while`-invariant*, which expresses a relationship between program variables that is preserved by any execution of the `while`'s body [12]. However, since both analyses treat the unknown hole `??` as non-deterministic choice $\{\text{true}, \text{false}\}$, the forward analysis infers the over-approximation of the inductive `while`-invariant, whereas the backward analysis infers the under-approximation of the inductive `while`-invariant. Thus, we use the inferred facts by forward and backward static analyses to generate the following implication constraints, called Constrained Horn Clauses (CHCs):

$$(\texttt{x=10} \wedge \texttt{y=0}) \implies Inv(\texttt{x},\texttt{y}) \quad (1)$$

$$Inv(\texttt{x},\texttt{y}) \wedge R(\texttt{x},\texttt{y}) \wedge \texttt{x'=x-1} \wedge \texttt{y'=y+1} \implies Inv(\texttt{x'},\texttt{y'}) \quad (2)$$

$$Inv(\texttt{x},\texttt{y}) \wedge \neg R(\texttt{x},\texttt{y}) \implies (\texttt{y=10}) \quad (3)$$

$$Inv(\texttt{x},\texttt{y}) \implies (\texttt{x} \leq 10 \wedge \texttt{x+y=10}) \quad (4)$$

$$\text{false} \implies Inv(\texttt{x},\texttt{y}) \quad (5)$$

$Inv(\texttt{x},\texttt{y})$ encodes an unknown predicate for the inductive `while`-invariant, and $R(\texttt{x},\texttt{y})$ encodes an unknown predicate for the missing `while`-guard `??`. Both unknown predicates $Inv(\texttt{x},\texttt{y})$ and $R(\texttt{x},\texttt{y})$ are defined over program variables `x` and `y` that are in the scope of the `while`. The implications (1) and (2) state that the `while`-invariant $Inv(\texttt{x},\texttt{y})$ is inductive. That is, (1) states that $Inv(\texttt{x},\texttt{y})$ is implied by the `while`'s precondition at loc. ②, whereas (2) states that $Inv(\texttt{x},\texttt{y})$ is preserved in each iteration of the `while`'s body, i.e. if $Inv(\texttt{x},\texttt{y})$ and the `while`-guard $R(\texttt{x},\texttt{y})$ are true and we execute the `while`'s body then $Inv(\texttt{x'},\texttt{y'})$ will be true after it, where `x',y'` are updated values of `x,y` after executing the `while`'s body. The implication (3) stipulates that when the `while` terminates, and so $Inv(\texttt{x},\texttt{y})$ and $\neg R(\texttt{x},\texttt{y})$ are true, then they are strong enough to imply the `while`'s postcondition at loc. ⑤ ensuring that the assertion must be valid. The implication (4) (resp., (5)) states that the analysis fact inferred at loc. ⓗ by forward (resp., backward) analysis is over- (resp., under-) approximation of $Inv(\texttt{x},\texttt{y})$.

In the second phase, our aim is to solve the generated CHCs by inferring interpretations (logical formulas) for $Inv(\texttt{x},\texttt{y})$ and $R(\texttt{x},\texttt{y})$ under which all CHCs (1) – (5) are valid. The CHC solving algorithm [11] reports the following solutions for the unknown predicates: $Inv(\texttt{x},\texttt{y}) \equiv (\texttt{x} \leq 10 \wedge \texttt{x+y=10})$ and $R(\texttt{x},\texttt{y}) \equiv (\texttt{x} \leq 10 \wedge \texttt{x+y=10} \wedge \texttt{x} \neq 0)$. Then, we call a SMT solver to simplify the formula $R(\texttt{x},\texttt{y}) \wedge \neg Inv(\texttt{x},\texttt{y})$, thus excluding sub-formulas of $R(\texttt{x},\texttt{y})$ that are also present in the invariant $Inv(\texttt{x},\texttt{y})$. Thus, the synthesized `while`-guard

will be only the strengthening of $R(\mathtt{x},\mathtt{y})$ with respect to $Inv(\mathtt{x},\mathtt{y})$ that is not part of the invariant $Inv(\mathtt{x},\mathtt{y})$. Hence, we fill the hole `??` at loc. ⓗ with the solution $(\mathtt{x} \neq 0)$.

In a similar vein, we can synthesize concrete `while`-guards in `while.c` (Fig. 1) with respect to different assertions. Assume that we consider $\mathtt{assert}(be)$. The CHCs (1), (2), (4), (5) stay the same as above, and we only change the right-hand side of CHC (3) that becomes: $Inv(\mathtt{x},\mathtt{y}) \wedge \neg R(\mathtt{x},\mathtt{y}) \implies (be)$. For example, for assertions $(\mathtt{y} > \mathtt{x})$, $(\mathtt{y}{=}\mathtt{x})$, $(\mathtt{x}{=}10)$, and $(\mathtt{x} > 15)$, the synthesized `while`-guards are: $(\mathtt{x} \geq 5)$, $(\mathtt{x} \neq 5)$, (false), and the problem is unrealizable (i.e., there is no solution that can be derived), respectively. Note that for $\mathtt{assert}(\mathtt{x} > 15)$, we obtain the same solutions for $Inv(\mathtt{x},\mathtt{y})$ and $R(\mathtt{x},\mathtt{y})$, that is $Inv(\mathtt{x},\mathtt{y}) \equiv R(\mathtt{x},\mathtt{y}) \equiv (\mathtt{x} \leq 10 \wedge \mathtt{x}{+}\mathtt{y}{=}10)$. For example, the implication (3): $Inv(\mathtt{x},\mathtt{y}) \wedge \neg R(\mathtt{x},\mathtt{y}) \implies (\mathtt{x} > 15)$ becomes vacuously valid in this case as the left-hand side of the above implication is (false). However, $(R(\mathtt{x},\mathtt{y}) \wedge \neg Inv(\mathtt{x},\mathtt{y})) \equiv$ false, so we conclude that there is no (non-vacuous) solution for this assertion (i.e., the problem is unrealizable). On the other hand, for $\mathtt{assert}(\mathtt{x}{=}10)$, we obtain the CHC solution $Inv(\mathtt{x},\mathtt{y}) \equiv (\mathtt{x} \leq 10 \wedge \mathtt{x}{+}\mathtt{y}{=}10)$ and $R(\mathtt{x},\mathtt{y}) \equiv$ (false), so we infer the solution (false) for `??` in this case.

III. Background

This section introduces the language we consider as well as its concrete and abstract semantics. Furthermore, we also formally define the CHC problem.

A. Language

We use a simple C-like imperative language for writing general-purpose programs. The program variables *Var* are statically allocated and the only data type is the set $\mathbb{Z}$ of mathematical integers. We use the hole constructs $\mathtt{??}_i$ to encode unknown `while`-guards. The holes $\mathtt{??}_i$ are placeholders that the synthesizer must replace with suitable Boolean expressions, such that the resulting complete program will satisfy all assertions. The syntax of the language is:

$$
\begin{array}{l}
s\,(s \in \mathit{Stm}) ::= \mathtt{skip} \mid \mathtt{x}{=}ae \mid s; s \mid \mathtt{assume}(be) \\
\qquad\qquad \mid \mathtt{if}\,(be')\ s\ \mathtt{else}\ s \mid \mathtt{while}\ l_h : (be)\ \mathtt{do}\ s \\
ae\,(ae \in \mathit{AExp}) ::= n \mid [n, n'] \mid \mathtt{x} \mid ae \oplus ae \\
be\,(be \in \mathit{BExp}) ::= \mathtt{??}_i \mid be' \\
be' ::= ae \bowtie ae \mid \neg be' \mid be' \wedge be' \mid be' \vee be'
\end{array}
$$

where n ranges over integers $\mathbb{Z}$, $\mathtt{x}$ ranges over program variables *Var*, $[n, n']$ over integer intervals, and $\oplus \in \{+, -, *, /\}$, $\bowtie \in \{<, \leq, =, \neq\}$. Integer intervals $[n, n']$ denote a random choice of an integer in the interval. We assume that statements are tagged with unique syntactic labels $l \in \mathbb{L}$. Note that `while` has an extra syntactic label $l_h \in \mathbb{L}$ at the `while`-head, i.e. between the `while` keyword and the guard. We assume, without loss of generality, that a program p is a sequence of statements followed by a single assertion "$l_i : s; l_f : \mathtt{assert}(be^f)$". We say that the program p satisfies its assertion (or the assertion is valid) if Boolean expression be^f evaluates to (true) whenever the control reaches the label l_f. Otherwise, the assertion is violated. We say that a program (statement) is *complete* if it contains no holes; otherwise, we say that it is *partial* (or *program sketch*).

$$
\begin{array}{l}
\overrightarrow{[\![\mathtt{skip}]\!]} S = S \\
\overrightarrow{[\![\mathtt{x} = ae]\!]} S = \{\sigma[\mathtt{x} \mapsto n] \mid \sigma \in S, n \in [\![ae]\!]\sigma\} \\
\overrightarrow{[\![s_1\ ;\ s_2]\!]} S = \overrightarrow{[\![s_2]\!]}(\overrightarrow{[\![s_1]\!]} S) \\
\overrightarrow{[\![\mathtt{assume}(be)]\!]} S = \{\sigma \in S \mid \mathsf{true} \in [\![be]\!]\sigma\} \\
\overrightarrow{[\![\mathtt{if}\ (be)\ \ s_1\ \mathtt{else}\ s_2]\!]} S = \overrightarrow{[\![s_1]\!]}\{\sigma \in S \mid \mathsf{true} \in [\![be]\!]\sigma\} \cup \\
\qquad\qquad\qquad\qquad\qquad\qquad \overrightarrow{[\![s_2]\!]}\{\sigma \in S \mid \mathsf{false} \in [\![be]\!]\sigma\} \\
\overrightarrow{[\![\mathtt{while}\ (be)\ \mathtt{do}\ s]\!]} S = \{\sigma \in \mathtt{lfp}\ \overrightarrow{\phi_S} \mid \mathsf{false} \in [\![be]\!]\sigma\} \\
\overrightarrow{\phi_S}(X) = S \cup \overrightarrow{[\![s]\!]}\{\sigma \in X \mid \mathsf{true} \in [\![be]\!]\sigma\}
\end{array}
$$

Fig. 2. Definitions of $\overrightarrow{[\![s]\!]} : \mathcal{P}(\Sigma) \to \mathcal{P}(\Sigma)$.

Remark. Note that in programs p we allow assumptions ($\mathtt{assume}(be)$) to freely occur in a sequence of statements s, while the assertion ($\mathtt{assert}(be)$) occurs only at the final location l_f. An assertion $\mathtt{assert}(be)$ specifies that every execution reaching it is expected to evaluate be to true, in which case we say that the assertion is valid. Otherwise, if the assertion is not valid, the program terminates early with an error. On the other hand, an assumption $\mathtt{assume}(be)$ specifies that every execution reaching it with be evaluated to false is terminated. However, unlike before, this termination is not erroneous, but it means that the programmer does not want to consider the rest of this execution when verifying the correctness of the program.

Let H be a set of uniquely labelled holes $\mathtt{??}_i$ in program p. A *control function* ϕ is a mapping from the set of holes H to complete Boolean expressions be'. We say that ϕ is *complete* if $dom(\phi) = H$, i.e. ϕ is defined for each hole in the program. Otherwise, if $dom(\phi) \subset H$, i.e. ϕ is $\perp$ (undefined) for some holes, we say that ϕ is a *partial* control function. We write $p[\phi]$ to denote the program obtained by substituting each $\mathtt{??}_i$ with $\phi(\mathtt{??}_i)$, if $\phi(\mathtt{??}_i)$ is defined.

Definition 3.1: A complete control function ϕ is a *solution* to the `while`-guard synthesis problem defined by program sketch p if $p[\phi]$ is a complete program that satisfies its assertion.

B. Concrete Semantics and Analyses

The concrete semantics describes the properties of the possible executions of a program. We now define the concrete semantics of our language, and use it to construct *reachability* or *invariance* (forward) as well as *sufficient condition* (backward) *concrete analyses*.

A memory *store*, denoted $\sigma \in \Sigma$, is a function mapping each program variable to an integer value: $\Sigma = \mathit{Var} \to \mathbb{Z}$. The concrete domain is the complete lattice of the powerset of stores [1] $\langle \mathcal{P}(\Sigma), \subseteq, \cup, \cap, \emptyset, \Sigma \rangle$. The semantics of arithmetic expressions $[\![ae]\!] : \Sigma \to \mathcal{P}(\mathbb{Z})$ and Boolean expressions $[\![be]\!] : \Sigma \to \mathcal{P}(\{\mathsf{true}, \mathsf{false}\})$ are the sets of possible (numerical

[1] The powerset of a set S, denoted $\mathcal{P}(S)$, is the set of all subsets of S.

$$
\begin{array}{l}
\overleftarrow{[\![\texttt{skip}]\!]}S = S \\
\overleftarrow{[\![\texttt{x = } ae]\!]}S = \{\sigma \mid \forall n \in [\![ae]\!]\sigma, \sigma[\texttt{x} \mapsto n] \in S\} \\
\overleftarrow{[\![s_1 \texttt{ ; } s_2]\!]}S = \overleftarrow{[\![s_1]\!]}(\overleftarrow{[\![s_2]\!]}S) \\
\overleftarrow{[\![\texttt{assume}(be)]\!]}S = S \cup \{\sigma \mid [\![be]\!]\sigma = \{\text{false}\}\} \\
\overleftarrow{[\![\texttt{if } (be) \texttt{ } s_1 \texttt{ else } s_2]\!]}S = \big(\overleftarrow{[\![s_1]\!]}S \cup \{\sigma \mid [\![be]\!]\sigma = \{\text{false}\}\}\big) \cap \\
\qquad\qquad \big(\overleftarrow{[\![s_2]\!]}S \cup \{\sigma \mid [\![\neg be]\!]\sigma = \{\text{false}\}\}\big) \\
\overleftarrow{[\![\texttt{while } (be) \texttt{ do } s]\!]}S = \texttt{gfp}\ \overleftarrow{\phi}_S \\
\overleftarrow{\phi}_S(X) = \big(S \cup \{\sigma \mid [\![\neg be]\!]\sigma = \{\text{false}\}\}\big) \cap \big(\overleftarrow{[\![s]\!]}X \cup \{\sigma \mid [\![be]\!]\sigma = \{\text{false}\}\}\big)
\end{array}
$$

Fig. 3. Definitions of $\overleftarrow{[\![s]\!]} : \mathcal{P}(\Sigma) \to \mathcal{P}(\Sigma)$.

and Boolean) values for expressions ae and be in a given store σ. For example, $[\![n]\!]\sigma = n$ and $[\![[n, n']]\!]\sigma = \{n, \ldots, n'\}$ for arithmetic expressions n and $[n, n']$, whereas $[\![\texttt{??}_i]\!]\sigma = \{\text{true}, \text{false}\}$ for Boolean expression $\texttt{??}_i$. A semantics definition associates with each statement (program) a concrete semantics property from $\mathcal{P}(\Sigma)$ representing some characteristics of its possible executions. We consider two semantics of statements (programs): a *reachability or invariance* (forward) semantics $\overrightarrow{[\![s]\!]} : \mathcal{P}(\Sigma) \to \mathcal{P}(\Sigma)$ that infers a set of reachable stores (invariants) from a given set of initial stores; and a *sufficient condition* (backward) semantics $\overleftarrow{[\![s]\!]} : \mathcal{P}(\Sigma) \to \mathcal{P}(\Sigma)$ that infers a set of stores (sufficient condition) from which only stores satisfying a given postcondition are reached. The definitions of $\overrightarrow{[\![s]\!]}$ and $\overleftarrow{[\![s]\!]}$ are given in Fig. 2 and Fig. 3, respectively. The reachability semantics [6] is built forward, so each function $\overrightarrow{[\![s]\!]}$ takes as input a set of stores S before statement s and returns a set of possible stores reached after executing s from S. The sufficient condition semantics [7] is built backward, so each function $\overleftarrow{[\![s]\!]}$ takes as input a set of stores S after statement s and returns a set of possible stores before s from which only stores from S are reached after executing s. For example, given a set of stores $S \in \mathcal{P}(\Sigma)$, we have that $\overrightarrow{[\![\texttt{x = } ae]\!]}S$ [2] is the set of final stores reachable after executing $\texttt{x = } ae$, whereas $\overleftarrow{[\![\texttt{x = } ae]\!]}S$ is the set of initial stores such that any execution of $\texttt{x = } ae$ from them leads to a store in S. The semantics of a `while` statement is given in a standard fixed-point formulation [6], [7] using the least and greatest fix-point operators `lfp` and `gfp`, where the fixed-point functionals $\overrightarrow{\phi}_S, \overleftarrow{\phi}_S : \mathcal{P}(\Sigma) \to \mathcal{P}(\Sigma)$, parameterized with the input set of stores S, accumulate possible stores after another `while` iteration from a set of stores X going in a forward and backward direction, respectively.

C. Abstract Semantics

The language we consider is Turing complete, thus making the concrete semantics and analyses uncomputable. We now define computable abstract analyses [6], [7], [8] that are approximations of the concrete semantics and analyses. The first basic choice in abstract interpretation is to design an abstract semantics domain $\mathbb{D}$, which is an approximate version of the concrete semantics domain $\mathcal{P}(\Sigma)$. More specifically, we replace the computation in the concrete domain $\mathcal{P}(\Sigma)$ with a computation in some numerical abstract domain $\mathbb{D}$ that reasons on the numerical properties of variables, such that there exists a concretization-based abstraction $\langle \mathcal{P}(\Sigma), \subseteq \rangle \xleftarrow{\gamma_{\mathbb{D}}} \langle \mathbb{D}, \sqsubseteq_{\mathbb{D}} \rangle$. [3] This abstraction works only with a concretization function $\gamma_{\mathbb{D}} : \mathbb{D} \to \mathcal{P}(\Sigma)$ expressing the meaning of abstract elements from $\mathbb{D}$ in terms of concrete elements from $\mathcal{P}(\Sigma)$. The abstract domain $\mathbb{D}$ is a set of computer-representable properties, called *abstract elements*, together with effective algorithms to implement sound abstract operators for forward and backward analyses. In particular, they have abstract operators for ordering $\sqsubseteq_{\mathbb{D}}$, least upper bound (join) $\sqcup_{\mathbb{D}}$, greatest lower bound (meet) $\sqcap_{\mathbb{D}}$, bottom $\bot_{\mathbb{D}}$, top $\top_{\mathbb{D}}$, widening $\triangledown_{\mathbb{D}}$, and narrowing $\triangle_{\mathbb{D}}$. There are forward transfer functions for assignments $\texttt{ASSIGN}_{\mathbb{D}} : \textit{Stm} \times \mathbb{D} \to \mathbb{D}$ and tests $\texttt{FILTER}_{\mathbb{D}} : \textit{BExp} \times \mathbb{D} \to \mathbb{D}$, which are sound over-approximations of the corresponding concrete functions. We let $\texttt{lfp}^{\#}$ denote an abstract fix-point operator, derived using widening $\triangledown_{\mathbb{D}}$ and narrowing $\triangle_{\mathbb{D}}$, that over-approximates the concrete `lfp`. There are also backward transfer functions for assignments $\texttt{B-ASSIGN}^u_{\mathbb{D}} : \textit{Stm} \times \mathbb{D} \to \mathbb{D}$, tests $\texttt{B-FILTER}^u_{\mathbb{D}} : \textit{BExp} \times \mathbb{D} \to \mathbb{D}$, and a lower widening $\underline{\triangledown}_{\mathbb{D}}$ [7], which are sound under-approximations of the corresponding concrete functions. We let $\texttt{gfp}^{\#}$ denote an abstract fixpoint operator, derived using lower widening $\underline{\triangledown}_{\mathbb{D}}$, that under-approximates the concrete `gfp`.

The abstract domain $\mathbb{D}$ can be employed to derive abstract reachability (resp., abstract sufficient condition) analysis that represents over-approximation (resp., under-approximation) of the corresponding concrete analysis. For each statement s, we define the abstract reachability semantics $\overrightarrow{[\![s]\!]}^{\sharp}$ and the abstract sufficient condition semantics $\overleftarrow{[\![s]\!]}^{\sharp}$ in Fig. 4 and Fig. 5, respectively. For a `while` loop, $\texttt{lfp}^{\sharp}\ \overrightarrow{\phi}^{\sharp}_d$ is the limit of the following increasing chain: $y_0 = d$, $y_{n+1} = y_n \triangledown_{\mathbb{D}} \overrightarrow{\phi}^{\sharp}_d(y_n)$ for forward analysis; whereas $\texttt{gfp}^{\sharp}\ \overleftarrow{\phi}^{\sharp}_d$ is the limit of the following decreasing chain: $y_0 = \texttt{B-FILTER}^u_{\mathbb{D}}(\neg be, d)$, $y_{n+1} = y_n \underline{\triangledown}_{\mathbb{D}} \overleftarrow{\phi}^{\sharp}_d(y_n)$ for backward analysis. Since $\texttt{FILTER}_{\mathbb{D}}(be, d) \sqsubseteq_{\mathbb{D}} d$ and $\texttt{B-FILTER}^u_{\mathbb{D}}(be, d) \sqsupseteq_{\mathbb{D}} d$, we use $\texttt{FILTER}_{\mathbb{D}}(\texttt{??}_i, d) = d$ and $\texttt{B-FILTER}^u_{\mathbb{D}}(\texttt{??}_i, d) = d$ to handle the Boolean expression hole $\texttt{??}_i$.

By the soundness of the operators of abstract domain $\mathbb{D}$ [6], [7], we prove the soundness of abstract semantics with respect to concrete semantics. That is, $\overrightarrow{[\![s]\!]}^{\sharp}$ over-approximates the set of reachable stores obtained by concrete semantics $\overrightarrow{[\![s]\!]}$, whereas $\overleftarrow{[\![s]\!]}^{\sharp}$ under-approximates the set of sufficient condition stores obtained by concrete semantics $\overleftarrow{[\![s]\!]}$.

Proposition 3.2 ([6], [7]): We have: $\overrightarrow{[\![s]\!]}\gamma_{\mathbb{D}}(d) \subseteq \overrightarrow{[\![s]\!]}^{\sharp}d$ and $\overleftarrow{[\![s]\!]}\gamma_{\mathbb{D}}(d) \supseteq \overleftarrow{[\![s]\!]}^{\sharp}d$.

[2] $\sigma[\texttt{x} \mapsto n]$ denotes the store that updates σ at variable $\texttt{x}$ to be equal to n.

[3] Concretization-based abstraction, which uses only a concretization function $\gamma_{\mathbb{D}}$ (e.g. Polyhedra domain), represents a relaxation of the well-known Galois connection that uses both abstraction and concretization functions.

$$
\begin{array}{l}
\overrightarrow{[\![\texttt{skip}]\!]^\sharp} d = d \\
\overrightarrow{[\![\texttt{x = } ae]\!]^\sharp} d = \texttt{ASSIGN}_{\mathbb{D}}(\texttt{x = } ae, d) \\
\overrightarrow{[\![s_1 \texttt{ ; } s_2]\!]^\sharp} d = \overrightarrow{[\![s_2]\!]^\sharp}(\overrightarrow{[\![s_1]\!]^\sharp} d) \\
\overrightarrow{[\![\texttt{assume}(be)]\!]^\sharp} d = \texttt{FILTER}_{\mathbb{D}}(be, d) \\
\overrightarrow{[\![\texttt{if } be \texttt{ } s_1 \texttt{ else } s_2]\!]^\sharp} d = \overrightarrow{[\![s_1]\!]^\sharp}(\texttt{FILTER}_{\mathbb{D}}(be, d)) \sqcup_{\mathbb{D}} \\
\qquad\qquad \overrightarrow{[\![s_2]\!]^\sharp}(\texttt{FILTER}_{\mathbb{D}}(\neg be, d)) \\
\overrightarrow{[\![\texttt{while } be \texttt{ do } s]\!]^\sharp} d = \texttt{FILTER}_{\mathbb{D}}(\neg be, \texttt{lfp}^\sharp\ \overrightarrow{\phi}^\sharp_d) \\

\overleftarrow{\phi}^\sharp_d(x) = \texttt{B-FILTER}^u_{\mathbb{D}}(\neg be, d) \sqcap_{\mathbb{D}} \texttt{B-FILTER}^u_{\mathbb{D}}(be, \overleftarrow{[\![s]\!]^\sharp} x)
\end{array}
$$

Fig. 5. Definitions of $\overleftarrow{[\![s]\!]^\sharp} : \mathbb{D} \to \mathbb{D}$.

The abstract domain $\mathbb{D}$ can be instantiated with different numerical abstract domains including Intervals [6], Octagons [7], and Polyhedra [14]. They differ in precision and computational complexity. In this work, we will mainly use the Polyhedra domain due to its precision. The *Polyhedra domain* [14] is a fully relational numerical abstract domain, which allows manipulating conjunctions of linear inequalities (constraints) of the form $\alpha_1 \texttt{x}_1 + \ldots + \alpha_n \texttt{x}_n \geq \beta$, where $\texttt{x}_1$, ..., $\texttt{x}_n$ are program variables and $\alpha_i, \beta \in \mathbb{Q}$ (rationals). The abstract operations, transfer functions, and the soundness of the Polyhedra domain are defined in [14].

Example 3.3: Consider the program sketch `while.c` in Fig. 1. Assume that the analysis fact $\top$ (true) holds at loc. ①. and we want to perform forward reachability analysis based on the Polyhedra domain. In order to enforce the convergence of the analysis, we apply the widening operator at loc. ⓗ. The analysis results inferred by our forward analysis at locs. from ① to ⑤ are shown in Fig. 6 (left).

Similarly, we assume that the analysis fact $(\texttt{y=10})$ holds at loc. ⑤ and we want to perform backward sufficient condition analysis based on the Polyhedra domain. To enforce the convergence, we apply the lower widening operator at loc. ⓗ. The analysis results inferred by our backward analysis at locs. from ⑤ to ① are shown in Fig. 6 (right).

D. Constrained Horn Clauses (CHCs)

Given a formula ϕ in a first-order theory $\mathcal{T}$, the SMT (Satisfiability Modulo Theory) solvers [18] decide the satisfiability of ϕ, i.e. they check if there is an assignment of values to variables in ϕ that makes ϕ true. To check the validity of ϕ, they check the unsatisfiability of $\neg\phi$. Examples of first-order theories are: linear integer arithmetic (LIA), arrays, etc.

① $\top$	⑤ $(\texttt{y=10})$
② $(\texttt{x=10} \wedge \texttt{y=0})$	ⓗ $\bot$
ⓗ $(\texttt{x} \leq 10 \wedge \texttt{x+y=10})$	④ $\bot$
③ $(\texttt{x} \leq 10 \wedge \texttt{x+y=10})$	③ $\bot$
④ $(\texttt{x} \leq 9 \wedge \texttt{x+y=9})$	② $\bot$
⑤ $(\texttt{x} \leq 10 \wedge \texttt{x+y=10})$	① $\bot$

Fig. 6. Analysis results of `while.c` inferred by forward (left) and backward (right) analysis.

Constrained Horn Clauses (CHCs) are a fragment of first-order theory $\mathcal{T}$ defined over a finite set of unknown predicates $\mathcal{R}$. A CHC is a formula that has one of the following forms:

$$\phi(\overrightarrow{\mathbf{x}_0}) \implies R_0(\overrightarrow{\mathbf{x}_0}) \quad (6)$$

$$\wedge_{0 \leq i \leq n} R_i(\overrightarrow{\mathbf{x}_i}) \wedge \phi(\overrightarrow{\mathbf{x}_0}, \ldots, \overrightarrow{\mathbf{x}_{n+1}}) \implies R_{n+1}(\overrightarrow{\mathbf{x}_{n+1}}) \quad (7)$$

$$\wedge_{0 \leq i \leq n} R_i(\overrightarrow{\mathbf{x}_i}) \implies \phi(\overrightarrow{\mathbf{x}_0}, \ldots, \overrightarrow{\mathbf{x}_n}) \quad (8)$$

where $R_i(\overrightarrow{\mathbf{x}_i}) \in \mathcal{R}$ $(0 \leq i \leq n+1)$ is an unknown predicate defined over a vector of variables $\overrightarrow{\mathbf{x}_i}$, and $\phi(\overrightarrow{\mathbf{x}_0}, \ldots, \overrightarrow{\mathbf{x}_n})$ is a first-order formula that does not contain any unknown predicates. The *body* (resp., *head*) of a CHC represents the left (resp., right) side of the implication. A CHC of type (6) is called *fact*, of type (7) is called *inductive*, and of type (8) is called *query*. A CHC is called *linear* if the number of unknown predicates in its body is one, otherwise it is called *non-linear*.

A *solution* to a set of CHCs defined over unknown predicates $\mathcal{R}$ is a mapping $\mathcal{M}$ from $\mathcal{R}$ to first-order formulas, such that all implications in the set become valid. That is, for each $R(\overrightarrow{\mathbf{x}}) \in \mathcal{R}$, $\mathcal{M}(R)$ represents a first-order formula ϕ defined over the variables $\overrightarrow{\mathbf{x}}$. The CHC solvers, like `Eldarica` [11], `Spacer` [10], `Duality` [15], and `FreqHorn` [16], contain algorithms, denoted `CHC-solve`, for computing the correct solutions to sets of CHCs.

IV. Synthesis Algorithm

In this section, we present our algorithm for solving the `while`-guard synthesis problem. In particular, we employ the abstract static analyses, $\overrightarrow{[\![s]\!]^\sharp}$ and $\overleftarrow{[\![s]\!]^\sharp}$, as well as the CHC solving procedure, `CHC-solve`, to automatically find Boolean expressions for the missing holes in a program sketch, so that the resulting complete program satisfies its assertion. That is, we establish a link between checking an assertion in a program and solving CHCs via abstract static analyses, which provide a way to transition from programs to CHCs.

A. Description

The $\texttt{WhileSketching}_{\texttt{CHC}}(p, H)$ synthesis procedure is shown in Algorithm 1. The procedure takes as input two parameters: a program sketch p, and a set of holes H in p representing missing `while`-guards. It returns as output a solution (complete control function ϕ) or the empty mapping $\emptyset$ if no solution exists. For each hole $\texttt{??}_i$ in H, we first generate an initial solution, which is a complete Boolean expression be'_i, such that all other holes are treated as non-deterministic

Algorithm 1: WhileSketching$_{\texttt{CHC}}(p, H)$

Input: Program sketch p, and a set of holes H
Output: Complete control function ϕ or an empty mapping $\emptyset$

1 $\phi := \phi' := \emptyset$;
2 **for** *(* $??_i \in H$*)* **do**
3 $(l: \texttt{while}\, l_h : (??_i)\, \texttt{do}\, \{l_b : s_b\}\, l' :) := \texttt{Extract}(p, ??_i)$;
4 $\phi_i^{ndet} := [??_i \mapsto \bot] \uplus \{[??_j \mapsto \mathcal{P}(\{\text{true}, \text{false}\})] \mid j \neq i\}$;
5 $be_i' := \texttt{OneHoleSynth}(p[\phi_i^{ndet}], s_b, l, l_h, l')$;
6 **if** $(be_i' = \emptyset)$ **then return** $\emptyset$ **;**
7 $\phi := \phi \uplus [\mathbf{??}_i \mapsto be_i']$
8 **while** $(\phi \neq \phi')$ **do**
9 **if** $(\phi' \neq \emptyset)$ **then** $\phi = \phi'; \phi' = \emptyset$;
10 **for** *(* $??_i \in H$*)* **do**
11 $(l: \texttt{while}\, l_h : (??_i)\, \texttt{do}\, \{l_b : s_b\}\, l' :) := \texttt{Extract}(p, ??_i)$;
12 $\phi_i := \phi[??_i \mapsto \bot]$;
13 $be_i'' := \texttt{OneHoleSynth}(p[\phi_i], s_b, l, l_h, l')$;
14 **if** $(be_i'' = \emptyset)$ **then return** $\emptyset$ **;**
15 $\phi' := \phi' \uplus [\mathbf{??}_i \mapsto be_i'']$
16 **return** ϕ

choices over Booleans, $\mathcal{P}(\{\text{true}, \text{false}\})$ (lines 2–7). First, we identify the statement "$(l : \texttt{while}\ l_h : (??_i)\ \texttt{do}\ \{l_b : s_b\}\ l' :)$" in which $??_i$ occurs by using $\texttt{Extract}(p, ??_i)$ procedure (line 3). Second, we construct a partial control function ϕ_i^{ndet}, such that $\phi_i^{ndet}(??_i) = \bot$ (undefined) and $\phi_i^{ndet}(??_j) = \mathcal{P}(\{\text{true}, \text{false}\})$ for all other $??_j \in H$ (line 4), and we generate a program sketch $p[\phi_i^{ndet}]$ in which the hole $??_i$ is the only one. This has the effect of treating any hole other than $??_i$ in $p[\phi_i^{ndet}]$ as a non-deterministic choice. Finally, we call the one-hole synthesis procedure, called $\texttt{OneHoleSynth}(p[\phi_i^{ndet}], s_b, l, l_h, l')$ to generate the solution be_i' corresponding to hole $??_i$ (line 5). This way, we generate an *initial* complete control function $\phi : [??_i \mapsto be_i']$ by using the above initial solutions for all holes $??_i$ in H.

Subsequently, Algorithm 1 goes through an iterative while-loop (lines 8-15) performing the weakening of the current solution ϕ, thus generating more general solutions ϕ'. The algorithm terminates when the refinement is no longer enabled, i.e. $\phi = \phi'$ (line 8). In particular, in each while-iteration we weaken the current solution ϕ by iteratively weakening ϕ-solutions for all holes (lines 10–15). To weaken the ϕ-solution for each $??_i$, we fix the ϕ-solutions be_j' for all other $??_j$ in a partial control function ϕ_i, such that $\phi_i(??_i) = \bot$ and $\phi_i(??_j) = \phi(??_j)$ for all other $??_j \in H$ (line 12). Then, we generate a program sketch $p[\phi_i]$ in which the hole $??_i$ is the only one. Finally, we call $\texttt{OneHoleSynth}(p[\phi_i^{ndet}], s_b, l, l_h, l')$ to find a weaker Boolean expression be_i'' for $??_i$ (line 13), which is located at statement $(l : \texttt{while}\ l_h : (??_i)\ \texttt{do}\ \{l_b : s_b\}\ l' :)$. The generated be_i'' will be included in the updated solution ϕ' (line 15). In particular, we use the solutions given by the current control function for all other holes and infer more general Boolean expression for $??_i$ that implies the assertion validity.

Algorithm 2: OneHoleSynth(p, s_b, l, l_t, l')

Input: Program sketch $p \equiv l_i : s; l_f : \texttt{assert}(be^f)$, while-body s_b, and labels l, l_h, l'
Output: Complete Boolean expression be' or an empty mapping $\emptyset$

1 $\texttt{Reach}^\sharp := \overrightarrow{[\![s]\!]}^\sharp \top_{\mathbb{D}}$;
2 $\texttt{Cond}^\sharp := \overleftarrow{[\![s]\!]}^\sharp \texttt{FILTER}_{\mathbb{D}}(be^f, \top_{\mathbb{D}})$;
3 $C_1 := (\texttt{Reach}^\sharp(l) \implies Inv(\overrightarrow{\mathbf{x}}))$;
4 $C_2 := (Inv(\overrightarrow{\mathbf{x}}) \wedge R(\overrightarrow{\mathbf{x}}) \wedge (\overrightarrow{[\![\overrightarrow{\mathbf{x'}} = \overrightarrow{\mathbf{x}}; s_b[\overrightarrow{\mathbf{x'}}/\overrightarrow{\mathbf{x}}]]\!]^\sharp} \top_{\mathbb{D}}) \implies Inv(\overrightarrow{\mathbf{x'}}))$;
5 $C_3 := (Inv(\overrightarrow{\mathbf{x}}) \wedge \neg R(\overrightarrow{\mathbf{x}}) \implies \texttt{Cond}^\sharp(l'))$;
6 $C_4 := (Inv(\overrightarrow{\mathbf{x}}) \implies \texttt{Reach}^\sharp(l_h))$;
7 $C_5 := (\texttt{Cond}^\sharp(l_h) \implies Inv(\overrightarrow{\mathbf{x}}))$;
8 $CHC := \{C_1, C_2, C_3, C_4, C_5\}$;
9 $\mathcal{M} := \texttt{CHC-solve}(CHC)$;
10 **if** $(\mathcal{M}(R(\overrightarrow{\mathbf{x}})) \Leftrightarrow \mathcal{M}(Inv(\overrightarrow{\mathbf{x}})))$ **then return** $\emptyset$ **;**
11 **return** $\texttt{SMTSimpl}((\mathcal{M}(R(\overrightarrow{\mathbf{x}})) \wedge \neg\mathcal{M}(Inv(\overrightarrow{\mathbf{x}}))))$

B. One-hole Synthesis Procedure

The $\texttt{OneHoleSynth}(p, s_b, l, l_t, l')$ procedure, shown in Algorithm 2, takes five parameters: a program sketch $p \equiv l_i : s; l_f : \texttt{assert}(be^f)$ with one hole in it, a body s_b of the while with missing guard in s, and three labels: l, l_h, and l', where the while-guard $??$ we want to handle is located (l and l' are locations before and after the while, and l_h is location at the while-head). We first call the forward abstract analysis $\overrightarrow{[\![s]\!]}^\sharp \top_{\mathbb{D}}$ (line 1) and the backward abstract analysis $\overleftarrow{[\![s]\!]}^\sharp d_{\mathcal{F}}$ (line 2), where $d_{\mathcal{F}} = \texttt{FILTER}_{\mathbb{D}}(be^f, \top_{\mathbb{D}})$ represents the assertion fact, that proceed by structural induction on the program syntax of s. This way, we compute the invariants $\texttt{Reach}^\sharp$ as well as the sufficient conditions $\texttt{Cond}^\sharp$ in all locations of p. Assume that $\texttt{Reach}^\sharp(l)$ is the inferred invariant at loc. l before the while, while $\texttt{Cond}^\sharp(l')$ is the inferred sufficient condition at loc. l' after the while that ensures assertion-safety of the code that comes after the hole $??$. Moreover, we assume that $\texttt{Reach}^\sharp(l_h)$ and $\texttt{Cond}^\sharp(l_h)$ are the inferred analysis facts at loc. l_h for the inductive while-invariant by the forward and backward analysis, respectively. By using the inferred $\texttt{Reach}^\sharp(l)$, $\texttt{Reach}^\sharp(l_h)$, $\texttt{Cond}^\sharp(l')$, and $\texttt{Cond}^\sharp(l_h)$, we then construct CHCs with two unknown predicates: $Inv(\overrightarrow{\mathbf{x}})$ and $R(\overrightarrow{\mathbf{x}})$ corresponding to the inductive while-invariant and the guard of the while with the hole $??$, where $\overrightarrow{\mathbf{x}}$ is a vector of all program variables defined in the scope of the given while. More specifically, we generate the following five CHC queries for all cases involving the given while. The inductive while-invariant $Inv(\overrightarrow{\mathbf{x}})$ expresses a relationship between the program variables that is implied by the while's precondition and is preserved by any execution of the while-body. For this aim, we use the CHCs C_1 and C_2 to ensure that the while-invariant $Inv(\overrightarrow{\mathbf{x}})$ is inductive. In particular, C_1 states that the invariant at the while's precondition $\texttt{Reach}^\sharp(l)$ implies $Inv(\overrightarrow{\mathbf{x}})$. To state

that $Inv(\overrightarrow{\mathbf{x}})$ is preserved in each iteration of the `while`'s body, we need a way of remembering the initial values of all variables $\overrightarrow{\mathbf{x}}$ in the scope of the given `while`. To do so, we analyze the program: $\overrightarrow{\mathbf{x'}} = \overrightarrow{\mathbf{x}}; s_b[\overrightarrow{\mathbf{x'}}/\overrightarrow{\mathbf{x}}]$, where $\overrightarrow{\mathbf{x'}} = \overrightarrow{\mathbf{x}}$ assign all program variables $\overrightarrow{\mathbf{x}}$ to their primed versions $\overrightarrow{\mathbf{x'}}$ and $s_b[\overrightarrow{\mathbf{x'}}/\overrightarrow{\mathbf{x}}]$ means that all variables $\overrightarrow{\mathbf{x}}$ in s_b are renamed to their primed versions $\overrightarrow{\mathbf{x'}}$. This way, we build the required CHC C_2 stating that if $Inv(\overrightarrow{\mathbf{x}})$ and $R(\overrightarrow{\mathbf{x}})$ hold and we analyze $\overrightarrow{\mathbf{x'}} = \overrightarrow{\mathbf{x}}; s_b[\overrightarrow{\mathbf{x'}}/\overrightarrow{\mathbf{x}}]$, then $Inv(\overrightarrow{\mathbf{x'}})$ will hold after that. That is, executing `while`'s body when $R(\overrightarrow{\mathbf{x}})$ holds re-establishes the `while`-invariant $Inv(\overrightarrow{\mathbf{x}})$. The CHC C_3 states that on `while` exit, the `while`-invariant $Inv(\overrightarrow{\mathbf{x}})$ strengthen with $\neg R(\overrightarrow{\mathbf{x}})$ are sufficiently strong to imply the `while`'s postcondition $\texttt{Cond}^\sharp(l')$ ensuring that the assertion is correct. The CHCs C_4 and C_5 state that the analysis facts $\texttt{Reach}^\sharp(l_h)$ and $\texttt{Cond}^\sharp(l_h)$ inferred at loc. l_h by forward and backward analysis are over- and under-approximations of $Inv(\overrightarrow{\mathbf{x}})$, respectively.

Finally, we call the `CHC-solve` procedure to find the solution (mapping) $\mathcal{M}$ of the constructed set of CHCs, such that $\mathcal{M}(Inv)$ and $\mathcal{M}(R)$ are first-order formulas defined over variables $\overrightarrow{\mathbf{x}}$. Since the solution $\mathcal{M}(R)$ represents a strengthen formula of $\mathcal{M}(Inv)$, we can use $\mathcal{M}(R) \wedge \neg\mathcal{M}(Inv)$ as the final solution be' to replace the given Boolean expression hole `??` (line 11). However, if $(\mathcal{M}(R) \Leftrightarrow \mathcal{M}(Inv))$, i.e. $\mathcal{M}(R)$ and $\mathcal{M}(Inv)$ are equivalent, then the given problem is not solvable and an empty mapping is returned (line 10).

C. Correctness

The following theorem states correctness of the $\texttt{WhileSketching}_{\texttt{CHC}}$ algorithm.

Theorem 1: $\texttt{WhileSketching}_{\texttt{CHC}}(p, H)$ is correct and terminates.

Proof: The procedure $\texttt{WhileSketching}_{\texttt{CHC}}(p, H)$ terminates since all steps in it are terminating. The `while`-loop (lines 8-15) terminates since in the worst case it will generate the weakest solutions true for all holes. The correctness of $\texttt{WhileSketching}_{\texttt{CHC}}(p, H)$ follows from the soundness of $\texttt{Reach}^\sharp$ and $\texttt{Cond}^\sharp$ (see Proposition 3.2) and the correctness of `CHC-solve` [11], [10], [15], [16]. ■

V. Abduction-based Synthesis

We now give an overview of the logical abduction-based approach for `while`-guard synthesis, called $\texttt{GenSketching}_{\texttt{Abd}}$, introduced in [5]. The logical abduction [9] is a technique for inferring a single unknown predicate $R(\overrightarrow{\mathbf{x}})$, which is defined over a vector of program variables $\overrightarrow{\mathbf{x}}$ from an implication formula:

$$R(\overrightarrow{\mathbf{x}}) \wedge \chi \implies C$$

where χ and C are first-order logical formulas. The solution to the above abduction problem is formula ϕ, which represents an interpretation of $R(\overrightarrow{\mathbf{x}})$, such that (1) $\phi \wedge \chi \not\models$ false; and (2) $\phi \wedge \chi \models C$. The procedure $\texttt{Abduce}(\chi, C, \overrightarrow{\mathbf{x}})$ that finds the logically weakest solution containing a fewest number of variables to the above abduction problem is implemented in the `EXPLAIN` tool [9].

We now show how to handle the case when there is a single hole in a sketch p, which occurs in the statement of the form: "l : (`while` l_h : (`??`) `do` $\{l_b : s_b\})\, l'$:". The case when there are more than one holes in a program sketch is handled similarly as in Algorithm 1. First, we perform forward and backward abstract static analyses of p to compute the invariants $\texttt{Reach}^\sharp$ and the sufficient conditions $\texttt{Cond}^\sharp$ in all locations of p. Then, we construct an abduction query where the premise is $\texttt{Reach}^\sharp(l_h)$, the desired conclusion is $\texttt{Cond}^\sharp(l')$, and the unknown predicate is $R_{false}(\overrightarrow{\mathbf{x}})$, that is: $\texttt{Reach}^\sharp(l_h) \wedge R_{false}(\overrightarrow{\mathbf{x}}) \implies \texttt{Cond}^\sharp(l')$. The meaning of this query is that when `while` terminates, the `while`-invariant $\texttt{Reach}^\sharp(l_h)$ and the negation of the missing `while`-guard, encoded via the unknown predicate $R_{false}(\overrightarrow{\mathbf{x}})$, should imply the sufficient condition $\texttt{Cond}^\sharp(l')$ ensuring that the code after `while` guarantees the assertion validity.

Next, we find $R_{true}(\overrightarrow{\mathbf{x}})$ that is the negation of the formula found for $R_{false}(\overrightarrow{\mathbf{x}})$, i.e. $R_{true}(\overrightarrow{\mathbf{x}}) \equiv (\neg R_{false}(\overrightarrow{\mathbf{x}}))$. Assume that $R_{true}(\overrightarrow{\mathbf{x}})$ is of the form: $\phi_1 \vee \ldots \vee \phi_n$, where ϕ_i is a conjunction of formulas. We perform n backward analyses defined as follows: $\overleftarrow{[\![p[\texttt{??} \mapsto (\phi_1 \wedge \texttt{??})]]\!]^\sharp}(\texttt{FILTER}_{\mathbb{D}}(be^f, \top_{\mathbb{D}})), \ldots, \texttt{Cond}^{\sharp,n} = \overleftarrow{[\![p[\texttt{??} \mapsto (\phi_n \wedge \texttt{??})]]\!]^\sharp}(\texttt{FILTER}_{\mathbb{D}}(be^f, \top_{\mathbb{D}}))$, where $p[\texttt{??} \mapsto (\phi_i \wedge \texttt{??})]$ is the sketch p in which the hole `??` is replaced with $(\phi_i \wedge \texttt{??})$. We create n abduction queries: $\texttt{Reach}^\sharp(l_h) \wedge R^1_{true}(\overrightarrow{\mathbf{x}}) \implies \texttt{Cond}^{\sharp,1}(l_b)$, ..., $\texttt{Reach}^\sharp(l_h) \wedge R^n_{true}(\overrightarrow{\mathbf{x}}) \implies \texttt{Cond}^{\sharp,n}(l_b)$. Finally, the solution for `??` is the Boolean expression: $(\phi_1 \wedge R^1_{true}(\overrightarrow{\mathbf{x}})) \vee \ldots \vee (\phi_n \wedge R^n_{true}(\overrightarrow{\mathbf{x}}))$. In the implementation, we can make some optimizations to reduce the number of calls to the abduction solver. For example, if $\texttt{Cond}^{\sharp,i}(l_b) =$ false then we can conclude that $R^i_{true}(\overrightarrow{\mathbf{x}}) \equiv$ (false) without calling the abduction solver.

Example 5.1: Consider the sketch `while.c` given in Fig. 1. The forward analysis infers the invariant $(\texttt{x} \leq 10) \wedge (\texttt{x+y=10})$ at loc. l_h. We construct the abduction query $(\texttt{x} \leq 10) \wedge (\texttt{x+y=10}) \wedge R_{false}(\texttt{x,y}) \implies (\texttt{y=10})$. The reported solution by EXPLAIN is $R_{false}(\texttt{x,y}) \equiv (\texttt{x=0})$. We compute $R_{true}(\texttt{x,y}) \equiv \neg R_{false}(\texttt{x,y}) \equiv (\texttt{x<0}) \vee (\texttt{x>0})$. Hence, we perform two backward analysis of `while.c` in which the `while`-guard is $(\texttt{x<0} \wedge \texttt{??}_1)$ and $(\texttt{x>0} \wedge \texttt{??}_2)$, respectively. They start with the fact $(\texttt{x=0} \wedge \texttt{y=10})$ at loc. ⑤. The first backward analysis for $(\texttt{x<0} \wedge \texttt{??}_1)$ infers the bottom ($\bot$) condition after the guard at loc. ③, whereas the second backward analysis for $(\texttt{x>0} \wedge \texttt{??}_2)$ infers $(1 \leq \texttt{x} \leq 11) \wedge (\texttt{x+y=10})$ after the guard at loc. ③. We construct two abduction queries: (1) $(\texttt{x} \leq 10 \wedge \texttt{x+y=10}) \wedge R^1_{true}(\texttt{x,y}) \implies$ false, and (2) $(\texttt{x} \leq 10 \wedge \texttt{x+y=10}) \wedge R^2_{true}(\texttt{x,y}) \implies (1 \leq \texttt{x} \leq 11) \wedge (\texttt{x+y=10})$. The obtained solutions are $R^1_{true}(\texttt{x,y}) \equiv$ false and $R^2_{true}(\texttt{x,y}) \equiv$ true. Hence, we fill the hole with $(\texttt{x>0})$.

VI. Evaluation

We now evaluate our approach based on abstract static analysis and CHC solving for synthesizing missing `while`-guards in numerical sketches written in C. We compare its performances against the approach that uses logical abduction for constraint solving.

```
void main(int n){
  assume(n ≥ 0)
  int i = 0;
  while (??) do{
      i = i+2;
  }
  assert(i==2*n);
 // assert(i==4*n);
 // assert(i==0);
 // assert(i<0);
}
```

Fig. 7. eq2.c.

```
void main(int x) {
  assume(x ≥ 0)
  int a = x;
  int y = 0;
  while(??) do{
    y = y+1;
    a = a-1;
  }
  assert(x==y);
 // assert(a==0);
 // assert(a+2==x);
 // assert(y<0);
}
```

Fig. 9. copy.c.

```
void main() {
  int i = 0;
  int j = 0;
  while(??) do{
    i = i+1;
    j = j+1;
  }
  assert(i+j==20);
 // assert(i+j>20);
 // assert(i+j≤15);
 // assert(i+j==15);
}
```

Fig. 8. loop2.c.

```
void main() {
  int x = 0;
  int y = 0;
  while(??) do{
    x = x+1;
    y = y+2;
  }
  assert(y==2*m);
 // assert(y==x);
 // assert(y==x && x>0);
 // assert(y==2*m+1);
}
```

Fig. 10. hola.c.

A. Implementation

We have implemented the proposed synthesis algorithm in a proof-of-concept tool, called $\texttt{WhileSketching}_{\texttt{CHC}}$. The abstract operations and transfer functions of the Polyhedra abstract domain [14] are provided by the APRON library [17]. The CHC and SMT queries are solved by the `Eldarica` [11] and the `Z3` [18] tools. Our proof-of-concept tool is written in OCAML and consists of around 7K lines of code. The tool accepts programs written in a subset of C. It currently provides only a limited support for arrays, pointers, `struct` and `union` types. The only basic data type is mathematical integers. The tool calls the APRON library for static analysis of the input program, then generates CHC constraints and calls the `Eldarica` tool to solve them. Finally, it handles the obtained results and reports the solutions.

B. Experiment setup and Benchmarks

All experiments are executed on a 64-bit Intel®Core^{TM} i5 CPU, VM Lubuntu 18.04, with 16 GB memory, and we use a timeout value of 60 sec. All times are reported as average over five independent executions. We compare two approaches:

(1) $\texttt{WhileSketching}_{\texttt{CHC}}$ based on abstract static analysis and CHC solving; and
(2) $\texttt{GenSketching}_{\texttt{Abd}}$ based on abstract static analysis and abduction solving.

We report TIME which is the total time to resolve a given problem, SOLVTIME which is the time taken by logical (CHC or abduction) solvers to solve the logical queries in the given synthesis task, and PREC which shows the precision of the reported solution. We use: ✓ when the tool finds correct solution for a given assertion; and × denotes the opposite, i.e. the tool cannot find a correct solution for the assertion.

The evaluation is performed on several C numerical sketches collected from SV-COMP, (https://sv-comp.sosy-lab.org/) and the literature [19], [5] In particular, we use the following benchmarks: `while.c` (Fig. 1), `eq2.c` (Fig. 7), `loop2.c` (Fig. 8), `copy.c` (Fig. 9), and `hola.c` (Fig. 10). In all benchmarks, we assume that `while`-guards are missing and we employ the aforementioned approaches to synthesize suitable Boolean expressions for them.

C. Performance Results

Table I shows the performance results of $\texttt{WhileSketching}_{\texttt{CHC}}$ and $\texttt{GenSketching}_{\texttt{Abd}}$.

We described in Section II how $\texttt{WhileSketching}_{\texttt{CHC}}$ successfully handles the sketch `while.c` given in Fig. 1. $\texttt{GenSketching}_{\texttt{Abd}}$ also finds the correct solutions for `while.c`, but for the first two assertions it needs two calls to the abduction solver, which results in slower running times.

The program sketch `eq2.c` in Fig. 7 has one local variable `i`, which is initialized to `0` and increased by `2` in every `while`-iteration. The forward static analysis infers the invariant $(\texttt{i=0} \wedge \texttt{n} \geq \texttt{0})$ before the `while` and $(\texttt{i} \geq \texttt{0} \wedge \texttt{n} \geq \texttt{0})$ at the `while`-head. For the specification `assert(i==2*n)`, $\texttt{WhileSketching}_{\texttt{CHC}}$ constructs the corresponding CHCs

and generates the solution (i ≠ n) for the while-guard ??. For the assertions (i==4⋆n), (i==0), and (i<0), we synthesize the following while-guards: (i ≠ 2⋆n), false, and the problem is unrealizable, respectively. On the other hand, GenSketching$_{Abd}$ reports the correct solutions for eq2.c, but it shows slower performance times than WhileSketching$_{CHC}$ for the first two assertions.

Consider the program sketch loop2.c in Fig. 8. The forward static analysis infers the invariant (i=0∧j=0) before the while and (i=0 ∧ i=j) at the while-head. Hence, WhileSketching$_{CHC}$ infers the solutions (i ≠ 10), (i ≤ 10), and false for the assertions (i+j==20), (i+j>20), and (i+j ≤ 15), respectively. However, for the assertion (i+j==15), we obtain that the problem is unrealizable (i.e., it has no solution). GenSketching$_{Abd}$ finds the correct solutions as well, but is slower for three assertions.

The program sketch copy.c in Fig. 9 copies the input value of the argument x into the local variable y. This is specified by the final assertion (x==y). The forward static analysis infers the invariant (x ≥ 0 ∧ y=0 ∧ x=a) before the while and (x ≥ 0 ∧ y=x−a ∧ x−a ≥ 0) at the while-head. Hence, WhileSketching$_{CHC}$ infers the solution (x ≠ y) for the missing while-guard ??. For the assertions (a==0), (a+2==x), and (y<0), it generates the while-guards: (x−y ≥ 1), (y ≠ 2), and the problem is unrealizable, respectively. On the other hand, GenSketching$_{Abd}$ fails to find solutions for three assertions.

Consider the program sketch hola.c in Fig. 10 [19]. The forward static analysis infers the invariant (x=0 ∧ y=0) before the while and (x ≥ 0 ∧ y=2⋆x) at the while-head. This way, WhileSketching$_{CHC}$ finds the solution (m ≠ x) for the assertion (y==2⋆m). For assertion (y==x) the solution is (false), whereas for assertions (y==x)∧(x>0) and (y==2⋆m+1) we obtain that the problems are unrealizable. GenSketching$_{Abd}$ fails to produce correct solutions for two assertions in this case.

Discussion: In summary, as Table I shows, the proposed technique WhileSketching$_{CHC}$ is quite effective at successfully synthesizing the missing while-guards ?? in all considered benchmarks. Note that the tasks that synthesize the solution (false) are the fastest ones for WhileSketching$_{CHC}$ achieving around 10% speed-up with respect to the other tasks for the same benchmark. Moreover, the CHC and abduction solvers take more than 95% of the total synthesis time for both WhileSketching$_{CHC}$ and GenSketching$_{Abd}$. The synthesis time of GenSketching$_{Abd}$ depends on how many times the abduction solver is called. When the Abduction solver is called once, then GenSketching$_{Abd}$ and WhileSketching$_{CHC}$ achieve comparable synthesis times, since WhileSketching$_{CHC}$ always calls the CHC solver once. However, we can see that GenSketching$_{Abd}$ cannot find solutions for five assertions, thus returning empty sets. On the one hand, this is due to the limitation of the abduction solver and the difficulty of static analyzers to infer precise inductive while-invariants in the presence of missing while-guards, but on the other hand, this is also due to the suitability of CHC solvers for handling complex control flow.

The current tool supports an interesting subset of C, so we can handle many interesting programs. The selected benchmarks are chosen to show some distinctive properties of our approach and its ability to be applied in practice.

VII. RELATED WORK

We divide our discussion of related work into three categories: program sketching; abstract static analysis; and CHC solving.

A. Program sketching

The widely-known SKETCH tool [2], [3] represents one of the earliest attempts to resolve program sketches in which missing holes can be only integer constants. It uses SAT-based counterexample-guided inductive synthesis. In particular, SKETCH iteratively generates a finite set of inputs and performs SAT queries to identify values for the holes such that the obtained complete program satisfies all assertions for the considered inputs. Additional SAT queries are then checked to establish whether the obtained program is correct on all possible inputs. SKETCH handles `while`-s by unrolling them, which makes its performance very sensitive to the degree of unrolling. Since it is based on SAT solvers, SKETCH is especially suited for handling bit-manipulating programs.

FAMILYSKETCHER [4], [20], [21] is another tool for solving the sketching problem by using lifted (family-based) static analysis based on abstract interpretation [22], [23]. The key idea underlying this approach is that the set of all possible sketch realizations can be represented as a program family (Software Product Line) with numerical features [24], [25], [26], which is subsequently statically analyzed to establish assertion validity. This way, the effort of conducting an effective search of all possible hole realizations is delegated to an efficient lifted static analyzer for program families (SPLs), which uses a specifically designed decision tree abstract domain. Since FAMILYSKETCHER is based on numerical abstract domains, it can handle unbounded `while`-s via widening and narrowing, and moreover it is very suited for handling numerical programs with integer data types.

However, SKETCH and FAMILYSKETCHER can only resolve program sketches in which unknown holes can be replaced by one constant value from a finite set of integers. $\texttt{GenSketching}_{\texttt{Abd}}$ [5] considers so-called generalized sketching problem, where each hole can be replaced by an arbitrary expression. It uses abstract static analysis for constraint generation and abduction solvers for constraint solving. Similarly to FAMILYSKETCHER, $\texttt{GenSketching}_{\texttt{Abd}}$ can handle unbounded `while`-s and numerical programs. However, this approach is not very effective in handling missing `while`-guards, and it often fails to find any solution. In this paper, we pursue this line of work by using CHC solvers rather than abduction solvers, which are more suitable for automatically handling more complex `while`-loops. The abduction solvers have also been applied in program synthesis to infer missing `if`-guards from low-level C code such that all buffer accesses are memory safe [27], to infer missing `#if`-guards from numerical program families so that a given assertion is valid in all members of the family [28], to find the weakest specifications of unknown (library) functions that ensure the safety of the program calling those external functions [29], [30], etc.

B. Abstract static analysis

Abstract interpretation [6], [14], [7], [31], [32] is a general theory for approximating the semantics of programs. It provides sound and efficient static analyses for inferring run-time properties of programs. The most popular static analyzers employ the well-known numerical abstract domains of Intervals [6], Octagons [7], and Polyhedra [14], that can be used for inferring numerical properties of program variables. Mine [32] has introduced the under-approximating backward polyhedral analysis for inferring sufficient conditions of non-deterministic programs, which has been implemented as part of the APRON library in the BANAL tool [32].

Several successful static analyzers based on abstract interpretation have been developed recently for verifying real-world programs. For example, ASTREE [33] is a static analyzer for verifying avionics software; ULITIMATE TAIPAN [34] is a software model checker that uses abstract interpretation to derive invariants for the path program corresponding to a given spurious counterexample; PAGAI [35] combines SMT-solving with abstract interpretation, etc.

Several approaches use a combination of forward and backward static analyses to infer more precise interesting properties of programs. More specifically, Rival [36] uses this combination to detect a set of traces leading to a bug; Bourdoncle [31] to generate preconditions ensuring validity of invariant and intermittent assertions; Dimovski and Legay [37] to compute the probability that a given assertion is satisfied (or violated); and Urban and Miné [8] to find ranking functions for proving termination.

C. Constraint Horn Clauses

Recently, the problem of CHC solving has gained a lot of attention due to their wide applications in program verification and program synthesis. Various algorithms and tools for CHC solving have been developed. Some of the most prominent tools are: `Eldarica` [11] that combines predicate abstraction with counterexample-guided abstraction refinement; `Spacer` [10] that uses generalized property-driven reachability analysis; `Duality` [15] that uses predicate abstraction and Craig interpolation for abstraction refinement; `FreqHorn` [16] that uses Syntax-Guided Synthesis (SyGuS) [38]. Optimal CHC solving [39], which calculates maximal and minimal solutions of a given set of CHCs, uses techniques from program termination analysis to check the optimality of a solution of CHCs. Algorithms for solving a richer formalism of existentially quantified Horn clauses have also been studied [40], [41].

CHC solving has found a number of applications in program verification and program synthesis. SEAHORN [42] and JAYHORN [43] are tools for verification of safety properties of C and Java programs by combining abstract interpretation and CHC solving. They encode Hoare logic-style verification conditions as CHCs, which are subsequently solved via CHC solvers. CHC solving has also been used for determining refinement types of higher-order functional programs [44], for analysis of business processes expressed as Petri nets [45], etc. The existential Horn clauses have been used for the weakest strategy synthesis of safety games [46].

CHC solving has also been applied for synthesizing imperative programs from input-output examples as specifications in the semantics-guided synthesis (SemGuS) framework [47], [48]. The syntax, semantics, and specifications of imperative

programs are represented as CHCs, thus effectively reducing the program synthesis problem into a proof search over CHCs. This approach is specialized on proving unrealizable problems by showing that no imperative program from a given grammar exists that satisfies the specification. The SemGuS framework is also used for synthesizing regular expressions, Boolean formulas, and SyGuS problems. There are other approaches for imperative program synthesis that are specialized for solving realizable problems. SIMPL [49] combines the enumerative search with abstract static analysis to infer programs from input-output examples, while IMPSYNTH [50] combines enumerative search, abstract static analysis, and SMT mutations [51] to infer programs from logic specifications.

VIII. Conclusion

In this work, we introduce a synthesis algorithm for automatically inferring arbitrary Boolean expressions for unknown `while`-guards in program sketches. It is implemented by interaction between abstract static analyses and CHC solving. By means of experiments, we demonstrate the effectiveness of our algorithm on a set of interesting C benchmarks that cannot be handled by other existing tools.

In the future, we plan to extend our approach by considering program sketches in which apart from `while`-guards, unknown holes can also be `if`-guards, arithmetic expressions in assignments, and ultimately arbitrary statements. We envision achieving this aim by further interplay between abstract static analyses, CHC solving, and abduction solving.

***Abstract*—We propose a meta-language-based approach enabling Large Language Models (LLMs) to reliably generate structured, machine-readable artifacts referred to as Meta-Language-defined Structures (MLDS) adapted to domain requirements, without adhering strictly to standard formats like JSON or XML. By embedding explicit schema instructions within prompts, we evaluated the method across diverse use cases, including automated Virtual Reality environment generation and automotive security modeling. Our experiments demonstrate that the meta-language approach significantly improves LLM-generated structure compliance, with an 88% validation rate across 132 test scenarios. Compared to traditional methods using LangChain and Pydantic, our MLDS method reduces setup complexity by approximately 80%, despite a marginally higher error rate. Furthermore, the MLDS artifacts produced were easily editable, enabling rapid iterative refinement. This flexibility greatly alleviates the "blank page syndrome" by providing structured initial artifacts suitable for immediate use or further human enhancement, making our approach highly practical for rapid prototyping and integration into complex industrial workflows.**

I. Introduction

INDUSTRIAL tools have become increasingly powerful and can now handle vast amounts of data. However, as their range of functions continues to grow, operating these tools often overshadows the core task of content or problem management. This situation is further exacerbated by the common "blank page syndrome," [1], a common phenomenon in complex design or modeling tasks, where the absence of any initial structure or guidance leads to hesitation, inefficiency, or even creative paralysis. In such cases, users face difficulty starting from scratch, especially when formal specifications or architectural expertise are required. This not only slows down the initial design process but may also prevent domain experts from effectively contributing to model-driven workflows. Consequently, the focus moves away from the substantive content toward the tool itself, lowering productivity and widening the gap between content and tooling

At the same time, LLMs offer new opportunities by helping domain experts generate creative impulses and mitigate the "blank page syndrome." These assisting tools have evolved rapidly—especially through the integration of AI capabilities—that they have become even more complex, making proper integration of LLMs into content creation workflows difficult. In particular, when domain-specific languages are used that deviate from common formats like JSON or XML, producing reliably machine-readable artifacts remains a significant challenge.

Our approach addresses this issue by defining a language specification (meta-language) that is adapted to the requirements of each domain, and which likewise does not rely on existing standard formats. This enables us to capture the structural differences and specific relationships of a domain. By combining LLMs with this meta-language, it becomes possible to produce customized, machine-readable artifacts without requiring domain experts to possess extensive knowledge of architectural or formal specifications.

To clarify our terminology, we define two key concepts central to this paper. A Meta-Language-defined Structure (MLDS) refers to a structured, machine-readable artifact that is generated based on natural language input, using a set of schema rules defined in a meta-language which we call Meta-Language-defined Structure Instructions (MLDSI) . The meta-language itself is a domain-specific specification that defines the structure of the expected artifact. It serves as a structural blueprint that guides the generation of MLDS artifacts and ensures that the resulting outputs conform to the expected semantics of the target domain.

Although recent approaches have explored how LLMs can be guided to generate structured outputs, they typically rely on rigid, domain-agnostic formats such as JSON or XML. These

*Both authors contributed equally to this work.

solutions offer limited semantic adaptability and often require specialized tools or substantial manual intervention. This highlights a persistent research gap: the lack of a lightweight, domain-adaptable framework for generating structured outputs from natural language in a way that is both semantically meaningful and technically accessible. Our work addresses this gap by introducing the MLDS approach, which enables domain experts to produce customized, machine-readable content with minimal setup effort and without requiring expertise in schema tooling or formal languages.

Whether this meta-language approach is viable and beneficial is examined by focusing on the following central question:

What conditions must be met for meta-languages to function as a bridging element between natural content descriptions and machine-readable structures, enabling the integration of LLMs into industrial toolchains?

This central question is addressed through the following three sub-questions:

- **R1:** Which methods can be used to incorporate meta-language definitions into a model?
- **R2:** What criteria can be considered to validate the output?
- **R3:** To what extent can reference examples be used to adapt the output to specific needs?

To ensure transparency and facilitate reproducibility, all relevant research artifacts, including evaluation results, domain-specific meta-language definitions and generated Meta-Language-defined Structures (MLDS) artifacts, have been made publicly available in our GitHub repository [2].

In the remainder of this paper, we present the technical background and motivation for our meta-language approach in Section II. An overview of related research follows in Section III, which positions our work within the broader field. Next, Section IV introduces our proposed methodology and the design of the meta-language. We then provide a comprehensive evaluation in Section V, showcasing its applicability across various domains. Section VI discusses our key findings and highlights potential limitations, while Section VII outlines promising avenues for future research. Finally, Section VIII concludes the paper with a summary of our main contributions.

II. Background and Motivation

In many technical and economic fields, there are specialized challenges that can only be successfully addressed with the help of experts. This is especially true for the development and implementation of complex software and system architectures [3]. A classic example is the collaboration between a person with architectural expertise (Architectural Domain Expert, ADE) and someone with substantive or specialized expertise (Content Domain Expert, CDE). While an architect generally possesses deep knowledge of a specific, clearly defined domain, the transfer of architectural concepts to other domains is often difficult and time-consuming. This hurdle complicates efficient collaboration and leads to practical inefficiencies when the same fundamental principle is applied in different fields.

The goal, therefore, is to allow CDEs in a given domain to create structured artifacts directly processable by machines, even without extensive knowledge of software or system architecture. These artifacts, which we refer to as MLDS, make it possible to model specialized requirements in detail. By using MLDS, ideas and requirements expressed in natural language are transformed into formal structures that adhere to certain rules and constraints. Consequently, the ADE's role shifts to a higher-level task: defining a structural specification (the "meta-language") that ensures the resulting MLDS meet the desired quality and formatting requirements.

Currently, structured outputs from natural language models, such as JSON-based responses, typically require specialized tools and significant manual intervention. Tools like Pydantic and LangChain have emerged to facilitate structured outputs by validating and enforcing schemas, thereby ensuring JSON structures are accurately generated and adhered to [4], [5]. However, effective use of these tools demands substantial technical expertise and familiarity with their underlying frameworks [6]. Moreover, these tools require ongoing adaptation to handle differences in how newer LLM architectures generate structured output, which introduces additional maintenance overhead and complexity.

Furthermore, not all LLMs inherently support structured output generation effectively. This limitation restricts their applicability to scenarios requiring strictly formatted outputs [7], [8]. For models that do support structured outputs, outputs often need post-processing and manual corrections due to subtle inconsistencies, ambiguities, or deviations from predefined structures, increasing complexity and effort [9].

To circumvent these challenges, our approach introduces MLDS Instructions—structured prompts explicitly designed to guide LLMs in generating precisely defined structured artifacts. LLMs are powerful models that can interpret and produce natural language [8]. However, a key issue arises because LLMs generally do not generate precise, user-defined structures unless these are already standard formats. This is precisely where our solution comes into play: with so-called "MLDS instructions," we provide the LLM with a meta-language characterized by a clear structure and defined relationships, without relying on existing standard formats.

The MLDS instructions inform the model about both the desired output format and the rules needed to produce it. This distinguishes our approach from classic procedures that require extensive fine-tuning of the model or force the output into a fixed format. Through the meta-language and its meta-levels, complex relationships within the MLDS can also be represented. In this way, MLDS builds a bridge between the conceptual problem statements formulated by CDE and a strictly formatted output that can be processed by machines.

Our approach is inspired by established metamodeling architectures, such as those found in the Meta-Object Facility (MOF) [10] and the Unified Modeling Language (UML) [11], and is structured into four layers:

- At the M0 level, the focus is on concrete data or instance-level elements—the real-world objects or executions that

result from applying the MLDS. This level is where the model "comes to life" and is directly processed by software systems.

- The M1 level, known as the model level, is where the MLDS artifacts reside. These artifacts are formal representations that capture the concrete, structured requirements of a domain, serving as blueprints derived from the natural language input provided by domain experts.
- The M2 level, or metamodel level, contains the meta-language. This layer defines the rules, constraints, and abstract syntax and semantics required for constructing valid MLDS artifacts. The MLDS instructions used to guide the LLM in generating structured outputs are derived from this meta-language.
- At the highest M3 level, the meta-meta model is defined. This layer establishes the fundamental constructs and abstractions upon which the meta-language is built. Although users do not normally interact directly with this level, it is necessary to ensure that the meta-language (M2) is consistent, which in turn ensures that the rules governing the MLDS (M1) are sound.

By organizing our approach into these four interconnected layers, M0 for instances, M1 for MLDS artifacts, M2 for the meta-language, and M3 for the meta-meta model, we create a structured, hierarchical approach that ensures domain-specific requirements are transformed consistently into machine-processable formats. While content domain experts focus on formulating concrete requirements at the M1 level, the meta-language at the M2 level ensures that these requirements are implemented within a consistent, formal scope. The M3 layer supports the whole system by providing a basis for the meta-language.

In this paper, we will illustrate the functionality of our MLDS instructions and the resulting MLDS outputs using two application scenarios: (1) Automotive Software Security and (2) Virtual Reality in business applications. By "Automotive Software Security," we mean the specific security and reliability requirements in vehicle software engineering, while "Virtual Reality in business applications" refers to immersive and interactive digital learning and work environments used within companies. These examples highlight how varied the domains can be in which experts (CDE)—for instance, from the security or VR fields—wish to express their specialized requirements in MLDS, without being trained as architects in the sense of software system architecture.

An illustrative use case demonstrates this: a VR specialist wants to model a virtual learning space for internal corporate training. Although this expert (CDE) has a clear understanding of the requirements for the learning space, they lack the experience to describe it in a precise architectural form. The existing tool for creating VR environments requires a clearly defined structure in the form of MLDS. Until now, it was the architect's job to convert these specialized requirements into the corresponding formal structure. With our approach, a natural language description of the desired learning space and the MLDS instructions satisfy for an LLM to generate the appropriate MLDS. Thanks to the MLDS instructions, the LLM knows exactly how the resulting artifact should be structured. As a result, the CDE's specialized requirements are transformed into a formally processable data format, without the need for the CDE to possess deeper knowledge of software architecture or formal languages.

III. Related Work

In our approach, we propose a meta-language framework that allows the creation of formally defined structures from purely natural-language descriptions *without* relying on standard formats like JSON or UML, nor requiring extensive fine-tuning.

A variety of prior studies already employ LLMs for structured output generation, yet they pursue either *more specialized* or *fundamentally different* techniques. For instance, Wang et al. [12] demonstrate a *grammar prompting* procedure, where LLMs are constrained by a Backus–Naur Form (BNF) grammar to produce strictly formal outputs. While this approach works very well for specific languages that fit into a context-free grammar, it often requires explicit modifications to the decoding process (such as restricting token choices) or relies on well-defined, existing grammar rules. By contrast, our focus is on designing a *flexible meta-language* that need not be encoded in BNF.

A related but narrower method is illustrated by Scholak et al. [13] with their *PICARD* approach, where an autoregressive model is incrementally validated against the desired language (e. g., SQL). Similar to grammar prompting, token decoding is continuously constrained during generation. However, in contrast to our meta-language paradigm, PICARD involves *invasive modifications* to the decoding algorithm. We rely instead on clearly defined meta-language instructions and LLM prompt processing, yielding more latitude for *language structures*.

Further research in retrieval augmentation or fine-tuning comes from Bassamzadeh and Methani [14], comparing whether structured code is best produced via specialized fine-tuning or optimized prompting techniques. While these findings are valuable for reducing errors and hallucinations, they typically assume a *known* format (e. g. JSON/YAML). In our method, no specialized model training is needed; we *generate* all target structures solely via prompt-based instructions and meta-language rules.

In the context of model-driven software development, Netz et al. [15] show how UML-like class diagrams (CD4A) can be generated by GPT-3.5/GPT-4 and transformed directly into complete web applications. However, they rely on *UML notations* and existing generator frameworks (e. g. MontiGem). This differs from our approach, which does *not* require any model-driven development toolchain or standardized notation. Instead, we allow arbitrary domain-specific structures—for instance, automotive security or VR scenarios—specified with a freely definable meta-language.

Key Contribution of Our Approach: While the mentioned studies employ various forms of grammar-based decoding,

fine-tuning, or predefined formats, our method provides a universal meta-language definition. Thus, architects or tool developers can prescribe any target structure (from security modeling to 3D scenes) at the meta-level so that an LLM subsequently outputs *machine-readable* artifacts in exactly that format–without training, without invasive decoder modifications, and without restricting to JSON/UML. Because our approach does not fix a specific output format, it supports both machine-driven and human refinements of the same structure, fostering an iterative co-creation process. Domain experts bring in new scenario descriptions, the LLM generates or extends the MLDS, and humans can then fine-tune or correct the result in the meta-language immediately. This openness, combined with a clear metamodel architecture, constitutes the central distinguishing feature of our work.

IV. Methodology

In this Section, we explain our proposed approach (Section II) in detail, showing how we use our custom meta-language together with the MLDS framework to solve the problem. We begin by outlining how the meta-language is derived from the tool's requirements, providing a starting point for the process. Next, we describe how to structure the descriptions of tasks and scenarios, setting up a foundation for generating the MLDS using LLMs. The complete procedure is shown in Figure 1.

To keep the process transparent, we provide examples that demonstrate how prompts are combined with the meta-language. A notable feature of our approach is that it allows users to influence different parts of the MLDS in various ways, making the method adaptable. After fully explaining the MLDS, we show how it can be directly imported into tools, and we conclude by demonstrating how this method addresses the blank page syndrome.

A. Conception of the Meta-Language

The core of our approach lies in developing a meta-language that incorporates the specific requirements of a domain or tool and organizes them into a structured form that is not bound to common standards. In contrast to JSON or XML, the meta-language may deliberately allow specialized object types, relationships, and value ranges that thoroughly reflect the peculiarities of a domain. The meta-language thus pursues two primary objectives: on the one hand, it provides the LLM with explicit guidelines on which structures, attributes, and relationships should appear in the generated MLDS. On the other hand, it is designed to be easily understandable and extendable by human domain experts, allowing them to add new elements or rules when necessary.

1) Reasons for a Meta-Language: One of the main challenges in automatically generating structured output is that LLMs initially lack any knowledge of custom formats. Although models can be adapted to standard formats, they often reach their limits when specialized domains require formats that differ from these standards or go beyond their semantics. Many advanced tools employ proprietary definitions that cannot readily be mapped onto common standards. Our meta-language addresses this gap by:

- Allowing freely definable object and relationship types to represent specific domain concepts.
- Defining clearly delimited value ranges (e.g., discrete selection options, predefined numerical ranges, or boolean variables) for each attribute, so that the LLM is not forced to "improvise" unnecessarily but instead chooses from a set of valid options.
- Providing structural guidelines that define the "skeleton" of an MLDS, ensuring that the generated output follows a meaningful and machine-readable architecture.

In this way, it is not necessary to extensively fine-tune the LLM. Instead, we present the model with precise rules via the meta-language and corresponding prompt instructions, which it follows when generating the MLDS.

2) Analysis of the Required Input: Before implementing the meta-language, it is necessary to determine which information a particular tool or domain actually needs. A standard example is a VR development tool that manages various object types (e.g., *rooms*, *avatars*, or *interactions*), each with specific properties (size, access rights, animation logic, etc.). These aspects are collected, categorized, and eventually transferred into the meta-language. On this basis, one can also estimate the relationships between objects—an *avatar*, for instance, may be assigned to a *room*, and an *interaction* may be tied to an *object*.

3) Extracting Relevant Objects and Properties: Once the domain analysis is complete, relevant objects are defined. An *object* corresponds to a central concept in the domain (e.g., learning environment, avatar, security component). A *learning environment*, for example, might have properties such as *name*, *maximum number of users*, or *room configuration*. Each property is assigned a corresponding value range (e.g., a fixed set of room types, numerical ranges for the number of users) to ensure consistency and comprehensibility.

4) Defining Relations: Another key to understanding and modeling complex relationships is specifying the links between objects. For instance, a *human actor* object at a certain *resilience level* could refer to an *attack* object, or multiple *vehicle features* could form a single item. These relationships may be configured hierarchically within the meta-language or refer to the same level, each implying different semantic connections. Such a relational network dictates the subsequent structure of the MLDS, guiding the LLM in how individual elements should interrelate.

5) Domain-Specific Meta-Language Instructions: In the following, we present three excerpts from a possible domain-specific meta-language design, illustrating its key concepts. Although the example involves a 3D scene for VR applications, the same underlying mechanisms can be applied to virtually any domain.

a) Defining the Scene Structure: The first step is to establish a top-level object that acts as a global container for all subsequent elements (Listing 1). In the VR domain, we call

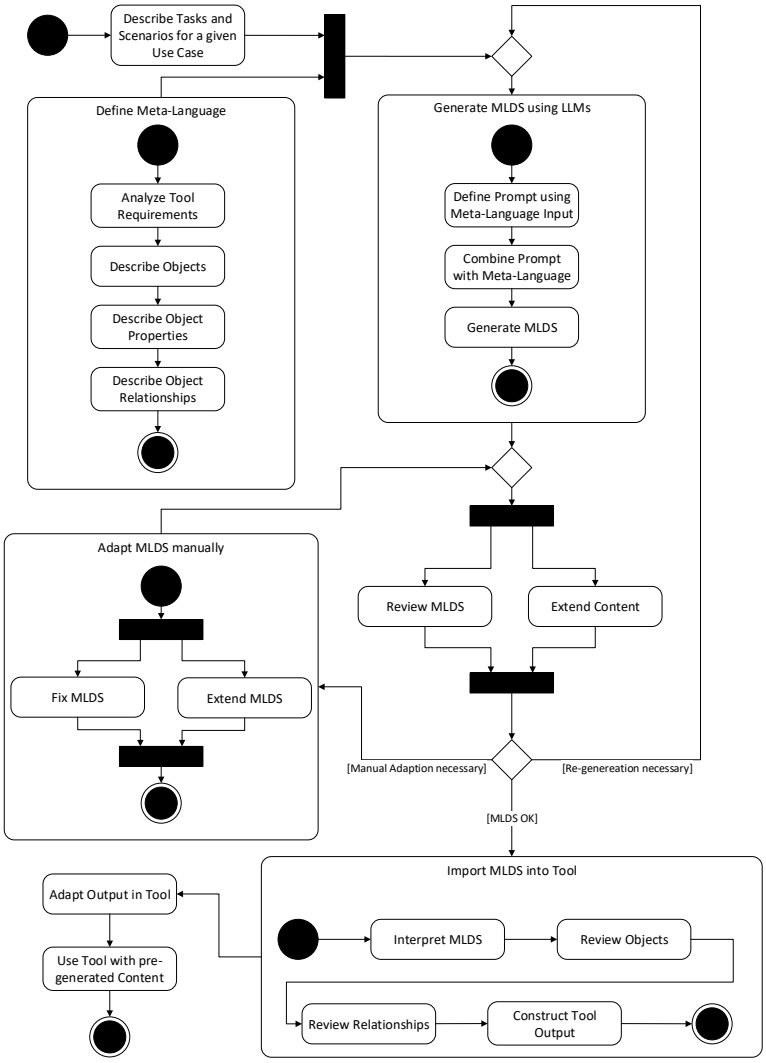

Fig. 1. Workflow for generating and refining MLDS from natural language input, combining meta-language specification, LLM-based structure generation, and iterative human-AI co-editing for tool integration.

this object `scene`, which holds basic environmental details and a list of objects.

```
{
  "scene":
  {
    "sceneName": "VR Training Room",
    "environment":
    {
      "type": "indoor",
      "dimensions": { "width": 10.0, "
          height": 3.0, "depth": 15.0 }
    },
    "objects":
    [
      /* Objects go here */
    ]
  }
}
```

Listing 1. Definition of the Scene Structure

In other domains, what is here called `"scene"` could be labeled `"system"` or `"project"` and might include completely different properties (e.g., `systemCategory` or `budget`). Nevertheless, the principle remains the same: a clearly defined parent object provides the framework in which all detailed elements and their attributes are nested.

b) Modeling Objects and Their Relationships: Each object has a unique `objectId` and is characterized by properties (e.g., `objectType`, `position`, `rotation`) as well as optional relational information. Listing 2 shows how to place an object (a table) relative to another object using `relativePositioning`.

```
{
  "objectId": "object_01",
  "objectType": "table",
  "position": { "x": 2, "y": 0, "z": 3 },
  "rotation": { "x": 0, "y": 45, "z": 0
      },
  "dimensions": { "width": 1.5, "height":
       0.75, "depth": 1.0 },
  "relativePositioning":
  {
    "referenceObject": "object_02",
    "relation": "next_to"
  },
  "offset": { "x": 0.2, "y": 0, "z": 0 }
}
```

Listing 2. Objects with Relative Positioning

In other domains, objects may have entirely different properties (for instance, `memoryLimit` or `location` in a cloud application). Similarly, a relationship like `next_to` could be replaced by something like `depends_on` if you want to describe software dependencies. By specifying such structures in a meta-language, you ensure that the LLM knows exactly which attributes exist and which values are permissible.

c) Hierarchical Nesting of Objects: To describe more complex scenarios, objects can themselves have *children* (Listing 3). This enables a hierarchical organization with subordinate elements.

```
{
  "objectId": "object_02",
  "objectType": "shelf",
  "relativePositioning":
  {
    "referenceObject": "object_03",
    "relation": "on_top_of"
  },
  "children":
  [
    {
      "objectId": "object_02_child_01",
      "objectType": "box",
      "relativePositioning": {
        "referenceObject": "object_02",
        "relation": "next_to"
      },
      "offset": { "x": 0.1, "y": 0, "z": 0
          }
    }
  ]
}
```

Listing 3. Object Hierarchies Using Children

This type of `children` property could represent, for example, submodules within a larger module in a software architecture or smaller processes within a bigger industrial workflow. Likewise, a relationship such as `"on_top_of"` is just an example of a hierarchical link; in other contexts, it might be `"contained_in"` or `"extends"`.

B. Generation of the MLDS

Once the meta-language is established, natural language descriptions or scenarios adapted to a specific use case can be created. As illustrated in Figure 1, the meta-language is developed as a separate module that, once finalized, can be reused for all subsequent generations.

In the most compact workflow, we concatenate the meta-language and the scenario into one composite prompt and pass it to a pretrained LLM via its API. Because the model already possesses broad world knowledge, it needs no task-specific fine-tuning; instead, the embedded meta-language rules channel the model towards a syntactically correct MLDS while the scenario text supplies the domain content. A prompt segment might therefore read:

```
<<META LANGUAGE>>
object room { width:float height:float
    depth:float ... }
...
<<SCENARIO>>
Create a training classroom with 20
    student desks, one teacher desk,
and a projector mounted to the ceiling.
```

Listing 4. Excerpt of a single-shot prompt that merges meta-language and scenario

For projects that demand stricter traceability or staged quality control, we separate the process into two calls. The first call feeds nothing but the meta-language to the LLM and receives back a condensed, token-optimised representation, the second call injects the scenario plus the condensed rules. This split makes it easy to inspect intermediate artifacts, attach unit tests to the generated schema, or swap in a different scenario without retransmitting an unchanged meta-language, an advantage when prompt length becomes a bottleneck.

Regardless of the single- or multi-step variant, the raw MLDS is fed through an automatic validator that flags missing attributes, illegal value ranges or broken references. Only after the MLDS passes this gatekeeper is it handed to the target tool, guaranteeing that the downstream pipeline never receives malformed input.

C. Adaption of the MLDS

In practice, generating the initial MLDS is only the first step in its full utilization. Because the MLDS can be produced in a format that is easily readable by humans, domain experts can readily validate its contents without a steep learning curve. Once generated, the MLDS may be scrutinized for correctness, and any missing information can be added. As illustrated in Figure 1, these iterative improvements can be carried out by the LLM itself, which can respond to feedback or correction prompts. At the same time, domain experts remain free to make manual adjustments, ensuring a high degree of precision where AI suggestions may not capture every nuance. This dual approach of automated and manual editing fosters a co-creative process, merging AI-driven speed and consistency with human expertise. Moreover, the MLDS's structured nature facilitates intuitive graphical interfaces, allowing content specialists to modify or enrich the MLDS without delving into the underlying code. By accommodating both fully automated and personalized interventions, the workflow remains flexible, transparent, and accessible to all involved stakeholders.

D. Integration into the Tool Environment

Once the finalized version of the MLDS is ready, it can be loaded directly into the target tool. The tool interprets the generated structure and creates the required output, representing all defined objects and their relationships according to the MLDS specifications. Additional modifications and enhancements can then be carried out directly within the tool, giving users the flexibility to refine or extend the setup as needed. This ensures that the produced content is fully leveraged, while minimizing both development effort and potential errors.

V. Evaluation

A. Objective and Approach

To demonstrate the developed Meta-Language approach, we selected two distinct domains: (1) the automated generation of Virtual Reality (VR) worlds and (2) the Security Modeling of embedded systems in the automotive context. The aim is to show that from a defined meta-language, a domain-specific MLDS can be generated that consistently follows the given specification. Furthermore, we highlight how this method mitigates the so-called "blank page syndrome," where a completely unstructured starting point often leads to high efforts in initial model or environment creation. By providing a machine-readable foundation, users can directly refine and adapt the generated MLDS artifacts.

B. Use Case: Automated VR World Generation

The first domain focuses on automatically generating VR worlds in Unity. A structured description is created to form a basic layout of the virtual environment. Designers provide a natural-language prompt (for instance: "Generate a classroom for 20 students"), which is then transformed into a JSON-based MLDS using our meta-language. Unity processes the resulting MLDS to position objects and define relationships in the 3D scene. Initially, placeholders (e.g., cubes) are placed to help visualize object arrangements. Designers can later replace these placeholders with final assets, ensuring a quick start for prototyping. This effectively reduces the blank page syndrome since each new scene already has a predefined structure.

Over 200 test scenarios (see Section IX) were conducted, demonstrating that LLMs are able to generate coherent object hierarchies and spatial relationships. For example, Listing 5 shows a parent-child relationship where a desk acts as the parent object, and a chair is placed relative to the desk. Positioning attributes and relational references (e.g., `in_front_of_positive_z`) are used to automate the placement in the 3D environment.

```
{
  "objectId": "studentDesk_r0_c0",
  "objectType": "student_desk",
  "assetName": "student_desk_asset",
  "position": {"x": -6, "y": 0.5, "z":
      8},
  "dimensions": {"width": 2, "height": 1
      ,"depth": 2},
  "group": "furniture",
  "children":
  [
    {
      "objectId": "studentChair_r0_c0",
      "objectType": "chair",
      "assetName": "student_chair_asset",
      "relativePositioning": {
        "referenceObject": "
            studentDesk_r0_c0",
        "relation": "in_front_of_positive_z
            ",
        "distance": 1
      },
      "dimensions": {"width": 0.5, "height
          ": 0.5, "depth": 0.75},
      "group": "furniture"
    }
  ]
}
```

Listing 5. VR Parent-Child Relation

By incorporating such parent-child relations, users benefit from an iterative co-creation process: the generated foundation can be refined either through extended prompts (in natural language) or direct modifications of the MLDS output.

C. Use Case: Security Modeling in Automotive

The second use case addresses Security Modeling for embedded systems in the automotive context. Building upon the metamodel proposed in [16], we define a meta-language for an MLDS that helps create a foundational security model. Security experts or systems engineers can outline potential threats or vulnerabilities in natural language (e.g., "unsecured wireless communication" or "man-in-the-middle attack"). An LLM then translates these descriptions into the MLDS, which is directly processable by a security modeling tool. Such a tool subsequently calculates risk levels or highlights vulnerabilities. Manual adjustments remain possible at any stage, ensuring a flexible co-creation process.

Listing 6 illustrates a JSON-based MLDS snippet with typical attributes for attack characterization, such as `AttackComplexity` and `UserInteraction`. By assigning initial values to these fields, the LLM provides a starting point for further risk assessments.

```
{
  "Name": "Man-in-the-middle:
      intercepting and manipulating
      wireless traffic",
  "AccessRequired": "Network",
  "AttackComplexity": "(H)igh",
  "PrivilegesRequired": "(N)one",
  "Urgency": "(L)ow",
  "UserInteraction": "(N)one",
  "AvailabilityImpact": "(L)ow",
  "ConfidentialityImpact": "(H)igh",
  "IntegrityImpact": "(L)ow",
  "SafetyRelevance": "(H)igh",
  "vulnerabilities":
  [
    {
      "Name": "Unsecured Wireless
          Communication Protocol"
```

```
16        }
17    ]
18 }
```

Listing 6. Automotive Security Attack Representation

Since risk or vulnerability scores are computed within the modeling tool itself, attributes assigned by the LLM can be refined later. This aligns with the cooperative design principle, where the model's first version is automatically generated and then iteratively improved.

D. Results and Insights

In both domains, we combined the language specification with natural-language prompts across several LLMs (including GPT 4o mini, GPT o3 mini, DeepSeek-R1, and DeepSeek-R1 14B running locally). Most generated MLDS files were syntactically correct and machine-readable. Occasional issues arose mainly from incomplete API responses or minor inaccuracies in the meta-language. Notably, even complex problem descriptions in natural language led to well-structured and valid MLDS artifacts. Key findings are:

- **High Machine-Readability:** The LLM outputs conform closely to the defined meta-language, minimizing parsing errors.
- **Blank Page Syndrome Mitigation:** In both VR world creation and security modeling, users start with a usable blueprint rather than a completely empty project.
- **Ease of Extension:** Generated models or VR scenes can be expanded using extended prompts or direct modifications.
- **Domain-Agnostic Feasibility:** The approach works effectively in multiple domains, provided a domain-specific meta-language is well-defined—for example, structuring content in education, automating routines in smart environments, modeling workflows in business, formalizing scenarios in healthcare, or generating logic in games and legal contexts.

We further evaluated our approach by systematically analyzing 132 generated MLDS files to quantify adherence to the prescribed meta-language schema. This analysis was automated through a custom Python-based parser validating each file against the defined schema.

E. Evaluation Setup

The evaluation dataset consisted of files categorized into two complexity levels: *easy* (n=72) and *medium* (n=60), selected from the VR dataset based on the required content complexity. The dataset aimed to enable an end-to-end pipeline for generating virtual environments. Furthermore, each complexity level had two variations: one employing semantic validators (*withValidator*) and one without validators (*withoutValidator*). These validators were applied downstream of the MLDS translation process and specifically assessed semantic correctness, such as checking for overlapping objects, rather than syntactic accuracy. As our analysis indicated no significant differences in syntactic correctness between these variations, we decided to merge them into a single unified dataset for evaluation purposes. Each file was evaluated based on structural validity, completeness of schema components, and the presence of specific parsing errors.

We defined the metrics as follows:

$$V = \sum \text{valid files}, \quad I = N - V \tag{1}$$

$$\text{Validity Rate } (\%) = \frac{V}{N} \times 100 \tag{2}$$

$$\text{Presence Rate } (\%) = \frac{\text{Files containing schema part}}{N} \times 100 \tag{3}$$

where N is the total number of evaluated files, V is the number of valid (correctly structured) files, and I is the number of invalid (incorrect) files.

F. Quantitative Results

Out of $N = 132$ files, $V = 116$ (87.9%) were valid, while $I = 16$ (12.1%) contained parsing errors (Fig. 2). Errors primarily arose from JSON parsing issues due to incorrect string formatting.

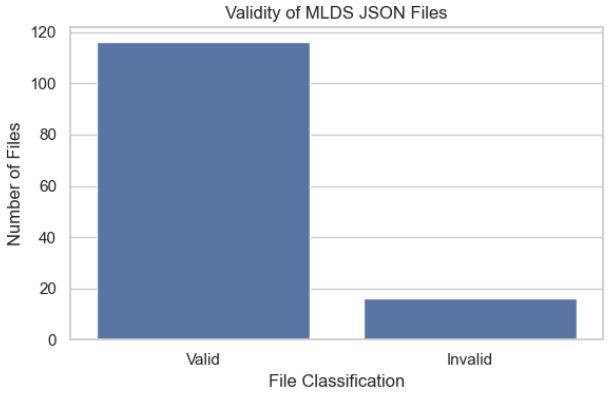

Fig. 2. Distribution of valid vs. invalid MLDS JSON files.

Out of the 16 invalid files, 15 exhibited a parsing error indicated by the message 'str' object has no attribute 'get'. This error occurred because the JSON parser expected a structured object but encountered a string instead. Only one file showed a different issue, specifically missing essential schema components: *environment* and *sceneName*.

Table I summarizes the presence rates of schema parts. Most elements showed high presence rates, indicating strong schema adherence, except for optional fields like `env.background`, which appeared less frequently (72.7%).

TABLE I
SCHEMA PART PRESENCE SUMMARY

Schema Part	Presence	Missing files
sceneName	87.9%	16
environment	87.9%	16
env.type	87.9%	16
env.dimensions	87.9%	16
env.lighting	85.6%	19
env.background	72.7%	36
objectGroups	87.9%	16
objects	88.6%	15
obj.objectId	87.9%	16
obj.objectType	87.1%	17
obj.position	87.9%	16
obj.rotation	87.1%	17
obj.dimensions	87.1%	17

Since we did not explicitly request the inclusion of background components and instead relied on the LLM's initiative to incorporate them as part of the MLDS, the observed number of omissions was anticipated. This could be improved by explicitly addressing background components within the input prompt, thus providing clearer guidance to the LLM.

Figure 3 visually presents these results and highlights areas for possible improvements.

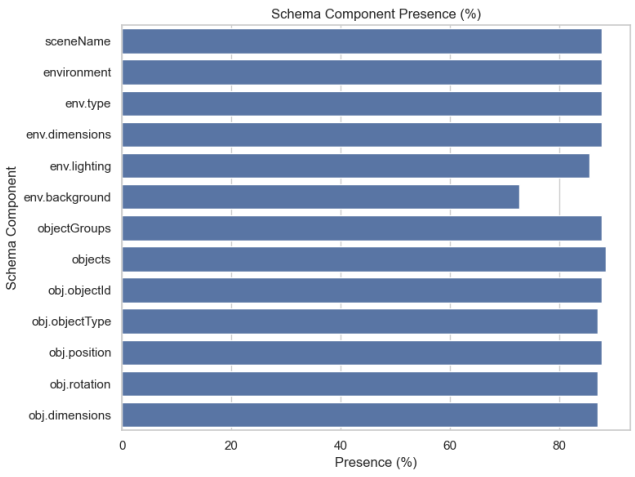

Fig. 3. Presence rates of schema parts in MLDS files.

Figures 4 and 5 highlight the complexity of generated files. Most scenarios had a moderate number of objects, suitable for realistic industrial applications, while nesting depth indicated well-structured JSON.

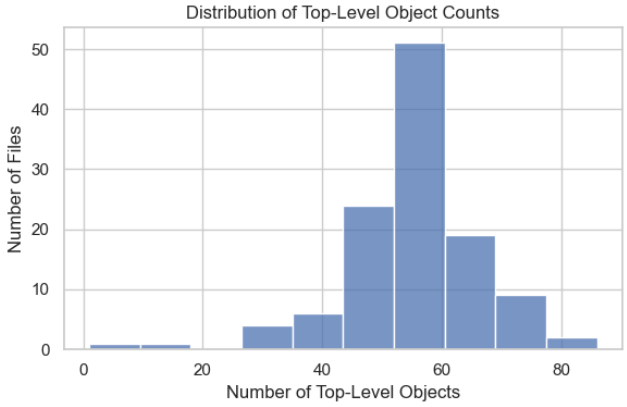

Fig. 4. Distribution of object counts per MLDS file.

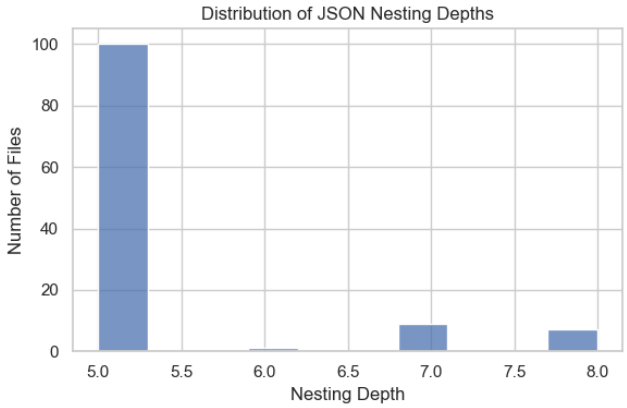

Fig. 5. Distribution of nesting depths in MLDS files.

The nesting depth was computed with the following Python function:

```
def compute_depth(obj, depth=0):
    if isinstance(obj, dict):
        return max([compute_depth(v, depth
            +1) for v in obj.values()] or [
            depth])
    if isinstance(obj, list):
        return max([compute_depth(i, depth
            +1) for i in obj] or [depth])
    return depth
```

Listing 7. Computing JSON nesting depth

G. Comparison with Traditional Approaches

We compared our MLDS approach directly against a traditional structured-output pipeline using LangChain and Pydantic [5], [4]. The implementation of the traditional approach took approximately five times longer than preparing our MLDS instructions, primarily due to the complexity and steep learning curve associated with LangChain and Pydantic. While the traditional approach consistently produced compilable results when successfully executed, approximately 7%

of pipeline runs failed entirely due to validation errors or incomplete responses. In contrast, our MLDS-based approach resulted in a slightly higher error rate (around 6% more errors), but significantly reduced the overall complexity, effort, and required expertise. Therefore, especially for rapid prototyping, iterative adjustments, or when specific expertise in Pydantic and LangChain is not readily available, our MLDS approach offers a clear practical advantage.

H. Implications

Explicitly embedding meta-language schema instructions within prompts enhances structural compliance and machine readability. This efficiency allows rapid prototyping and seamless integration into diverse industrial workflows, underscoring the practical effectiveness of our approach.

VI. Discussion

In this Section, we revisit the insights gained from our evaluation in light of the research questions posed in Section I. We then compare our approach to existing work (see Section III) and critically examine potential limitations as well as threats to validity.

A. Interpretation of Evaluation Results

1) Research Question R1: Methods for Incorporating Meta-Language Definitions into Models: Our experiments in the domains of Virtual Reality (VR) world generation and Automotive Security indicate that a well-specified meta-language can effectively convey structural and relational constraints to LLMs. The results suggest that this method scales to both creative (VR design) and safety-critical (automotive security) fields. We observed that generating complex MLDS artifacts worked particularly well when the meta-language was sufficiently fine-grained and included specific object definitions and enumerated attribute values (e.g., *relativePositioning*). This confirms that incorporating meta-language definitions does not require adherence to standardized formats, so long as the underlying structure is clear and domain-relevant.

2) Research Question R2: Criteria for Validating the Generated Output: Our evaluation revealed that, on one hand, formal aspects such as syntax and mandatory attributes can be automatically validated. On the other hand, certain domain-specific or semantic aspects (e.g., the correctness of spatial relationships in VR scenarios or the accuracy of security attributes in automotive models) often benefit from human review. Thus, a purely syntactic validation is a valuable first step but does not eliminate the need for *semantic* validation. A cooperative feedback loop—where experts refine machine-generated MLDS artifacts and tools provide automated format checks—leverages the strengths of both human expertise and automated structure enforcement.

3) Research Question R3: Adapting Output via Reference Examples: Including examples (e.g., prototype *scene* definitions for VR environments or sample *attack* entities in security modeling) improved both the consistency and format of the generated outputs. The LLM relies on these "exemplary" structures to align with domain-specific expectations. Notably, references can demonstrate not only value ranges but also relational patterns (*children* objects, hierarchy levels, dependencies). Moreover, the use of *templates* allows for targeted adjustments of the desired model detail, for instance by distinguishing between *minimal* or *extended* output variants.

B. Comparison with Related Work

Meta-languages for architecture and modeling are well-established in research, typically appearing in the form of DSMLs (Domain-Specific Modeling Languages) or UML profiles. Our approach extends these ideas by leveraging LLMs: instead of conforming strictly to standardized outputs (e.g., UML diagrams or XML), we demonstrate that "custom" meta-languages can be reliably processed by LLMs, provided the rules are clearly specified. This addresses a gap often left by other methods: reliable *and* flexible structured modeling without extensive fine-tuning of the model or proprietary export layers.

C. Implications and Practical Benefits

Our findings suggest that the proposed MLDS approach offers a flexible means of translating domain-centric (natural-language) descriptions into formally processable artifacts, even for users lacking deep architecture knowledge. In both domains, the technique reduced the "blank page syndrome," as users begin with a ready-to-use framework rather than an empty project. At the same time, the generated MLDS remains open to subsequent modifications, either by further prompting or by direct model editing.

Looking ahead, this could reshape workflows in software architecture and engineering. Architects may focus on designing and maintaining the meta-language, while domain experts continue to think in natural-language scenarios. This division of responsibilities can foster more productive, model-based processes and raise the adoption of structured modeling methods.

D. Limitations and Threats to Validity

While our results are encouraging, some constraints remain:

- **Domain-Specific Complexity:** As domains grow more detailed, the meta-language itself can become large and complex. An insufficiently granular metamodel may produce vague or incomplete MLDS artifacts.
- **Dependence on Prompt Quality:** The clarity of the natural-language input significantly affects the generated output. Ambiguous or insufficiently detailed prompts may result in incomplete models.
- **Technical Limitations of LLMs:** Issues such as model confusion or output truncation can arise with especially lengthy or nested structures. While example MLDS patterns help mitigate these risks, LLMs are not foolproof.
- **Generalizability:** Although we explored two notably different domains (VR and automotive security), other domains could impose even more specialized requirements that warrant extended validation.

VII. Future Directions

The integration of LLMs and meta-languages opens up several research areas. One is the development of automated *quality checks* that address both syntactic and semantic coherence (e.g., inconsistencies in hierarchical relationships). Another is exploring multi-prompting strategies or incremental fine-tuning to further improve MLDS consistency. There is also potential value in establishing a cross-domain *vocabulary* for reusable structural elements (e.g., `children`, `parent`, `referenceObject`).

Lastly, a more collaborative platform could be developed, where architects design new meta-languages while domain experts contribute reference MLDS examples. Such a shared knowledge base could be continuously updated and utilized by LLMs, enabling more efficient and accurate generation of structured domain artifacts.

VIII. Conclusion

We presented a domain-adaptable method for generating machine-readable, structured outputs from natural language prompts using Large Language Models. Our approach combines a custom-defined meta-language with schema-aware prompting to enable the creation of Meta-Language-defined Structures (MLDS). Evaluation results across two distinct use cases demonstrated a high validation rate (88%) and a substantial reduction in setup complexity (approx. 80% compared to LangChain and Pydantic). The resulting artifacts were interpretable and easy to refine, supporting rapid iterations in industrial workflows.

This approach is particularly valuable in domains where structured modeling is required but formal schema design presents a bottleneck. In addition to the use cases analyzed in this paper, we have successfully applied MLDS-based methods in a parallel study on immersive learning environments in Virtual Reality. There, natural language descriptions were used to generate didactically structured 3D scenes, allowing instructors to prototype entire VR labs without 3D design expertise, significantly reducing creation time while maintaining structural consistency.

These examples illustrate the broader potential for MLDS-based modeling in industries such as digital twin development, technical education, process automation, and safety-critical system design. Here, our method enables faster prototyping, reduces reliance on technical tooling, and facilitates interdisciplinary collaboration between domain experts and system architects.

Future work may explore the integration of MLDS with execution engines, real-time simulation tools, or graphical editors, as well as an expansion of the approach to additional modeling paradigms.

To reproduce our findings, please consult the readme file in our repository as referenced in Section IX.

IX. Data Availability

We have made all relevant research artifacts publicly available in the interest of fostering open science. Our repository contains two domain-specific meta-languages as well as additional MLDS artifacts generated with the help of these meta-languages. All materials can be accessed at the following GitHub repository: https://github.com/CoNaLaDe-MLDS/Artifacts.

Statement Concerning Generative AIs

We would like to clarify that this paper does not include substantial Sections of text directly produced by Generative AI, including LLMs.

However, since the primary objective of our work is to explore effective integration and utilization of LLMs in structured data generation and domain-specific modeling, we have naturally employed GenAI-generated outputs as part of our technical approach. In particular, LLMs were utilized to automatically generate structured MLDS files, code snippets, and example artifacts crucial to our experiments. Additionally, in selected cases, GenAI models assisted in translating specific text segments from German into English to enhance readability and accuracy.

We have clearly indicated within the paper all instances where GenAI-generated content was integrated, and provided an explicit analysis of its impact, including both benefits and limitations.

***Abstract*—Accurately predicting whether consent for organ donation will be granted is essential for optimizing timing and resource use in donor management. This study develops and evaluates machine learning models to estimate the likelihood of obtaining consent based on donor and contextual factors. The goal is to support early clinical decision-making by identifying cases where consent is more or less likely. Using real-world data from a regional transplant center operating under an opt-in system, we conduct data preprocessing, feature selection, and model training with various algorithms. Model performance is assessed using standard classification metrics, and key predictors of consent outcomes are identified. Results show accuracy levels exceeding 80%, highlighting the importance of including information about the relatives responsible for the decision. We also find that prediction accuracy varies with donor nationality, being higher for non-Italian donors. These findings demonstrate the value of predictive analytics in improving organ procurement efficiency and reducing unnecessary costs.**

***Index Terms*—Health care, Modeling and prediction, Machine learning, Decision support**

I. Introduction

ORGAN transplantation remains the most effective and economically viable treatment for patients with end-stage organ failure. However, despite ongoing efforts to raise awareness and increase donor registrations, a persistent and critical gap remains between the demand for and supply of transplantable organs [1], [2]. Among the key barriers contributing to this shortage is the high rate of opposition to organ donation, particularly when consent must be obtained post-mortem from next-of-kin.

This work has been partially funded by the European Union–Next Generation EU within the framework of PRIN 2022 Project "MEDICINE+AI, Law and Ethics for an Augmented and Human-Centered Medicine" (2022YB89EH) – CUP E53D23007020006

The acquisition of consent is a pivotal step in the organ donation process. In systems where explicit authorization is required—such as the *opt-in* framework in place in many regions—the inability to secure timely consent can lead to lost donation opportunities, unnecessary delays, and avoidable costs. Even in jurisdictions with *opt-out* legislation, in practice, healthcare professionals often still seek family confirmation, making the consent process a practical and ethical bottleneck.

In this paper, we propose a data-driven approach to support and optimize the consent acquisition phase through predictive modeling. Specifically, we develop and evaluate machine learning models aimed at forecasting the likelihood of obtaining consent for organ donation. By leveraging available demographic, clinical, and contextual data, our models seek to provide early estimates of consent probability, offering valuable decision support for clinicians involved in donor management.

As it is better discussed in Section III-B, this predictive capability has the potential to significantly enhance operational efficiency. For example, if a high probability of consent is anticipated, preparatory clinical activities can be initiated earlier, minimizing the time to transplantation and reducing organ deterioration risks. Conversely, in cases where consent is unlikely, healthcare teams may choose to delay or forego certain cost-intensive procedures, thus conserving resources.

Our study contributes to the field of healthcare information systems by introducing a predictive tool for estimating the likelihood of consent or opposition in organ donation. The practical relevance of such predictions lies in their integration into transplant logistics, where they can support informed decision-making and improve both clinical efficiency and cost-effectiveness.

The main contributions of the paper are as follows.

- We develop predictive models based on established machine learning algorithms to estimate the likelihood of family consent (or opposition) to organ donation, with a focus on the Italian opt-in system.
- We present a context-specific analysis using real-world data from the Lazio region, contributing the first known predictive study on consent acquisition in Europe.
- We compare various machine learning algorithms and identify the most effective approaches for consent prediction under data scarcity conditions.
- We highlight differences in predictive performance across different nationality groups.

The remainder of the paper is organized as follows. In Section II, we review the relevant literature. In Section III, we describe the donor management process, with a particular focus on the critical role of consent acquisition. The input data used in this study, along with the preprocessing and transformation procedures (including feature deletion, grouping, and refinement), are presented in Section IV. In Section V, we outline the predictive modeling methodology, detailing the algorithms, performance metrics, and selected features. The results of the predictive analysis are reported and discussed in Section VI. Finally, conclusions and future research directions are presented in Section VII.

II. Related literature

Organ donation consent is a critical component of the transplantation process, with direct implications for timing, cost, and overall success rates. As highlighted in the introduction, delays in consent acquisition can lead to suboptimal organ preservation and increased process costs [3]–[6]. In this section, we review the literature across three main areas: (i) barriers and refusal patterns in consent acquisition, (ii) strategies and policy frameworks aimed at improving consent rates, and (iii) the use of artificial intelligence and predictive analytics in organ transplantation.

A number of studies have investigated the sociocultural and procedural factors that hinder the acquisition of post-mortem consent. For example, the refusal rate in South Korea was examined in [7], where the authors identified structural and cultural barriers to obtaining consent. The intersection of ethics, religion, and policy was found to influence organ donation practices in South Asia [8]. Similarly, Lewis et al. discussed general barriers to organ donation across different populations [9]. In the Italian context, Grossi et al. found that refusal rates were significantly higher among immigrant populations compared to native citizens, highlighting the importance of demographic and cultural variables in consent prediction [10].

Efforts to proactively increase donation rates and consent have also been widely studied. In [11], hospitals were benchmarked based on their consent rates, with key influencing factors including donor age and ethnic background. A number of studies [9], [12], [13] have compared opt-in and opt-out systems, with opt-out systems generally associated with higher donation rates. However, these studies also acknowledge the complex ethical and political considerations surrounding such transitions. The role of family members in the final consent decision is emphasized in [14]–[16], even in jurisdictions with presumed consent. Additionally, many studies have revealed that one of the most influential issues is the expertise of the person approaching the family to obtain consent for organ donation. For instance, [17] highlighted the crucial influence of healthcare professionals' engagement and communication skills in facilitating positive consent outcomes, while [18] reviews studies on differences in consent rates based on the type of professional doing the asking. Expanding on these findings, [19] presents the practices adopted by Spanish transplant coordinators during consent requests for Irreversible Cessation of Circulatory and Respiratory Functions (ICOD). The study outlines the sequence of preparatory steps coordinators follow prior to engaging families in decision-making. Many of these steps are not only rooted in a structured and empathetic communication approach but are also recognized as best practices in broader organ donation contexts. This method has been associated with a notably low rate of family refusals, reinforcing the importance of professional training and protocol in achieving favorable consent outcomes. Additionally, some studies explore effective strategies for obtaining consent from families. For example, [19] presents the practices adopted by Spanish transplant coordinators when requesting consent for Irreversible Cessation of Circulatory and Respiratory Functions (ICOD). The study outlines the sequence of steps coordinators follow before engaging the family in decision-making. Many of these steps are recognized as best practices in broader organ donation contexts and are associated with a notably low rate of family refusals.

Broader applications of AI in organ donation and transplantation have also been explored. In [20], a comprehensive review was conducted on the use of artificial intelligence across various stages of the transplant process, including organ allocation, process optimization, and clinical decision support. However, the application of AI specifically to predict consent outcomes remains largely unexplored.

While the importance of timely consent acquisition in organ donation is widely acknowledged, research employing predictive modeling in this context remains limited. Notable exceptions include the studies by Khan et

al. [2] and Tutun et al. [21], both of which apply machine learning techniques to forecast consent outcomes. In particular, the methodologies proposed by Khan et al. [2] demonstrate high levels of accuracy, indicating that such approaches are both viable and effective. Ultimately, they have the potential to increase consent rates and thereby save more lives among individuals on organ transplant waiting lists.

In [2], the authors develop a predictive framework that integrates machine learning and network science to estimate the likelihood of family consent in organ donation. Their model is designed not only to predict outcomes but also to uncover the most influential factors driving family decisions. The basic goal is to provide Organ Procurement Organizations (OPOs) and hospital staff with actionable insights that support more effective communication strategies during consent discussions. This work emphasizes the role of predictive models as expert systems to improve consent rates and, by extension, help mitigate the persistent mismatch between organ supply and demand.

Similarly, Tutun et al. [21] propose a responsible AI framework that merges network science with machine learning to enhance consent prediction. Their study leverages a large dataset collected from approximately 1,500 consent discussions across 92 hospitals in New York, recorded between January 2016 and March 2018. Results indicate that incorporating network-based features significantly improves the performance of traditional ML algorithms. The study highlights how algorithmic insights can support ethical and effective approaches to organ procurement.

Despite their relevance, both studies above differ from our work. First, their primary objective is to reduce the rate of family refusal, with a strong focus on optimizing the approach strategies of healthcare professionals. In contrast, our goal is to develop a predictive framework that provides a probabilistic estimate of consent likelihood, which can be integrated into transplant logistics and used to inform cost-effective and timely decision-making throughout the donor management process. Second, the methodological approaches vary considerably. While [2] and [21] rely on extensive sets of features and large datasets—enabling more complex models and improved predictive performance—our study operates on a significantly smaller dataset collected in Italy. This naturally constrains model complexity but provides a novel, context-specific perspective.

This context-specific perspective builds on previous investigations of the Italian case study [22], [23]. In [22], a probabilistic model was developed to estimate the time required to obtain consent, using real-world data from successful organ donation cases in the Lazio region, where an opt-in consent system is in effect. However, that study focused on modeling the timing of consent acquisition, rather than predicting the binary outcome of whether consent would be granted. The same case study was further explored in [23], where the pre-transplant process was modeled and simulated to identify time-critical activities through critical path analysis. Building on that work, [24] conducted a cost-benefit analysis to evaluate management strategies aimed at balancing time efficiency and cost-effectiveness throughout the pre-transplant phase.

To the best of our knowledge, our study is the first to address consent prediction using real-world data from Italy, and more broadly, among the first of its kind in Europe. This regional focus enables us to explore consent dynamics within the specific legal and procedural framework of an opt-in system, offering valuable insights for local policy and process optimization.

III. Overview of Donor Management and Consent Dynamics

Transplant centers worldwide generally follow a hierarchical structure, with a national coordinating authority and regional and local healthcare facilities. This is also the case in the center we consider here. Namely, we focus on the Italian Transplant System, involving the National Transplant Center (NTC), Regional Transplant Centers (RTCs), and local hospital units. Organ transplantation is a complex process involving many phases and actors. In this paper, we are interested in the process leading to consent acquisition. In this section, we describe the donor management process and the relevance of the timeliness of consent acquisition for the overall efficiency of the process.

A. The organ donor management process

The organ donor management process is a structured set of activities that begins with the identification of a potential donor and ends with the retrieval of organs and their allocation to compatible recipients. Its primary aim is to ensure the quality and availability of transplantable organs while safeguarding recipient health.

This work focuses on the process currently implemented at the RTC of the Lazio region in Italy. The UML (Unified Modelling Language) diagram in Figure 1 represents a sketch of the donation process, which begins when a potential donor is identified. The identification of a donor starts with the recognition of the brain death status of a patient, which qualifies him/her as a potential donor. A six-hour period is required for Brain Death Assessment (BDA). After BDA, two parallel streams of activities are triggered:

- Acquisition of consent for organ donation;
- Initial clinical and diagnostic evaluations.

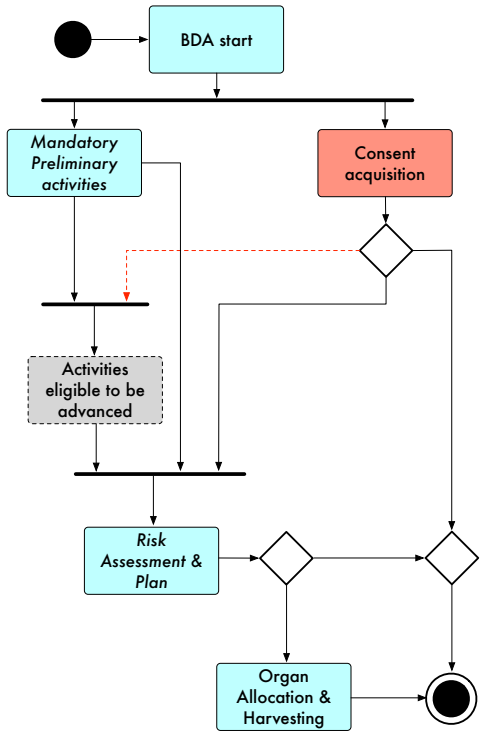

Fig. 1: Compact UML diagram of the process.

The following phases involve a comprehensive assessment of donor suitability, including laboratory analyses, virological testing, and instrumental diagnostics. Although there are no strict technical constraints, higher-cost exams are generally performed only after consent is obtained, in order to avoid unnecessary expenses when the transplant cannot proceed due to a lack of consent. If consent arrives in due time, it allows the medical staff to proceed with all the medical tests needed to properly carry out the transplant. If consent is denied, any further medical test for transplant is cancelled. Some activities are susceptible to be advanced, i.e., carried out even if consent has not arrived yet, so as to reduce the overall process time. Those activities are shown as *advance-eligible* in Fig. 1. Dashed arrows indicate precedence relations that are not mandatory. After the examinations are carried out to assess the clinical suitability of the potential donor, a risk level is defined—sometimes following consultation with the Second Opinion team appointed by the National Transplant Center (NTC). If the evaluations indicate that the donor presents an unacceptable risk to recipients, the process is immediately stopped. Once the donor's risk level has been defined, the process moves into the Organ Allocation and Harvesting phase. In this stage, potential recipients are identified and matched based on clinical compatibility and logistical considerations, through coordinated efforts involving the NTC, Regional Transplant Centers (RTCs), local transplant teams, and logistics services, ensuring timely and efficient organ retrieval and distribution.

B. Impact of Consent activity on process time and cost

If a potential donor has not expressed their wishes regarding organ donation while alive, the responsibility for releasing consent is transferred to their relatives. The Consent acquisition phase becomes a critical crosspoint in the donation process—regardless of whether consent is ultimately granted or denied by those legally empowered to decide. This phase significantly affects both the duration and cost of the process.

To illustrate, imagine that the family or other authorized individuals communicate their decision at some unknown time point T after the donation process begins. By that time, a possibly empty subset S of activities (eligible to be initiated before the consent is given) may already have been started or completed. Let c_S denote the cumulative cost of these activities. If consent is not granted, then a cost c_S is effectively wasted.

This would suggest a conservative strategy: delaying costly actions until consent is confirmed to keep S, and thus c_S, minimal. However, such caution comes at a price. Postponing action until the decision time T prolongs the process—especially in cases where consent is eventually given. The more activities completed before T, the more progress has been made by the time consent is secured, allowing transplantation to proceed more quickly. Since organs are perishable and their viability deteriorates over time, any delay can compromise the success of the transplant.

This tension calls for a cost-benefit analysis to guide decision-making, weighing the trade-off between minimizing wasted costs and maximizing time efficiency in cases where consent is ultimately granted (see [24]). In short, cost-efficiency favors deferring activities until consent is certain, while time-sensitivity and organ viability argue for initiating tasks early—even at the risk of incurring unrecoverable costs if consent is later denied, particularly when T is large. If we indicate the process times as T_{adv} and $T_{\mathrm{del}} > T_{\mathrm{adv}}$, respectively, when activities are advanced or postponed with respect to consent acquisition, we can summarize the time-cost trade-offs in the matrix shown in Fig. 2, where each bracket contains the time needed to complete the process and the wasted cost.

In this context, a predictive tool that can estimate the likelihood of consent with reasonable accuracy would be highly valuable. High confidence in a positive outcome justifies starting preparations sooner, improving both patient outcomes and resource utilization. Conversely, if the predicted probability of denial is high, delaying

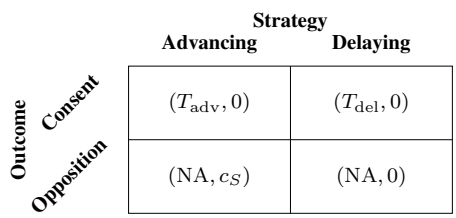

Fig. 2: Trade-offs in donor management process strategy

costly tasks becomes the prudent course, helping to avoid unnecessary expenditure.

IV. Dataset

We collected and analysed a dataset concerning potential donors at the Regional Transplant Center for the Lazio region in Italy. In Italy, the opt-in regulation applies where the potential donor may have given or denied his/her consent to transplant when they were alive. In the case the potential donor did not express their decision concerning organ transplant during their life, it is up to the family members to decide after the potential donor's brain death. The decision about donation as well as the personal details of the potential donor and their relatives are recorder. In this section, we describe the dataset including that information.

Our data collection took place over four years, from 2021 to 2024. We can first see how the consent information is distributed over the years in Table I. A significant growth year-on-year can be observed, with a CAGR (Compound Annual Growth Rate) of 6.7%. The overall number of instances is 867 (the data for 2024 do not cover the whole year). However, the dataset is heavily imbalanced, with the *Silent* group (i.e., those not expressing their opinion during their lifetime) being the large majority (80.2% of the total). The overall dataset has been processed through Bootstrap and 10-fold cross-validation to get the final dataset to be fed to the algorithms described in Section V-A for training and testing. Since our focus is to predict consent for potential donors after brain death (DBD), we are not interested in those donors expressing their consent during their lifetime. Actually, for those potential donors, the donor management process either starts with all the medical tests to be carried out as soon as possible, or does not start at all. Hence, in the following, we will focus on the silent potential donors. After examining the dataset, we removed those instances where most features are absent. The overall number of silent donors has then reduced to 653, which is the reference number we will consider in the following.

In addition, in order to examine how the nationality of the donor may influence the decision and may be predicted with larger or lesser accuracy, we considered the following subsets of potential donors:

- European donors;
- Italian donors;
- non-Italian donors.

TABLE I: Consent expression in the dataset

Year	Consent	Opposition	Silent	Total
2021	18	18	196	232
2022	32	14	202	248
2023	34	28	202	264
2024	23	5	95	123
Total	107	65	695	867

TABLE II: Number of silent donors by nationality

Nationality	Numerosity
European	585
Italian	542
non-Italian	111

The numerosity of the three subsets is shown in Table II. As can be seen, Italians make up roughly 90% of the whole set of European potential donors, as expected.

We can see in Fig. 3 how nationality influences the decision about organ donation during lifetime. While we see a balanced distribution for European and South American potential donors, the distribution is heavily imbalanced for the other continents. The culture of donation is quite widespread in North America, where just a small minority opts for opposing donation. On the other end of the spectrum, we find Asia and Africa, where oppositions largely outnumber consents.

For each potential donor, 67 features have been collected. Those features may be subdivided into six groups:

1) General;
2) Personal data;
3) Information on relatives;
4) Risk level;
5) Organ information;
6) Consent.

Group 1 contains information related to the death of the potential donor, including time and cause of death. Group 2 includes all personal data pertaining to the donor: name, surname, age, gender, date of birth, place of birth, place of residence, height, and weight. Group 3 provides data necessary to determine the degree of kinship of the relatives involved in the consent process (e.g., parents or siblings). Group 4 comprises information regarding the donor's risk profile, based on second opinions obtained by the medical staff during the organ compatibility assessment. Finally, Group 5 is

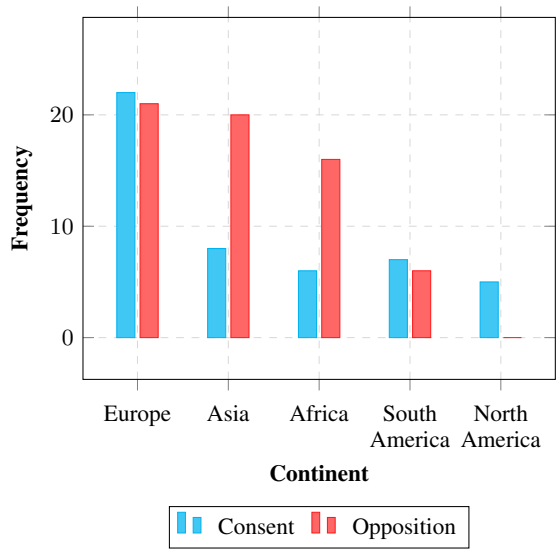

Fig. 3: Frequency of support and opposition by continent

included only if consent has been obtained, and contains specific details about the organ that may be considered for transplantation.

It is to be noted that Group 6 actually includes the target variable (whether Consent has been released), but also information on the source of consent (the donors themselves or their relatives).

V. Methodology

The problem of consent prediction has been modelled as a binary classification one, where the two classes are Consent or Opposition (Consent denial) and the potential features are the 67 mentioned in Section IV. In this section, we describe the classification algorithms that we have employed, the performance metrics that we have adopted to assess the algorithms, and the feature selection process.

A. Algorithms and tools

We have employed the following established classification algorithms:

- Decision Tree;
- Logistic Regression;
- AdaBoost;
- Feedforward neural network.

Each method in this selection has its own characteristics.

Decision Trees split data into subsets using feature thresholds, creating a tree-like structure where each node represents a feature condition, and leaves represent class labels. They are easy to interpret, but are prone to overfitting, especially on small datasets like ours.

Logistic Regression is a linear model where the probability of a class is predicted by using a logistic function. Regularization is achieved through LASSO (L1 Regularization) by adding a penalty term to reduce overfitting and performing feature selection by shrinking some coefficients to zero. It is simple, interpretable, good for high-dimensional data with irrelevant features. It has been chosen since we have a relatively large number of features (we are considering non-image data) many of which may prove to be not relevant. It has limited capacity for complex relationships.

AdaBoost (Adaptive Boosting) is an ensemble method that combines multiple weak learners (often decision stumps) by iteratively focusing on previously misclassified examples. It should be more accurate than single models like decision trees or logistic regression and works well with less data (as in our case). However, it is sensitive to noisy data and outliers.

Finally, feedforward Neural Networks represent a very simple type of deep learning model where data flows through multiple layers of interconnected nodes (neurons) from input to output. They are powerful for modeling complex, non-linear relationships. However, they require large datasets, which we do not have at present, and are less interpretable.

In the following we describe the configuration details for each classification algorithm.

For decision trees we have employed a general (non-binary) structure, where splitting was carried out just for nodes with at least five instances. The maximum tree depth was kept at 50 and pruning was employed for nodes where the majority class includes more than 95% of the instances.

Logistic Regression was employed with LASSO regularization with L1 norm and the classification threshold set at 0.5 probability..

In AdaBoost 60 trees were used as base estimators, with the learning rate set to 1.

A multilayer network with 100 neurons per hidden layer was employed with a feedforward structure. A logistic sigmoid function was chosen as the activation function used, and ADAM was selected as solver, based on the gradient descent algorithm for calculating weights during the training phase [25]. The maximum number of iterations (stopping condition) was set to 200.

B. Performance metrics

Our aim is to identify the cases where consent to donation is obtained. We have then a binary classifier, where we label as Positive the cases where consent is actually obtained. With the usual 4-cell confusion matrix, we have then the following possible outcomes: True and False Positives (TP and FP, respectively) as well as True

TABLE III: MOST SIGNIFICANT FEATURES

Feature	Overall	European	Italian	non-Italian
Donor's hospital	✓	✓	✓	✓
Nationality	✓	✓		
Birthplace region	✓	✓	✓	
Continent	✓			✓
Cause of death	✓	✓	✓	✓
Region of residence	✓	✓	✓	✓
Donor's age	✓	✓	✓	✓
Size of birth city	✓	✓	✓	
Donor gender	✓	✓	✓	✓
Year of death	✓	✓	✓	✓
Donor blood type	✓		✓	
Size of city of residence	✓	✓	✓	✓
Part of Italy (residence)	✓	✓	✓	✓
Country of birth				✓
Country of residence				✓

and False Negatives (TN and FN, respectively). We adopt the following extablished performance metrics [26]:

- Accuracy = $\frac{TP+TN}{TP+TN+FP+FN}$
- Precision = $\frac{TP}{TP+FP}$
- Recall = $\frac{TP}{TP+FN}$
- F1 Score = $2\frac{1}{\frac{1}{\text{Precision}}+\frac{1}{\text{Recall}}}$

C. Features

Though we have a large number of potential features (67), most of them have proved to be of small significance for the performance. For that reason, we have chosen a subset of significant features by employing three metrics: the information gain, the gain ratio, and the Gini index. The choice of features depends on the subset of interest, so that we have selected the most relevant features for each data subset. In Table III, we show the selection for the full dataset and the three subsets investigated in this paper. Some features appear to be significant for all the sets, namely: Donor's hospital, Cause of death, Location of residence, Donor's age, Year of death, and Size of city of residence.

VI. RESULTS

We have examined our dataset by employing all the four algorithms described in Section V-A. We first consider the results obtained for the whole set of silent donors, i.e., those potential donors who did not express their consent (or denial) during their lifetime, so that the decision has been left to their relatives. Then we examine the results for the nationality subsets defined in Section IV.

In Table IV, we show the major performance metrics. Linear Regression is by far the worst performer, exhibiting figures below 70% on all four metrics. We see a significant improvement by roughly ten percentage points with decision trees. However, if we abandon the intrinsic explainability of decision trees, both ensemble techniques (AdaBoost in this case) and neural networks

TABLE IV: MODEL PERFORMANCE USING BOOTSTRAP ON THE SILENT DATASET

Technique	Accuracy	F1 Score	Precision	Recall
Tree	0.76	0.76	0.76	0.76
LASSO	0.66	0.64	0.65	0.66
AdaBoost	0.85	0.85	0.85	0.85
Neural Net	0.82	0.82	0.82	0.82

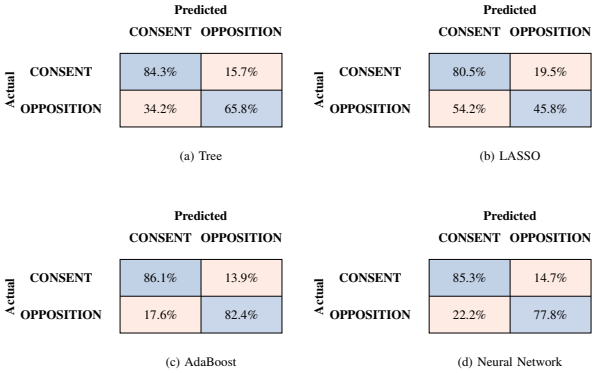

Fig. 4: Confusion matrices (percentages) using Bootstrap on the silent dataset

(though in their simple feedforward configuration) allow us to reach good performances achieving figures well beyond 80% on all metrics. AdaBoost appears the best overall performer.

We can take a closer look at the performance by examining the confusion matrices in Fig. 4. Linear regression (LASSO) shows the worst imbalance in performance, being good in recognizing Consent decisions, but failing by misclassifying a major portion of Opposition decisions (performing even worse than a random classifier). The imbalance in performance decreases but is still significant in decision trees (though the majority of oppositions is now classified correctly). The per-class performance improves significantly with AdaBoost and neural networks. The imbalance across classes is very small for AdaBoost and a bit larger for neural networks. In both cases, the imbalance works against oppositions, which are classified correctly in less than 80% of the instances with neural networks.

Summing up, Adaboost appears as the best classifier, both overall and over either class, exhibiting well-balanced performances.

We can now examine the performances on the subsets described in Section IV, considering European, Italian, and non-Italian potential donors.

In Table V, we show the performance metrics for European donors. The performance is quite similar to what we have obtained on the overall dataset, though a bit better. This may suggest that European donors may

TABLE V: MODEL PERFORMANCE USING BOOTSTRAP ON EUROPEAN DONORS

Technique	Accuracy	F1 Score	Precision	Recall
Tree	0.78	0.78	0.78	0.78
LASSO	0.67	0.66	0.66	0.67
AdaBoost	0.84	0.84	0.84	0.84
Neural Net	0.85	0.85	0.85	0.85

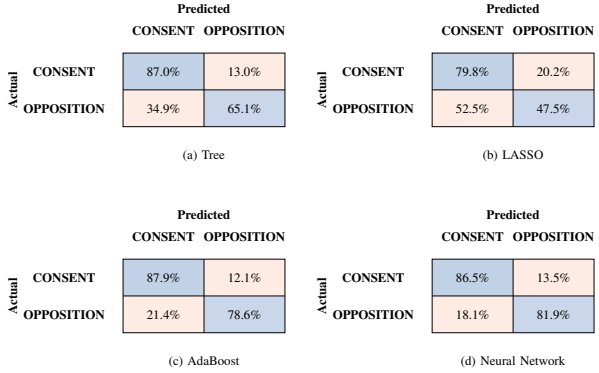

Fig. 5: Confusion matrices (percentages) using Bootstrap on the European dataset

be predicted more reliably than non-European donors.

Similarly to what we did for the whole dataset, we can examine the performance metrics on either class by looking at the confusion matrices in Fig. 5. We see again that decision trees have similar performances as the best performing algorithms for the Consent class. It is the performance on the Opposition class that brings the overall accuracy down. The imbalance between the performance for the two classes is high for the LASSO regression. Neural networks appear as the most balanced algorithm for this subset.

If we focus on Italian donors, which are, as expected, the largest nationality subgroup by far, we obtain the results shown in Table VI. We do not see significant changes with respect to the results that we have already shown. The pertaining confusion matrix is shown in Fig. 6.

What removes some doubts about the reliability of predictions for nationals is the examination of Table VII, where the performance improves significantly. We can

TABLE VI: MODEL PERFORMANCE WITH BOOTSTRAP ON ITALIAN DONORS

Technique	Accuracy	F1 Score	Precision	Recall
Tree	0.77	0.76	0.77	0.77
LASSO	0.69	0.67	0.68	0.69
AdaBoost	0.81	0.81	0.81	0.81
Neural Net	0.83	0.83	0.83	0.83

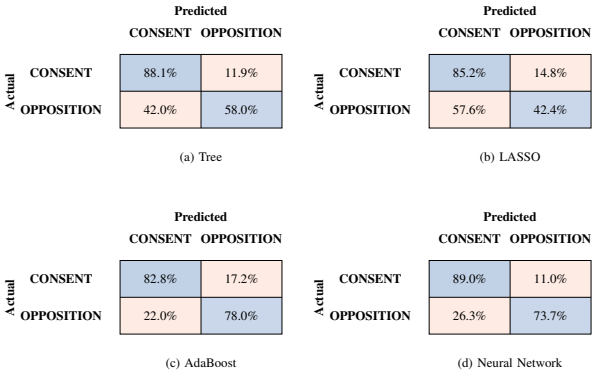

Fig. 6: Confusion matrix (percentages) for Neural Network using Bootstrap on the Italian dataset

TABLE VII: MODEL PERFORMANCE WITH BOOTSTRAP ON NON-ITALIAN DONORS

Technique	Accuracy	F1 Score	Precision	Recall
Tree	0.71	0.71	0.71	0.71
LASSO	0.71	0.71	0.71	0.71
AdaBoost	0.86	0.86	0.86	0.86
Neural Net	0.85	0.85	0.85	0.85

conclude that, though AdaBoost and neural networks provide accuracy values over 80% in any case, predictions are more accurate for non-Italian potential donors than for Italian ones. though the size of the non-Italian subsample is not very large, it appears that the features that we have employed give much clearer indications for non-Italian donors.

Finally, we have examined the possibility of improving the forecasting accuracy by introducing features related to family members. The results in Table VIII clearly show a significant improvement for the worst performing algorithms (decision trees and LASSO regres-

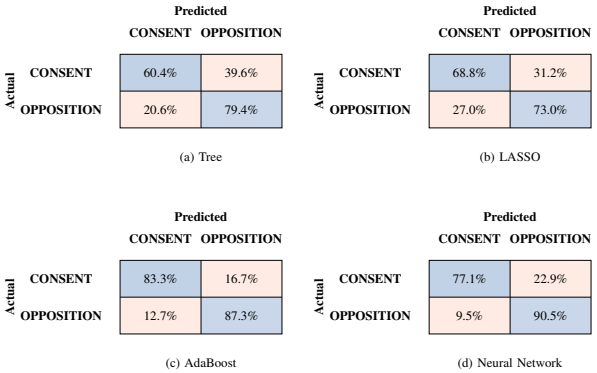

Fig. 7: Confusion matrices (percentages) using Bootstrap on the non-Italian dataset

TABLE VIII: MODEL PERFORMANCE WITH BOOTSTRAP BY ADDING INFO ON FAMILY MEMBERS

Technique	Accuracy	F1 Score	Precision	Recall
Tree	0.80	0.79	0.80	0.80
LASSO	0.79	0.79	0.79	0.79
AdaBoost	0.88	0.88	0.88	0.88
Neural Net	0.86	0.86	0.86	0.86

sion) and a small improvement for the best-performing algorithm (AdaBoost and neural networks). For the latter algorithms, the accuracy gets closer to 90%. The addition of that information, though notoriously difficult to get, is then highly recommended.

VII. CONCLUSIONS

This study has demonstrated the feasibility and effectiveness of using machine learning techniques to forecast consent outcomes in the organ donation process. By leveraging a comprehensive set of socio-demographic, clinical, and contextual features, our models—particularly AdaBoost and neural networks—achieved strong predictive performance, with accuracies exceeding 85% and well-balanced classification across both Consent and Opposition cases. These results affirm the value of predictive modeling in addressing one of the most critical and uncertain phases of organ donation: the acquisition of consent.

The practical implications of this work are substantial. In a process where timing is critical and resources are constrained, early estimation of the likelihood of obtaining consent enables healthcare professionals to tailor their actions. High predicted probabilities of consent support the early initiation of cost-intensive diagnostic and preparatory procedures, thereby minimizing delays and reducing the risk of organ deterioration. Conversely, low predicted probabilities can help avoid unnecessary expenditures and optimize allocation of staff and equipment. The integration of such predictive tools into clinical decision support systems can therefore enhance both operational efficiency and cost-effectiveness in transplant logistics.

Looking ahead, several promising directions could further extend this research on consent prediction in solid organ transplantation. First, integrating additional qualitative and behavioral data—such as prior interactions with healthcare staff or known family attitudes—may enhance predictive accuracy and provide deeper contextual understanding. Second, the development of real-time, interpretable models tailored for clinical settings would improve usability and foster trust among healthcare professionals, potentially leveraging more advanced and explainable forecasting architectures [27].

Third, conducting cross-regional studies with data from multiple transplant centers would allow for broader validation and support the generalization of findings, thus laying the groundwork for national or even international implementation of consent prediction tools within organ donation systems.

Finally, we believe that embedding the proposed model within a comprehensive decision-support framework—capable of optimizing various components of the donor management process, including logistical challenges such as organ transportation [28]–[31]—could significantly improve the overall performance and efficiency of the system (see, e.g., [32]).

ACKNOWLEDGMENT

The authors wish to express their sincere gratitude to the staff of the Regional Transplant Center of Lazio for their invaluable support. Their detailed explanations of the donor management process, particularly the procedures and challenges related to consent acquisition, as well as their essential contributions to data collection and analysis, were fundamental to the development of this study.

***Abstract*—Many combinatorial optimization problems arise in the context of resource allocation. In this paper, we study the problem of allocating shareable resources of different types to jobs, where each job consists of multiple tasks, and each task has a demand of a given duration to a single resource type. All resources are available over a common time interval. Several copies from each resource may be allocated. In a valid solution, at any given time, each job may be processed by at most one resource, and each resource may process at most one job. The objective is to complete all jobs while minimizing the total cost of the allocated resources.**

We focus on the power of preemptions in this model, analyzing how much the total cost can be reduced when jobs are allowed to be preempted — that is, when the processing of tasks can be split into multiple intervals.

We present both theoretical and experimental results, distinguishing between environments where jobs may be preempted but all intervals of a task must be processed on the same resource copy (weak preemptions), and environments where jobs may split the processing of a task among different resource copies (strong preemptions). Without preemptions, the problem is clearly NP-hard, as it generalizes the classical Bin Packing problem. We provide an optimal polynomial-time algorithm for the strong-preemption model, as well as a polynomial-time algorithm for the non-preemption model under a restricted class of task durations. Our empirical evaluation investigates the performance of several greedy heuristics, showing that even simple methods can achieve near-optimal results.

I. Introduction

SUSTAINABILITY plays a crucial role in various aspects of our future on Earth. Growing awareness of the need to protect the environment, combined with the ability to communicate easily, has led to new trends in resource consumption. Users have become more flexible about consumption and are willing and able to share resources in new ways. The new ways to consume resources give rise to new combinatorial problems related to allocation and utilization of shareable resources. In this work, we define and study problem of this kind.

We consider a *resource sharing* model, where each resource is capable of being used or leased for any duration within its availability window. For example, consider Amazon drivers who perform deliveries in their assigned regions, using trucks of different sizes tailored to specific delivery needs. A similar setting arises in large organizations, where departments might share meeting rooms of various capacities, or in workplaces where part-time or hybrid employees share desks, cubicles, or workstations. Likewise, in residential communities, neighbors may collaboratively use equipment such as electric vehicle charging stations [18], lawn mowers or other landscaping tools.

In our resource sharing problem, every user (job) is associated with a demand for several resources. For every user and resource, it is known for how long the user needs the resource. Without sharing, every user is allocated one copy from each resource. However, different users can share the same resource if they use it at different times. Assume that every copy of a resource is associated with a given cost. The goal is to schedule the users on different copies of the resources such that the total cost of allocated resources is minimal. In the basic setting of this model, every user is using each resource consequently and with no interruptions. When preemptions are allowed, a user may split the use of a resource into several segments. It is well known that in many scheduling problems, preemptions significantly affect the objective function value and the computational complexity of the problem. For example, the classical load balancing problem of minimizing the completion time of a schedule (the makespan) is NP-hard if preemptions are not allowed [5] and is solved by a linear-time algorithm if preemptions are allowed

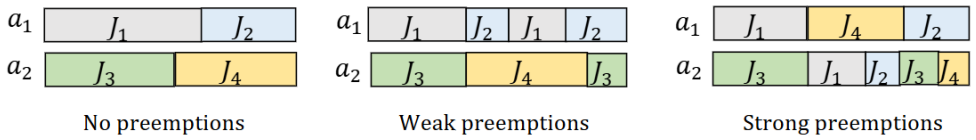

Fig. 1. Possible schedules of four jobs on two copies of resource type a.

[11]. In this work, we study the power of preemption in the resource sharing model. Practically, the power of preemption measures how the flexibility of users in the way they are ready to use the resource affects the total cost.

The resource sharing problem is dual to *open-shop scheduling*, in which we have one copy of each resource type, and the goal is to minimize the schedule's completion time (the makespan). For a single resource type, our problem is identical to the well-known NP-hard *bin-packing* problem in which items of different sizes need to be packed in a minimal number of identical bins. In the bin-packing problem, if items can split among several bins, the problem becomes trivial. In our setting, such splits correspond to job-preemptions. Thus, our problem can be viewed as a generalization of bin-packing. In this generalization with several resource types, the power of preemption has not been studied in the past.

In our analysis we distinguish between four types of resource consumption: (i) no resource sharing, (ii) resource sharing without preemptions, (iii) resource sharing with weak preemptions, where the processing of a task can be paused and resumed on the same resource copy, and (iv) resource sharing with strong preemptions, where tasks may pause and resume, and also migrate across different resource copies. We present an optimal algorithm for the problem with strong preemptions allowed, and analyze theoretically and by experiments the performance of some natural greedy heuristics, in general and for restricted classes of instances. As we show, even simple heuristics can achieve near-optimal performance.

A. Notation and Problem Statement

An instance of the *resource sharing* problem is given by a tuple $\langle \mathcal{J}, M, (p_{ij})_{i\in M, j\in\mathcal{J}}, (c_i)_{i\in M}, T\rangle$, where $\mathcal{J}$ is a set of $n \geq 1$ jobs, M is a set of $m \geq 1$ resource-types, p is an $n \times m$ matrix of processing requests, $c_i > 0$, is the cost of each copy of resource i, and $[0, T]$ is the availability interval of each of the resource copies. We use the term resource i to denote resource-type i. Each job $j \in \mathcal{J}$ consists of several tasks. Formally, each job is associated with a set of resource types $S_j \subseteq M$ corresponding to the tasks composing it (for which $p_{ij} > 0$). For each $i \in S_j$, job j should be processed on a resource of type i for p_{ij} time units. In a valid instance $\sum_i p_{ij} \leq T$. Let $J_i = |\{j \in \mathcal{J} \mid i \in S_j\}|$ be the number of jobs that need resource i.

The idea in the sharing model is that several jobs can share a single copy of a resource, as long as each copy services at most one job in each time slot. Therefore, the number of copies required from resource i may be lower than J_i. It is easy to see that the actual number of copies required from resource i is between $\left\lceil \sum_j p_{ij}/T \right\rceil$ and J_i.

A *non-preemptive schedule* of an instance is denoted by $\sigma = (\sigma_j)_{j\in\mathcal{J}}$. For every job j, $\sigma_j = (\sigma_{ji})_{i\in S_j}$ is the schedule of job j, given by the set of intervals in which j uses the resources it needs. Specifically, $\sigma_{ji} = [start(\sigma_{ji}), end(\sigma_{ji}))$ is the interval in which job j uses resource i in σ. In a feasible solution, $end(\sigma_{ji}) - start(\sigma_{ji}) = p_{ij}$; that is, job j is assigned to the resource for p_{ij} time units. The intervals in which a job uses different resources must be disjoint; that is, for all j and any i_1, i_2, it holds that $\sigma_{ji_1} \cap \sigma_{ji_2} = \emptyset$.

For a given schedule σ, for any time $0 \leq t \leq T$, let $N_i(\sigma, t) = |\{j \in \mathcal{J} \mid t \in \sigma_{ji}\}|$ be the number of jobs $j \in \mathcal{J}$ that use resource i at time t. Let $N_i(\sigma) = \max_{0\leq t<T} N_i(\sigma, t)$. That is, $N_i(\sigma)$ is the maximal number of jobs who simultaneously use resource i throughout the schedule. It holds that $N_i(\sigma)$ is the number of copies of resource i needed to satisfy all job requirements. The cost of a schedule σ is the total cost of the resources used in σ, given by $cost(\sigma) = \sum_{i=1}^{m} N_i(\sigma) \cdot c_i$. The goal is to satisfy all job requirements at a minimum total resource cost, i.e., find a schedule σ such that $cost(\sigma)$ is minimal.

When preemptions are allowed, the processing of a task on one resource may split into several disjoint intervals. We distinguish between two types of preemptions (see Figure 1).

1) Weak Preemptions - for every job j and type $i \in S_j$, the processing of the task of type i of job j may split into several intervals, all of them are on the same copy of a resource of type i.
2) Strong Preemptions - for every job j and type $i \in S_j$, the processing of the task of type i of job j may split into several intervals, which can be processed on different copies of resources of type i.

For an instance I, let $OPT_{nopmtn}(I)$, $OPT_{Wpmtn}(I)$, $OPT_{Spmtn}(I)$ denote the minimal cost of a feasible schedule of I without preemptions, with weak preemptions, and with strong preemptions, respectively.

Definition 1.1: Let I be an instance of a resource sharing problem. The power of weak preemption for I is $\mathrm{PoWP}(I) = \frac{OPT_{nopmtn}(I)}{OPT_{Wpmtn}(I)}$. The power of strong preemption for I is $\mathrm{PoSP}(I) = \frac{OPT_{nopmtn}(I)}{OPT_{Spmtn}(I)}$.

Definition 1.2: For a class $\mathcal{I}$ of instances, let $\mathrm{PoWP}(\mathcal{I}) = \max_{I\in\mathcal{I}} \mathrm{PoWP}(I)$, and $\mathrm{PoSP}(\mathcal{I}) = \max_{\mathcal{I}\in\mathcal{I}} \mathrm{PoSP}(\mathcal{I})$.

When weak preemptions are allowed, a job may split its processing but must remain in the same copy of a resource. The next definition, of the power of migration, isolates the benefit from allowing jobs to split a task among several different copies of a resources.

Definition 1.3: Let I be an instance of a *Resource Sharing* problem and $\mathcal{I}$ a class of instances. The power of migration for I is $\mathrm{PoM}(I) = \frac{\mathrm{PoWP(I)}}{\mathrm{PoSP(I)}}$, and the power of migration for $\mathcal{I}$ is $\mathrm{PoM}(\mathcal{I}) = \max_{I\in\mathcal{I}} \frac{\mathrm{PoWP}(I)}{\mathrm{PoSP}(I)}$.

We conclude the introduction with an example, demonstrating the power of preemption. Consider an instance I with $n = 6$ jobs and $m = 5$ resource types. The jobs' demands are given in the table in Figure 2. Assume that all resources have the same unit cost per copy. Assume also that $T = 5$. Figure 2 presents two possible schedules. The left schedule is an optimal schedule with weak preemptions. In this schedule exactly one copy of each resource is allocated, therefore $OPT_{Wpmtn}(I) = 5$. The right schedule is an optimal non-preemptive schedule. It holds that $OPT_{nopmtn}(I) = 8$. We can see that the left schedule uses exactly $\left\lceil \sum_j p_{ij}/T \right\rceil$ copies of each resource type i, which is clearly the minimal possible. We conclude that $\mathrm{PoWP}(I) = \mathrm{PoSP}(I) = \frac{8}{5} = 1.6$.

The above example can be generalized to show that for every $n \geq 2$, there exists an instance I_n with n jobs and $m = n+1$ resource types of unit cost such that $\mathrm{PoWP}(I_n) = \mathrm{PoSP}(I_n) = \frac{2n}{n+1} = 2 - \frac{2}{n+1}$. In this construction, one job needs all m resources for a short duration ε, while each of the remaining $n-1$ jobs needs a distinct resource for $T - \varepsilon$ time units. In the non-preemptive schedule, the first and last resources can be shared and require a single copy each, while each of the remaining $m-2$ resources requires two copies, yielding a total cost of $2(n-1)+2 = 2n$. In contrast, a preemptive schedule allows all jobs to be assigned efficiently with only one copy per resource, giving a cost of $m = n+1$, and thus the claimed ratio.

B. Related Work

There is an extensive body of literature dedicated to job scheduling on parallel machines of various types. As previously mentioned, the resource sharing problem is dual to the well-studied open-shop problem. An instance of *open-shop* scheduling consists of $m \geq 1$ machines (or processors). Each of these machines is capable to perform a single task type. The machines are available at time $t = 0$, and, unlike our model, do not have limited active time, that is, $T = \infty$. In the problem $O||C_{max}$ the goal is to minimize the makespan of the schedule, given by the last completion time of a job. When preemptions are allowed, the problem $O|pmtn|C_{max}$ can be solved in linear-time [6], [10] for any number of machines. In contrast, for the non-preemptive variant, a poly-time algorithm is known only for $m \leq 2$.

For $m \geq 3$, $O||C_{max}$ is NP-complete [6]. A known approximation algorithm guarantees an approximation to the optimal solution that is dependent on the ratio between the maximal total demand for a single machine and the maximal demand of a single job on a single machine [4]. The hardness of the approximation for $O||C_{max}$ has also been studied. It is known that, unless P=NP, there does not exist a polynomial-time approximation algorithm that constructs a schedule with length guaranteed to be strictly less than $\frac{5}{4}$ times the optimal length [17]. When m is fixed, there exists a $(1+\epsilon)$-approximation scheme for the problem that is polynomial in the size of the instance, but exponential in m and $\frac{1}{\epsilon}$ [14]. Optimal algorithm

or better approximal factors were given for restricted classes, such as unit-length jobs [12], [1], or limited number of jobs or machines [3].

The *Power-of-Preemption* (PoP) has been analyzed mainly for the problem $R||C_{max}$ of minimizing the makespan on unrelated parallel machines. In [7] it is shown that the PoP is exactly 4, by showing a lower bound to the PoP, after an upper bound as well as approximation algorithms for restricted classes were given in [2], [13], [15]. The paper [16] studies the PoP and the power of limited preemptions (where only a limited number of preemptions is allowed) for multiple variants of machine environments, job characteristics and objective functions.

Besides the resemblance to the shop-scheduling models, our resource sharing problem with $m = 1$ is identical to the *Bin-Packing* problem (BP). An instance of BP is given by n items, each has a size in (0,1], and the objective is to pack the items into a minimum number of bins, subject to the constraint that the total item sizes in each bin is at most 1. The bin-packing problem has been studied extensively. It is known to be NP-hard and has an FPTAS whose approximation ratio is $(1+\epsilon)$, with a run time of $O(n^{\frac{4}{\epsilon^2}+1})$ [8], [9].

C. Our Results

In this work, we make several contributions that address the scheduling of shared resources under preemptive and non-preemptive settings, and examine how preemptions may reduce the total resource cost. Our results are listed below.

a) Optimal Algorithm with Strong Preemptions: We present a polynomial-time optimal algorithm for the resource sharing problem when strong preemptions are allowed. Our solution is based on a reduction to open-shop scheduling with preemptions ($O|pmtn|C_{\max}$), and reveals that, under strong preemptions, a minimal-cost schedule, in which for all i, there are exactly $\left\lceil \sum_j p_{ij}/T \right\rceil$ copies of resource i, can be computed efficiently.

b) Power of Preemption in the Class $p_{ij} \in \{0, p\}$: For the restricted class of instances in which every task is either of length p or zero, we showed that both non-preemptive and strong-preemptive scheduling can be computed in polynomial time. Yet, the benefit from preemptions may be significant. We prove that the Power of Strong Preemption (PoSP) for this class is bounded by 2, and this is tight.

c) Greedy Heuristics and Empirical Evaluation: Since non-preemptive resource sharing is NP-hard in the general case, we design and evaluate several heuristic algorithms. Our experiments measure how these heuristics perform as problem parameters (number of jobs, resource costs, variation of processing times) vary, and quantify the benefit of preemptions in practice.

Together, these results offer both theoretical and empirical insights into the power of preemptions in shared resource scheduling. We identify tractable cases, establish tight bounds on preemption benefits, and demonstrate through experiments how simple heuristics behave across realistic settings. Our work highlights the fundamental trade-offs between scheduling flexibility, computational complexity, and solution cost.

II. Resource sharing With Strong Preemptions Allowed

In this section we consider settings with strong preemption allowed. We first present and analyze natural greedy algorithms. Similar greedy algorithms are known to be optimal for makespan minimization and for the Bin Packing problem [11]. However, as we show, the greedy approach fails in the resource sharing problem. We then present an optimal, yet more elaborate, polynomial-time optimal algorithm for resource sharing with strong preemptions allowed.

Greedy Algorithm: Algorithm 1 considers the resources one after the other. For every resource i, it assigns the jobs for which $i \in S_j$ one after the other. Every task of length p_{ij} is assigned to the earliest set of disjoint intervals of total length p_{ij} available on open copies of resource i, or on a new copy of resource i if required. The interval must be disjoint with intervals already allocated to previous tasks of job j. Figure 3 presents an execution of Algorithm 1, and demonstrates that it is sub-optimal.

Algorithm 1 - A greedy algorithm for computing a schedule with strong preemptions.

```
All jobs are initially unassigned.
for i = 1 to m do
    for j = 1 to n do
        if i ∈ S_j then: then
            Assign task i of job j on the earliest feasible
            disjoint intervals of total length p_ij on copies of
            resource i. Open a new copy of resource i if
            needed.
        end if
    end for
end for
```

It is easy to see that additional greedy heuristics, which apply a different assignment order (e.g., the outer loop considers the jobs one after the other), are sub-optimal as well,

hinting that an optimal algorithm for resource sharing with strong preemptions, should be more involved.

Optimal Algorithm: Our algorithm for scheduling with strong preemptions allowed employs an optimal algorithm for the problem $O|pmtn|C_{\max}$ as a black box [6]. Recall that in an Open-Shop $O|pmtn|C_{\max}$ problem, we are given a set of n jobs, a set of m machines, and the processing time, p_{ij} of task i of job j. The jobs should be assigned to the machines (a single copy of each machine) such that different tasks of job j are processed in disjoint time intervals. The goal is to minimize the makespan – defined as the last completion time of a job. Let $A_j = \sum_i p_{ij}$ be the total length of job j's tasks. Let $L_i = \sum_j p_{ij}$ be the length of tasks that need to be performed on machine i.

The optimal algorithm for $O|pmtn|C_{\max}$ presented in [6] computes a schedule whose makespan is $\alpha = \max(\max_j A_j, \max_i L_i)$. Since each of these values is a lower bound for the optimal makespan, the algorithm is clearly optimal.

Given an instance of resource sharing, we construct an instance of an open-shop problem as follows:

For every $1 \leq i \leq m$, we define and allocate $\lceil L_i/T \rceil$ machines that will process the tasks of type i. Denote by M_i the set of machines of type i. For every $1 \leq j \leq n$, there is a single job, whose tasks are determined as described in Algorithm 2. The tasks are defined such that for all $i \in S_j$, the total length of tasks on machines in M_i is p_{ij}, and for every machine in M_i, the total length of tasks that need to be processed on M_i is at most T. An example of our reduction is given in Figure 4.

Algorithm 2 - An optimal algorithm with strong preemptions allowed.

1: Given a set J of $n \geq 1$ jobs and a set M of $m \geq 1$ resource types, $p_{ij}, \forall i, j$, and T.
2: For $1 \leq i \leq m$, allocate a set M_i of $\lceil L_i/T \rceil$ machines.
3: Let $m' = \sum_{1 \leq i \leq m} |M_i|$.
4: Construct an instance of $O|pmtn|C_{\max}$ with n jobs and m' machines.
5: **for** $i = 1$ to m **do**
6: **for** $j = 1$ to n **do**
7: **while** $p_{ij} > 0$ **do**
8: Let $i^\star$ be the lowest index of a machine in M_i with total load $l_i^\star < T$.
9: Let $p_{i^\star j} = min(p_{ij}, T - l_i^\star)$.
10: $l_i^\star = l_i^\star + p_{i^\star j}$
11: $p_{ij} = p_{ij} - p_{i^\star j}$
12: **end while**
13: **end for**
14: **end for**
15: Solve $O|pmtn|C_{\max}$ on the resulting instance.

Theorem 2.1: Algorithm 2 computes in polynomial time an optimal solution to the resource sharing problem with strong preemptions allowed.

Proof: Let $\sigma^\star$ be the schedule produced by Algorithm 2. The algorithm reduces the resource sharing instance to an instance of the open-shop problem $O|pmtn|C_{\max}$ by allocating, for each resource i, exactly $\lceil L_i/T \rceil$ machines, and distributing the tasks of each job j across these machines such that the

total processing time per resource equals p_{ij}. This guarantees that the constructed open-shop instance satisfies the time constraints of resource sharing and respects the job-resource requirements.

The schedule $\sigma^\star$ is computed using the optimal algorithm for $O|pmtn|C_{\max}$ from [6], which produces a schedule of makespan $\alpha = \max(\max_j A_j, \max_i B_i)$, where $A_j = \sum_i p_{ij}$ and $B_i = \sum_j p_{ij}$. Our construction guarantees (steps 8-9) that in the open-shop instance, each machine is allocated at most T time units, that is $\forall i, B_i \leq T$. In addition, by definition of the resource rental problem, the total length of each job is at most T, that is, $\forall j, A_j \leq T$. This implies that $\alpha \leq T$, and the resulting makespan is at most T.

Since each machine in the open-shop solution corresponds to one copy of a resource in resource sharing, and all jobs are scheduled such that their tasks are disjoint on each machine, the resulting schedule is feasible in resource sharing under strong preemptions. Furthermore, the number of machines used for each resource is the minimal possible given the total load and capacity T, meaning the total cost (i.e., number of machines) is minimized. Hence, $\sigma^\star$ is a feasible resource sharing schedule with minimal cost. The time complexity of the algorithm is clearly polynomial and is dominated by the time complexity of the algorithm for $O|pmtn|C_{\max}$ [6], which is $\mathcal{O}(r^2)$, where r is the number of non-zero tasks - typically smaller than $\mathcal{O}(n^2)$. ∎

III. The Class $\mathcal{I}_{0,p}$: instances in which $p_{ij} \in \{0, p\}$

In this section we analyze the class $\mathcal{I}_{0,p}$ of resource sharing instances with $p_{ij} \in \{0, p\}$. That is, all the non-empty tasks have the same length p. As a restricted class of the general problem, our optimal algorithm for strong-preemptive applies for this class as well, making the strong-preemptive problem polynomially solvable.

We show that this class is polynomially solvable even when preemptions are not allowed. Given an instance in $\mathcal{I}_{0,p}$, let r_i denote the number of the non-zero tasks which require resource i. Thus, the total demand for resource i is $p \cdot r_i$. Our optimal solution reduces the problem to $O|p_{ij} \in \{0,1\}|C_{\max}$, that is, minimum makespan in an open-shop environment with unit processing times. An optimal poly-time solution for this problem, based on a reduction to minimum edge coloring in a bipartite graph, is presented in [17].

Overview of our algorithm: In the first step, we determine how many copies are required from each resource type. It is easy to see that for all $1 \leq i \leq m$, $\lceil r_i / \lfloor T/p \rfloor \rceil$ is a lower bound for this number. We define an instance of $O|p_{ij} \in \{0,1\}|C_{\max}$ with $\lceil r_i/\lfloor T/p \rfloor \rceil$ machines of type i. We then use the algorithm in [17] to get an optimal schedule for the resulting $O|p_{ij} \in \{0,1\}|C_{\max}$ problem, and conclude an optimal solution to our resource rental problem. Formally:

Theorem 3.1: Computing an optimal solution for a resource sharing problem in $\mathcal{I}_{0,p}$ can be done in polynomial time.

Proof: Let I be an instance of resource sharing in $\mathcal{I}_{0,p}$, with availability time T. For each resource i, let r_i denote the number of jobs j for which $p_{ij} = p$. Since each job requires either 0 or p units on each resource, and each copy of i can process at most $\lfloor T/p \rfloor$ tasks of length p, it follows that at least $\lceil r_i/\lfloor T/p \rfloor \rceil$ copies of resource i are required.

We reduce this instance to an instance of open-shop scheduling $O|p_{ij} \in \{0,1\}|C_{\max}$ with unit-length tasks. Note that since $p_{ij} \in \{0,1\}$, such an instance is defined by determining a set of machines, a set of jobs, and the subset of machines required by each job. For each resource i in the resource rental problem, we introduce $\lceil r_i/\lfloor T/p \rfloor \rceil$ machines of type i, and for every job j with $p_{ij} = p$, we add one of these machines to the subset of machines required by job j. This assignment is done such that each machine is required by at most $\lfloor T/p \rfloor$ jobs. In this way, we guarantee that the load on every machine in the resulting open-shop instance is at most $\lfloor T/p \rfloor$.

The constructed instance is a valid $O|p_{ij} \in \{0,1\}|C_{\max}$ problem, which is known to admit a polynomial-time optimal solution via a reduction to minimum edge coloring in bipartite graphs [17]. The solution is the maximum between the load on a single machine and the total demand of a job. Our construction guarantees that this value is at most $\lfloor T/p \rfloor$. The resulting open-shop schedule induces a feasible resource sharing schedule by stretching each unit-length task to a length p. The resulting makespan is T - that fits the availability time of the resources.

Since our construction uses the minimal number of machines per resource (matching the lower bound), and produces a feasible schedule, it is optimal. We conclude that resource sharing with $p_{ij} \in \{0, p\}$ can be solved optimally in polynomial time. ∎

Next, we bound the power of strong preemption for this class. It is interesting to note that $PoSP > 1$ even though the problem is polynomially solvable in both the preemptive and the non-preemptive models. Thus, preemptions do not affect the computational complexity of the problem but reduce the cost of an optimal solution.

Theorem 3.2: $\text{PoSP}(\mathcal{I}_{0,p}) = 2$.

Proof: Let $I \in \mathcal{I}_{0,p}$ be a resource sharing instance with $p_{ij} \in \{0, p\}$, time T, and resource costs c_i. Let r_i denote

the number of jobs that require resource i. The total load on resource i is therefore $r_i \cdot p$.

As discussed in Section II, the cost of an optimal solution with strong preemptions allowed is

$$\text{cost}_{\text{pre}}(I) = \sum_i \left\lceil \frac{\sum_j p_{ij}}{T} \right\rceil c_i = \sum_i \left\lceil \frac{r_i \cdot p}{T} \right\rceil c_i = \sum_i \left\lceil \frac{r_i}{T/p} \right\rceil c_i,$$

and the cost of an optimal solution *without* preemptions is:

$$\text{cost}_{\text{non-pre}}(I) = \sum_i \left\lceil \frac{r_i}{\lfloor T/p \rfloor} \right\rceil c_i.$$

We first note that if p divides T, then an optimal solution with preemptions allowed, does not use any preemptions, implying that $PoSP(I) = 1$. If p does not divide T, then since $p \leq T$, it holds that $\frac{T}{p} \geq 1$, implying $(T/p)/\lfloor T/p \rfloor < 2$. Therefore,

$$PoSP(I) = \frac{\sum_i \lceil r_i / \lfloor \frac{T}{p} \rfloor \rceil c_i}{\sum_i \left\lceil r_i / \frac{T}{p} \right\rceil c_i} < 2.$$

We show that the above analysis is tight, that is, we can get arbitrarily close to a $PoSP$ of 2. Specifically, given $0 < \delta \leq \frac{1}{2}$, we present an instance I such that $PoSP(I) \geq 2 - \delta$. As we show, a tight example exists already for instances with a single resource type.

Given $0 < \delta \leq \frac{1}{2}$, let $\epsilon \leq \delta$ such that $\frac{2-\epsilon}{\epsilon}$ and $\frac{1}{\epsilon}$ are integers. Let $T = 1$, $m = 1$, $n = \frac{2-\epsilon}{\epsilon}$, $p = \frac{1}{2-\epsilon}$ and $p_{1,j} = p$ for any $1 \leq j \leq n$.

Since $\frac{1}{2} < p \leq 1$, without preemptions no two jobs can share a copy of the resource, therefore, n copies of resource i are required, implying that the cost on any solution without preemptions is exactly $n = \frac{2-\epsilon}{\epsilon} = \frac{2}{\epsilon} - 1$.

On the other hand, the number of copies required with preemptions allowed is

$$\left\lceil \frac{r_1}{\frac{T}{p}} \right\rceil = \left\lceil \frac{n}{\frac{T}{p}} \right\rceil = \left\lceil \frac{(2-\epsilon)/\epsilon}{1/\frac{1}{2-\epsilon}} \right\rceil = \left\lceil \frac{(2-\epsilon)/\epsilon}{2-\epsilon} \right\rceil = \left\lceil \frac{1}{\epsilon} \right\rceil = \frac{1}{\epsilon}.$$

Therefore,

$$PoSP(I) = \frac{2/\epsilon - 1}{1/\epsilon} = \frac{2/\epsilon}{1/\epsilon} - \frac{1}{1/\epsilon} = 2 - \epsilon \geq 2 - \delta.$$

■

IV. Greedy Heuristics and Empirical Evaluation Experiment

A. Key Questions

In our experiments, we addressed the following questions regarding the performance of some natural greedy heuristics and the impact of preemptions in the resource sharing setting:

1) **Evaluate the performance of natural greedy algorithms**
   Since non-preemptive resource sharing is NP-hard, we rely on greedy heuristics as approximate solutions. Our goal is to test whether even simple heuristics produce significant cut down in resource costs.
2) **Investigate how parameter variations influence the efficiency of allocations with no preemptions, weak, and strong preemptions.**
   We systematically vary the number of jobs (n), the number of resources (m) and the variance of distributions of job lengths (p_{ij}). Our goal is to see how these changes amplify or diminish the empirical advantages of preemptions compared to non-preemptive allocations.
3) **Estimating the Power of Preemption.** For the restricted class $p_{ij} \in \{0, p\}$, we proved that PoSP cannot exceed 2 (see Section III). For general instances, we lack a theoretical upper bound for either PoSP or PoWP. To explore them, we compare the performance of our three algorithms (non-preemptive, weak-preemptive, and strong-preemptive). Even while not optimal, these heuristics provide a practical view of preemption benefits across diverse instances.

B. Experiment Design

In order to address the key questions outlined in Section IV-A, we built a simulator that generates a variety of resource sharing instances and evaluated the schedules produced for these instances by several greedy heuristics under different preemptive settings.

We measured the performance of each heuristic by comparing the total cost of its resulting schedule against two baseline values:

- The **optimal cost**, achieved when strong preemptions are allowed, and given by

$$C_{\text{opt}}(I) = \sum_{i \in M} c_i \cdot \left\lceil \frac{\sum_{j \in \mathcal{J}} p_{ij}}{T} \right\rceil.$$

- The **no-sharing cost**, which assumes that each non-empty task $p_{ij} > 0$ is assigned its own dedicated copy. This cost represents a naive allocation strategy and is given by:

$$C_{\text{no-share}}(I) = \sum_{i \in M} c_i \cdot |\{j \in \mathcal{J} \mid p_{ij} > 0\}|.$$

When evaluating the efficiency of various heuristics, we used the no-sharing cost as a normalization baseline.

For simplicity, all instances used in our experiments assume unit resource costs; that is, $c_i = 1$ for all $i \in M$. This

allows us to focus solely on the structural differences between scheduling strategies without the added complexity of cost heterogeneity.

1) Heuristics: We implemented three heuristics to resource sharing, corresponding to non-preemptive, weak-preemptive, and strong-preemptive scheduling. All three heuristics share the same core idea: iteratively assign each job's tasks to available resource copies using a first-fit strategy.

For scheduling with strong-preemptions we have used Algorithm 1, augmented with the following resource-sorting step: Before assigning a job, we sort its required resources in descending order of task duration. That is, for each job j, we reorder its set of required resources S_j according to p_{ij}, scheduling longer tasks first. This helps accommodating shorter tasks in the remaining gaps, and by that improving success rate of sharing the resources. For scheduling with weak-preemptions we used the same algorithm; however, in Step 5, we only considered assignments on a single copy.

Algorithm 3 below describes our heuristic for non-preemptive scheduling. In the non-preemptive setting, partial assignments may block later tasks of the same job and prevent any feasible solution. For example, if $T = 6$ and a job consists of two tasks of length 3, then the second task cannot be performed non-preemptively if the first task is not processed in $[0, 3)$ or in $[3, 6)$. To address this, we keep for each job a variable $left_j$ that stores the leftmost time-point in $[0, T]$ in which it is assigned. We schedule the job using a left-aligned strategy: tasks are scheduled one after the other, with each task placed as early as possible (starting at a leftmost time) and within a carefully restricted interval to ensure that it ends early enough -enabling the remaining tasks to be assigned such that the job completes by time T. If no such interval exists on an already-open copy of the corresponding resource, then a new copy is activated.

All three algorithms share the same Python implementation framework, managing available time segments in each machine's schedule and placing tasks accordingly. The final cost is computed by summing up the number of machines used for each resource.

2) Dataset Generation: Our method for creating benchmark instances generates task durations for each job in a consistent, yet randomized manner. Every instance is characterized by four parameters: number of jobs, n; number of resources, m; task-length variance $0 \leq \texttt{variance} \leq 1$; and job length as a fraction of T, $\texttt{span} \leq 1$.

For a given set of parameters, we construct a set of n jobs each consisting of m tasks, such that (i) for each job $1 \leq j \leq n$ and resource $1 \leq i \leq m$, with probability 0.2 the task of job j corresponding to resource i is empty, that is, $p_{ij} = 0$. (ii) Each of the remaining tasks has a length drawn uniformly from the range $[1-\texttt{variance}, 1+\texttt{variance}]$, and then scaled such that the total tasks length is $\texttt{span}$. We assume that $T = 1$. This is w.l.o.g. since in the last step, the task durations are scaled such that the total job length is $\texttt{span} \cdot T$.

Algorithm 3 Greedy Algorithms for Non-Preemptive Scheduling

1: **for** each job $j \in \mathcal{J}$ **do**
2: Sort S_j (the required resources of j) by non-increasing order of p_{ij}
3: Let $left_j \leftarrow 0$, $p_j \leftarrow \sum_{i \in S_j} p_{ij}$, $scheduled \leftarrow 0$
4: **for** each $i \in S_j$ where $p_{ij} > 0$ **do**
5: Let $remaining \leftarrow p_j - scheduled$
6: Let $latest_end \leftarrow T - (remaining - p_{ij})$
7: Assign task (i, j) as a single interval of length p_{ij} on an existing copy, or a new copy of resource i within $[left_j, latest_end]$
8: Let $left_j \leftarrow$ end time of assigned interval
9: Let $scheduled \leftarrow scheduled + p_{ij}$
10: Update current solution and resource state
11: **end for**
12: **end for**

To evaluate how different structural parameters affect scheduling performance, we generated four large sets of instances, each containing 1000 samples. In each set, we fixed three parameters and systematically varied the fourth: number of jobs, number of resources, variance, or span. This design isolates the influence of each factor on the heuristics' relative performance. When fixed, we used the following parameters: $n = 10$ jobs, $m = 3$ resources, variance 0.9, and span 1. Our experiments show that these values best capture the characteristics of each heuristic.

V. Experimental Results

We begin by presenting the raw results of our experiments. Figures 5- 8 summarize the efficiency of each of the heuristics with respect to four parameters: number of jobs, number of resources, variance, and span. For each experiment (of 1000 samples) we calculated the average solution cost of the three heuristics, as well as the optimal cost. These costs are normalized relative to the no-sharing baseline, giving the *efficiency* of each heuristic, which is depicted in the figures.

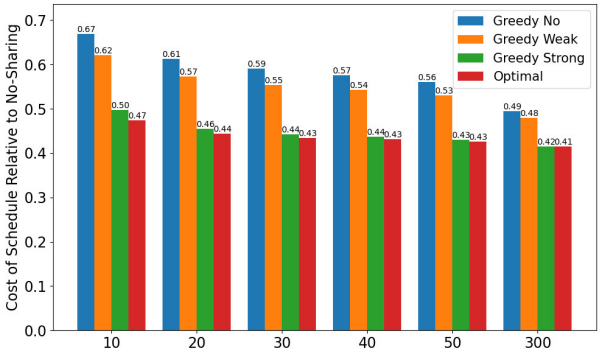

Fig. 5. Efficiency for variable the number of jobs.

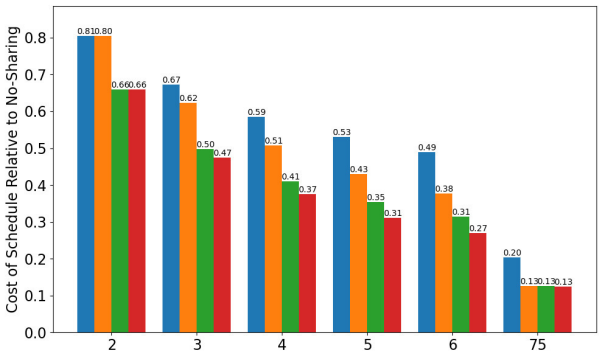

Fig. 6. Efficiency for variable number of resources.

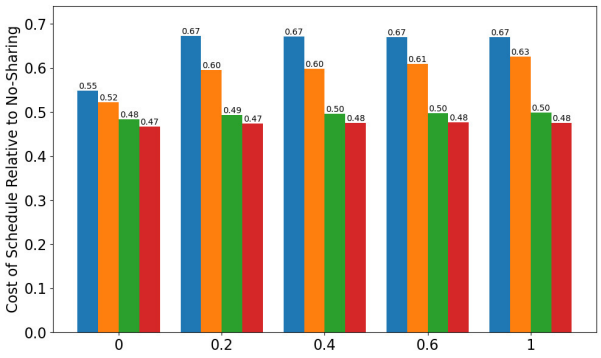

Fig. 7. Efficiency for variable `variance`.

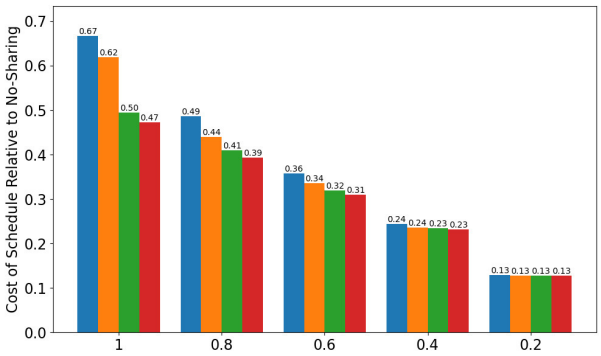

Fig. 8. Efficiency for variable `span` (total job length as a fraction of T).

We now turn to interpreting these results in light of the three research questions introduced earlier.

A. (Q1) How well do the greedy algorithms approximate optimal schedules?

Our results show that all greedy algorithms remain within a constant factor of the optimal strong-preemptive schedule across all tested parameters. In favorable cases, greedy schedules approximate the optimum within ratio 1.1. In more constrained scenarios (e.g., with many resources), the gap may increase, but none of the heuristics exceeded a factor of 2. This empirical observation supports the practical use of these heuristics even in the absence of theoretical guarantees.

B. (Q2) What is the effect of parameter variations on preemption benefits?

We observed how each structural parameter shaped the cost gap between non-preemptive, weak-preemptive, and strong-preemptive settings:

a) Number of Jobs (n): As n increases, all algorithms achieve improved efficiency relative to the no-sharing baseline. The strong-preemptive heuristic continues to closely approximate the optimal cost. Meanwhile, the non-preemptive heuristic gets increasingly closer to the weak-preemptive approach, and both converge to approximately 1.25 times the cost of the optimal solution.

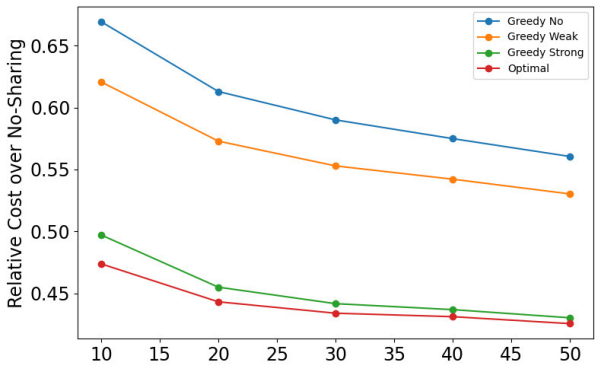

Fig. 9. Relative cost over no-sharing cost as number of jobs increases.

b) Number of Resources (m): As m increases, all of our algorithms achieve improved efficiency relative to the no-sharing baseline. The strong-preemptive heuristic continues to produce near-optimal results, and the weak-preemptive algorithm closely follows it, with the gap between them narrowing as m grows. The non-preemptive heuristic also benefits from increased resources, but to a lesser extent - its relative cost remains around 1.5 times the optimal.

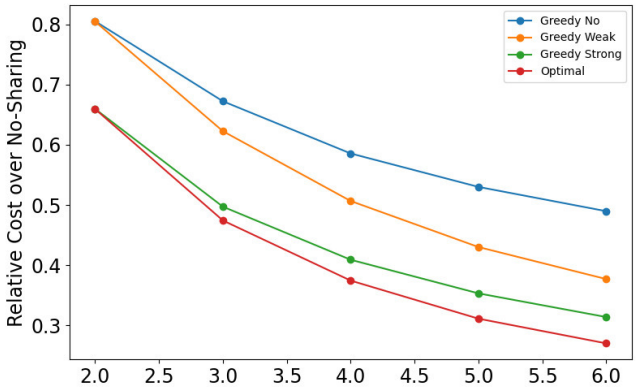

Fig. 10. Relative cost over no-sharing cost as number of resources increases.

c) Variance of Task Durations: Our results indicate that variance in task durations significantly impacts scheduling performance when it first appears (transitioning from zero variance to some positive value). However, beyond this initial effect, the magnitude of variance has minimal influence on the algorithm performance. Once some level of variance exists, increasing it further does not substantially change the gap between the heuristics, suggesting that it is the presence of variance, rather than its magnitude, that defines the difficulty of the instances.

d) Span: Recall that the span determines the total length of the jobs' tasks. As expected, decreasing the span consistently makes the problem easier, since tasks can be more flexibly scheduled without conflicts, leading to lower overall costs. Our results show that beyond a certain point, the problem becomes nearly trivial, with all algorithms, in particular the non-preemptive one, achieving near-optimal results.

C. (Q3) Estimating the Power of Preemption in General Cases

In the general case, across a wide range of tested instances with relatively low values of n and m, the three approaches—non-preemptive, weak-preemptive, and strong-preemptive - are relatively comparable. In those values, we find that non-preemptive schedules cost on average approximately 50% more than strong-preemptive ones, while weak-preemptive schedules cost about 25% more than strong-preemptive schedules. Thus, on average, the *power of strong preemption* is $PoSP(I) = 1.5$, and the *power of migration* is $PoM(I) = 1.25$. While these results are based on smaller parameter settings, the trends observed in earlier sections indicate similar or even stronger effects for larger instances. In particular, as the number of jobs increases, the non-preemptive and weak-preemptive heuristics converges toward a relative cost of approximately 1.25 compared to the optimal. While as the number of resources increases, the weak-preemptive algorithm achieves near-optimal performance, closing the gap with the strong-preemptive approach.

VI. Summary and Future Work

In this paper we analyzed a scheduling problem arising in environments in which resources may be shared by several users. The goal is to minimize the total cost of allocated resources. We summarize below our contribution and the main takeaways from our theoretical and empirical study of the resource sharing problem.

a) Optimal Algorithm for Scheduling with Preemptions Allowed: We developed an algorithm for solving the problem optimally when strong preemptions are allowed. Our optimal algorithm is suitable for all classes of instances, and achieves the lowest possible cost, given by

$$C_{\text{opt}}(I) = \sum_{i \in M} c_i \cdot \left\lceil \frac{\sum_{j \in \mathcal{J}} p_{ij}}{T} \right\rceil .$$

b) Tight analysis of the class $\mathcal{I}_{0,p}$: For the class $\mathcal{I}_{0,p}$, we developed an optimal algorithm for scheduling without preemptions and established a tight bound of 2 for the power of strong preemptions. We conjecture that this bound is valid for additional classes.

c) Greedy Approaches and Approximation: We developed three greedy heuristics for resource sharing: non-preemptive, weak-preemptive, and strong-preemptive, and found that all provide efficient approximations. As expected, the weak and strong preemptive variants consistently outperform the non-preemptive approach. In all parameter regimes, the heuristics remained within a constant factor of the optimal cost.

Our work leaves open several directions for future work:

1) *Theoretical analysis of the general case:* A deeper understanding of the general case is still needed. Two specific directions stand out:
   - Determining tight upper bounds for the power of weak and strong preemptions (PoWP and PoSP), as well as the power of migration (PoM).
   - Deriving theoretical worst-case approximation guarantees for the proposed heuristics, complementing the observed empirical performance.
2) *Analysis of additional restricted classes of instances:* Beyond the $\mathcal{I}_{0,p}$ class, it would be interesting to analyze additional classes of instances, arising in real-world applications.

- Instances with a constant number of job types, where all jobs of the same type have the same resource requirements.
- Instances with job-dependent or resource-dependent processing times, e.g., $p_{ij} = p_j$ or $p_{ij} = p_i$.
- Instances in which each job consists of a bounded number of tasks (e.g., $|S_j| = 2$ for all j).

For each such class, future work should aim to determine whether an optimal solution can be computed in polynomial time, or alternatively prove hardness and develop approximation algorithms.

3) *Modeling costs for preemptions and migrations:* Our model assumes that preemptions and migrations are not associated with a cost. In real-world settings, however, splitting or migrating tasks may involve setup or transition costs. Extending the model to incorporate these costs may yield richer structural insights and lead to new trade-offs between flexibility and efficiency. Analyzing the effect of such costs on both the complexity and the power of preemptions is a promising direction for future work.

***Abstract*—This study provides a systematic review of how the impact and adaptation of digital assistant technologies (DATs) are defined, operationalized, and studied, synthesizing key domains where DATs generate or are expected to generate value. Based on an analysis of 61 articles published since 2013, it identifies five main areas of impact: productivity and efficiency, business development, resource optimization, quality enhancement, and the promotion of learning and creativity. The review highlights DAT adoption across various disciplines and industries, while revealing limited longitudinal research on benefits and adaptation. Key gaps remain in understanding strategic use and sustained impact. Future research should explore longitudinal comparisons of recently introduced generative AI-driven DATs and their organizational implications. This review contributes to information systems research by structuring current knowledge on DAT adoption and outcomes, and by proposing a research agenda to support deeper exploration of their value and long-term integration.**

***Index Terms*—DATs, SLR, generative artificial intelligence, assistant, chatbot, agent, Copilot, Gemini, ChatGPT, productivity software.**

I. Introduction

DIGITAL assistant technologies (DATs)—such as intelligent agents, chatbots, and voice assistants—hold significant transformative potential for large enterprises by automating routine tasks, enhancing data-driven decision-making, and enriching user interactions across various business contexts [1]. The rapid breakthroughs in artificial intelligence (AI), particularly in generative artificial intelligence (GAI), have further amplified the capabilities of DATs sparking a competitive race among organizations to identify and leverage optimal use cases [2], [3], [4]. As a result, substantial investments are being directed toward AI-driven DATs aimed at enhancing productivity, efficiency, and strategic value [5]. These DATs enable automation, reduce non-value-adding or repetitive tasks, and improve user interactions across diverse business contexts. Despite their growing adoption and capabilities, particularly with the emergence of GAI, the specific mechanisms enabling organizations to capture productivity benefits from DATs remain insufficiently understood [1]. This research gap is particularly evident in widely adopted productivity platforms such as Microsoft 365 and Google Workspace, where DAT integration is in its early stages [6], [7]. These platforms dominate the productivity software market: as of February 2024, Google Workspace held over 44% of the global market, and Microsoft 365 approximately 30%, with some estimates exceeding 48%, representing over 345 million active paid users [8], [9], [10]. Given their market dominance, future academic research into these technologies is expected to yield substantial insights regarding their impact on productivity. Therefore, a critical—yet underexplored—area within IS research involves understanding how these technologies are embedded into everyday work processes and what factors influence their successful adoption.

Given these developments, it is also essential to examine how DATs were applied in the pre-GAI era, what impacts were studied, and how these insights can inform the integration of GAI-enhanced DATs within productivity software contexts today.

This systematic literature review (SLR) aims to synthesize and contextualize existing research on DAT adoption, identify key areas of impact, and articulate their operational and strategic implications for organizations. Beyond mapping the current knowledge base, it advances a research agenda that addresses pressing questions arising from the emergence of GAI in DAT-focused IS research. The following research questions guide the focus of this SLR:

- RQ1: How does existing literature evaluate and characterize the impact of DATs in organizational settings, particularly in terms of measurement, intended outcomes, and the reallocation of freed-up capacity?
- RQ2: How does existing literature examine the use of DAT in conjunction with proprietary productivity software in organizational contexts?

The study begins with background information, followed by methodology, findings (including bibliometric and data analyses), discussion addressing the research questions with critical reflections and recommendations. It concludes with key findings, implications, limitations, and a research agenda outlining thematic and methodological directions.

II. Research background

The recent proliferation of AI-related concepts—including machine learning, GAI, and transformer architectures—reflects their growing relevance across organizational contexts [1], [11]. Central to these developments are DATs, which encompass chatbots, intelligent personal assistants, virtual assistants (VA), and intelligent agents [12]. These technologies increasingly manifest in branded forms such as Gemini, Claude, and ChatGPT, illustrating the convergence of GAI

and DATs in organizational environments [13], [14], [15], [16]. GAI, as an advanced form of machine learning, generates novel content (e.g., text, images, audio, and video) by analyzing large-scale datasets [17]. GAI an advanced form of machine learning, has evolved with large language models (LLMs) like ChatGPT and Google Gemini, enabling the creation of novel text, images, audio, and video from large-scale data sets [6], [17], [18]. Unlike traditional predictive AI, it emphasizes creative generation and signals progress toward artificial general intelligence, enabling a wide range of potential use cases for organizations. With expanding multimodal capabilities, LLMs have become key drivers of innovation across sectors and are increasingly deployed through DATs in organizational contexts [1], [19]. Microsoft Copilot for 365 and Google Gemini for Workspace serve as VAs, highlighting the convergence of GAI and workplace productivity—reshaping workflows, enhancing collaboration, and transforming enterprise ecosystems [4], [12], [20], [21].

Productivity software—also known as office productivity software [22], [23]—extends beyond traditional tasks like text writing, spreadsheets, and presentations. It now encompasses intelligent collaboration, automation, and workflow orchestration—tools that are increasingly infused with GAI to support knowledge work at scale [24], [25]. The integration of GAI into productivity software represents a major paradigm shift [22]. Consequently, this study adopts the term "productivity software" to reflect this expanded functionality by products such as Microsoft 365 and Google Workspace.

III. Research Methodology

This section outlines the methodological framework guiding the SLR. The review systematically examines the literature within DAT research [27]. By aggregating and analyzing existing research, it provides an in-depth overview of the current scholarly discourse [28], [29]. Following the structure proposed by [30], the process unfolds in three phases: planning (i), review (ii), and dissemination (iii).

In the planning phase, the study's objectives and research questions—introduced in Chapter 1—are articulated to establish a clear conceptual basis. This phase also involves adopting structured, transparent, and replicable methods to identify, select, and evaluate relevant articles [30]. ensuring methodological rigor. The subsequent phases involve systematic data extraction and in-depth analysis [31], [32].

An initial search in the Scopus database yielded 5,469 articles. During the review phase (ii), iterative keyword and sample refinement using the PRISMA method narrowed the sample to 61 articles, prioritizing relevance and rigor [31]. In the dissemination phase (iii), data were extracted and synthesized, enabling critical interpretation of the findings.

ChatGPT-4o was employed to "identify synonyms, related terms, and language variations" [30, p. 87] for constructing the initial review sample, ultimately resulting in the manual creation of the final search string incorporating findings from [1].

IV. Planning the Review (I): Initial Review Sample

The initial search string was intentionally broad, focusing on keywords related to the three DAT concepts: assistant, agent, and chatbot [1]. Additional keywords such as "digital," "virtual," and "artificial intelligence" were included to define the scope and direction of the research [12]. Adjectives describing broader potential benefits of DAT applications were deliberately excluded to ensure neutrality, avoid bias, and minimize the risk of overlooking relevant research streams or topics. These keywords were specifically targeted within the title, keywords, or abstract of articles.

The search string was structured into two keyword buckets: one representing the DAT concept and the other indicating digital characteristics. The buckets were linked using AND for a systematic search, while keywords within each bucket were combined with OR (see Table I). The first bucket was designed to address jingle-jangle fallacies in the DAT domain, ensuring comprehensive coverage of all relevant research streams and preventing the exclusion of pertinent DATs due to inconsistent terminology [1]. We included journal articles for their recognized credibility [34], [35], [36], [37] and peer-reviewed conference proceedings for their role in providing early insights into emerging knowledge, particularly relevant to IS and GAI research [38]. To ensure comprehensive coverage, our search targeted German and English publications across all subject areas, capturing a wide range of industries benefiting from VA. Our focus was on articles and proceedings published after 2013, restricting the scope to completed research publications. To ensure the inclusion of all relevant and representative IS outlets in the initial sample, we utilized the '3XL' filter from Litbaskets.io, accessed on January 19, 2025, which is a curated set of 847 ranked IS journals [39]. Litbaskets.io effectively supports literature searches via Scopus, the largest multidisciplinary database [40], resulting in a total of 5,469 articles.

TABLE I
INITIAL SEARCH STRING

Basket 3XL / 847 essential IS journals	
searched in title, keywords, or abstract of a article or proceeding	
published after 2013 until January 19th 2025	
English / German only	
Keywords	
Technology **AND**	characteristic
agent* **OR** assistant* **OR** chatbot*	"artificial intelligence" **OR** digital **OR** virtual
5,469 articles	

We utilized VOSviewer 1.6.20 to examine the initial search results, creating visualization maps that depict articles and keywords as circles, where the size and proximity reflect activity levels and the strength of relationships [41]. A thesaurus file was used to standardize variations in spelling and plural forms of keywords (e.g., GAI/generative artificial intelligence, assistant/assistants). 37,415 unique keywords, grouping 1,552 (with a minimum occurrence of 10) into five distinct clusters based on co-occurrence patterns, as shown in Fig. 1. The analysis focuses on keywords related to RQ1—operational efficiency, workforce productivity, and business performance.

Cluster 1 (red) contains 778 items. The most prominent keyword in this cluster is "artificial intelligence," which appears 2,011 times with a total link strength of 19,020, indicating its central role in the research landscape.

A deeper examination of the keyword distribution highlights several terms associated with quality and efficiency. Notable terms include "quality of service" (569, occurrences: 65), "quality of life" (1,194, occurrences: 46), "health care quality" (416, occurrences: 16), "high quality" (97, occurrences: 13), "data quality" (238, occurrences: 11), and "image quality" (266, occurrences: 11). Efficiency is reinforced by "efficiency" (453, occurrences: 46) and "business process" (87, occurrences: 11), underscoring AI's role in optimizing operations and performance.

Cluster 2 (green) contains 442 items and is centered around the keyword "humans" (link strength: 25,335), which appears 1,180 times. Notably, despite having nearly half the occurrences of "artificial intelligence", this keyword exhibits a stronger link strength to other clusters. This extensive connectivity may stem from the focus of research on human-machine interaction.

Rather than presenting a unified theme, Cluster 2 consists of keywords commonly associated with human-machine interaction and healthcare digitization. The intensive linkage between Cluster 1 and Cluster 2 further emphasizes the high research focus and the growing significance of DATs, particularly in healthcare. This is reflected in key terms such as "chatbots" (link strength: 5,839, occurrences: 641), "conversational agents" (2,888, occurrences: 251), "personal digital assistant" (2,959, occurrences: 180), and "artificial intelligence chatbots" (797, occurrences: 62). Supporting this healthcare-driven focus are keywords like "health care" (2,226, occurrences: 132), "digital health" (2,432, occurrences: 101), and "communication" (2,118, occurrences: 112), all of which reinforce the relevance of AI-driven conversational technologies in the medical domain. The keyword "productivity"—appearing 11 times with a link strength of 156—is particularly relevant to the RQs and is positioned between Clusters 1 and 2 (within cluster 2). Its placement indicates the significance of productivity implications across both fields, further emphasizing DATs' potential impact.

Cluster 3 (blue), which contains 183 keywords related to research articles on molecular medicine and drug research.

Similarly, Cluster 4 (yellow) consists of 106 items and is centered around "algorithms" (link strength: 4,676, occurrences: 245). The primary theme of this cluster revolves around computer-aided or assisted diagnosis, as illustrated by keywords such as "computer-aided diagnosis" (446, occurrences: 24) and "computer-assisted diagnosis" (677, occurrences: 23). However, this cluster does not directly relate to the benefits of DATs in the context of large organizations.

Cluster 5 (purple), the smallest cluster with only 31 items, focuses on diabetes and potential treatments. However, its scattered position in the network indicates weak linkage to Clusters 1 and 2 and no significant relevance to the RQs. As a result, Clusters 3–5 were considered peripheral and filtered out.

The initial keyword analysis identifies terms for the final search query. With 5,469 articles, no content analysis was conducted, so keyword interpretations should be considered with caution. Still, three key insights emerge for refinement and expansion in the final search query:

- AI-related terms dominate, emphasizing its role in efficiency, quality, and business operations. Keywords such as "efficiency," "quality of service," and "business process" highlight AI's impact on optimizing workflows and enhancing productivity.
- Cluster 2 focuses on human-machine interaction, particularly in healthcare. Terms like "chatbots," "conversational agents," and "digital health" reflect the presents of DATs. Context analysis is needed to filter out peripheral medical topics.
- To ensure relevance, "quality," "efficiency," "productivity," and "business process" should be included in the next search string. These terms align with the RQs, help exclude irrelevant Clusters 3–5 and will help capture all relevant research streams.

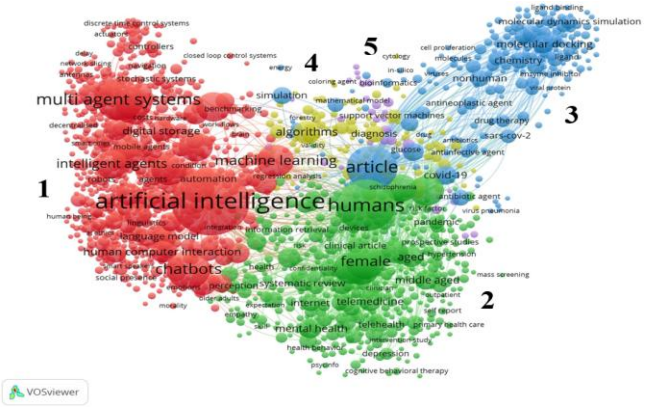

Fig. 1. Keyword co-occurrence network visualization - initial review sample (n= 5,469)

V. Performing the Review (II): Final Search Query

Based on the initial sample analysis, the final search string was refined with additional keywords, resulting in the query: ((agent* OR assistant* OR chatbot*) AND ("artificial intelligence" OR digital OR virtual) AND (quality OR efficiency OR productivity OR "business process*")). This refinement yielded a comprehensive dataset of 1,141 articles, exported on February 1, 2025. Following the PRISMA framework [31] (see Fig. 2), we performed a systematic selection process, including: (a) removal of duplicate or withdrawn articles, (b) screening of titles and abstracts based on predefined exclusion criteria, (c) a comprehensive full-text review to identify articles meeting the inclusion criteria, and (d) backward and forward citation searches to identify additional relevant articles [35], [37]. Following [34] we repeated the process for newly added articles until the sample achieved depth, consistency, and clarity.

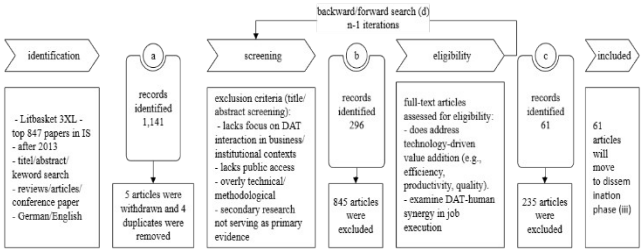

Fig. 2. Steps of the SLR with PRIMSA method according to [31]

VI. Dissemination (iii): Key findings & synthesis

A. Bibliometric Examination of the included dataset

The refinement process (see chapter V) yielded 61 articles containing 723 keywords, visualized in Fig. 3.This analysis identified three primary clusters: (1) DAT technologies and sales/customer service, (2) AI-related functional patterns and DATs, and (3) DAT and AI in research. The keyword 'artificial intelligence' emerged as the central node, serving as the nucleus and primary connector within this dataset.

This significance is driven by the pervasive integration of AI and GAI across various domains, which is "generating significant interest due to its potential to enhance personal efficiency" [4, p. 5]. The bibliometric analysis of the included sample reveals a steady increase in DAT adoption within corporate and institutional contexts. The number of relevant publications has grown from a single publication in 2019 to four in 2020, followed by seven in 2021 and six in 2022. Notably, a sharp increase was observed following the introduction of ChatGPT in November 2022 [18], with 13 publications in 2023 and 26 in 2024. Interestingly, in January 2025 alone, four articles have already been published, suggesting the potential for continued significant growth if this trend persists.

Keyword analysis. Conducting a keyword and co-occurrence analysis on the inclusion sample further reinforces a homogeneous pattern, as illustrated in Fig. 3. A total of 40 keywords met the threshold of three or more co-occurrences, with AI being the most prevalent term (40 occurrences). Notably, six distinct DATs were identified: chatbot (30), ChatGPT (14), artificial intelligence chatbots (4), intelligent assistants (4), conversational agents (4), VA (4), and intelligent agents (3). Copilot for M365 and Gemini for Google Workspace were not present in the key-word co-occurrence analysis. Collectively, these DAT terms account for 23.8% of the full co-occurrence sample. In relation to RQ1, the analysis further identified four keywords representing distinct measures for evaluating the potential impact of DAT integration within the final sample: efficiency (4), accuracy (3), high quality (3), and quality of service (3). These terms emphasize key dimensions in assessing the effectiveness and performance of DAT adoption across different contexts. Notably, productivity no longer appeared as a keyword in this sample.

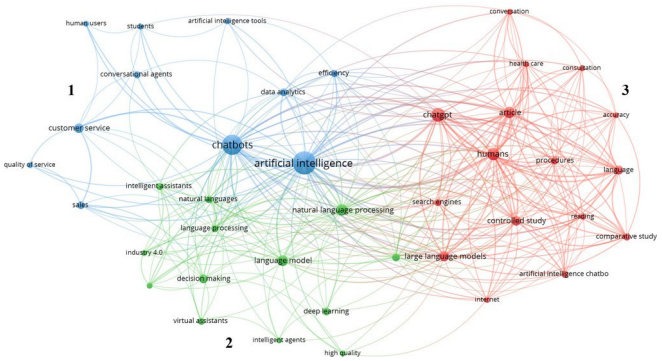

Fig. 3 Keyword co-occurrence network visualization (n=61 articles)

Documents by outlets. The examination of document types revealed the following distribution: journal articles (47; 77%) and conference papers (14; 23%). The prevalence of journal articles suggests that the topic has been extensively studied within a short period of time (since 2019), indicating strong scholarly engagement in the field [42]. The 61 publications analyzed were spread across 47 distinct outlets (see Table II). The top three publication outlets were the Journal of Medical Internet Research (6 articles; 15.4%), IFIP Advances in Information and Communication Technology (3 articles; 7.7%), and CEUR Workshop Proceedings (3 articles; 7.7%). This distribution underscores the interdisciplinary nature of the research, with contributions spanning medical informatics, information and communication technology, and other IS outlets. This emphasis likely accounts for the human-centered cluster 3 in Fig. 3, which highlights extensive research on human-machine interaction and healthcare.

Table II

Distribution of journals by total count and citation sum in the final sample (count >2)

Journal	Count		Sum citations/journal	
Journal of Medical Internet Research	6	9.8%	87	11.9%
IFIP Advances in Information and Communication Technology	3	4.9%	9	1.2%
CEUR Workshop Proceedings	3	4.9%	4	0.5%
Lecture Notes in Business Information Processing	2	3.3%	12	1.6%
International Journal of Medical Informatics	2	3.3%	16	2.2%
International Conference on Software Business	2	3.3%	2	0.3%
Expert Systems with Applications	2	3.3%	74	10.1%
Electronic Commerce Research and Applications	2	3.3%	4	0.5%
Other 39 journals count < 2	39	63.9%	734	77.9%
Total	61	100.0%	942	100.0%

Co-Authorship and author analysis. The analysis identified the key contributors within this sample, revealing that only 13 researchers had at least two co-authorships, defined as collab-

orative efforts between scholars contributing to the same publication. This group represents less than 12% of the total 285 authors in the dataset. Notably, these 13 researchers accounted for 43.7% of the total citation count, with Yu Chen having two co-authorships and 200 citations. The small number of scholars with >1 article underscores a potential gap indicating that relatively few researchers are consistently contributing within the domain. Among the 285 contributors, only one network is linked through six publications, primarily due to the work of Massimo Mecella. His research encompasses conversational agents in business process models [43], chatbots in digital factories [44], and an assistant for legal users [45]. The scarcity of strong interconnections and collaborative efforts among re-searchers highlights a highly segmented field with limited cooperation [46]. From an article perspective, the top 15 most influential publications in the sample account for 811 citations, representing 86.1% of the total 942 citations. Online appendix Table I highlights these key contributions, illustrating their impact on the overall sample through substantial citation counts. Overall, the absence of strong connections between authors, as indicated by link strength, may suggest a lack of collaborative research efforts within the DAT domain.

B. Data Analysis of existing literature

Data analysis – type of research. We analyzed the sample and present an overview of the research design and approach in Table III, with article-level details illustrated in Fig. 4 [47]. The findings reveal a strong emphasis on empirical research, with 56 articles (91.8%) adopting empirical approaches. Among these, quantitative designs are most common (26/42.6%), typically aligned with positivist (21/34.4%) and post-positivist (11/18.0%) worldviews (see Fig. 4), reflecting a focus on objectivity, measurement, and causal inference.

TABLE III

OVERVIEW OF RESEARCH DESIGN AND APPROACH

Design	count	Research approach	count
Quantitative	26	experimental	14
		survey	6
		comparative assessment	5
		interviews	1
Qualitative	15	experimental	4
		design science res.	3
		case study	2
		interviews	2
		co-design study	1
		comparative assessment	1
		survey	1
		systematic mapping	1
Mixed method	15	design science res.	6
		experimental	4
		convergent parallel	2
		exploratory sequential	2
		comparative assessment	1
Non-empir.	5	design science res.	3
		conceptual analysis	1
		practise-based	1

Notably, not a single study employed longitudinal research design. Despite the dominance of empirical methods, all 61 articles relied on alternative research approaches, as detailed throughout this chapter. This absence of longitudinal inquiry highlights a significant gap in understanding the sustained use, adaptation, and long-term impact of DAT within real-world contexts [48]. It underscores the importance of future research that extends beyond immediate performance metrics to investigate how users, systems, and organizational environments co-evolve over time.

Qualitative designs (15/24.6%) show stronger ties to interpretivist perspectives (7/11.5%), aiming to capture contextual depth and user experiences, though still secondary in representation. Mixed methods articles (15/24.6%) often reflect a pragmatist worldview (22/36.1%), blending quantitative and qualitative paradigms to pursue practical, problem-solving goals. The dominance of pragmatist and positivist orientations (shaped by inclusion criteria) reflects a focus on outcome-driven research, emphasizing quantifiable data and replicable cause-and-effect relationships [49]. The remaining non-empirical research (5/8.2%)—including design science, conceptual analysis, and practice-based work—supports theoretical exploration and methodological innovation, though it remains limited in volume. Overall, the analysis reflect a field focused on solution-oriented inquiry, emphasizing real-world performance, usability, and iterative refinement of DAT [50], [51].

While empirical inquiry dominates, the limited use of established IS theories reinforces the field's developmental stage. Only four articles explicitly employed IS theories, further underscoring this empirical orientation [52]. These include the Technology Acceptance Model (TAM) and DeLone & McLean IS Success Model [53], the Decomposed Theory of Planned Behavior [54], Fit-Viability Theory [55], and Attribution Theory [55]. The limited use of theory reflects the field's exploratory, application-driven nature, where technical feasibility often takes precedence. However, as DAT become more embedded in daily life, the growing uptake of IS theories since 2021 signals a timely shift toward deeper conceptual integration and a stronger focus on adoption. [52].

Notably, purely secondary research (e.g., SLRs, taxonomies, or frameworks) was excluded in the PRISMA process. In sum, research on DAT is empirical, pragmatic, and impact-driven, with a clear focus on performance and usability. However, the limited use of IS theories and interpretive lenses signals a need for deeper conceptual grounding and contextual insight [50].

Data Analysis – Concepts and DAT used in final sample. We further analyzed the concepts and technologies referenced in each publication to understand their application across various domains and use cases. Our review found that the assistant concept appears 34 times (55.7%), making it the most prevalent, followed by the agent concept, which is featured in 22 articles (36.1%). Some articles discuss multiple concepts or DATs, which is why the total does not sum to 61 in the more detailed Fig. 4. For example, Copilot and Gemini fall

| Reference | Entity: corporate | Entity: institutional | Segment/industry: academia | automotive | process management | construction | e-commerce | education | finance | general | healthcare | insurance | justice | logistics | manufacturing | marketing | public sector | social media | software development/coding | User group: authorities | bunker | business decision maker | customer service | customer service/sales agents | dentistry staff | engineers | knowledge worker | legal users | librarian | manufactoring worker | market maker | medical staff | mental health staff | patients | platform providers/content moderation | process designer | programmer | purchaser/buyer | questioner | researcher | students | teaching staff | trader | DAT concept studied: assistant | agent | chatbot | assistant Bard | assistant ChatGPT | assistant Claude | assistant Copilot | assistant Gemini | assistant Bloomz | AI technology: DL | GAI | ML | NLP | RL | SL | unspecified | Research setup: Philosopical worldview | Research design | Reserach approach | # Total quant sample size |
|---|---|---

into how each segment adopts and prioritizes DATs—particularly valuable for future research focused on specific sectors, such as large enterprises. 17 industries or segments were also identified, listed alphabetically by frequency. Fig. 4 presents the coded matrix of user groups within their respective application domains. The distribution in Fig. 4 underscores the multidisciplinary scope of DAT applications, with healthcare and general applications as the dominant domains, followed by software development/coding, education, and manufacturing. The term general (14/23%) encompasses publications with a broad scope, spanning multiple industries, general applications, or lacking a distinct focus. The most prominent industry-specific fields are healthcare (15/24.6%) and software development/coding (5/8.2%). Together, these three fields account for 34 (55.7%) of the total sample, illustrating the primary domains of the researched domain. However, a significant portion of the re-search remains broad and use-case unrelated, categorized under "general." This imbalance may suggest a need for more specialized research to generate deeper insights across various fields and broaden the understanding beyond the dominant healthcare domain.

Fig. 4 also illustrates the distribution of user groups addressed by the DAT, along with their respective counts and percentages. The most present user groups overall are knowledge workers (11/18.0%), medical staff (11/18.0%), and customer service (7/11.5%) which includes the single-occurrence customer service and sales agent group. In the corporate sector, knowledge workers dominate (10/16.4%), followed by customer service roles (7/11.5%), which exist exclusively in the corporate environment in this sample. The institutional sector is primarily driven by healthcare-related professionals (9/14.8%), though healthcare also appears in the corporate sector with 4 occurrences (6.6%), indicating its cross-sector relevance. Interestingly, DATs are also well established in supporting both institutional and corporate users in programming and software development (6/9.8%) across multiple domains, highlighting their significance in technological and digital advancements.

From a technology perspective, corporate research primarily focuses on assistants (18/45%) and chatbots (17/4%), which together represent 88% of articles in this category. One study examined both concepts jointly. Agents (4/10%) play a minor role in corporate research. A similar but more pronounced trend is observed in institutional research, where assistants account for 76% of articles and chatbots for 24%, primarily in healthcare, academia, and education. Agents are absent in institutional research, as they typically operate within clear and closed boundaries, handling structured tasks [5]. A detailed list of DAT occurrences in each article and its corresponding domain is provided in Fig. 4.

VII. Main findings

This section represents the core contribution of this SLR, synthesizing key findings on DAT applications, their intended functions, and the metrics and objectives guiding their implementation. It directly addresses RQ1 and RQ2 by examining the distinct characteristics of DAT utilization across the 61 analyzed articles. Table IV provides a structured overview of the five focus clusters identified through open coding, which were subsequently categorized into five application goal clusters using axial coding [60]. Each of these clusters is further explored and described in the following sections. The most prevalent subcategory, efficiency/quality, was examined in 13 articles and is analyzed in greater detail in online appendix Fig. 1. The categories will be briefly outlined, with an emphasis on the key measures that define them. Since some subcategories combine multiple measures within individual articles, not every specific combination will be discussed separately. However, their occurrence has been systematically coded within the analyzed articles.

Productivity & efficiency. Productivity and efficiency form the most dominant cluster (32/52.5%), serving as key drivers in business and institutional settings by optimizing resource use, accelerating operations, and availability [28, 65]. A major focus is efficiency and quality (13/21.3%), where DATs streamline processes while maintaining high standards, reducing manual effort and improving accuracy [61]. For example, Calisto et al. (2021) examined the impact of DATs on workflow efficiency and diagnostic quality in breast cancer [62], while Belhaj et al. (2021) demonstrated how such technologies can enhance the quality and efficiency of student-oriented services [63]. Productivity (9/14.8%) is closely linked, as DATs boost output by minimizing inefficiencies and accelerating task execution [5]. Brachten et al. (2021) argue that "chatbots should be positioned as personal technologies designed to support users and enhance productivity" [49 p. 11]. Efficiency (5/8.2%) reflects the role of DATs in eliminating bottlenecks and optimizing workflows, particularly in enterprise automation [28]. Some articles highlight a combined impact on efficiency and productivity (2/3.3%), where DATs simultaneously reduce resource waste and enhance overall performance [66]. Beyond speed and optimization, efficiency and effectiveness (1/1.6%) emphasize DATs' role in enhancing goal achievement and adaptive decision-making [67]. Finally, productivity and health protection (1/1.6%) highlight how DATs support both output and worker well-being [68].

Business growth & development. Business growth and development emerges as the second most prominent cluster (14/23%), underscoring the pivotal role of DATs strategic business expansion, decision-making, and revenue optimization. By facilitating value-driven tasks, business scalability, and cost efficiency, DATs enhance organizational competitiveness [44], [64], [65]. A key application goal within this cluster is enhancing focus on value-added tasks (7/11.5%) by reducing redundant activities, thereby improving overall performance, quality, and work-load efficiency. De Luzi (2023) finds that ChatGPT reduces processing time in legal work, freeing up time for higher-value tasks [45]. By automating mundane tasks, DATs enable employees to prioritize strategic and creative functions over routine administrative work, fostering innovation and workforce optimization, particularly in

knowledge-intensive industries [45], [66]. Closely linked, decision-making support, efficiency, and quality (3/4.9%) reflects DATs' capacity to enhance analytical capabilities, enabling organizations to navigate dynamic market conditions with optimized strategies [56], [67]. Kudryavtsev (2024) states that AI assistants enhance business development by accelerating design processes, lowering decision-making risks, and offering accessible, professional-level support [56]. Business expansion and development (2/3.3%) highlights DATs' contributions to scalability, market entry, and operational agility [56], [68]. The financial impact is evident in revenue growth and cost reduction (2/3.3%), where AI-driven insights and automation maximize profitability while minimizing expenses [54], [69].

Cost & resource optimization. Cost & resource optimization (7/11.5%) remains a critical objective, ensuring organizations maximize output while minimizing financial and operational inefficiencies. DATs support these goals through automation, predictive analytics, and streamlined processes, leading to enhanced cost efficiency and resource utilization [12]. Capacity increase (3/4.9%) highlights how AI-driven automation enables organizations to handle higher workloads without proportionally increasing resources, fostering scalability in customer service, operations, and production [14], [21], [70]. Cost reduction (3/4.9%) underscores DATs' role in eliminating inefficiencies, automating repetitive tasks, and optimizing resource allocation, significantly lowering operational expenses [71]. Bird and Lotfi (2024), for example, strengthen the narrative that chatbots in customer service are more cost-effective than fully human-operated models[72]. Organizations integrating intelligent automation in HR, finance, and customer service achieve substantial reductions in labor costs and time-intensive processes (cost-)effectiveness/process automation (1/1.6%) further demonstrates how DATs enhance efficiency through intelligent workflows, reducing manual interventions and improving process standardization across business functions [64].

Quality. The quality cluster (4/6.6%) highlights the role of DATs in enabling and maintaining higher standards across products, services, and decision-making. DATs enhance quality (2/3.3%) by automating tasks, minimizing human errors, enabling data-driven decisions, and accelerating creativity [73]. The combined category of quality and productivity (2/3.3%) emphasizes the dual impact of DATs in enhancing service reliability while optimizing operational efficiency [74]. Chen et al. (2023) confirm that AI chatbots improve service quality, thereby strengthening customer loyalty and driving business success [75].

Creativity and learning. The creativity and learning cluster (4/6.6%) highlights the expanding role of DATs in knowledge work, idea generation, and creativity enhancement. These technologies lower entry barriers to learning and support continuous professional development [76], [77], [78]. Creativity and efficiency (2/3.3%) enabled by DATs enhance ideation, design, and content creation while streamlining workflows and reducing cognitive load, driving faster innovation and execution [65], [79]. Cheng et al. (2023) positively evaluated the use of AI to increase efficiency in abstract writing for preclinical research [80]. Similarly, learning (2/3.3%) leverages AI-powered training to support skill development, personalized learning, and adaptive programs, improving feedback and knowledge retention by, for example, reducing language barriers and enhancing content accessibility [53], [81].

TABLE IV

KEY FOCUS AREAS OF DAT APPLICATION

Productivity & efficiency (32/52.5%)	**Business growth & development (14/23%)**
Efficiency/quality (13/21.3%)	Focus on value added tasks (7/11.5%)
Productivity (9/14.8%)	Decision making support/efficiency/quality (3/4.9%)
Efficiency (5/8.2%)	Business expansion/development (2/3.3%)
Efficiency/productivity (2/3.3%)	Revenue growth/cost reduction (2/3.3%)
Efficiency/effectiveness (1/1.6%)	**Quality (4/6.6%)**
Efficiency/quality/productivity (1/1.6%)	Quality (2/3.3%)
Productivity/health protection (1/1.6%)	Quality/productivity (2/3.3%)
Cost & resource optimization (7/11.5%)	**Creativity & learning (4/6.6%)**
Capacity increase (3/4.9%)	Creativity/efficiency (2/3.3%)
Cost reduction (3/4.9%)	Learning (2/3.3%)
(cost-)effectiveness/process automation (1/1.6%)	

VIII. RESEARCH AGENDA

Based on the five main focus areas identified through our SLR, we propose a research agenda that highlights key gaps and formulates future research questions within the most relevant and emerging research streams (see Fig. 5). Our analysis shows that the adoption of GAI-driven DATs hold the potential to reshape productivity, efficiency, business models, and strategy [55], [82], [83]. However, a critical gap remains: the lack of empirical, longitudinal evidence on the impact of DATs. While many articles focus on DAT implementation and task- or user-level benefits, few explore how organizations leverage the capacity freed by these technologies or how such changes influence strategic and operational adaptation—an area warranting deeper investigation [84], [85], [86]. Despite the widespread adoption of Microsoft 365 and Google Workspace, these platforms are notably absent from the current research sample. This is also true for articles addressing post-adoption dynamics, largely due to the novelty of GAI-enabled DATs [87]. Although our findings suggest positive effects, comprehensive empirical validation—particularly within large enterprise contexts and across industries—remains limited. To address these gaps, we suggest leveraging established IS theories [88]. The TAM can support research on individual adoption and sustained use. The technology–organization–environment (TOE) framework offers a holistic lens for analyzing organizational adoption conditions. For

post-adoption dynamics, dynamic capabilities theory can explain how firms reconfigure resources to generate long-term value, while adaptive structuration theory provides insight into how DATs shape and are shaped by evolving work practices. We recommend longitudinal and case-based methods to trace adoption trajectories and long-term impact, complemented by controlled experiments, expert interviews, and large-scale surveys [42], [47], [59]. Beyond performance metrics, articles should examine structural shifts—such as evolving roles, skills, and workforce distribution—and their implications for strategy and competitiveness. Fig. 5 outlines potential research questions across five key research streams, organized into two rows: the first focuses on motivations and considerations for adopting GAI-enabled DATs in proprietary productivity software; the second highlights organizational shifts resulting from their usage and adoption.

IX. Conclusion and Limitations

This SLR analyzed 61 articles on organizational support via DATs and their strategic implications. In response to RQ1, the review identified five primary areas of impact: productivity and efficiency enhancement, strategic business growth, resource optimization, quality improvement, and the promotion of creativity and learning. Regarding RQ2, the findings highlight a lack of research on long-term strategic adaptations, largely due to the novelty of GAI-enabled DATs. Addressing this gap is essential to advance scholarly understanding of effective DAT implementation.

Limitations of the paper at hand include exclusive reliance on IS journals indexed in Scopus, potentially overlooking interdisciplinary insights. Additionally, the frequency-based analytical methods and VOSviewer utilized in this study may introduce algorithmic biases and do not permit the establish-

	Research stream				
	Productivity & efficiency	**Business growth & development**	**Cost & resource optimization**	**Quality**	**Creativity & learning**
Key focus areas for organizations using GAI-enabled DATs in proprietary productivity software. (referred to as DAT for readability in this table)	• To what extent do DAT impact productivity and operational performance over a X-year period? • By how much do DAT reduce mental health sick leaves by alleviating high workloads? • How do proprietary DATs transform workplace productivity and efficiency? • What is the critical mass of adoption within companies required to realize productivity gains from Copilot? • What key tasks see the greatest efficiency improvements through DAT integration?	• How can DATs impact organizational expansion? • What measurable impact do DATs have on business cycle time reduction? • By how much does market capitalization increase through DAT implementation? • How do DATs qualitatively reshape strategic business growth and value creation processes? • What business areas demonstrate significant growth potential due to DAT deployment? • What new strategic directions can organizations pursue based on DAT capabilities?	• What are the cost savings achievable through DAT? • How does the implementation of DAT impact the average number of work hours saved per employee per week? • What specific business functions achieve the highest cost savings through DAT implementation? • What specific business functions achieve the highest cost savings through DAT implementation? • What resource allocation strategies are most effective when incorporating DAT-driven automation?	• How do DAT influence work/output quality (e.g. NPS, customer satisfaction)? • To what extent do DAT help reduce cull across different work processes? • What changes in quality and service delivery occur through DAT integration? • What quality assurance processes are most significantly improved through DAT integration? • What quality-related KPIs show measurable improvement due to DAT usage?	• How many additional non-native speakers are employed through DAT application and support? • What alterations in creative processes and learning methods are driven by DATs? • What creative processes/job benefit most from DAT support? • What competencies/skills are essential for maximizing the effectiveness of DAT usage? • What learning outcomes are most significantly enhanced by DAT integration?
Organizational shifts driven by GAI-enabled DATs in proprietary productivity software.	• How does overall business performance change after reallocated capacity is freed up? • What changes in workforce roles and team dynamics are driven by DATs? • What is the critical mass of adoption within companies required to realize productivity gains from Copilot? • How does DAT implementation affect workforce dynamics, job roles, and team performance?	• What impact can DAT have on organizational strategy, overall performance, and market perception? • What proportion of business growth can be attributed to improved operational efficiency from GAI-enabled DATs • What changes in organizational structure and governance are attributed to DAT implementation? • How do DAT reshape organizational strategies and business processes? • What new strategic directions can organizations pursue based on DAT capabilities?	• How effectively do organizations measure the financial impact of DAT-driven resource reallocation? • How do companies perceive and manage cost savings and resource reallocations? • What impacts occur from resource redistribution post-DAT implementation? • What resource allocation strategies are most effective when incorporating DAT-driven automation?	• How do organizations track quality improvements from DAT integration? • What adaptations occur in governance to maintain quality post-DAT implementation? • What quality assurance processes are most significantly improved through DAT integration? • What KPIs show measurable improvement due to DAT usage?	• How can organizations assess DAT-driven innovation outcomes? • How much additional innovation is driven by DAT implementation? • How do DATs influence creativity, learning processes, and innovation within organizations? • What creative processes benefit most from DAT support? • What learning outcomes are most significantly enhanced by DAT integration?

Fig. 5. Indicative potential research questions in DAT research

ment of causal relationships [41], [89]. Finally, the narrow search strategy could have resulted in biases toward specific terminologies or perspectives, thereby limiting the broader applicability of findings due to terminological ambiguities, commonly referred to as jingle-jangle fallacies, surrounding DAT [1]. Future articles should broaden their methodological scope to comprehensively capture interdisciplinary insights and mitigate these limitations.

***Abstract*—Photovoltaic platforms enable a single agent to simultaneously act as both a producer and a consumer of power, facilitating *self-consumption* strategies. This trend aligns with the goal of reducing CO2 emissions and is poised to significantly transform the structure of energy markets. It also introduces specific challenges—both tactical (e.g., pricing) and operational (e.g., routing, scheduling)—related to synchronizing energy production with consumption. In this work, we address the problem of efficiently routing a fleet of electric autonomous vehicles (EAVs), using energy that is either produced by a photovoltaic platform or purchased from the general power grid. We propose an exact Mixed-Integer Linear Programming (MILP) formulation of the problem, along with a heuristic approach that approximates the power production component of the model using surrogate representations.**

I. Introduction

RENEWABLE energy sources (e.g., photovoltaic, wind, hydrogen) are driving the emergence of local, in situ producers who simultaneously consume energy—such as factories and farms. In this context, the energy production-consumption process becomes partially endogenous, forming a closed-loop system under the *self-consumption* paradigm [15]. This paradigm is expected to have a significant impact on energy economics [11], [14]. It raises various challenges, ranging from operational issues—related to the scheduling and synchronization of production and consumption—to tactical and strategic decisions, such as pricing, storage, and interaction with the central grid. In scenarios where the decentralized producer-consumer entity is a consortium of independent agents, each with its own schedule and shared access to the production platform, fairly distributing costs and benefits raises the *cooperative* issue.

We consider here the problem of routing a fleet of electric autonomous vehicles (EAVs), powered either by photovoltaic-generated electricity—available at time-dependent rates—or by electricity purchased from the general grid at time-dependent prices. This *Vehicle Routing under Energy Production Costs* (**VR_EPC**) problem requires fleet managers to synchronize vehicle activity with energy production and procurement, while taking into account the limited storage capacities of both the platform and the vehicles.

A. State of the Art

Numerous studies have explored the routing of electric vehicles with the aim of minimizing energy costs or addressing environmental concerns, such as in the *Green Vehicle Routing Problem* (Green VRP), the *Pollution Routing Problem*, and the *Hybrid Vehicle Routing Problem*: [5], [16], [21],[19]). They most often proposed models involving refueling transactions subject to time windows or shared access constraints. For example:

- Erdoğan and al. [6] introduced the *Green VRP*, which minimizes both total travel distance and the number of refueling transactions.
- Franceschetti and al. [8] proposed a *Pollution-Routing* model, incorporating time-dependent costs and an objective function accounting for driver wages and fuel costs.
- Koç and al. [12] focused on determining where and how much vehicles should be recharged, considering access-to-energy constraints.
- In [21], authors addressed customer sequencing, while explicitly accounting for the recharge capacity of the charging stations.

Some authors also dealt with CO2 emitting vehicles, with the purpose of controlling related CO2 emission:

- Raylan and al. [17] minimized emissions resulting from both routing and load-related factors.
- Sachenbacher and al. [18] accounted for time-dependent factors and refueling schemes, adapting shortest path algorithms accordingly.
- Kuo [13] explored speed control to balance energy consumption, distance, and time.
- Schneider and al. [19] developed heuristics for a Vehicle Routing problem with time windows and safety-specific refueling constraints.
- Lajunen [14] performed simulation-based comparisons of energy savings across urban shuttle and bus configurations.

Despite these contributions, few studies have jointly managed both energy production and consumption. Addressing this challenge requires integrating heterogeneous routing and scheduling processes while accounting for storage constraints (see [2], [3], [1]). Some formulations borrow from the *Lot*

Sizing framework or its multi-level scheduling variants (see [4], [10], [20]), but these models involve highly heterogeneous variables and constraints, often leading to poor performance of linear relaxations. Moreover, they implicitly rely on the existence of a single decider provided with full control and full information with respect to the system, inducing an assumption which does not fit most real life contexts. Alternatives such as constraint programming and bi-level formulations may help coordinate interactions across decision levels. Nonetheless, whatever be the point of view (centralized or collaborative), designing efficient solution algorithms remains a major challenge. A recent trend—facilitated by machine learning—is to approximate complex sub-models using surrogate constraints or cost functions.

B. Main Achievements

Since our **VR_EPC** problem is likely to involve in practice collaborative features making it difficult to suppose the existence of a global decider, we adopt here the point of view of the EAV. Also, we skip the uncertainty issue, while supposing that the behavior of our system, and more specifically of the photovoltaic platform, is deterministic. Then we propose two solution approaches for the **VR_EPC** problem.

- The first one is an exact MILP formulation that considers the *vehicle* variables as master variables and includes specific *Recharge Decomposition* constraints requiring the application of a specific separation procedure, which works in polynomial time. This MILP model is solved using a branch-and-cut method. However, this approach becomes computationally inefficient for large instances.
- So we also design 2 heuristic algorithms, which makes the EAV decide under a partial knowledge of the behavior of the photovoltaic platform, while using an approximation of the energy production model. The resulting algorithms pave the way for more efficient handling of uncertainty and collaboration challenges, particularly in scenarios where the photovoltaic (PV) platform and the vehicles are run by distinct players, who do not fully share neither the same goals nor the access to information.

The paper is organized as follows. Section II provides a detailed description of the *Vehicle Routing under Energy Production Costs* problem (**VR_EPC**). In Section III, we present the MILP formulation and its resolution using a branch-and-cut approach. Section IV offers a statistical analysis that provides the basis for the development and testing of 2 local search heuristic. We conclude briefly in Section V.

II. The Vehicle Routing under Energy Production Costs Problem

We consider a photovoltaic (PV) micro-plant, referred to as **PVP**, along with a fleet of electric autonomous vehicles (EAV) in charge of visiting a set of stations. These two components interact through recharge transactions when the vehicles return to the micro-plant to recharge (see Fig. 1). For the sake of simplicity, we limit our study to a single vehicle that must complete a *Traveling Salesman*-type tour, and we assume the system operates in a deterministic manner. Thus, the main components of our target system are:

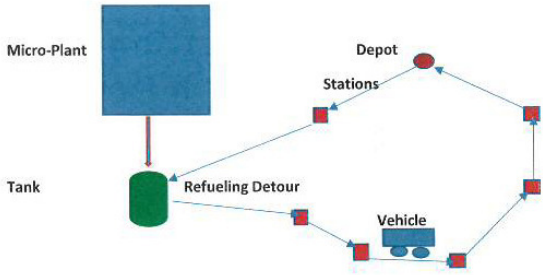

Fig. 1. The PV-Micro-Plant Interacting with a Vehicle Route

- **A Photo-Voltaic Micro-Plant PVP**
  The time horizon of **PVP** is divided into N periods $i = 0, \ldots, N-1$, all with a same duration p. Thus the starting timestamp of period i is equal to $p \cdot i$ and its ending timestamp equal to $p \cdot (i+1)$. During a period i, **PVP** is expected to produce R_i energy units. It may also buy an additional amount y_i of power, that cannot exceed a *charge* capacity denoted by C^{Ch}. The cost of buying such an additional energy amount y_i depends on both i and y_i and may be written $\Phi_i(y)$, where Φ_i is a piecewise linear increasing convex function. The convexity of this cost function Φ_i expresses the fact that marginal power purchase prices are usually increasing. **PVP** is provided with a macro-battery, with storage capacity $C^{PVP} \geq C^{Ch}$ and initial load H_0^{PVP}. It must manage its purchase operations in a way which makes it able to meet vehicle's demand without exceeding storage and charge capacities, while ending the process with a load at least equal to H_0^{PVP} and minimizing related purchase costs.
- **An Electric Autonomous Vehicle EVeh and a Set of Stations J**
  This vehicle, denoted by **EVeh**, is initially located at a specific station *Depot*. It must visit and service, within the time horizon $[0, N.p]$, a set $\mathbf{J} = \{1, \ldots, M\}$ of stations according to a TSP (*Traveling Salesman*) route Γ, before coming back to *Depot*. Moving from a station j to a station k requires $E_{j,k}$ energy units and $T_{j,k}$ time units, service times being included into the $T_{j,k}$ values. We suppose that vectors T, θ, θ^* $(E, \epsilon, \epsilon^*)$ define a distance on the set defined by $Depot$, **PVP** and **J**. **EVeh** is provided with a battery, with storage capacity C^{Veh} and initial load H_0^{Veh}. It must end with a load at least equal to H_0^{Veh} while minimizing the time when it returns to $Depot$. $Depot$ is considered as a station, identified as $Depot = 0$ at the beginning of the process and $Depot = M + 1$ at the end. By the same way, **PVP** is also considered as a station, identified as **PVP** $= -1$

- **Recharge Transactions**
  Because of its storage capacity C^{Veh} and the constraint about its load at the end of the process, **EVeh** must periodically move to **PVP** in order to recharge. Such a *recharge transaction* can be achieved in a single period i and takes place between two stations j, k consecutive according to the route Γ: **EVeh** moves from j to **PVP** in order to arrive before time $p \cdot i$, receives some amount $m \leq Inf(C^{Ch}, C^{Veh})$ of energy, and starts again from **PVP** at time $p\cdot(i+1)$ in order to reach k. Since the vehicle is a kind of robot, this recharge transaction, denoted by $\omega = (i, j, k, m)$, involves some human resource and so it induces a cost Ψ_i. This human resource cost depends on i and is independent on m. For the sake of safety, purchasing power is forbidden during the period i when the recharge transaction ω takes place. Moving from j to **PVP** requires ϵ_j energy units and θ_j additional time, while moving from **PVP** to k requires ϵ_k^* energy units and θ_k^* additional time. A recharge transaction may impose **EVeh** to wait at **PVP** until the beginning of period i in case it arrives before time $p\cdot i$. If we denote by τ_j the time when **EVeh** arrives at j, by V_j^{Veh} its energy load and by V_i^{PVP} the energy load of the PV-plant at the beginning of period i, then we must have:
  - $p \cdot i \geq \tau_j + \theta_j$; $\tau_k = p \cdot (i+1) + \theta_k^*$;
  - $V_{i+1}^{MP} = V_i^P - m \geq 0$;
  - The load of **EVeh** at the end of period i must be equal to $V_j^{Veh} - \epsilon_j + m \leq C^{Veh}$;
  - The load of **EVeh** at the beginning of period i must be equal to $V_j^{Veh} - \epsilon_j \geq 0$.

Since the system described this way involves two players, each provided with its own performance criterion, resulting problem might be set according to the bi-objective format. Yet, our focus here is on the algorithms. Therefore, we introduce a *time versus money* coefficient α, and formulate **VR_EPC** as a mono-objective problem. By the same way, since we tend here to adopt the point of view of the vehicle manager **EVeh**, we set related model as a bi-level one.

VR_EPC: ***Vehicle Routing with Energy Production Costs*** : {Compute the route Γ followed by **EVeh** together with the recharge transactions that link **PVP** and **EVeh** in such a way that:

- All stations are visited once within the time horizon $[0, p \cdot N]$.
- Vehicle storage capacity constraints and energy requirements are satisfied.
- Some extended cost $PCost+\alpha.Veh_Time$ is minimized, where $PCost$ means the optimal cost value induced by the **PVP** sub-problem consisting in deciding the purchase vector $y = (y_i, i = 0, \ldots, N-1)$ in such a way that:
  - It meets **PVP** storage and charge capacities;
  - It meets the needs related to the recharge transactions while allowing **PVP** to end with at least as much energy as when it started;
  - $PCost = \sum_i (\Psi_i \cdot \delta_i + \Phi_i(y_i)).\}$

TABLE I
PRODUCTION RATES, UNIT PURCHASE PRICES AND RECHARGE COSTS

i	0	1	2	3	4	5	6	7	8	9	10	11	12	13
R_i	2	2	0	0	4	4	4	0	0	0	0	2	2	0
P_i	2	3	5	5	1	1	1	5	5	5	5	2	2	5
Ψ_i	1	1	1	1	2	2	1	1	1	1	1	1	2	2

An Example: Let us suppose that:

- M = 5, $N = 14$, $p = 2$; $\alpha = 1$;
- $C^{Veh} = 16, H^{Veh} = 9, C^{PVP} = 20, H^{PVP} = 5, C^{Ch} = 15$;
- Expected productions $R_i, i = 0, \ldots, N-1$ come as in Table I;
- For any period i, function Φ_i comes as: $\Phi_i(y) = P_i \cdot y$, y denoting the additional energy bought at period i and prices P_i come according to table I.

Let us consider a route $\Gamma = \{0, 1, 2, 3, 4, 5, 6\}$ together with time and energy requirements given according to Figure 2:

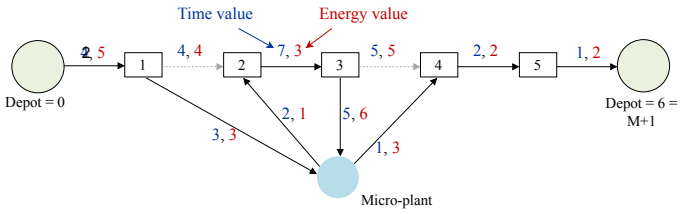

Fig. 2. The Route Γ, together with the time and energy requirements

Then we get a feasible **VR_EPC** solution involving Γ by specifying the recharge transactions as follows:

- A first recharge transaction occurs at period 3, while **EVeh** is moving from station 1 to station 2. Related energy amount m is equal to 10.
- Another recharge transaction occurs at period 11, while **EVeh** is moving from station 3 to station 4. Related energy amount m is equal to 15.
- **PVP** buys 3 energy units at period 0 and 3 energy units at period 1. Those operations induce a purchase cost equal to $3 \cdot 3 + 2 \cdot 3 = 15$.
- The 2 recharge transactions induce a cost equal to 2, which makes the $PCost$ value equal to $15+2 = 17$, while the value Veh_Time is equal to $14 \cdot 2 = 28$, inducing a generalized cost value $\alpha \cdot PCost + \beta \cdot Veh_Time$ equal to $1 \cdot 17 + 1 \cdot 28 = 45$.

III. A MILP MODEL

Though **VR_EPC** is too complex for an exact handling of large size instances, casting it into the MILP format is important, not only because resulting **MILP_VR_EPC** model will provide us with benchmark results in the case of small instances, but also because it will contain a structural analysis of the problem.

A. The Variables of the ***MILP_VR_EPC*** model

Getting a MILP formulation first requires identifying the variables. Since we adopt here the point of view of the vehicle manager, our master variables are going to be 2 $\{0,1\}$-valued vectors $Z = (Z_{j,k}, k \neq j \in \{-1, 0, \ldots, M+1\})$ and $X = (X_{j,k}, k \neq j \in \{0, \ldots, M+1\})$, that respectively describe the routes followed by the vehicle with and without the detours induced by the recharging transactions. Those main *vehicle* variables are going to be completed by auxiliary variables related to the time values when the vehicle visits the stations and to its energy load at this time. We also need *PV-Plant* variables that allow us to describe the evolution along the periods of the power load stored inside the **PVP** macro-battery. Finally, we need *Recharge Transaction* variables, linking the respective trajectories of the vehicle **EVeh** and the PV-Plant **PVP**. This leads us to introduce the following variables:

- **Vehicle** variables:
  - $\{0,1\}$-valued variables $Z_{j,k}, k \neq j \in \{-1, 0, \ldots, M+1\}$: $Z_{j,k} = 1$ iff the vehicle moves from j to k: -1 denotes here the micro-plant **PVP**.
  - $\{0,1\}$-valued variables $X_{j,k}, k \neq j \in \{0, \ldots, M+1\}$: $X_{j,k} = 1$ iff the vehicle moves either from j to k or from j to **PVP**, and next from **PVP** to k.
  - Non negative variables $L_j^{Veh}, j = 0, \ldots, M$: L_j^{MP} means the energy transferred to **EVeh** just after j, in case $Z_{j,-1} = 1$;
  - Non negative variables$V_j^{Veh}, j = 0, \ldots, M+1$: V_j^{Veh} means the energy stored by **EVeh** when it arrives at j;
  - Non negative variables $\tau_j, j = 0, \ldots, M+1$: τ_j means the time when **EVeh** arrives at j;
  - Non negative variables $\tau_j^*, j = 0, \ldots, M+1$: If $Z_{j,-1} = 1$ then τ_j^* means the time when **EVeh** starts recharging after station j in case $Z_{j,-1} = 1$.
- **PV-Plant** variables:
  - Non negative variables $y_i, i = 0, \ldots, N-1$: y_i means the energy amount bought by the PV-Plant's during period i;
  - $\{0,1\}$-valued variables $\delta_i, i = 0, \ldots, N-1$: $\delta_i = 1$ means that some recharge transaction takes place at i;
  - Non negative variables $V_i^{PVP}, i = 0, \ldots, N-1, N$: V_i^{PVP} means the energy stored by **PVP** at the beginning of i;
  - Non negative variables $L_i^{PVP}, i = 0, \ldots, N-1$: L_i^{PVP} means the energy transferred from **PVP** period i in case in case $\delta_i = 1$.
- **Recharge Transaction** variables:
  - $\{0,1\}$-valued variables $U_{i,j}, i = 0, \ldots, N-1, j = 0, \ldots, M$: $U_{i,j} = 1$ means that some recharge transactions occurs at period i that involves station j and its sucessor in Γ;
  - Non negative variables $m_{i,j}, i = 0, \ldots, N-1, j = 0, \ldots, M$: $m_{i,j}$ means related amount of energy.

B. Structural Recharge Decomposition Vehicle Constraints

Z and X describe the full route followed by **EVeh**. They must clearly meet the following standard *vehicle routing* constraints:

- $Z_{M+1,0} = 1; \quad \forall j : Z_{j,j} = 0;$ (VR1)
- $\forall j = 0, \ldots, M+1$: $\sum_{k=-1,\ldots,M+1} Z_{j,k} = 1 = \sum_{k=-1,\ldots,M+1} Z_{k,j}$; (VR2)
- $\sum_{j=0,\ldots,M+1} Z_{j,-1} = \sum_{j=0,\ldots,M+1} Z_{-1,j} \geq 1;$ (VR3)
- $\forall j, k \in \{0, \ldots, M+1\}: \quad X_{j,k} \geq Z_{j,k}$; (VR4)
- $\forall j \in \{0, \ldots, M+1\}$: $\sum_{k=0,1,\ldots,M+1} X_{j,k} = 1 = \sum_{k=0,1,\ldots,M+1} X_{k,j}$; (VR5)

Yet we see that (VR1, ..., VR5) are not enough to ensure that we may interpret Z, X as a route followed by **EVeh**, feasible with respect to the energy requirements. In fact, they are not enough to prevent us from the existence of standard *Traveling Salesman sub-tours*. So we must reinforce them. We do it by noticing that if **EVeh** spends W energy while moving inside or at the boarder of some station subset A which does contain the micro-plant, then it must move at least $\lceil \frac{W}{C^{Veh}} \rceil$ times towards **PVP** in order to refuel. In order to formalize this, we must introduce some additional notations:

- For any such a subset A of $\{-1, 0, \ldots, M, M+1\}$:
  - $Cl(A) = \{(j,k)$ s.t at least j or k is in $A\}$;
  - $\delta(A) = \{(j,k)$, s.t $j \notin A$ and $k \in A\}$.
- For any (j,k):
  - $\Pi_{j,k} = E_0$ if $(j,k) = (M+1, 0)$ and $\Pi_{j,k} = C^{Veh}$ else.
  - $\Pi^*_{j,k} = C^{Veh} - E_0$ if $(j,k) = (M+1, 0)$ and $\Pi^*_{j,k} = C^{Veh}$ else.

Then we become able to derive the following *Recharge Decomposition* constraints that reinforce (VR1, ..., VR5):

- For any $A \subseteq \{0, \ldots, M+1\}$, $\sum_{(j,k)\in\delta(A)} \Pi_{j,k} \cdot Z_{j,k} \geq \sum_{(j,k)\in Cl(A)} E_{j,k} \cdot Z_{j,k}$ (VR6)
- For any $A \subseteq \{0, \ldots, M+1\}$, $\sum_{(j,k)\in\delta(J-A)} \Pi^*_{j,k} \cdot Z_{j,k} \geq \sum_{(j,k)\in Cl(A)} E_{j,k} \cdot Z_{j,k}$ (VR6-Bis)

The following Lemma 1 provides us with the structural meaning of these constraints: It tells us that adding them to (VR1, ..., VR5) ensures us that (Z, X) are going to describe a vehicle route that excludes *sub-tours* and can be decomposed into a sequence of sub-routes ($Depot \rightarrow$ **PVP**), (**PVP** $\rightarrow$ **PVP**) and (**PVP** $\rightarrow Depot$), all feasible with respect to the energy requirements.

Lemma 1: *The VRP constraints (VR1, ..., VR6-Bis) hold if and only if the arcs (j,k) such that $Z_{j,k} = 1$ define a collection γ of sub-tours $\gamma_s, s = 0, \ldots, S$ such that:*

- *γ_0 starts from $Depot = 0$, ends into **PVP** $= -1$, and spends less than H_0^{Veh} energy.* (SUB1)
- *γ_S starts from **PVP** $= -1$, ends into $Depot = 0$, and spends less than $C^{Veh} - H_0^{Veh}$ energy.* (SUB2)
- *For any $s = 1, \ldots, S-1$, γ_s starts from **PVP** $= -1$, ends into -1 and does not require more than C^{Veh} energy.* (SUB3)
- *Every station $j = 1, \ldots, M$ is visited once.* (SUB4)

Proof. We only need to simultaneously follow the TSP route defined by X and its extension defined by Z. **End-Proof**

Remark 1: Constraints (VR6, VR6-Bis) neither tells in which order the sub-routes $\gamma_s, s = 0, \ldots, S$ must be performed, nor it ensures the feasibility of resulting route with respect to the time horizon $p \cdot N$.

Separating the Recharge Decomposition Constraints: As usually when it comes to the management of constraints on the subsets of a given set, we must cope with the separability issue. Given 2 possibly non integral vectors (Z, X), separating the constraints (VR6, VR6-Bis) means checking that all those constraints are satisfied by (Z, X) and, in case they are not, computing a subset $A \subseteq \{0, \ldots, M+1\}$ such that related VR6 or VR6-Bis constraint is violated by (Z, X). Theorem 1 below not only tells us that separating (VR6, VR6-Bis) can be done in polynomial time, but related proof provides us with a polynomial time algorithm that will perform this separation process.

Theorem 1: *The Recharge Decomposition constraints can be separated in polynomial time, by application of a min cost flow algorithm.*

Sketch of the Proof: Let us restrict ourselves to the case of the constraints VR6 (the case of the constraints VR6-Bis is quite similar). Given Z, possibly non integral. Separating VR6 means searching for $A \subseteq \{0, \ldots, M+1\}$, which does not contain -1 and is such that:

$$\sum_{(j,k) \in \delta(A)} \Pi_{j,k} \cdot Z_{j,k} < \sum_{(j,k) \in Cl(A)} E_{j,k} \cdot Z_{j,k},$$

or equivalently for $B = \{-1, 0, \ldots, M+1\} \setminus A$, which contains -1 and is such that: (*)

$$\sum_{(j,k)\ s.t. j \in B, k \notin B} \Pi_{j,k} \cdot Z_{j,k} + \sum_{(j,k)\ s.t. j \in B, k \in B} E_{j,k} \cdot Z_{j,k} < \sum_{(j,k)} E_{j,k} \cdot Z_{j,k}.$$

Let us set $\Delta = \sum_{(j,k)} E_{j,k} \cdot Z_{j,k}$, and let us construct an auxiliary multi-graph $G = (X, A)$ as follows:

- $X = \{Source = -1, 0, \ldots, M+1, M+2 = Sink\}$;
- A is defined as the set of all *simple-arc* $(j,k), j \neq k \in \{-1, 0, \ldots, M+1\}$, augmented, for every j, with *copy-arcs* $(j, M+1)^k, k \neq j \in \{-1, 0, \ldots, M+1\}$, which connect j to $Sink = (M+2)$ and are provided with label k. Every *copy-arc* $a = (j, M+1)^k$ is provided with a weight w_a equal to $E_{j,k} \cdot Z_{j,k}$. Every *simple-arc* $a = (j,k)$ is provided with a weight w_a equal to $\Pi_{j,k} \cdot Z_{j,k} - E_{j,k} \cdot Z_{j,k}$.

Then we easily check that computing B such that (*) holds means computing a cut B' which separates $Source = -1$ from $Sink = M+2$ in G and is such that $\sum_{a\ s.t.\ origin(a) \in B', destination(a) \notin B'} w_a < \Delta$. We know that this can be done in polynomial time through a simple Max-Flow algorithm. **End-Proof**.

C. The *VR_EPC_MILP* MILP formulation

We are now able to extend the structural *vehicle routing* constraints VR1, ..., VR6-Bis into a **VR_EPC_MILP** setting of **VR_EPC**. We do it while distinguishing 3 main groups of constraints:

- The **PV-Plant Constraints**: They involve the variables related to the purchase of power and express the evolution along the periods of the load V_i^{PVP} of the **PVP** battery, the fact that this load cannot exceed the capacity C^{PVP}, and the fact that the final load V_N^{PVP} must be no smaller than the initial load H_0^{PVP}.
- The **Vehicle Routing Constraints**: They contain VR1, ..., VR6-Bis, together with constraints related to the time values when the vehicle arrives to the stations or to **PVP** for the recharging transactions. Those temporal constraints fix the order according to which the sub-routes involved in Lemma 1 are visited. The *Vehicle Routing* constraints also contain constraints which express the evolution along the route defined by (Z, X) of the load V_j^{Veh} of the **EVeh** battery, the fact that this load cannot exceed the capacity C^{Veh}, and the fact that the final load V_{M+1}^{Veh} must be no smaller than the initial load H_0^{Veh}.
- The **Synchronization Constraints**: They link together the **PVP** periods and the time horizon $[0, p \cdot N]$ of the vehicle, and synchronize the energy received by the vehicle and the energy delivered by the PV-Plant during the recharge transactions.

Those constraints may be formalized as follows (for the sake of simplicity, we replace the "Big M" formulations by implications):

VR_EPC Constraints and Objective Function:

- **Objective**: Minimize $\sum_i (\Psi_i.\delta_i + \Phi_i(y_i) + \alpha.\tau_{M+1}$
- **PV-Plant Constraints**
  - $\forall i = 1, \ldots, N-1$: $y_i \leq C^{Ch} \cdot (1 - \delta_i)$; (PC1)
  - $\forall i = 0, \ldots, N$: $V_i^{PVP} \leq C^{PVP}$; (PC2)
  - $V_0^{PVP} = H_0^{PVP}$; $V_N^{PVP} \geq H_0^{PVP}$; (PC3)
  - $\forall i = 1, \ldots, N$: $V_i^{PVP} = V_{i-1}^{PVP} + y_i - L_i^{PVP}$; (PC4)
- **Vehicle Routing Constraints**
  - (VR1, ..., VR6-Bis) involved in Lemma 1;
  - $V_0^{Veh} = H_0^{Veh}$; $V_{M+1}^{Veh} \geq H_0^{Veh}$; (VR7)
  - $\forall j = 0, \ldots, M+1$: $E_{j,-1} \leq V_j^{Veh} \leq C^{Veh}$; (VR8)
  - $\forall j, k = 0, \ldots, M+1$: $X_{j,k} \rightarrow (V_k^{Veh} + E_{j,k} + (Z_{j,k} - 1) \cdot (\epsilon_j + \epsilon_k - E_{j,k})) \leq (V_j^{Veh} + L_j^{Veh})$; (VR9)
  - $\forall j = 0, \ldots, M$: $Z_{j,-1} \rightarrow (V_j^{Veh} \geq \epsilon_j)$; (VR10)
  - $\forall j = 0, \ldots, M$: $Z_{j,-1} \rightarrow (V_j^{Veh} + L_j^{Veh} \leq \epsilon_j + C^{Veh})$; (VR10-Bis)
  - $\tau_0 = 0$; $\tau_{M+1} \leq p \cdot N$; (VR11)
  - $\forall j, k = 0, \ldots, M+1$: $Z_{j,k} \rightarrow (\tau_j + T_{j,k} \leq \tau_k)$; (VR12)
  - $\forall j, k = 0, \ldots, M+1$: $(X_{j,k} - Z_{j,k} = 1) \rightarrow (\tau_j^* + p + T_{-1,k} \leq \tau_k)$; (VR13)
  - $\forall j = 0, \ldots, M+1$: $(Z_{j,-1}) \rightarrow (\tau_j + T_{j,-1} \leq -\tau_j^*)$; (VR13-Bis)
- **Synchronization Constraints**
  - $\forall j = 0, \ldots, M$: $\sum_{i=0,\ldots,N-1} U_{i,j} = Z_{j,-1}$; (SY1)
  - $\forall j = 0, \ldots, M$: $\sum_{i=0,\ldots,N-1} m_{i,j} = L_j^{Veh}$; (SY1-Bis)
  - $\forall i = 0, \ldots, N-1$: $\sum_{j=0,\ldots,M} U_{i,j} = \delta_i$; (SY2)

- $\forall i = 0, \ldots, N-1$: $\sum_{j=0,\ldots,M} m_{i,j} = L_i^{PVP}$; (SY2-Bis)
- $\forall j = 0, \ldots, M$: $\sum_{i=0,\ldots,N-1} p \cdot i \cdot U_{i,j} = \tau_j^*$; (SY3)
- $\forall i = 0, \ldots, N-1, j = 0, \ldots, M$: $m_{i,j} \leq Inf(C^{PVP}, C^{Veh}) \cdot U_{i,j}$; (SY4)

Theorem 2: *Above **VR_EPC_MILP** MILP model solves **VR_EPC** in an exact way.*

Proof: Lemma 1 tells us that X, Z define a feasible vehicle route Γ. Constraints (SY1, SY2) link the variables U, m with the route Z and the energy received by the vehicle, with the PV-Plant variables δ and the energy transferred by **PVP**. (SY4) makes those energy amounts be consistent with the storage capacities. (SY3) links the time values of **PVP** and **EVeh**. (PC4) describes the evolution throughout the time of the energy stored by **PVP**. Vehicle constraints (VR7, ..., VR10) describe the evolution throughout the time of the energy stored by **EVeh**. They keep this energy from becoming negative or larger than the capacity C^{Veh}. (VR11, ..., VR13-Bis) describe the evolution of the time while the vehicle follows the route described by X and Z. **End-Proof**

Practical Handling of the VR_EPC_MILP MILP model. We handle **VR_EPC_MILP** through Branch and Cut, while applying the auxiliary graph and the Max-Flow algorithm involved in Theorem 1 in order to separate the *Recharge Decomposition* constraints.

D. Numerical Experiments

Purpose: Evaluating the **VR_EPC_MILP** MILP model.

Technical Context: The experiments are performed on a computer with AMD EPYC 7H12 64-Core processor, and are running under Gnu/linux Ubuntu 20.04.2. The MILP library CPLEX 12.10 is used in a single-thread mode.

1) Instance generation: The main parameters of every instance are the station number M, the period number N, and the length p of the periods. M varies from 5 to 30; N varies from 40 to 320; p takes values in $\{1, 2, 4\}$. We derive from the instances with $p = 1$ the instances with $p = 2$ and $p = 4$ by merging the periods in a natural way, the length $TMax = p \cdot N$ of the time horizon remaining the same.

Vehicle coefficients: The M stations, together with $Depot$ and **HMP** are generated as integral points of a square in the 2D plane. Vectors T, θ, θ^* corresponds to a rounding of the Euclidean distance, and vectors E, ϵ, ϵ^* correspond to the Manhattan distance.

PV-Plant coefficients: We cluster production periods into 5 super-periods of same length, each provided with symbolic mean production and cost values $\overline{R_{cl}}$, $\overline{Cost_{cl}}$ in $\{Low, Medium, High\}$. Then, integral time dependent production coefficients R_i, together with time dependent cost convex piecewise (2 pieces) linear functions $\Phi_i, i = 0, \ldots, N-1$, are generated accordingly in such a way that resulting instance is feasible and that this feasibility requires the purchase of additional power.

Storage capacities: We control the number of recharge transactions by maintaining $\frac{C^{PVP}}{C^{Veh}}$ between 0.5 and 3.

TABLE II
BEHAVIOR OF **VR_EPC_MILP**

Id	(N, M, p)	LBG_LP	UBG_LP
1	(160, 10, 1)	56,7	173

10-2	(320, 30, 2)	63,08	163

Scaling coefficients α: We do in such a way that the weights of respectively $PCost$ and $\alpha.Veh_Time$ remain integral and comparable.

For every instance Id (Tables II), we provide input values values N, M, p. We tested 242 instances. Yet, we restrict ourselves here to 20 instances, with $p = 1$, referred to as Id, and $p = 2$ referred to as $Id - 2$.

2) Results: For every instance, Table II displays The lower bound LBG_LP and the upper bound UBG_UB computed through Branch and Cut by the CPLEX library in 2 CPU hours (7200 seconds). We boost the computation of upper bounds UBG_UB with the CPLEX parameter $MIP_emphasis_switch$.

Comments: Even when allowed to run during 2 hours, the model never reaches optimality, though it often allows the computation of a good feasible solution. That is why we are now going to derive from some statistical analysis some efficient heuristics for our problem.

IV. HEURISTIC HANDLING OF VR_EPC

The bi-level structure of **VR_EPC** and the fact that this bi-level structure will correspond in most cases to some collaborative decision context, suggests to manage **VR_EPC** while acting on the master route Γ through local search operators and devices that anticipate the behavior of resulting sub-problem **VR_EPC**(Γ) through the use of simple devices. There exists many ways to proceed this way. The approach which we are going to propose here relies on a statistical analysis of the correlation which may exist between the optimal value of **VR_EPC** and some key features of the route Γ.

In order to keep on, we need some additional notations:

- We denote by **VR_EPC**(Γ) the **VR_EPC** instance induced by fixing Γ (that means, referring to the **VR_EPC_MILP** MILP model, if we fix X in such a

TABLE III

NRT	11	10	9	9	6	6	6	7	7

way it meets (VR3, VR4) and does not induce any sub-tour). We denote by $W(\Gamma)$ its optimal value;
- We denote by $L^T(\Gamma), L^E(\Gamma)$ the lengths of Γ in the sense of respectively vectors T and E.

Let us also recall the way the standard *Traveling Salesman 2_Opt* and *Reloc* operators act on any current route Γ through 2 parameters j_1, j_2 in $\mathbf{J} + \{Depot\}$:

- *2_Opt*(Γ, j_1, j_2) replaces the moves from j_1 to its successor $\bar{j}_1$ and from j_2 to its successor $\bar{j}_2$ by moves from j_1 to j_2 and from $\bar{j}_1$ to $\bar{j}_2$, and reverses the orientation of Γ between j_2 and $\bar{j}_1$;
- *Reloc*(Γ, j_1, j_2) relocates j_1 between j_2 and $\bar{j}_2$.

A. Experimentally Linking $W(\Gamma)$, $L^T(\Gamma)$ and $L^E(\Gamma)$

Tables III, ..., VI show that $W(\Gamma)$, $L^T(\Gamma)$, $L^E(\Gamma)$ and the number NRT of recharge transactions are strongly correlated along the 36 iterations $It = 1, \ldots, 36$ of a descent loop involving *2_Opt* and *Reloc* and performed on 20 stations. We observe the same kind of correlation when performing the same experimental process on all the instances involved in table II.

B. A Simple PDYN_EPC Algorithm for the Computation of an Upper Bound $W_Aux(\Gamma)$ of $W(\Gamma)$

Though fixing Γ deeply simplifies the **VR_EPC_MILP** MILP model, it does make it suitable for repeated applications inside a local search process. So we briefly describe here a simple dynamic programming algorithm *PDYN_EPC* which computes an upper bound $W_Aux(\Gamma)$ of $W(\Gamma)$ under running times that allow its insertion into such a local search process. We design *PDYN_EPC* by noticing that once Γ is fixed, a full solution is determined by the sequence of recharge transactions linking **EVeh** and **PVP** together, augmented with the amounts of power bought during the periods separating 2 consecutive recharge transactions. More precisely, *PDYN_EPC* searches for a path (a sequence of transitions) in a *state* graph whose nodes (the states) and arcs (decisions and transitions) are defined as follows:

- A *state* in the sense of *PDYN_EPC* is a 4-uple $S = (j, i, V_j^{Veh}, V_i^{PVP})$, where j is a station, i a period, V_j^{Veh} is the power load of **EVeh** when it leaves j and V_i^{PVP} the power load of **PVP** at the end of i, with the implicit meaning that a recharge transaction involving i and j has just been performed. Such a state S comes with the smallest cost value $\Pi(S)$ of the cost of a path connecting initial state S_0 to S according to the *PDYN_EPC* process.
- A decision consists, in a natural way, in a 4-uple $(j_1, i_1, m_1, \bar{y})$, where (j_1, i_1, m_1) means the next recharge transaction, and $\bar{y}$ means the power which is going to be bought by **PVP** during the periods $i + 1, \ldots, i_1 - 1$. Resulting state and feasibility constraints derive in a natural way from the **VR_EPC_MILP** setting.
- The cost of related transition is $p \cdot (i_1 - i)$ augmented with the purchase cost of $\bar{y}$. This purchase cost corresponds to the optimal value of some convex optimization program. Since it does not depend on the vehicle inputs, it is computed as part of a pre-process and stored in a table Pr_Cost which, with any pair of periods i, i_1 and any purchase value $\bar{y}$ in a target discrete set, associates the optimal cost of purchasing $\bar{y}$ energy during the periods $i + 1, \ldots, i_1 - 1$.
- Initial state S_0 is a 4-uple $(Depot, -1, H_0^{EVeh}, H_0^{PVP})$. A final state is any 4-uple $(Depot, N - 1, V_j^{Veh} \geq H_0^{EVeh}, V_j^{PVP} \geq H_0^{PVP})$, taking into account that this final state is not related to any recharge transaction and that the cost of related transition must be adapted in order to refer to the time when **EVeh** is back to $Depot$.

We do not detail the description of *PDYN_EPC*, which by many ways works as the standard path search algorithm *A**, and restrict ourselves to say that:

- In order to make this algorithm run fast, we fix an upper bound $NDec$ (in our case, we shall set $NDec = 10$) on the number of feasible decisions that may be tried from a given state S. A consequence is that *PDYN_EPC*$(NDec)$ is only a heuristic algorithm, that provides us with an upper bound for the optimal value $W(\Gamma)$ of **VR_EPC**(Γ).
- We introduce a lower bound computation device, which, to any state $S = (j, i, V_j^{Veh}, V_i^{PVP})$, makes correspond some lower bound $VAL(S)$ of the cost of a path in the state graph that would connect S to some final state. This lower bound device allows us to discard states S which appear to be poorly promising according to related values

C. Two Simple Heuristic Algorithms

As told at the beginning of this section, above experiments suggest handling Γ while partially short-cutting the computation of $W(\Gamma)$ and relying on $L^T(\Gamma)$ and $L^E(\Gamma)$ in order to drive Γ towards good solutions. We do it here in two ways:

- A GRASP Algorithm *GRASP_VR_EPC*(Q), Q being a number of replications, that perform Q descent processes on Q randomly generated linear combinations of $L^T(\Gamma)$ and $L^E(\Gamma)$;
- An Algorithm *Descent_VR_EPC* that pipelines *GRASP_VR_EPC*(Q) and some pseudo-descent process parametrized by 2 flexibility parameters δ^{Time} and δ^{Ener}, that allow modifying the route Γ even when neither δ^{Time} nor δ^{Ener} decreases.

The GRASP Algorithm *GRASP_VR_EPC*.
It considers a replication parameter Q and works as follows:

1) At any replication q, it randomly generates two non negative scaling parameters ω^{Time} and ω^{Ener} together with an initial route $\Gamma(q)$;
2) Then it applies *2_Opt* and *Reloc* until $\Gamma(q)$ becomes a local optimum with respect to the surrogate objective function $\omega^{Time} \cdot L^T(\Gamma) + \omega^{Ener} \cdot L^E(\Gamma)$;
3) Finally it computes $W_Aux(\Gamma(q))$ while applying the *PDYN_EPC* algorithm and updates the best current route $\Gamma(q_{Best})$. When the whole process is over, it computes the exact value $W(\Gamma(q_{Best}))$ while applying the restriction of **VR_EPC_MILP** to Γ.

This is summarized by Algorithm 1:

Algorithm 1: GRASP_VR_EPC(Replication Parameter Q).

input : The inputs of the **VR_EPC Problem**, that we suppose to be feasible
output: A best route Γ^{Best} and related value W^{Best}

$\Gamma^{Best} \leftarrow Undefined$; $W_Aux^{Best} \leftarrow +\infty$;
for $q = 0, \ldots, Q$ **do**
  Randomly generate coefficients ω^{Time} and ω^{Ener} ;
  Randomly generate $\Gamma(q)$; `Stop` $\leftarrow$ `False` ;
  while not `Stop` **do**
    By applying *2_Opt* or *Reloc*, decrease $\omega^{Time} \cdot L^T(\Gamma(q)) + \omega^{Ener} \cdot L^E(\Gamma(q))$;
    if *Fail(decrease)* **then**
      `Stop` $\leftarrow$ `True`
    else
      Modify $\Gamma(q)$ accordingly
    end
  end
  Compute $W_Aux(\Gamma(q))$ by applying *PDYN_EPC*;
  if $W_Aux^{Best} > W_Aux(\Gamma(q))$ **then**
    $\Gamma^{Best} \leftarrow \Gamma(q)$; $W_Aux^{Best} \leftarrow W_Aux(\Gamma(q))$;
end
Compute the exact value W^{Best} (by application of the restriction of **VR_EPC_MILP** to Γ^{Best};
return Γ^{Best} and W^{Best}.

The Pseudo-Descent Algorithm *Descent_VR_EPC*: Clearly, it may occur that current route Γ may be improved by operators *2_Opt* and *Reloc* while neither $L^{Time}(\Gamma)$ nor $L^{Ener}(\Gamma)$ may be improved. This suggests allowing the *2_Opt* and *Reloc* operators to slightly deteriorate the values $L^{Time}(\Gamma)$ and $L^{Ener}(\Gamma)$ and deciding about their application after computing $W_Aux(\Gamma)$ while relying on the algorithm *PDYN_EPC*. More precisely, let us consider 2 parameters $\delta^{Time} > 0, \delta^{Ener} > 0$ and 2 routes Γ_1, Γ_2. We say that Γ_2 deteriorates Γ_1 by no more than $(\delta^{Time}, \delta^{Ener})$ if at least one of the 2 following inequalities holds:

1) $L^{Time}(\Gamma_2) - L^{Time}(\Gamma_1) \leq \delta_1$;
2) $L^{Ener}(\Gamma_2) - L^{Ener}(\Gamma_1) \leq \delta_2$.

Then the parametric *Descent_VR_EPC*($\delta^{Time}, \delta^{Ener}$) algorithm works according to the following descent loop:

1) It initializes Γ as a *good quality* route (for instance by applying *GRASP_SVR_EP*(1) (1 replication));
2) At any iteration of the descent process, it generates all the *2_Opt* and *Reloc* parameters (j_1, j_2) such that resulting route deteriorates Γ by no more than $(\delta^{Time}, \delta^{Ener})$;
3) For any parameter (j_1, j_2) selected this way and any resulting route Γ_1 it tests its impact on the value $W_Aux(\Gamma_1)$ obtained through application of the *PDYN_EPC* Algorithm;
4) If improving Γ this way is possible, then it does it according to a *Best Descent* strategy else it stops. In case it stops then it compute the exact current value $W(\Gamma)$.

This is summarized by Algorithm 2:

Remark 2: Both *GRASP_VR_EPC* and *Descent_VR_EPC* might be easily extended along more sophisticated metaheuristic scheme, more specifically genetic and ant colony based schemes (see [9] and [7]).

D. Numerical Experiments

Table VII involves the same instances as Table II. It displays:

- The value $GRASP_50$ obtained by *GRASP_VR_EPC*(50) (50 replications) and related CPU time CPU_Grasp_50.
- The value $GRASP_150$ obtained by *GRASP_VR_EPC*(150) (150 replications).

Table VIII considers the same instances as Table III and displays The value $Desc_1 + LS$ obtained by the application of the following pipeline: *GRASP_VR_EPC*(1) (1 replication) $\rightarrow$ *Descent_VR_EPC*(4, 4), together with related CPU time $CPU_Desc + LS$.

Comments: *GRASP_VR_EPC* with 150 replications most often reaches quasi-optimality. It outperforms the upper bound computed by CPLEX in 4 CPU hours in 8 among the 20 instances and obtains the same value as CPLEX in 6 other instances. This trend is reinforced when $M = 30$.

Algorithm 2: Descent_VR_EPC(Parameters $\delta^{Time} \geq 0, \delta^{Ener} \geq 0$).

input : The inputs of the **VR_EPC Problem**, that we suppose to be feasible
output: A (good quality) route Γ

Initialize Γ and compute an approximation W of $W(\Gamma)$ by applying the *PDYN_EPC* Algorithm (value $W_Aux(\Gamma)$);
`Stop` $\leftarrow$ `False` ;
while not `Stop` **do**
  Generate all the parameters j_1, j_2 of the *2_Opt* operator such that applying *2_Opt* or *Reloc* to Γ deteriorates Γ by no more than $(\delta^{Time}, \delta^{Ener})$;
  for *Any 3-uple* (Op, j_1, j_2) *(Op meaning either Reloc or 2_Opt) generated this way* **do**
    Apply the *PDYN_EPC* Algorithm to the route resulting from application of (Op, j_1, j_2) to Γ;
  end
  if *A decrease of* $W_Aux(\Gamma)$ *with respect to* W *is obtained at least once* **then**
    Replace Γ by $Op(\Gamma, j_1, j_2)$ and W by related W_Aux value (*PDYN_EPC* Algorithm), with (Op, j_1, j_2) related to the best improvement
  else
    `Stop` $\leftarrow$ `False`;
  end
end
Compute the exact value $W(\Gamma)$ (by application of the restriction of **VR_EPC_MILP** to Γ;
return Γ and $W(\Gamma)$.

Applying the pipe-line *GRASP_VR_EPC*(1) (1 replication) $\rightarrow$ *Descent_VR_EPC*(4, 4) improves the value obtained by *GRASP_VR_EP5*(50) in 8 among the 20 instances, and the value obtained by *GRASP_VR_EPC*(150) in 5 among the 20 instances. The running times induced by the calls to *Descent_VR_EPC*(4, 4) are rather high, due to the fact that we did not optimize the transformation of a route Γ into a *PDYN_EPC* input. Also, we may notice that in some cases, *Descent_VR_EPC*(4, 4) yields poor results (if we refer to *GRASP_VR_EP5*(50)) due to a poor initial route computed by a single *GRASP_VR_EPC*(1) run.

V. Conclusion

We dealt here with a complex model which make interact a routing process with an energy production process. W adopted a centralized point of view, which skips uncertainties, and tried both an exact MILP approach and a heuristic approach based upon a statistical correlation analysis. In the future, it will of course be interesting to try other methods. Also we plan dealing with *collaborative* contexts, when several *consumers* interact, each provided with its own agenda and incomplete information, and with the issue related to the uncertainty induced by solar energy production.

***Abstract*—Various scientific fields are seeking to exploit tensors, which are multi-dimensional arrays that expand on the concept of matrices. Here, we consider an application arising from complex biological systems where the data can be processed and analyzed using tensors. Our modeling framework is the reaction-diffusion master equation (RDME) used to describe the dynamics of biological systems involving both reaction and diffusion processes. It is already notoriously hard to solve the more familiar chemical master equation (CME) that only involves reaction processes. Solving the RDME is even harder because its state space is considerably larger compared to that of the CME, and this further motivates the utilization of tensors. Our study is an illustrative example of how tensor techniques can be used to make predictions on the dynamics of a metapopulation model based on its RDME formulation.**

I. Introduction

TENSORS, fundamentally, are extensions of vectors, and matrices, with the ability to represent and manipulate data in multiple dimensions. Classical linear algebra approaches can circumvent tensors by flattening the data through mechanisms known as matricization or vectorization, although doing so can increase the computational overhead, especially as dimensionality grows. By contrast, specialized tensor methods avoid unfolding the tensor into a matrix format, with the trade-off that the preserved multi-dimensional format drastically complicates the design and implementation of algorithms, not to mention their subsequent understanding and maintenance by others than the original software architects.

Tensor methods encompass the efficient utilization of tensors for the purpose of problem-solving, data analysis, and the extraction of significant patterns from high-dimensional datasets. Tensors find utility not only in the biological application considered here, but also in many other areas, including popular image processing applications (e.g., facial recognition, analysis of musical scores, and identification of cliques within social networks [1], [2]). Together with earlier works on tensors and their decompositions that go back to 1927 [3], we note that more recent literature overviews of tensor techniques for large-scale numerical computations are given in [4], [5], [6], geared towards a scientific computing audience. Of course, there are way more applications of tensors than we can reasonably cite in a communication such as this one.

In the field of biochemistry, complex networks are shown to emerge as a result of the interactions among many cellular components, including DNA and RNA molecules. Determining the time-varying probability distribution of their states involves solving the chemical master equation (CME) [7]. The stochastic simulation algorithm (SSA) [8] is useful for analyzing the CME. An alternative method for addressing the CME is the finite state projection algorithm (FSP) [9], which amounts to solving differential equations that characterize the evolution of the probability distribution of the underlying Markov chain of the CME over time.

Spatial heterogeneity is a frequent property of many cellular habitats, which are not homogeneous in space. A number of distinct but similar mathematical techniques have been used to model stochastic reaction-diffusion systems in biological cells [10], [11]. For example, Smoluchowski proposed a modeling approach named the spatially continuous diffusion-limited reaction (SCDLR) [12]. Unlike these approaches, the reaction-diffusion master equation (RDME) [13] is obtained when we treat the diffusion at the molecular level as a unique set of reactions in the CME.

The space is partitioned into compartments in the RDME. Every compartment is thought to be thoroughly mixed, and the reactions found within a specific compartment are thought to be consistent with the homogeneous scenario. Additionally, molecules can diffuse (jump) in between neighboring compartments, and here we will model the jump processes as reactions. Similar to the CME but with a much larger dimensionality, the RDME explains the time-dependent probability distribution function (PDF) of the system state. The works in [14], [15], [16] provide instances of the SSA being used in reaction-diffusion systems with the space being one dimensional. The next reaction method (NRM) [17] is an efficient version of the SSA. A software called MesoRD [18] offers a specialized implementation of the NRM, which is designed for diffusive systems and known as the next subvolume method (NSM) [19].

In this contribution rooted in [20], our aim is to illustrate

how a tensor-based approach, specifically a quantized tensor-train decomposition, can be effectively used to manage the potentially high-dimensional state space arising in the RDME of a metapopulation model. Although the RDME shares similarities with the CME, it necessitates greater computational resources due to its considerably larger state space. We employ the tensor technique to derive the marginal distribution of the relevant species. By comparing the tensor technique with the classical FSP, this work aims to highlight the capability of tensors to reduce computational overhead while maintaining accuracy and generalizability across diverse applications.

II. Preliminaries

A. Tensors

We will soon recap how the CME and RDME lead to formulations involving tensors. We begin with some background to define the notation and situate our context. More formally, tensors are multi-dimensional arrays in $\mathbb{K}^{I_1 \times \cdots \times I_N}$, where N is the order, i.e., the number of dimensions, which are called modes or ways, and $I_1, \ldots, I_N$, are index ranges in each dimension. Tensors extend the notion of vectors and matrices, referred to as 1-way and 2-way tensors, respectively, whereas a 3-way tensor $\mathcal{X} \in \mathbb{R}^{I_1 \times I_2 \times I_3}$, depicted in Fig. 1, is a cuboid (or cube-like) with elements $x_{ijk} \equiv \mathcal{X}(i, j, k)$, $1 \leq i \leq I_1, 1 \leq j \leq I_2, 1 \leq k \leq I_3$. The field $\mathbb{K}$ will be $\mathbb{R}$ in our application but it can be $\mathbb{C}$ in general.

Index fixing can be used to build subarrays. A typical scenario is when all indices are fixed except one, in which case the resulting subarrays are referred to as fibers, c.f. Fig. 2. They can alternatively be thought of as mode-n fibers that are produced when all indices are fixed except the nth one. Another common scenario is when all indices are fixed except two, yielding the examples of slices depicted on Fig. 3 for a 3-way tensor. These examples make clear that there are many different possible orderings, meaning that software developers must agree on common conventions for consistency in their codes. If we stack the resulting fibers or slices, we are performing what is termed vectorization or matricization. In general, tensor unfolding denotes the mechanism by which to flatten a tensor to systematically arrange its entries into a matrix, thereby providing a bridge to circumvent tensors and revert to classical linear algebra operations.

On tensors of equal sizes, simple operations like addition and subtraction are performed component-by-component. However, beyond ordinary matrix-like definitions, there are other tensor-specific operations and decompositions that are much more sophisticated by far.

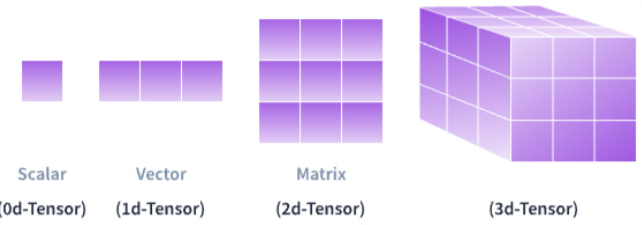

Fig. 1. Tensors of order 0, 1, 2, and 3.

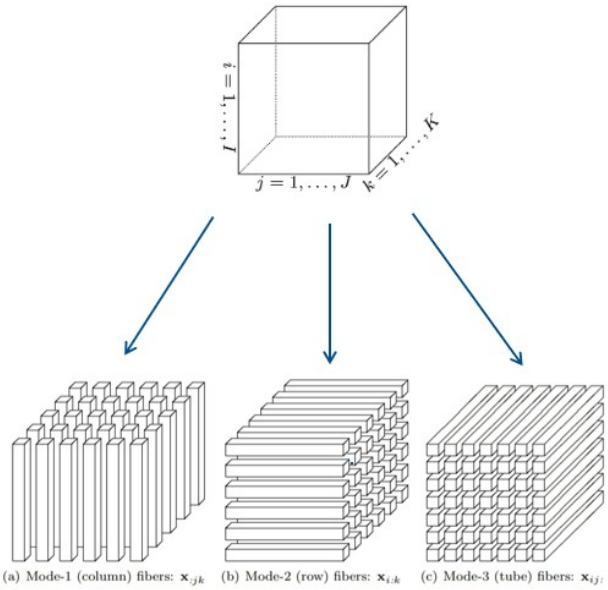

Fig. 2. Different fibers of a 3-mode tensor.

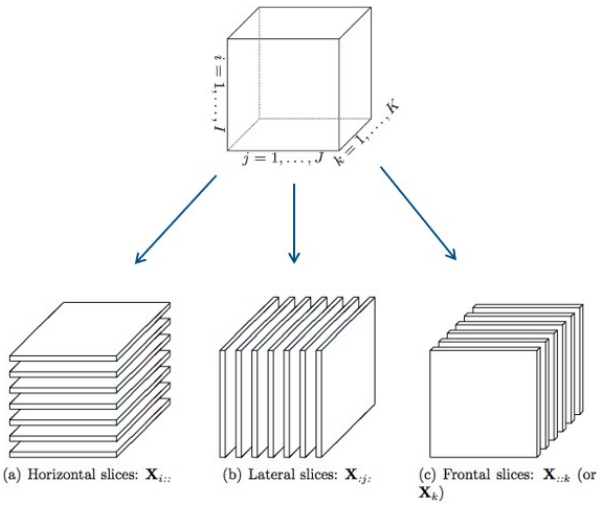

Fig. 3. Different slices of a 3-mode tensor.

B. Higher Order Singular Value Decomposition (HOSVD)

Consider the Singular Value Decomposition (SVD), which is a fundamental matrix factorization that represents any matrix as the product of two orthogonal matrices together with a diagonal matrix of singular values, encapsulating the inherent geometric characteristics of the data. Higher Order Singular Value Decomposition (HOSVD) generalizes this concept to multi-dimensional tensors, by decomposing them into a core tensor and a collection of orthogonal matrices corresponding to each mode. Below we reproduce a characterization of the HOSVD [21], mainly to illustrate how concepts that are familiar with matrices can quickly become drastically harder to grasp when reformulated through tensors.

Theorem II-B.1: Every tensor $\mathcal{X} \in \mathbb{R}^{I_1 \times I_2 \times \cdots \times I_N}$ can be written as

$$\mathcal{X} = \mathcal{G} \times_1 \mathbf{A}^{(1)} \times_2 \mathbf{A}^{(2)} \cdots \times_N \mathbf{A}^{(N)},$$

where

1) $\mathbf{A}^{(n)} = \begin{pmatrix} A_1^{(n)} & A_2^{(n)} & \cdots & A_{I_n}^{(n)} \end{pmatrix}$ is an orthogonal matrix of order $I_n \times I_n$,
2) $\mathcal{G} \in \mathbb{R}^{I_1 \times I_2 \times \cdots \times I_N}$ of which the subtensors $\mathcal{G}_{i_n=\alpha}$, attained by fixing the nth index to α, have the properties of
   (i) ordering:
   $$\|\mathcal{G}_{i_n=1}\|_F \geq \|\mathcal{G}_{i_n=2}\|_F \geq \cdots \geq \|\mathcal{G}_{i_n=I_n}\|_F \geq 0,$$
   for all possible values of n,
   (ii) all-orthogonality: for all possible values of n, α and β, two subtensors $\mathcal{G}_{i_n=\alpha}$ and $\mathcal{G}_{i_n=\beta}$ are orthogonal subject to $\alpha \neq \beta$:
   $$\langle \mathcal{G}_{i_n=\alpha}, \mathcal{G}_{i_n=\beta} \rangle = 0 \text{ for } \alpha \neq \beta.$$
3) $\mathcal{G} = \mathcal{X} \times_1 \mathbf{A}^{(1)T} \times_2 \mathbf{A}^{(2)T} \cdots \times_N \mathbf{A}^{(N)T}$.

The vector $A_i^{(n)}$ is an n-mode singular vector and the Frobenius-norms $\|\mathcal{G}_{i_n=i}\|_F$ are n-mode singular values of $\mathcal{X}$. N denotes the total number of modes of the tensor, and $n \in \{1, \ldots, N\}$ refers to an arbitrary mode index. The symbol $\times_n$ denotes the mode-n product, which is an operation where each mode-n fiber of a tensor is multiplied by a matrix, affecting only the nth dimension while keeping others fixed.

C. CANDECOMP/PARAFAC (CP) Decomposition

A popular decomposition in practice is the CP decomposition, which for $\mathcal{X} \in \mathbb{R}^{I_1 \times \cdots \times I_N}$, is given by [22],

$$\mathcal{X} = \mathcal{I} \times_1 \mathbf{A}^{(1)} \cdots \times_N \mathbf{A}^{(N)} \equiv \left[\!\!\left[\mathbf{A}^{(1)}, \cdots, \mathbf{A}^{(N)} \right]\!\!\right] \quad (1)$$

where $\mathcal{I}$ is the identity tensor having ones along the super-diagonal and zeros elsewhere, and each $\mathbf{A}^{(n)} \in \mathbb{R}^{I_n \times R}$ for $n = 1, \ldots, N$ is a factor matrix. The notation $[\![\cdot]\!]$ denotes the CP decomposition as a sum of R rank-one tensors formed by outer products of the columns of the factor matrices. The CP rank $R \in \mathbb{N}$ is left as a parameter that tunes the accuracy of the decomposition. The fact that CP boils down to resorting to matrices explains its appeal and popularity.

According to [23], (1) can be written element-wise as a sum of products of the entries of those matrices

$$\mathcal{X}(i_1, \ldots, i_N) = \sum_{r=1}^{R} \mathbf{A}^{(1)}(i_1, r) \cdots \mathbf{A}^{(N)}(i_N, r). \quad (2)$$

Equation (3) below is another compact notation for writing (1) or (2) via the outer product

$$\mathcal{X} = \sum_{r=1}^{R} \mathbf{a}_r^{(1)} \circ \cdots \circ \mathbf{a}_r^{(N)}. \quad (3)$$

by referencing columns of $\mathbf{A}^{(n)} = \begin{pmatrix} \mathbf{a}_1^{(n)} & \ldots & \mathbf{a}_R^{(n)} \end{pmatrix} \in \mathbb{R}^{I_n \times R}, n = 1, \ldots, N$.

D. Tensor Train (TT) Decomposition

Our present numerical implementation is based on another decomposition, namely the tensor train (TT) decomposition. For any $\mathcal{X} \in \mathbb{R}^{I_1 \times \cdots \times I_N}$, it can be shown that its entries can be written in the form [24],

$$\mathcal{X}(i_1, \ldots, i_N) = \mathcal{G}_1(i_1) \cdot \ldots \cdot \mathcal{G}_N(i_N). \quad (4)$$

Here, $\mathcal{G}_n(i_n) \in \mathbb{R}^{r_{n-1} \times r_n}$ are matrices (slices) of the cuboid (3-way) tensors $\mathcal{G}_n \in \mathbb{R}^{r_{n-1} \times r_n \times r_n}$, which are called TT cores. Moreover, "boundary conditions" $r_0 = r_N = 1$ are imposed so that the chain product (4) always yields a scalar. TT ranks are defined as $(r_1, \cdots, r_{N-1})$.

An explicit storage of $\mathcal{X}$ would cost $\prod_{n=1}^{N} I_n = O(I^N)$, where $I = \max_{1 \leq n \leq N} I_n$, so that if $N = 10$ in a CME application and $I \approx 10$, its corresponding matrix (7) would be of immense size $10^{10} \times 10^{10}$ and even much more for the RDME. By contrast, the TT format only stores the TT cores at a total cost of $O(r_{TT}^2 \cdot N \cdot I)$, where $r_{TT} = \max_{1 \leq n \leq N} r_n$. Thus, provided that the maximum rank r_{TT} is not large, the storage of the TT format scales linearly with N, leading to dramatic savings from the explicit format where the storage scales exponentially with N. Our actual code builds on another variant, specifically the quantized tensor train (QTT) format that brings the storage requirements further down to $O(r_{QTT}^2 \cdot N \cdot \log_2 I)$. Although r_{QTT} is not necessarily r_{TT}, this reduction remarkably means a linear cost in the number of modes and logarithmic in the mode sizes.

Our implementation did not have to invent everything from scratch. Rather, we leveraged past research, including [25], [26], and the TT toolbox software [24]. Our contribution here is sharing the findings of our hands-on experience on these topics and their application to the RDME context that we describe next.

E. CME and FSP in tensor format

Consider a chemical reacting system in a spatial domain Ω involving N species $\{S_1, \ldots, S_N\}$, represented by the state vector $\mathbf{X}(t) = [X_1(t), \ldots, X_N(t)]^T$, where each $X_i(t)$ is a non-negative integer denoting the population of species S_i at time t. Suppose there are M reaction channels, denoted

by $\{R_1, \ldots, R_M\}$, and assume that the system is well mixed and in thermal equilibrium. The dynamics of the jth reaction channel R_j is characterized by

(i) the propensity function $a_j(\mathbf{x})$, which indicates how likely it is that R_j will occur given the system's current state $\mathbf{x}$, and

(ii) the stoichiometric (or state change) vector $\boldsymbol{\nu}_j = [\nu_{1j}, \ldots, \nu_{Nj}]^T$, which specifies the change in the population count of each species that results from one occurrence of R_j.

Thus, $a_j(\mathbf{x})dt$ gives the probability that, given $\mathbf{X}(t) = \mathbf{x}$, one R_j reaction will occur in the next infinitesimal time interval $[t, t + dt]$, and ν_{ij} gives the change in X_i induced by one R_j reaction. This system can be modeled as a Markov chain, with its behavior determined by the Chemical Master Equation (CME) [7]

$$\frac{dP(\mathbf{x},t)}{dt} = \sum_{j=1}^{M} \Big[a_j(\mathbf{x} - \boldsymbol{\nu}_j)P(\mathbf{x} - \boldsymbol{\nu}_j, t) - a_j(\mathbf{x})P(\mathbf{x},t)\Big], \tag{5}$$

where the function $P(\mathbf{x}, t)$ denotes the probability that $\mathbf{X}(t)$ will be $\mathbf{x}$. Equation (5) may be written in an equivalent matrix–vector form by enumerating all the states. If there are n possible states, $\mathbf{x}_1, \ldots, \mathbf{x}_n$, the CME takes the form of a system of linear ordinary differential equations (ODEs),

$$\dot{\mathbf{P}}(t) = \boldsymbol{\mathcal{M}} \cdot \mathbf{P}(t), \tag{6}$$

where the probability vector $\mathbf{P} = [p_1, \ldots, p_n]^T$ is such that each component $p_i \equiv P(\mathbf{x}_i, t) \equiv \text{Prob}\{\mathbf{X}(t) = \mathbf{x}_i\}$, the probability of being at state $\mathbf{x}_i$ at time t, for $i = 1, \ldots, n$.

The matrix $\boldsymbol{\mathcal{M}}$ is a sparse $n \times n$ matrix that is populated by the propensities and it represents the transition rate matrix of the Markov chain underlying the CME. Its entries are constructed using

$$\boldsymbol{\mathcal{M}}(i,j) = \begin{cases} a_k(\mathbf{x}_j) \text{ if } \mathbf{x}_i = \mathbf{x}_j + \boldsymbol{\nu}_k \\ -\sum_{k=1}^{M} a_k(\mathbf{x}_j) \text{ if } i = j \\ 0 \text{ otherwise} \end{cases}. \tag{7}$$

The FSP method [9] and improvements such as [27] directly compute an approximation to the solution of the CME. The FSP method solves the CME and estimates the probability vector (PV) of the populations in a chemical reaction system using a truncated state space. For a truncated transition matrix $\boldsymbol{\mathcal{M}}_T$ and initial truncated PV denoted by $\mathbf{P}_T(0)$, the FSP finds the PV at any time $\mathbf{P}_T(t)$ by the following,

$$\dot{\mathbf{P}}_T(t) = \boldsymbol{\mathcal{M}}_T \cdot \mathbf{P}_T(t). \tag{8}$$

Equation (8) is a system of linear ODEs and the solution is given by

$$\mathbf{P}_T(t) = \exp(\boldsymbol{\mathcal{M}}_T t)\, \mathbf{P}_T(0). \tag{9}$$

The CME matrix $\boldsymbol{\mathcal{M}}$ remains sparse under any order relation imposed on the enumeration of the states, and it is natural to use the lexicographic order on the state space as a subset of $\mathbb{N}$, the set of nonnegative natural numbers. If we impose the lexicographic order on a state space $\mathbb{X}$ in the form of a window of lower bounds $(lb^{(1)}, \ldots, lb^{(N)})$ and upper bounds $(ub^{(1)}, \ldots, ub^{(N)})$, i.e., $\mathbb{X}$ consists of states $\mathbf{x} = (x_1, \cdots, x_N)^T$ such that $lb^{(s)} \le x_s \le ub^{(s)}, \forall s = 1, \ldots, N$, then the transition rate matrix can be decomposed into a sum of Kronecker products [28], [29]

$$\boldsymbol{\mathcal{M}} = \sum_{k=1}^{M} \left(\otimes_{s=1}^{N} \mathbf{S}_k^{(s)} - \mathbf{I}\right) \mathbf{M}_k. \tag{10}$$

Each term in the sum (10) corresponds to a reaction: $\mathbf{S}_k^{(s)}$ is a "shift-diagonal" matrix corresponding to the change in species s when reaction k happens; $\mathbf{I}$ is the identity matrix; and $\mathbf{M}_k$ is the diagonal matrix that stores the values of the propensity function a_k. Precisely, let $I_s = ub^{(s)} - lb^{(s)} + 1$ be the window size for each species, $n = I_1 \cdot \ldots \cdot I_N$ is the total number of states in $\mathbb{X}$, and denote $\boldsymbol{\nu}_k = \left(\nu_k^{(1)}, \cdots, \nu_k^{(N)}\right)^T$. The identity matrix $\mathbf{I}$ is then of order n, $\mathbf{S}_k^{(s)} \in \mathbb{R}^{I_s \times I_s}$ is given by

$$\mathbf{S}_k^{(s)} \equiv \begin{cases} \begin{pmatrix} 0 & \cdots & 1 & & \\ & \ddots & & \ddots & \\ & & \ddots & & 1 \\ & & & \ddots & \vdots \\ & & & & 0 \end{pmatrix} & \text{if } \nu_k^{(s)} < 0, \text{shifted up } \left|\nu_k^{(s)}\right| \text{ rows} \\ \begin{pmatrix} 0 & & & & \\ \vdots & \ddots & & & \\ 1 & & \ddots & & \\ & \ddots & & \ddots & \\ & & 1 & \cdots & 0 \end{pmatrix} & \text{if } \nu_k^{(s)} \ge 0, \text{shifted down } \nu_k^{(s)} \text{ rows} \end{cases}$$

and

$$\mathbf{M}_k \equiv \text{diag}\left(a_k(\mathbf{x}_1), \cdots, a_k(\mathbf{x}_n)\right), \tag{11}$$

where $\mathbf{x}_1, \cdots, \mathbf{x}_n$ are states of $\mathbb{X}$ in the increasing lexicographic order. Furthermore, by assuming that the propensity functions are separable, i.e.,

$$a_k(\mathbf{x}) = a_k^{(1)}(x_1) \cdot \ldots \cdot a_k^{(N)}(x_N), \quad k = 1, \cdots, M,$$

where $a_k^{(\cdot)} \ge 0$ are scalar functions, (11) can be rewritten as

$$\mathbf{M}_k = \otimes_{s=1}^{N} \text{diag}\ a_k^{(s)},$$

where, for $s = 1, \cdots, N$,

$$\text{diag}\, a_k^{(s)} \equiv \text{diag}\left(a_k^{(s)}(lb^{(s)}), \cdots, a_k^{(s)}(ub^{(s)})\right).$$

Under these assumptions, the transition matrix (10) can be represented by simple matrices of small sizes,

$$\boldsymbol{\mathcal{M}} = \sum_{k=1}^{M} \left(\otimes_{s=1}^{N} \mathbf{S}_k^{(s)} - \mathbf{I}\right) \left(\otimes_{s=1}^{N} \text{diag}\ a_k^{(s)}\right). \tag{12}$$

In [26], the lower and upper bounds are in the form $lb^{(s)} = 0$ and $ub^{(s)} = I_s - 1$, yielding

$$\operatorname{diag} a_k^{(s)} = \operatorname{diag}\left(a_k^{(s)}(0), \cdots, a_k^{(s)}(I_s - 1)\right).$$

The reason for holding the lower bounds anchored at 0 was to help attenuate some of the complexity of dealing with tensor train decompositions when their sizes changed adaptively. Subsequent improvements in [25] allowed both the lower and upper bounds to slide dynamically. A central aspect in our body of research [25], [20], [26] has been that by keeping the state space in the form of a hyper-rectangle,

$$\mathbf{x} \in \left[lb^{(1)} : ub^{(1)}\right] \times \cdots \times \left[lb^{(N)} : ub^{(N)}\right],$$

both the transition operator $\boldsymbol{\mathcal{M}}$ and the probability distribution $\mathbf{P}$ can be represented as multi-dimensional arrays that allow us to use tensor decompositions as pioneered in [28], [29] to resolve storage issues.

F. RDME

Assume the spatial domain Ω is partitioned into compartments (voxels), denoted V_k, $k = 1, \ldots, K$. Within each compartment, species have the ability to react with one another as well as diffuse (jump) over the boundaries to reach adjacent compartments. Let $X_{i,k}(t)$ be the population count of species S_i in compartment V_k at time t. Then each species in the domain is given by the subvector $\mathbf{X}_i(t) = [X_{i,1}(t), \ldots, X_{i,K}(t)]$, $i = 1, \ldots, N$. Hence, $\mathbf{X}_1$ is the subvector which represents the species 1 in all compartments. Likewise, $\mathbf{X}_2$ represents species 2 in all compartments, and so on. Thus, the state vector of the system is $\mathbf{X} = [\mathbf{X}_1, \ldots, \mathbf{X}_N]$. The diffusion propensity function $d_{i,j,k}$ and the state change vector $\boldsymbol{\mu}_{k,j}$ characterize the dynamics of the diffusion of species S_i from compartment V_k to V_j. The vector $\boldsymbol{\mu}_{k,j}$ has a length of K with -1 in the kth position, 1 in the jth position, and 0 elsewhere. Given $\mathbf{X}(t) = \mathbf{x}$, the diffusion master equation (DME) can be written as

$$\begin{aligned}\frac{dP(\mathbf{x},t)}{dt} = \sum_{i=1}^{N}\sum_{k=1}^{K}\sum_{j=1}^{K}\Big[d_{i,j,k}(\mathbf{x}_i - \boldsymbol{\mu}_{k,j})P(\mathbf{x}_1, \ldots, \\ \mathbf{x}_i - \boldsymbol{\mu}_{k,j}, \ldots, \mathbf{x}_N, t) - d_{i,j,k}(\mathbf{x}_i)P(\mathbf{x},t)\Big].\end{aligned} \tag{13}$$

We take the diffusion propensity function $d_{i,j,k}(\mathbf{x}_i) = D/l^2$, for $k = j \pm 1$, where D is the diffusion rate and l is the characteristic length of the compartment, meaning that our setting ultimately assumes that $d_{i,j,k} \equiv d$ is constant. Some other settings could make different choices. If $\boldsymbol{\mathcal{D}}$ is the transition matrix describing the diffusion (or jump) of species between compartments, the equivalent matrix–vector form of (13) can be written as

$$\dot{\mathbf{P}}(t) = \boldsymbol{\mathcal{D}} \cdot \mathbf{P}(t). \tag{14}$$

Combining equations (6) and (14) we get the matrix-vector form of the RDME,

$$\dot{\mathbf{P}}(t) = \boldsymbol{\mathcal{M}} \cdot \mathbf{P}(t) + \boldsymbol{\mathcal{D}} \cdot \mathbf{P}(t). \tag{15}$$

Equation (15) is a system of linear constant coefficient ODEs and gives us more possible states than the CME, and so its corresponding transition matrix is substantially extended to represent species in compartments. However, it should be remembered that it is ultimately a tensor representation of the form (12) that is used in the calculations.

III. Study Findings

A. Metapopulation Model

Populations that are segmented into smaller groups linked by migration are studied using metapopulation models. Metapopulation models often employ reaction-diffusion principles to describe spatial dynamics [30]. In a reaction-diffusion metapopulation model, the reaction term depicts the occurences of births and deaths within each subpopulation, whereas the diffusion term captures the mobility of an individual between nearby subpopulations. By taking into account both diffusion and reaction terms, the model can better capture complex interactions between local population dynamics and spatial dispersal. Using the RDME in a metapopulation model, each subpopulation's population is modeled as a stochastic process with birth, death, and migration events occurring randomly. We examine a simple reaction scheme in this study that conserves the population count in order to empirically provide a proof-of-concept

$$\beta \xrightarrow{c_1} \alpha, \tag{16}$$

$$\alpha + \beta \xrightarrow{c_2} 2\beta. \tag{17}$$

In the context of our metapopulation model, α species represent normal species (healthy individuals) and β species represent active species (infected individuals) intermingling from area to area. This scheme is also known as the SIS model (Susceptible-Infectious-Susceptible) [31]. Recall that when we analyze this model without considering compartments and diffusion, the stoichiometric matrix is

$$S = \begin{array}{c} \\ \alpha \\ \beta \end{array} \begin{array}{c} \begin{array}{cc|cc} \alpha & \beta & \alpha & \beta \end{array} \\ \left(\begin{array}{cc|cc} 0 & 1 & 1 & 0 \\ 1 & 1 & 0 & 2 \end{array}\right) \end{array}$$

in which the first and second row of the matrix stand for reactions (16) and (17) respectively. The two left columns contain the coefficients of the reactants while the other two right columns contain the coefficients of the products. Meaning that from $S = (s_{ij})$, the components of the state change vector associated to a reaction R_k, $k = 1, \ldots, M$, are effectively

$$(s_{k,N+1:2N} - s_{k,1:N}) \tag{18}$$

where in this example $N = 2$ and $M = 2$. It is less error prone to set S and programmatically proceed as shown above.

We now consider two neighboring areas (i.e., compartments) where both the healthy and infected individuals can move back and forth. We label the areas as Area 1 and Area 2. Consequently, the scheme can be represented by a reaction-diffusion process where reactions (16) and (17) can take place inside both areas separately and the individuals can move back

and forth between Area 1 and Area 2. An illustration is shown in Fig. 4. (Imagine Area 1 as indoor and Area 2 as outdoor.)

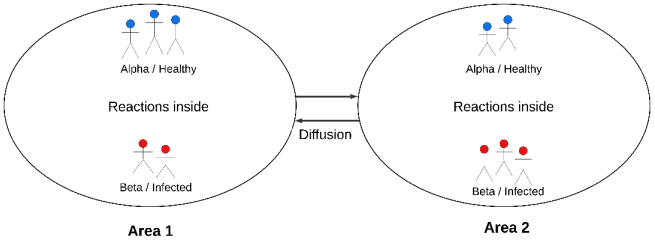

Fig. 4. Illustration of the metapopulation example.

The process is a random process and can be modeled by the RDME consisting of two reactions with two compartments. By our construction, species change forms without creating or destroying themselves, hence the overall population count in the process stays constant.

To make the details clear, we take a small example where we assume that initially, Area 1 has $\alpha = 2$ healthy individuals and $\beta = 1$ infected individual. Area 2 has $\alpha = 1$ healthy individual and $\beta = 2$ infected individuals. With the convention of section II-F, the initial state vector is therefore

$$[\overbrace{\underbrace{2}_{\text{Area 1}},\underbrace{1}_{\text{Area 2}}}^{\alpha},\overbrace{\underbrace{1}_{\text{Area 1}},\underbrace{2}_{\text{Area 2}}}^{\beta}] \tag{19}$$

with diacritical annotations in (19) meant to ease the interpretation of the indexing of the components. We set the reaction parameters $c_1 = .30$ and $c_2 = 1.0$, and the diffusion parameters $D = 1.0$ and $l = 10$, yielding $d = D/l^2 = 10^{-2}$. The RDME gives us all the possible states we can get when those individuals react and diffuse randomly, and recall that along a similar spirit to [32, Eq. (4)], diffusion in our context is modeled via stochastic jump processes through additional reactions,

$$(\text{Area 1})\ \alpha \underset{d}{\overset{d}{\rightleftharpoons}} \alpha\ (\text{Area 2}), \tag{20}$$

$$(\text{Area 1})\ \beta \underset{d}{\overset{d}{\rightleftharpoons}} \beta\ (\text{Area 2}). \tag{21}$$

Now that we are considering the system in two areas where diffusion also occurs, the stoichiometric matrix grows much larger to take the form below.

$$S = \begin{array}{c} \\ \textbf{Area\#} \\ \\ \\ \\ \\ \\ \\ \\ \end{array} \begin{array}{c} \overbrace{\qquad\qquad\qquad\qquad}^{\textbf{Reactants}} \qquad \overbrace{\qquad\qquad\qquad\qquad}^{\textbf{Products}} \\ \overbrace{\quad}^{\alpha}\ \overbrace{\quad}^{\beta}\ \overbrace{\quad}^{\alpha}\ \overbrace{\quad}^{\beta} \\ \textbf{1}\ \ \textbf{2}\ \ \textbf{1}\ \ \textbf{2}\ \ \textbf{1}\ \ \textbf{2}\ \ \textbf{1}\ \ \textbf{2} \\ \hline \\ \\ \\ \\ \hline \\ \\ \\ \\ \end{array} \begin{pmatrix} 0 & 0 & 1 & 0 & 1 & 0 & 0 & 0 \\ 1 & 0 & 1 & 0 & 0 & 0 & 2 & 0 \\ 0 & 0 & 0 & 1 & 0 & 1 & 0 & 0 \\ 0 & 1 & 0 & 1 & 0 & 0 & 0 & 2 \\ \hline 1 & 0 & 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 1 & 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 1 & 0 & 0 & 1 & 0 \end{pmatrix} \begin{array}{l} \\ \\ \\ \\ \\ \textbf{Reactions} \\ \\ \\ \\ \textbf{Diffusions} \end{array}$$

The annotations here are also aimed at easing the connection of how to map the location of entries with the convention of section II-F. In the matrix, the first two rows indicate reactions (16) and (17) inside Area 1. The third and fourth rows represent the same reactions respectively in Area 2. Diffusions (20) and (21) are characterized by the last four rows. The four left columns contain the coefficients of the reactants and the other four right columns contain the coefficients of the products. Using (18) with $N = 4$ and $M = 8$ gives the state change vectors.

Even starting with a simple initial state as $[2, 1, 1, 2]$ explained in (19), the system explodes to a total of 84 possible states (and quickly much more if we set larger starting values as we alerted before). We solve the associated RDME using the classical FSP equation (9) with a state space truncated to 70 to continue our empirical illustration of the computational building blocks. Taking $t = 10$, we obtain an approximation of the marginal probability distribution of the healthy and infected individuals in the two areas. Results are shown in Fig. 5.

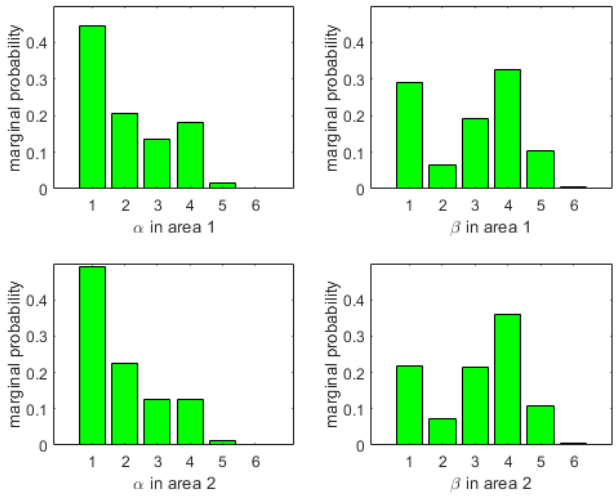

Fig. 5. Marginal probability distribution of the number of healthy and infected individuals in the two areas using the classical FSP at time $t = 10$.

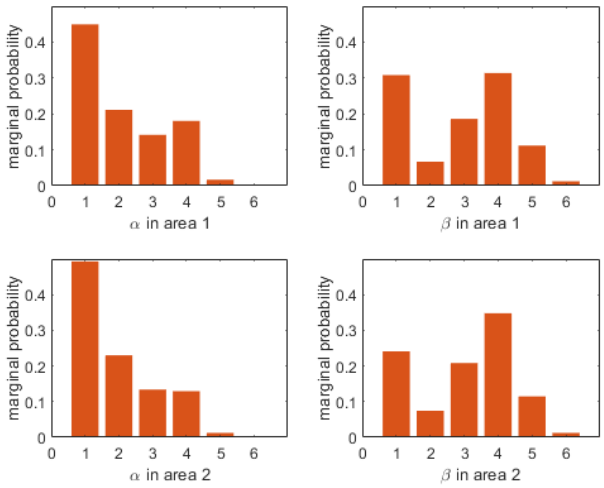

Fig. 6. Marginal probability distribution of the number of healthy and infected individuals in the two areas using tensors at time $t = 10$.

Having obtained a reference solution via the classical FSP, we now attempt to reproduce results using tensors on the same metapopulation model. As explained in the text, the main concept is to express a high-dimensional tensor as an ordered product of smaller tensors that can scale better as problems become more complex than the simple example shown here for illustration and ease of interpretation. For our purposes, the marginal probability distribution of the individuals are found by using the adaptive tensor code in [25], which has already been demonstrated to be effective on much larger problems albeit in the CME context. Fig. 6 shows the computed marginal probability distribution of the healthy and infected individuals in the two areas using the tensor technique in our RDME prototype. Fig. 7 illustrates the accuracy of the implementation of tensors by showing the near alignment of the marginal distributions obtained using the two alternative approaches.

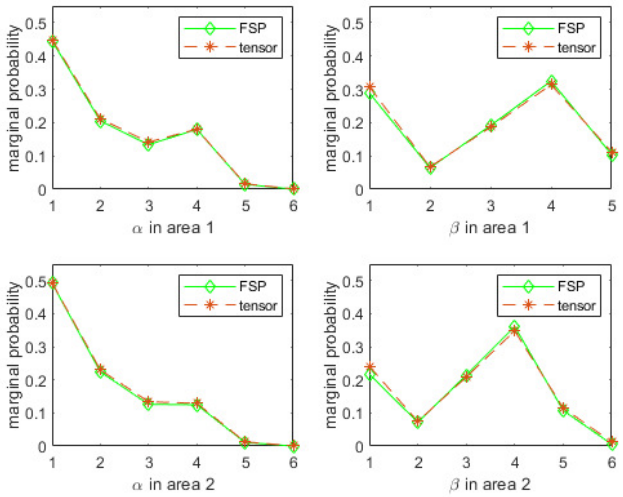

Fig. 7. Comparison of the marginal probability distributions computed using the classical FSP vs tensors.

IV. Conclusions

We have applied the RDME formulation in a metapopulation model that includes both reaction and diffusion processes. Although our initialization was kept simple to detail the algorithmic steps, it is perhaps worth mentioning that the broader significance of the metapopulation model with reaction-diffusion is to represent the interplay between local population dynamics and migration. It is a way of understanding how populations behave when they are distributed across discrete, interconnected areas and subject to both local environmental factors (birth/death rates) and movement between these areas (diffusion). This model is of value in the literature because it provides insights into how populations persist, grow, or face extinction in fragmented landscapes. The model is essential for addressing real-world issues such as conservation, habitat fragmentation, disease spread, and the management of invasive species, where the dynamics of movement and local interactions play key roles in shaping long-term outcomes.

Therefore, the fact that we have an RDME formulation opens avenues for further computerized simulations. Here, we have utilized the FSP and tensors to approximate the marginal probability distribution. Rather than taking into account all possible states, the FSP operates with a reduced state space. On top of that, the compact representation of the transition matrix via tensors goes hand in hand with tensor train decompositions. Our body of research has shown that tensors scale very well to tackle multi-dimensional CME problems, suggesting promising prospects for their application in the RDME as we illustrated in this case study. Although the tensor approach introduces a significant complexity in the derivation of algorithms, it offers distinct scalability advantages. It excels in

managing high-dimensional problems by efficiently representing extensive state spaces with reduced memory requirements, making it particularly effective in scenarios where the classical matrix-based FSP becomes computationally expensive or infeasible.

***Abstract*—The IT Business Partner (ITBP) role is increasingly adopted to bridge the gap between business and IT and foster strategic alignment. Even though organizations still struggle with implementing an effective collaboration between business and IT, the design of this role and the challenges it faces remain underexplored. This study is the first scientific paper to examine the ITBP. Through a case study and expert interviews, it derives eleven key tasks, with relationship management and advice at its core, and 14 required skills for effectiveness. It identifies challenges of the ITBP role, such as organizational integration, skill gaps and a lack of strategic focus. This study contributes to the field by offering a comprehensive understanding of the ITBP's design and role for business IT alignment. It provides organizations with guidance on the implementation and skill development of the ITBP role. Future research should validate findings and further explore the role's effectiveness.**

***Index Terms*— IT business partner, business relationship manager, IT role design, tasks, skills, challenges, business-IT alignment.**

I. Introduction

IN TIMES of digital transformation, it becomes a competitive advantage to work in an integrated way and align the business and information technology (IT) mindsets across the organization [1]. However, a survey reveals that only 30% of the 114 responding managers perceive their collaboration between business and IT units as adequate [2]. The majority struggles with IT optimization decisions and highlights a poor and complex collaboration process. To improve collaboration between business and IT, companies implement interface roles like IT Business Partner (ITBP), Business Analyst, and similar positions. In 2018, Gartner Inc. introduces such a role highlighting its importance for alignment and value creation [3].

Literature recognizes the importance of these interface functions for business-IT alignment (BITA) and to establish relational mechanisms [4], [5]. IT management frameworks such as Information Technology Infrastructure Library (ITIL) and Technology Business Management (TBM) mention a Business Relationship Manager (BRM) as a relevant role to build a strong relationship between the IT organization and the business units [6], [7]. Even though the role becomes increasingly important, and organizations still struggle to implement it effectively, to our knowledge, there is no academic, peer-reviewed in-depth study that examines this role at the interface between business and IT and its contribution to bringing business and IT closer together. The objective of this paper is, therefore, to provide a detailed understanding of the ITBP role, including its role design, key tasks, required skills, and challenges. To address this, we pose two research questions (RQ): (1) *How can organizations design the interface role of the IT Business Partner for effective business-IT collaboration?* and (2) *What practical challenges does the IT Business Partner face in organizations?* By answering these questions, we expand the theoretical knowledge about the interface role and its impact on business-IT alignment. Additionally, we provide practical support in designing the role and selecting individuals with the relevant skills to fulfil it.

The article is structured as follows: the second section examines the theoretical background on collaboration between business and IT and the ITBP role. We then outline our methodological approach triangulating a case study and expert interviews for an in-depth, practical study. Section four presents the findings, followed by a discussion of the results in the context of successful implementation within organizations. Finally, we conclude with the study's limitations and offer an outlook for future research.

II. Background And Related Work

Effective collaboration between the business and the IT department is the basis for achieving added value through IT [4]. Thus, we first introduce research on this collaboration. Then, we examine roles at the interface and the ITBP role with its "mission to increase business value" [3].

A. Business-IT Collaboration

The collaboration between business and IT has been a central focus of research for decades, as organizations strive to bridge the gap between strategic goals and technological implementation by aligning the two disciplines [1], [8]. A foundational framework for understanding this relationship is the Strategic Alignment Model (SAM) introduced by [9]: it describes alignment as the dynamic interplay between strategic and operational levels and the functional integration of business and IT domains. Notably, alignment is not a static state but an ongoing process requiring continuous communication, mutual understanding, and shared objectives [10]. A higher degree of maturity in this alignment directly contributes to improved organizational performance, innovative ability, and competitive advantage [8]. According to Luftman's maturity model [11], strong Business-IT partnerships and effective communication are enablers of alignment. Fostering such a partnership requires, among other things, building trust through a shared understanding of the value of IT and shared goals and risks. The *COBIT 2019* framework also highlights that one IT Governance and Management objective for organizations are managed relationships (APO08) in order to create improved outcomes, mutual trust and effective use of resources [12]. While a former study shows that in traditional organizations roles from business and IT at different hierarchical levels (including top-, middle-, lower-level management and non-management level) are involved in strategic alignment [13], COBIT mentions the necessity to implement a role that manages these business-IT relations. An interface role, such as the ITBP, may foster this partnership acting as a bridge between business and IT departments, ensuring that both sides understand each other's needs and priorities [5].

B. Roles at the interface between Business and IT

The critical role of fostering collaboration between business and IT, driving innovation, and achieving business goals through technology solutions may be referred to as an "IT business partner" or "IT business relationship manager" [14], [15], [16]. Reference [17] call this role a "boundary spanner": the role acts as a translator, mediator and aligner between business and IT, as well as a motivator for both sides and a representative of IT to business and vice versa. Reference [18] describes how organizations structure this role in IT business partner organizations to foster business-IT collaboration and communication. Reference [16] emphasizes the overlap with other roles and gives an overview about three main tasks of the ITBP: close collaboration, network maintenance and continuous integration of IT into the business units While, to our knowledge, except for two German articles [16], [18], academic peer-reviewed literature does not outline the role of the ITBP, several IT management frameworks mention its necessity for organizations: TBM introduces a BRM acting like an account manager responsible for the business, understanding their plans and proposing solutions. They should be able to communicate the business value of IT and therefore, require knowledge about the portfolio, service costs, and business consumption. To that end, they work closely together with other IT roles such as service owners or EAs [7]. ITIL mentions, besides fostering collaboration, main tasks of an ITBP such as demand management, stakeholder management and support in service management when it comes to service level agreements (SLAs) and the strategic optimization of IT services [6]. The *Skill Framework for the Information Age* (SFIA) states a business analysis role with a more operative focus responsible for investigating operational issues and finding new business solutions [19]. Other frameworks such as COBIT 2019, the scaled agile framework (SAFe) and The Open Group Architecture Framework (TOGAF) do not explicitly mention the ITBP role. Yet, they stress the importance of business-IT alignment, stakeholder engagement and value delivery [20] as well as relationship management, coordination, and communication with the business [12]. While there are various terms for describing the interface role, we use ITBP in this paper while encompassing relevant literature for both.

The design of interface roles between business and IT varies from company to company. ITBPs are typically positioned at the middle management level but can also hold higher positions such as directors [14]. Existing literature shows that interface roles can be part of the IT department [21] or they can also be located in dedicated digitalization or innovation departments or directly in the business units [22]. The role of the ITBP can be performed as a primary or secondary occupation. If it is the primary occupation, the employees are often organizationally grouped into an IT Business Partner Organization (ITBPO) [18], [23]. If the function of an ITBP is performed as a secondary occupation, ITBP tasks are embedded into other roles. For example, architects or demand managers often act as ITBPs. Architects are considered a critical function for successful BITA, as they shape an organization's IT landscape [24]. Thus, [24] mentions business or domain architects, who primarily represent individual functions or processes in this landscape. Demand managers can also improve the relationship between business and IT by implementing strategic planning and portfolio management [25], thus overlapping with classic ITBP roles. Related to the collaboration between business and IT the SFIA names stakeholder relationship management as a relevant competency in the information age. It describes the skill to "systematically analyze, manage and influence stakeholder relationships to achieve mutually beneficial outcomes through structured engagement" [19]. However, the mentioned literature neither give insights into the design and implementation of the ITBP role, nor about the challenges ITBPs face in their daily business.

III. Methodology

As the design of roles in organizations is influenced by the context, earlier research on interface roles between business and IT applied qualitative methods such as expert interviews in an exploratory study [17] or case study research [26]. We answer our research questions by applying a triangulation of these methods and data from various sources, which enriches

insights and the validity of findings [27]. We triangulate a parallel approach of one case study and expert interviews. The case study enables research of a phenomenon in its real-world context [28] such as to explore ITBP implementation in-depth in a specific organizational context. Expert interviews lead to a comprehensive picture of the phenomenon in practice [29].

A. Case Study

We follow case study research guidelines to design our study and to select our case [28], [30]. Our case was an international consumer goods company with a size of about 30.000 employees, a central IT department and a dedicated IT governance department. The central IT department provides services for the twelve international business divisions (i.e. legal entities differentiated by product line and region) and other central functions (e.g., HR, procurement or finance). We chose this single-case design for two reasons: First, our company reflects a common case [28], as it is representative of large, globally active production companies with central IT structures and therefore has a high transferability to similar contexts. Second, through an existing and trusting relationship between the researchers and the company, the case study could benefit from access to internal information as well as open and honest discussions with the participants.

For the alignment between business and IT, the company established an ITBPO within the IT department. In order to study the ITBP role in depth and enhance the insights, we focused on multiple units of analysis [28], as the ITBPO consists of one leading ITBP and five ITBPs at different locations. Each of the five ITBPs is responsible for partnering one or more business divisions. Furthermore, the organization employs two EAs to strategically plan and align the enterprise target landscape with the business. For the delimitation of the ITBP role with its tasks and required skills, we included a review of the EA role in our study. We could accompany the case for 1.5 years from June 2023 to December 2024.

For the data collection, different sources of evidence, mainly documents, interviews, and focus groups are used [28] (see Fig 1). We reviewed the overall organizational structure and IT operating model to set up the case. The role descriptions served as the basis for the analysis of the ITBP role. We observed meetings between ITBPs and their business counterparts, to understand current interaction and derive responsibilities and skills. We further conducted note-based semi-structured interviews with the ITBPs and EAs to understand their perception of their tasks based on their specific challenges within their individual location. The workshop with the stakeholders aligned different views, the understanding of their role, responsibilities and skills and challenges throughout the whole organization.

B. Expert Interviews

We carried out seven expert interviews to broaden the insights on the ITBP role in different organizational contexts. The interviews were semi-structured to have the opportunity to ask more detailed follow-up questions during the conversation [29], [31]. We chose interviewees considering the following criteria: First, the interviewees needed to have specific knowledge about the ITBP role due to performing it, being responsible for an ITBPO or ITBPs in an organization or having experienced it from an external perspective. Second, they needed to be able to consider the overall perspective of the role in terms of practical implementation within organizations. Therefore, we chose ITBPs with several years of experience and managers that were leading ITBPs. Third, we wanted to cover a broad spectrum of organizational contexts in the interviews to get as complete a perspective on the ITBP role as possible. Therefore, the interviewees have various backgrounds coming from different industries, organizational sizes, and digital maturities. All interviewees were already part of the network of the research team. Table I shows an overview of all interviewees (I) (chronological listing based on the date of the interview). The guiding questions that were used during the interviews are:

1. Why do you implement an interface role between business and IT?
2. How do you integrate the role in the company?
3. What are the main tasks of the ITBP? Are other tasks performed additionally?
4. What are the skills required to be an ITBP?
5. What challenges do you observe for an ITBP?

TABLE I. OVERVIEW INTERVIEWEES AND GUIDING QUESTIONS

ID	Function	Industry	# of Employees (EMP)
I1	CIO	Equipment Manufacturing	~3.500 EMP
I2	CIO	Transportation and Logistics	~6.500 EMP
I3	IT Business Partner	Consumer Goods	~1.500 EMP
I4	CEO	IT Consultancy	50 EMP
I5	TBM Consultant	Free Lancer in TBM Consulting	-
I6	IT Business Partner	Medical Technology	~9.400 EMP
I7	IT Business Partner	Retail	~99.000 EMP

The interviews were performed between October 2024 and February 2025 by the first author via Microsoft Teams in German or English. For data collection, they were either recorded and transcribed during the sessions using Microsoft Copilot or notes were taken. After the interview phase, we proofread and anonymized the automatic transcripts of all interviews and summarized notes.

C. Data Analysis

The triangulation of qualitative methods with parallel set up and data collection in case study and expert interview was then followed by a data analysis. This overall methodology is displayed in Fig 1. For our overall data analysis, we conducted qualitative coding [32]. This entailed the assignment of respective codes to the data in three iterations, in accordance with the guidelines for open and selective coding. The first coding was conducted by the first author. In two further iterations, the research team, comprising four researchers, undertook a review and adjustment of the codes to derive tasks

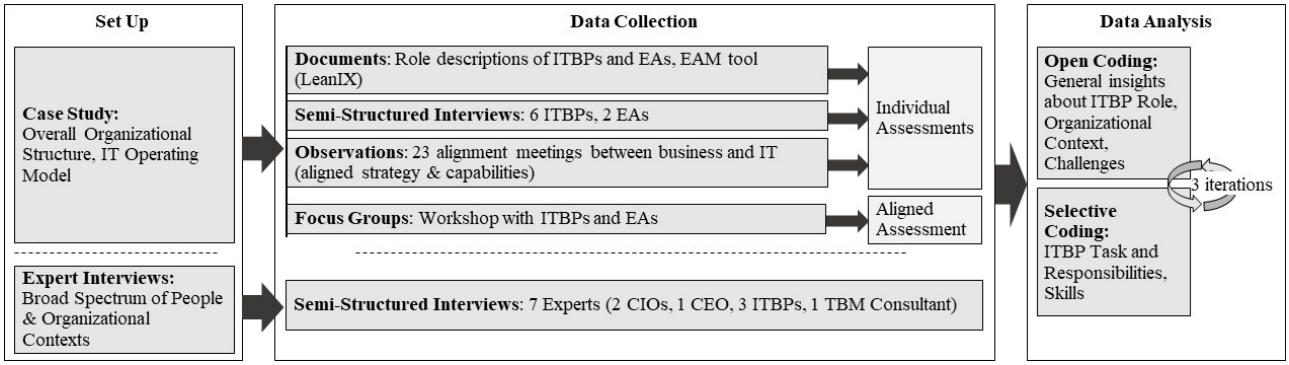

Fig 1. Methodology for Set Up, Data Collection and Data Analysis

and responsibilities as well as required skills for the role. A digital whiteboard tool was used to visualize and structure the coding process. This enabled collaborative and iterative coding of the interview data, whereby codes, categories and correlations were visually recorded, grouped and further developed. Furthermore, we identified and analyzed the challenges of the ITBP role. Table II indicates examples of the qualitative coding results.

TABLE II. EXAMPLES OF QUALITATIVE CODING

Source	Citation or Notes	Qual. Analysis (Category > Codes >> Subcodes)
I4	"Understanding depends on personal factors. People often talking about one another rather than with one another"	Challenge > Human factor >> lack of open communication >> personal factor Skills > Networking & Interpersonal Skills >> Build relationship on personal level
I6	"I give input and ideas from IT side to see how we can help and support for a given problem and how to approach the problem."	Task > Advice and Guidance Skill > Requirements Analysis, Analytical thinking
I7	"We have too many tasks for the IT business partners. And if you have too many roles at once, you no longer have the capacity."	Challenge > role's definition >> lack of task delimitation

IV. FINDINGS

The qualitative study shows that the purpose of an ITBP is always related to the alignment of business and IT. The following section presents eleven tasks with associated responsibilities and 14 skills divided into soft and hard skills to describe the role of the ITBP. Then, we outline five challenges ITBPs are facing.

A. The role of the IT Business Partner

The design of the interface role of the ITBP is "almost like a belief – you can put it in business, you can put it in IT, or you can even put it somewhere in between as a separate function, so there are different models" (I1). Our study shows different characteristics of the ITBP role in different organizational contexts. In Table III we indicate their title, their organizational integration, and their purpose as basis for answering our first RQ: (1) *How can organizations design the interface role of the IT Business Partner for effective business-IT collaboration?*

TABLE III. CHARACTERISTICS OF IT BUSINESS PARTNERS IN DIFFERENT ORGANIZATIONAL SETTINGS

Source	Name	Organizational Integration	Purpose of the role
Case Study	IT Business Partner Manager	6 full time ITBP in the IT unit divided by business divisions with a regional focus	"Develop and maintain collaborative relationships between IT and key business stakeholders to successfully establish and maintain strategic & operational alignment"
I1	Business Engager	Planned ITBP Role in the IT unit divided by business functions	Engage with counterparts ("PMO Leads") in business focusing on alignment and bringing in the IT knowledge and process perspective
I2	Business Systems Function	3 full time ITBP in a separate digital unit in the business divided by business functions	Work closely with business counterparts within the business functions to steer demands, develop requirements and execute IT projects in collaboration with IT experts
I3	Business Analyst/ Partner	3 full time ITBP in the IT unit divided by business functions	Currently, Business Analyst with focus on demands and representation of business domain. Future goal to become a strategic partner with decision rights to support shaping the domain and consulting them strategically
I4, I5	Business Relationship Manager	*I4 and I5 share experience from working in consultancy in different settings.*	"In general, ITBPs are integrators between business and IT" (I4) with a main purpose to "conduct value conversations to drive partnership and IT business value" (I5)
I6	IT Business Partner	10 part time ITBPs in the IT unit divided by business functions and regions	First contact point for business in IT aiming to understand business issues, and propose and coordinate solutions to drive value of IT
I7	IT Business Partner	10 full time ITBPs in the IT unit divided by business functions	"The two main tasks are representing both the business and IT while identifying challenges and finding solutions."

Table IV presents the tasks of ITBPs derived from our triangulation, structured by tasks and the mentioned responsibilities ordered by the number of mentions. The execution of tasks and the individual responsibilities vary depending on their specific job description. However, some tasks are always

mentioned as core activities of the ITBPs, which are **relationship management** and **advice and guidance**. In addition, most ITBPs also take on (strategic) demand management. Further responsibilities were partially identified, either as part of the formal role description or as responsibilities that were overtaken by the ITBP due to a lack of clear delineation from other areas. For instance, I6 with a dual role oversees IT demand, IT project, and IT portfolio management, besides the role as ITBP. The ITBP I7 has a full-time role as ITBP but due to special expertise also supports innovation and organizational change management. The ITBPs within the case study reported engagement in IT project and IT service management activities, in addition to providing support in enterprise architecture management (EAM).

TABLE IV. TASKS AND RESPONSIBILITIES OF IT BUSINESS PARTNERS

Task	Responsibilities	CS	I1	I2	I3	I4	I5	I6	I7
Relationship Management	• Primary business contact and relationship development • Trust building, communication and continuous relationship improvement • Stakeholder engagement, feedback and personalized involvement • Strategic collaboration, integration and alignment of business and IT	x	x	x	x	x	x	x	x
Advice and Guidance	• IT input, ideation, and innovation advisory • Proactive consultancy and orchestration of IT ideas, demands and projects • Value conversations and strategic guidance	x	x	x	x	x	x	x	x
(Strategic) Demand Management	• Idea-to-demand support and derivation, synergies identification • Demand preparation and management • (Initial) Requirements analysis	x	x	x	x			x	x
IT Project Management	• Facilitation of technical solutions, support project implementations • Proof of concept support for technical solutions • Strategic Project Management and Implementation Coordination	x		x	x			x	x
IT Portfolio Management	• Strategic domain planning, resource identification • IT project portfolio accountability	x		x	x			x	x
Enterprise Architecture Management	• Solution architecture coordination • IT landscape modeling and target planning support	x			x			x	x
IT Cost Management	• Cost savings identification and efficiency improvement • Budget management	x				x	x		
IT Service Management	• Major incident management • SLA definition and monitoring for IT services	x					x		
IT Governance, Risk and Compliance	• IT governance and audit compliance assurance • Education and training on IT policies and procedures	x							x
Org. Change Management	• Organizational change management support								x
Innovation Management	• Ideation and business innovation enablement								x

To perform these tasks, ITBPs require skills that are crucial for success. Table V describes these skills, however, "above all, IT Business Partners must be generalists. They should have knowledge across various domains but do not need to master them in detail" (I7).

TABLE V. SKILL MAP OF AN IT BUSINESS PARTNER

	Skill	Ability to…
Soft Skills	Discussion Skills	…conduct eye-level discussions with business leaders (CS,I3,I7), advise and consult on IT solutions and business processes (CS,I1,I6,I7), and use mediation skills (CS,I7).
	Leadership Skills	…think strategically and conceptually (CS,I7), support and make informed decisions (I3), and lead people effectively (CS,I6,I7).
	Communication Skills	…communicate, present, and interact with stakeholders on all hierarchical levels and different languages (CS,I6,I5), speak a "common language" with the business (I4,I7), and foster business-IT talkability (I1,I2,I3).
	Team Understanding	…understand team structures and individual roles within teams (I7,CS), identify the relevant stakeholders for strategic conversations (CS), comprehend team dynamics (I7), and establish understanding for each other (cultivate an exchange culture) (I2).
	Networking & Interpersonal Skills	…build relationships (also on a personal level) (CS,I7), become a trusted partner (CS), and bring people together (CS,I6).
	Analytical Thinking	…collect and analyze the relevant data (I2,I3), develop informed solutions to solve problems (CS), and pay attention to details to prevent errors and inconsistencies (CS).
	Flexibility	…adapt to change (CS), react resiliently (CS,I7), and operate creatively within dynamic environments (I3,I7).
Hard Skills	Business Acumen	…understand the business model and strategy (CS), understand business capabilities (CS,I3,I6,I7), and comprehend business processes in detail as well as in their broader context (I3,I6,I7).
	IT & Data Literacy	…understand and maintain consistent data and data relationships (I3,I2), understand technologies and digital solutions (CS,I1,I6,I7), and use IT tools (for project management, architecture, etc.) (CS,I7).
	Requirements Analysis	…understand and translate requirements of business and IT stakeholders (I3), propose adequate IT solutions (I7), and leverage technology and its manyfold use (I3).
	Project Management	…plan and manage projects (CS,I7), identify risks and manage major incidents (CS), and track and report on progress (CS,I6).
	Strategic Management	…comprehend strategic perspectives and demands (CS, I7), develop long-term goals and objectives (CS), and align projects with overarching strategic directions to develop a portfolio (CS,I6).
	Governance Expertise	… understand organizational decision structures and service level agreements (CS), comprehend IT

		security, legal compliance and risk regulations (including data protection) (I7), continuously improve through critical success factors and key performance indicators (CS,I4,I5), and support business value realization (CS,I4,I5).
	Enterprise Architecture Knowledge	…understand (IT) organization and (IT) processes (I1,I7), know current IT applications and the IT landscape (I7,CS), and comprehend the "big picture" and overarching correlations (I6, I7).

B. Challenges of an IT Business Partner

We identified several challenges the ITBP faces that impact its effectiveness and integration within organizations. We thereby answer our RQ *(2) What practical challenges does the IT Business Partner face in organizations?* One key issue is the **human factor**, which is reflected in the lack of open, two-way communication across hierarchical levels. Instead of a meaningful dialogue, interactions are often characterized by "talking about one another rather than with one another" (I4). Furthermore, understanding the role often depends on individual perspectives and personal factors, leading to inconsistencies. While in some cases the ITBP facilitates excellent collaboration, in others he struggles to achieve alignment or discussions on eye-level (CS, I3, I6, I7).

Another significant challenge is the **role's definition and integration within the organization**. Despite the need for a clear understanding of the ITBP's responsibilities, its boundaries with other roles, such as EA or domain architects, project or service managers, are often blurred (CS, I2, I3, I7). This lack of clarity complicates collaboration and role alignment with business stakeholders and IT colleagues. But even if "the role is described clearly on paper, this does not lead to successful integration and acceptance automatically" (I7). Organizations face a challenge to introduce the role in a structured approach, with clear responsibilities and to distinguish it from similar roles like the product owner (I6) or demand manager (I7). Thus, the role lacks acceptance or even face competitiveness with IT colleagues (I7).

The **lack of methodological approach and organizational structure** is mentioned as another challenge for the ITBP role. The ITBPs work closely with the relevant business units, often making them feel more part of the business than part of IT or of an ITBPO, especially as explicit ITBPOs are often underrepresented or not managed at all. As a result, there is a lack of identity as an ITBP team and a lack of opportunities to share ideas with each other. But even when such an organizational structure is in place and a clear job description exists, it is a challenge to compare results and identify synergies, because "every ITBP approached it in their own way, resulting in ten different approaches" (I7).

A further difficulty lies in the **limited time for focused work and absence of strategic alignment**. ITBPs are frequently consumed by operational tasks and "firefighting" (CS), leaving little room to focus on long-term strategic initiatives (CS, I3). Urgent demands, combined with tight collaboration timeframes, often divert attention from value-driven work (I5, I6). Organizationally, the demand for IT support often exceeds the available capacity, forcing the ITBP to act as a mediator between IT and the business instead of a strategic enabler (CS, I6). The study also showed that discussions between ITBP and the business often focus on projects and progress rather than on strategy or deriving necessary future measures from this.

Finally, **skill gaps of the ITBP** present a major obstacle. There are significant differences in maturity levels and knowledge on both sides, with business often lacking sufficient understanding of IT processes and IT stakeholders failing to adopt lean and strategic approaches to support business needs (CS, I1, I4, I5, I6). Communication skills and the ability of business-IT talkability are, therefore, critical for ITBPs where deficiencies are observed (CS, I2, I3, I4, I5, I6). In addition, ITBPs may lack leadership skills and decision-making competence to strategically support and drive decisions (CS, I3, I7). As a result, the ITBP role is not always effectively implemented, limiting its ability to drive value and organizational alignment.

V. DISCUSSION

The findings do not only show a variety of tasks and required skills of an ITBP but also challenges they face in their daily business. In the following we discuss how the design of the role may support overcoming the identified challenges. We focus on the delimitation of the role and required capacities, the opportunities for organizations to find skilled people to act as ITBP and discuss its contribution to strategic alignment.

A. Determining the Organizational Integration of an IT Business Partner

The in-depth study shows various designs of the ITBP role. One decision that a company needs to take is the organizational embedment of the ITBPs. Depending on the existing structure, an organization needs to determine whether the ITBPs support the business divisionally, functionally, or regionally. I6 stated that there were both functionally assigned ITBPs and those assigned to specific regions. In the case study, ITBPs were assigned to business divisions. Divisional ITBPs are required to know the division-specific product and the complete end-to-end operation. In a regional setting, the location-specific requirements and the cultural aspect may be addressed better. A functional allocation has the advantage of allowing the ITBP to develop domain-specific skills, enabling better business communication and leveraging synergy effects.

Another aspect is to design the ITBP role as a primary or secondary responsibility [14]. The study showed that a primary ITBP role allows for greater focus on core activities but may limit networking opportunities, requiring proactive information gathering with other IT colleagues. When an ITBP performs as a secondary role, it is often assigned to individuals in senior positions with strong networks and close business interactions through their primary task in project or portfolio management (I6). While this facilitates relationship-building, it limits the focus on partnering and strategical guidance unless specific time and capacity are allocated. However, even

full-time ITBPs face challenges in balancing their workload and ensuring a standardized approach of all ITBPs (I7). Establishing an ITBPO, aligning the way of work of all ITBPs, and following a structured methodological approach for communication between business and IT may support a clear positioning of the ITBP and the standardized sharing of information towards business and IT [33], regardless of whether the employment is full-time or part-time.

B. Overcoming the Skill Gap in IT Business Partner Positions

The study highlights that, in addition to hard skills, soft skills are particularly relevant for the relationship-intensive role of ITBP. One of the skills emphasized is communication. This is not only essential for establishing a common understanding but is also a proven prerequisite for Business-IT Alignment [11]. Communication involves both clarity and language proficiency—often English in an international context. However, it is equally important to establish a common ground in communication, frequently referred to as a "common language" [5]. This means that an ITBP must be able to communicate fluently in both business and IT terminology, ensuring a seamless flow of information linking business stakeholders and IT colleagues. Language training might therefore be mandatory for ITBPs, and job rotation could ease the establishment of a common language to the business counterparts.

Beyond communication, other soft skills, such as understanding team dynamics, were particularly evident in the case study. It is crucial to be familiar with the corporate culture, actively engage in it, and navigate hierarchies without being discouraged by them [5], [13]. In its role as a boundary spanner [17], an ITBP must act as a connector, bringing people together and serving as a central point of coordination (I6). This skill is difficult to teach, making it essential to consider interpersonal skills during recruitment or to fill the role internally with individuals who are already well-connected and established within the organization [13].

To address the skill gap between business and IT, job descriptions for ITBPs should clearly outline the necessary competencies. When developing job descriptions, identifying key skills through profile challenges can be beneficial [19]. The skill map outlined in Table V can support organizations in designing an effective ITBP job description. Additionally, companies can use this transparency to assess and develop the skills of current ITBPs, enabling organizations to upskill existing employees in this role. This approach allows ITBPs to "plan their professional development and career progression" [19]. It also contributes to human resource development, career planning and the provision of learning paths, which, as seen in SFIA, can be structured into different levels.

C. Focusing on Core Tasks and Strategic Business-IT Alignment

The findings illustrate that an issue for ITBPs is having to perform a variety of tasks without a clear focus. For an ITBP to fulfil their purpose to relate business and IT and strategically align both perspectives, the study shows that relationship management and advice and guidance should be the core tasks (see Fig 2). As “already for relationship management and advisory together with demand management, an ITBP needs business and IT knowledge and many interactions, there is no time for more without making mistakes” (I7). Therefore, the ITBP requires a clear mandate and capacity for these core activities, to achieve their alignment goals and being accepted by business and IT colleagues.

While demand management is often also covered by the ITBP, organizations should clearly define the transition to project, service, portfolio, or EAM. According to ITIL [6], ITBPs work closely with service owners and service level managers, which emphasizes the importance of defining the interface. TBM highlights further relations to the EAs [7]. Reference [24] mentions in this context domain architects, who support a functional business domain and align strategically with them. During the case study, the distinction in tasks and assigned business stakeholders between ITBPs and EAs was defined: The EAs take on the domain-specific alignment with business functions, whereas the ITBPs focus on alignment with business divisions. This helped to distinguish between the roles. The close interaction of the ITBP with other stakeholders emphasizes the need for internal alignment with IT colleagues to share knowledge and a clear distinction to leverage effective collaboration [33]. Other IT disciplines such as IT cost management, IT governance, organizational

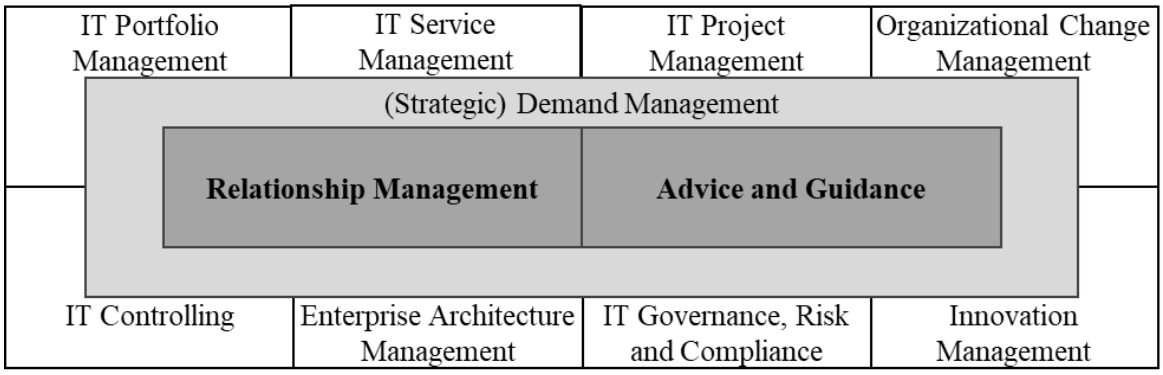

Fig 2. Core Tasks and Further Responsibilities of IT Business Partners

change, and innovation management may be used by the ITBP to gather and feedback information, but decision makers should be careful in delegating active responsibility of the ITBP in these tasks.

Besides the lack of focus, the ITBP, being primarily driven by operational tasks, often tends to neglect strategic work. However, it is essential that the ITBP has sufficient capacity "to make sure that its work contributes to the strategic alignment" (I7). The Strategic Alignment Model (SAM) by [9] provides a suitable framework for illustrating how the ITBP's activities contribute to strategic alignment. According to the SAM, strategic alignment is based on a complex, multidimensional relationship between business and IT. The ITBP plays a crucial role in this process by building and maintaining **relationships**, **advising** on IT matters by proactively consulting stakeholders, and driving value-oriented discussions. Through these core activities, the ITBP triggers further responsibilities within his/her role and can contribute to strategic alignment in multiple ways through exchanges with their business counterparts: They can capture business requirements, align them with **IT governance, risk & compliance** policies and transfer the requirements into operative **demands / projects** (strategy execution). They can receive **strategic demands**, consolidate them, and derive necessary IT capabilities, IT processes, implications for the **enterprise architecture**, and the **IT portfolio** together with IT (technology transformation). They can communicate technological **innovations** and new IT capabilities and identify possible strategic application and necessary **organizational changes** together with the business (competitive potential). They can identify opportunities for the operational use of new technologies in business within **IT services** and discuss **cost saving** potential (service level). Similar considerations are discussed for the ITBPO and their impact on strategic alignment [18]. This contribution to strategic alignment underscores the critical importance of the ITBP role, as business value can only be realized through the effective alignment of IT with strategic objectives [4].

Overall, a role description of the ITBP must be the baseline to define how they operate within the organization [23]. This description first needs to determine the organizational embedment (division, function, or region) and the capacity (primary or secondary). Also, it needs to include tasks and responsibilities (e.g. following the descriptions in Table IV), give a ration about time effort for each task, and list required hard as well as soft skills. A success factor is a clear distinction to other roles and designing internal alignment mechanisms (according to the adjacent disciplines as shown in Figure 2). This role description can be used to challenge existing ITBPs or during recruitment to find suitable candidates.

VI. Conclusion

The role of the ITBP is increasingly being implemented in organizations to bridge the gap between business and IT, thereby driving strategic alignment. Through the triangulation of a case study and expert interviews, this study provides an in-depth exploration of ITBP's role design and challenges. The findings reveal that the role is highly versatile, with responsibilities that vary depending on the organizational context. We identify eleven key tasks that ITBPs perform to different extents, with relationship management and advice and guidance at the core. These core tasks enable ITBPs to drive strategic business-IT alignment. To be effective in this role, 14 essential skills are identified, including communication, networking, business acumen, and IT, data, and process literacy. However, challenges such as organizational integration, skill gaps, and excessive operational workload often limit the ITBP's ability to drive the business-IT partnership and foster strategic alignment and should therefore be part of a clear role description.

This study contributes to both research and practice. From an academic perspective, the study advances research on business-IT alignment by operationalizing the role of the ITBP within organizations and contributing to the broader discourse on IT professions and their interaction with business functions. For organizations, it provides guidance on structuring the ITBP role and defining key responsibilities that support business-IT alignment. For HR professionals, the identified skill sets provide valuable insights for hiring, career development, and training initiatives for ITBPs. In addition, CIOs gain an understanding of the challenges of the role, particularly the need to allocate sufficient capacity for strategic alignment efforts.

Despite its contributions, the study has limitations. It primarily examines the ITBP role from an IT perspective, whereas its success is also influenced by organizational culture and business counterparts. Future research should include both business and IT perspectives to provide a more holistic understanding of the role. Additionally, the chosen case is a large, international company with a centralized IT department. Future studies could examine other organizational setting such as more decentralized structures or small-and-medium-sized companies for comparison and drawing conclusion based on the organizational set-ups. While this qualitative study provides in-depth insights, a follow-up quantitative study could help validate the identified challenges on a broader scale. Further research could also examine the impact of corporate culture and individual business counterparts on ITBP effectiveness, analyze different job descriptions within IT organizations, and differentiate roles based on IT-relevant tasks.

***Abstract*—Effective and efficient disease detection is crucial, particularly for economically important crops like cotton. In this paper, we move from the initial development of a deep-learning model for cotton leaf disease detection, called Deep-CCNet, to a more comprehensive comparison of different feature selection algorithms, such as RainWater Algorithm, Particle Swarm Optimization, Bee Evolutionary Algorithm, Genetic Algorithm, and Binary Dragonfly Algorithm. Although Deep-CCNet achieved satisfactory classification performance, the goal of this study is to improve the classification performance and efficiency of deep learning models with meta-heuristic feature selection techniques. This study aims to determine which feature selection method achieves the best balance between performance and computational efficiency. We used the Kaggle "cotton leaf disease dataset", which has 1,711 images from four classes (namely curl virus, bacterial blight, fusarium wilt, and healthy leaf images), to compare these techniques systematically. Our research attempts to find the most effective method that maximizes model performance while minimizing computing resources, in addition to benchmarking the computational and performance parameters of each approach. The results of this study provide a new approach for the choice of feature selection methods in plant pathology, leading to better early disease diagnosis and increased crop resilience via efficient farming practices.**

I. Introduction

COTTON, also referred to as the "silver fiber", is among the most significant world agricultural products, the cornerstone of the textile industry, and a means of livelihood for millions of farmers, exporters, processors, and producers, particularly in developing nations [1], [2]. Cotton production, however, is facing threats from numerous pests and diseases, which considerably reduce the quantity and quality of the cotton crop, resulting in significant economic losses [3], [4]. Some of these issues are cotton leaf diseases, which are directly harmful to the health of a plant and ultimately its fiber production. Some familiar infections include fusarium wilt, bacterial blight, and cotton leaf curl virus. These diseases reduce crop yield and weaken plants, increasing vulnerability to pests and secondary infections. [3].

Studies show that pests and diseases cause a loss of approximately 42% of world agricultural production each year [4]. Traditional disease diagnosis methods, which are mainly based on manual inspection and chemical treatment, are labor-intensive, time-consuming, and often prone to errors. For rural areas where agricultural experts are not available, a precise manual diagnosis is even harder. Therefore, there is a critical need for improved, more efficient, accurate, and timely disease diagnosis techniques [5], [6].

To address the above limitations, the farm sector has witnessed a strong shift towards applying computer vision (CV) and artificial intelligence (AI) technology to automatic, early detection of plant disease [7]–[9]. Leaves have been discovered to be most suitable for such analysis due to their ease of access and visibility compared to other plant components, including stems and roots [10]. Modern CV pipelines typically involve processes such as dataset collection, image pre-processing, feature extraction, feature selection, and classification [11], [12].

Deep convolutional neural networks (DCNNs) have been found effective for automatic feature extraction and classification [13]. In particular, the fully connected layers in DCNNs play an important role by integrating spatial features, such as edges, textures, and color intensities, from the preceding layers to predict the correct class labels [14]. Nevertheless, deep models tend to generate an enormous number of redundant or irrelevant features, thereby leading to overfitting and inefficiencies.

To enhance model resilience and performance, optimization-based feature selection algorithms have been gaining momentum [15]. Techniques such as Particle Swarm Optimization (PSO) [16], Binary Dragonfly Algorithm (BDA) [17], and various meta-heuristic techniques are well suited to select the most salient features with the elimination of noisy or uninformative features. This process of feature selection not only enhances classification accuracy but also reduces the computational cost and results in models that are efficient and lightweight.

In the context of these advancements, this study proposes an integrated approach in which a novel Deep-CCNet deep

learning (DL) model is coupled with meta-heuristic feature selection methods to better improve cotton leaf disease classification performance. Through optimization of feature subsets derived using DeepCCNetFS, we aim to develop a robust and computationally capable model with real-time usage potential in precision farming.

A. Motivation

The key aim of this work is to fulfill the essential requirement of proper early diagnosis of cotton leaf diseases with the least dependency on chemical treatment and facilitate farmers in taking wise decisions using real-time tools. Being highly susceptible to diseases, cotton crops need precise and timely diagnosis for sustainable agriculture, enhanced crop management, and improved yield.

But the use of DL models in such tasks is generally hindered by high-dimensional feature spaces that not only incur computational expense but also introduce redundant information, leading to overfitting and reduced generalization capability. Thus, efficient feature selection is very important in avoiding these constraints.

Lastly, this research seeks to facilitate sustainable agriculture by reducing the application of unnecessary pesticides through efficient early disease detection while making such AI tools accessible and feasible for in-field implementation in cotton farming.

B. Feature Selection Strategies and Proposed Framework

Feature selection is a key component of the modern machine learning pipeline, particularly when dealing with high-dimensional learned feature spaces from deep neural networks. It is crucial to select a subset of the most critical features in building lightweight, efficient, but very accurate models [18]. Without effective feature selection, models can overfit, become computationally more expensive, and be less generalizable, characteristics particularly undesirable in real-world applications such as smart agriculture.

In this context, the deep features extracted from the DeepCCNet model need to be passed from the feature selection step. Since the extracted feature vectors have a high dimensionality, an optimal feature optimization method is essential to enhance the model's performance with computational efficiency.

To address this, we comprehensively evaluate and compare five meta-heuristic feature selection algorithms with different approaches to dynamic exploration and exploitation of the vast and complex feature space: Rainwater Algorithm (RWA) [19], Genetic Algorithm (GA) [20], Particle Swarm Optimization (PSO) [21], Binary Dragonfly Algorithm (BDA) [22], and Bee Evolutionary Algorithm (BEA) [23].

All of these methods are implemented within the DeepCCNet pipeline to optimize feature subsets derived from DeepCCNet for the highest classification performance and the lowest model complexity. Comparative evaluation of these feature selection algorithms is performed based on two key criteria:

1) Classification Performance: Assessment of how well the selected features enable accurate disease diagnosis over the cotton leaf disease dataset.
2) Computational Efficiency: Measuring the overall execution time, feature selection time, and classification time, which is important for effective deployment in resource-constrained agricultural settings.

Furthermore, we used the grid search to carefully optimize the hyperparameters, guaranteeing the best possible model efficiency and performance. For empirical validation, we employ the publicly available Cotton Leaf Disease dataset with 1710 images corresponding to four classes of diseases.

II. Related Works

Recently, the accurate and early detection of cotton leaf diseases using computational methods has been the subject of much research because of its potential effects on agricultural production and sustainability. Conventional ML methods have been the mainstay of previous research, but deep learning (DL) and evolutionary algorithms (nature-inspired feature selection) techniques have lately gained traction and provided notable gains in automation and accuracy.

A. Traditional Methods

Image processing methods and traditional ML algorithms were the main tools used in the early stages of plant disease identification efforts. For example, Sarangdhar et al., [24] proposed a method for the classification and control of diseases on cotton leaf along with soil quality monitoring. The study suggested a regression approach based on support vector machines (SVM) for the diagnosis of five diseases that affect cotton leaves: Alternaria, Bacterial Blight, Cereospra, Fusarium wilt, and Gray Mildew. Farmers were given access to the identification of disease along with its cures through an Android app upon illness detection. Along with the water level in a tank, the Android app was also utilized to display the values of soil factors, including temperature, moisture content, and humidity. Shakel et al., [25] divided the images of Cercospora cotton leaves into clusters using the K-means clustering technique. The hybrid approach for extracting texture and color characteristics was used to extract features. Ultimately, Cercospora cotton leaves were classified using SVM. Similarly, a Multi-SVM-based categorization system for cotton leaf diseases was proposed by Jenifa et al. [26]. The suggested algorithm processed the crops automatically at every stage, identifying defects at an early stage and preventing losses to the farmer in terms of products and money. When provided with the necessary data, the aforementioned Multi-SVM algorithm models, which are either human or robot-supervised, enable the segmentation and classification of various disease kinds. Despite being innovative, these methods have several difficulties. The quality and diversity of the input photos had a significant impact on the accuracy of disease identification, and the manual feature extraction procedure was labor-intensive and prone to human error, which made it challenging to scale and adapt to various plant diseases.

B. Deep Learning Advances

To address the shortcomings of manual feature extraction, the shift towards DL, particularly DCNNs, has significantly

enhanced the robustness and accuracy of plant disease detection systems. These models automate the feature extraction process, capturing complex patterns more effectively than traditional methods. Compared to conventional techniques, these models capture complicated patterns more successfully by automating the feature extraction process [27]. For example, Rai et al. [28] concentrated on developing an enhanced DCNN-based model to address the issue of disease detection and classification in cotton plants. Three distinct experimental setups were examined to examine the effects of varying data split ratios, pooling layer selections (max-pooling vs. average-pooling), and epoch length. A collection including 2293 photos of plants and cotton leaves was used to train the models. Four different leaf classes, plant disease combinations, and the corresponding categories were included in the data. The paper in [29] introduces a dynamic feature selection methodology applied to deep neural networks for univariate and multivariate time series forecasting, based on the Coronavirus Optimization Algorithm [30]. The proposed method, evaluated against random forest models, demonstrated superior performance in terms of mean squared error, highlighting the efficiency and effectiveness of dynamic feature selection. The network that Rajasekar et al. [31] proposed outperformed previous state-of-the-art methods by combining the advantages of the Xception component with the ResNet pre-trained on ImageNet. Kotian et al. [32] used the ResNet50 and KNN ML model for the classification of cotton leaf diseases. Numerous studies have lately used DL methods for the categorization of cotton leaf diseases, as Table 1 illustrates. However, for real-world agricultural applications, their high computing complexity and opaque decision-making procedures often make them more difficult to trust and less accessible. In addition to the studies discussed above, several other DL-based approaches are summarized in Table I for completeness and broader context.

C. Limitations

Our research intends to solve the following important shortcomings of current approaches, despite significant advances in agricultural diagnostics, especially in the diagnosis of cotton leaf disease:

1) Limited Integration of Feature Selection with DL: DL models are commonly used in plant pathology research to detect diseases, although adaptive and dynamic-feature selection methods are not fully integrated. DL models are extremely strong, but their efficacy is sometimes limited by static feature sets that don't change in response to fresh information or intricate disease patterns. Moreover, evolutionary algorithms are rarely used in research, despite their potential to improve model accuracy and computing efficiency by constantly optimizing and refining feature selection.

2) Computational Efficiency and Practical Deployment: The computing needs of training large-scale models are often overlooked by DL techniques, which restricts their application in resource-constrained situations common to many agricultural contexts. This disparity emphasizes the requirement for optimal models that strike a compromise between operational viability and performance.

D. Solutions

Presently, our research methodology rigorously examines and assesses several feature selection algorithms inside the Deep-CCNet approach, including RWA, PSO, BDA, GA, and BEA. The goal of this comparison study is to evaluate how each strategy affects the model's accuracy, computing efficiency, flexibility, and understandability. By doing this, we close important knowledge gaps regarding feature selection efficiencies in agricultural applications and establish new standards for the creation of systems that are scalable, trustworthy, and understandable for the diagnosis of cotton leaf disease. This effort opens the door for more sophisticated AI-driven agriculture systems to be used on a global scale.

III. Methodology

We performed two types of experiments. Firstly, we conducted end-to-end training, validation, and testing of our Deep-CCNet model. Secondly, to improve the performance and reduce the computational cost of our approach, we extracted deep features from the last fully connected layer of the Deep-CCNet model and subjected them to various feature selection algorithms to determine their effectiveness in reducing feature dimensionality and improving classifier performance. We used SVM, KNN, Decision Tree, and Naive Bayes classifiers for the classification of the selection features. The basic workflow of the proposed method is given in Fig. 1.

A. Image Resizing

To maintain uniformity in input size throughout the dataset, all input images are resized to 224 by 224 pixels.

B. Dataset Partitioning

The Deep-CCNet model is evaluated with a twofold approach: 10% of the images are used as a hold-out test set for testing, and the rest, 90% are used in a five-fold cross-validation setup, where in each iteration a different fold (data) is used as a validation set. This approach ensures strong testing against overfitting and encourages generalization.

C. Deep-CCNet Architecture details

The architecture of the Deep-CCNet model is based on the ResNet18's architectural principles; however, it also includes notable modifications specifically designed to maximize the classification performance and reduce computational costs (Table II). The proposed Deep-CCNet architecture is a lightweight convolutional neural network that is optimized for efficiency and fast convergence, ideal for small or medium-sized datasets such as cotton leaf disease classification. Deep-CCNet possesses approximately 5.4 million learnable parameters, significantly lower than ResNet18's 11.18 million parameters. Unlike ResNet18, which uses default ReLU activations, Deep-CCNet uses Leaky ReLU activation units throughout the network to correct the dying neuron problem and facilitate gradient flow.

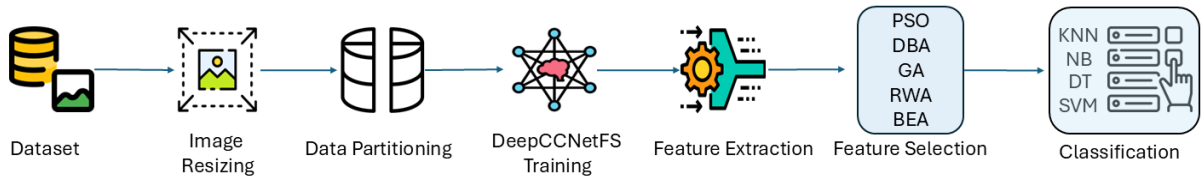

Fig. 1. Overview of the proposed methodology for cotton leaf disease classification.

Furthermore, Deep-CCNet reduces the residual block architecture by eliminating every other convolutional block, creating a shallower but effective model without over-sacrificing feature learning. Deep-CCNet introduces an additional fully connected layer of 1096 neurons preceded by a dropout layer (probability = 0.5) to mitigate overfitting, which is not included in ResNet18.

Moreover, although both networks employ strided convolutions to downsample, Deep-CCNet is specifically architected to predict for 4 classes (i.e., three types of cotton leaf diseases and a healthy class), as opposed to ResNet18's native 1000-class ImageNet configuration. This change in structure yields a computationally more lightweight model that is simpler to train and better suited to domain-specific classification tasks.

D. Feature Extraction

Following preprocessing, images are sent to the DeepCC-NetFS, where feature extraction is handled by many layers. Images are subjected to several filter applications as they go through the convolutional layers, such as conv1 of the first residual unit, which produces feature maps that capture different

TABLE II
KEY DIFFERENCES BETWEEN RESNET18 AND DEEPCCNETFS.

S. No	Property	DeepCCNetFS	ResNet18
1	Number of Learnable Layers	12	18

9	Total learnable parameters	5.4 Million	11.18 Million
10	Residual Blocks	4	8

aspects of the images, such as edges and textures, and can be represented as:

$$\mathrm{f}_{ij}^{k} = \sum((c^{k} \times x) + b_k) \tag{1}$$

Here, x represents the local region of the image being convolved, k is used to represent the kth layer, f denotes the feature's value, (i, j) represents pixel coordinates, c^k represents the convolution kernel of current layer, and b_k denotes the bias. Batch normalization layers are then used to normalize these feature maps, which reduces internal covariate shifts and allows for faster and more stable training.

Max pooling layers, such as pool1, assist in lowering the computational burden and model complexity by controlling overfitting and summarizing the convolutional layer outputs into more abstract representations. This reduces the spatial dimension. The network can learn identification functions from residual connections, like res2a, to make sure that no data is lost between layers. Because these connections give gradients direct paths during backpropagation, they are essential for enabling the training of very deep networks. The function $f(x)$ yields the ideal feature map.

$$f(x) = max(x1, x2, x3, ...x_n) \tag{2}$$

where $x_1, x_2, x_3, \ldots, x_n$ are the activation values within a local region (e.g., 3×3 window) of the feature map. This operation retains the most prominent features while discarding less significant ones, making the representation more robust and compact. Higher-level reasoning in the network takes place in the FC layers, where fc7 and fc8 are essential building blocks for condensing the distilled information into a format appropriate for categorization. The most important characteristics in Deep-CCNet are effectively highlighted by a global average pooling layer (pool5) that first reduces the feature maps to a single value per map.

The output from the last fully connected layer (fc8) serves as the extracted feature set for downstream tasks. Finally, the softmax layer computes class probabilities, enabling the model to classify cotton leaf images into specific disease categories.

E. Feature Selection Algorithms

Our study's feature selection procedure uses sophisticated algorithms that combine local and global search techniques to extract the most pertinent characteristics from high-dimensional data. By removing redundant and unnecessary features, these techniques decrease the dimensionality of the data and improve the classification models' performance.

1) Binary Dragonfly Algorithm (BDA): The BDA is a nature-inspired optimization method based on the foraging behavior of dragonflies. This algorithm uses a swarm of candidate solutions as binary vectors. It iterates in steps where each solution is updated according to local best (exploitation) and global best (exploration) strategies. The algorithm uses a combination of velocity updates and binary transformations (with sigmoid-like updates) to search the feature space for an optimal feature subset. The fitness function evaluates the feature subsets using a classification model, with the best features selected based on minimum classification error.

2) Bee Evolutionary Algorithm (BEA): The BEA is inspired by the foraging process of bees, i.e., employed, onlooker, and scout stages. The algorithm starts by initializing a population of binary solutions (representations of feature subsets) and evaluating their fitness based on a classification model (KNN). The employed bees attempt to mutate solutions to reach better fitness, and onlooker bees select solutions probabilistically based on fitness. Scout bees search randomly in the solution space when they cannot find better solutions. These steps are repeated by the algorithm iteratively, tracking convergence and improving the population for better feature selection.

3) Genetic Algorithm (GA): The GA is a metaheuristic algorithm inspired by natural selection that is used to solve search and optimization problems. In this algorithm, every member of the population is a binary vector where every bit corresponds to a feature being included or not. The algorithm determines the fitness of every member by training a classifier (for example, KNN) using the selected features. In each generation, the population is refreshed using selection, crossover, and mutation. Selection serves as a promise of

carrying forward superior individuals to the next generation. Crossover exchanges traits among individuals, and mutation introduces randomness using bit flipping. The iterations are iterated over a defined number of generations, and the optimal individual (set of features) is employed in model construction.

4) Particle Swarm Optimization (PSO): The PSO algorithm is an optimization method that is based on the social behavior of bird flocking. The PSO uses a population of particles, and each particle is a possible feature subset. Each particle updates its position according to its own best position and the global best position discovered by the swarm. The algorithm balances exploration (moving towards new areas of the solution space) and exploitation (refining current good solutions) through velocity updates. The particles converge to an optimal subset of features after iterating around the solution space. Fitness is evaluated in terms of classification accuracy on a selected set of features.

5) RainWater Algorithm (RWA): RWA is inspired by raindrop movement, where raindrops "move down" to lower levels, representing a natural minimization search for the location of the minimum in the feature space. It simulates raindrop behavior through iterative solution movement by fitness in trying to achieve the best set of features, reducing classification error. The solutions (sets of features as subsets) are refined through multiple iterations. The algorithm initializes with a random population of feature subsets, computes their fitness from their sum of feature values, and shifts them to a new position by adjusting velocities toward the optimal solution. A dynamic threshold guarantees that the correct features are selected, even when the initial threshold does not yield any selection.

IV. Results and Discussion

A. Dataset

In this work, a publicly available Kaggle data set named the "Cotton leaf disease data set" is used [43]. The dataset consists of 1,711 images representing four classes: Curl Virus (418 images), Bacterial Blight (448 images), Fusarium Wilt (419 images), and Healthy (426 images). The images were captured under real-world conditions in the fields of the Southern Punjab region of Pakistan, a major cotton-producing area. Some of the images were also downloaded from the internet. This dataset aims to assist in the identification and classification of cotton leaf diseases, which are critical for the agriculture industry, particularly for cotton cultivation and export to Europe and the US. The representative samples of the dataset are given in Figure 2.

B. Performance of Deep-CCNet without Feature Selection

The Deep-CCNet model is first evaluated without feature selection as a baseline performance. The five-fold cross-validation results are shown in Table III, and the test results on unseen data are shown in Table IV.

Deep-CCNet achieved a good mean accuracy of 98.06% under cross-validation, with precision, recall, and F1 score all well aligned around 98.0% (Table III). The model is very stable in its performance, indicated by the low standard deviations (below 0.7 for all metrics) and low variance values. The best accuracy achieved is 99.03%, indicating the model generalized well when trained.

On unseen test samples (Table IV), the model performed consistently with a mean accuracy of 96.13%, precision of 96.09%, recall of 96.26%, and F1-score of 96.15%. The results show minimal performance loss between the validation and testing phases, indicating the generalizability of the model. Furthermore, the values of standard deviation on the test set remained low, pointing towards the stability of the model across different data splits.

Overall, the Deep-CCNet model alone without feature selection already exhibits a very good classification capacity for the detection of cotton leaf disease and offers a high baseline for achievable improvement through feature selection techniques.

TABLE III
Five-Fold cross-validation results for the cotton leaf disease dataset (validation).

Metric	Accuracy	Precision	Recall	F1-score
Average	98.06	97.97	98.02	97.99
Median	97.73	97.70	97.80	97.75
Maximum	99.03	98.72	98.72	98.71
Minimum	97.09	97.07	97.08	97.08

Variance	0.20	0.23	0.14	0.20

C. Performance Evaluation of Meta-Heuristic Feature Selection Methods

The objective of this experiment is to evaluate systematically the performance of various meta-heuristic feature selection algorithms, including RWA, PSO, DBA, GA, and BEA, in improving the performance of classification models of cotton leaf disease. The classification using four different classifiers—SVM, Naïve Bayes, KNN, and Decision Tree is shown in Table V.

Among the tested methods, the BEA algorithm combined with Naïve Bayes yielded the best overall performance, achieving the highest accuracy (97.66%), precision (97.62%), recall (97.65%), and F1-score (97.63%). The next best results are obtained using BEA with KNN (accuracy: 97.08%, F1-score: 97.07%) and SVM (accuracy: 95.32%, F1-score: 95.30%)

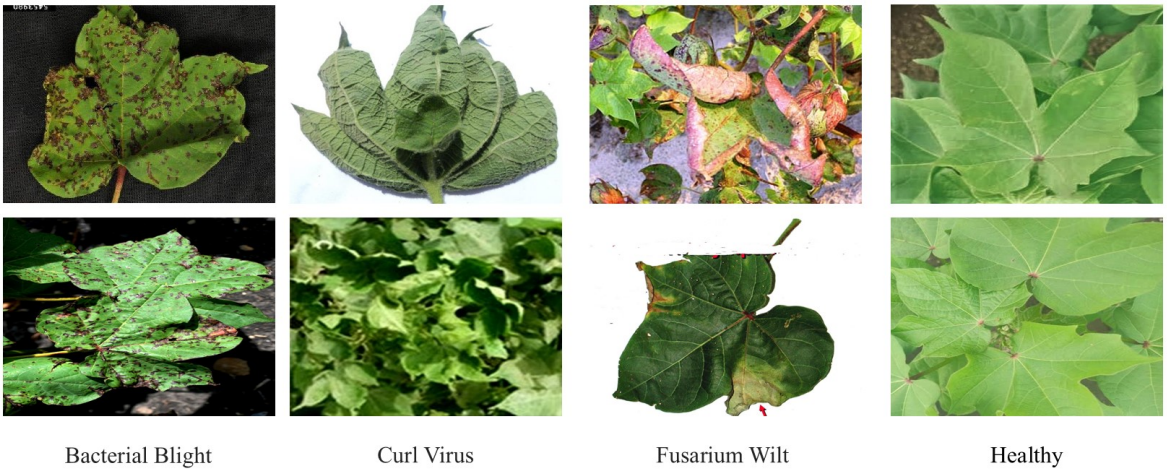

Fig. 2. Sample images from the Cotton Leaf Disease Dataset.

classifiers, respectively. The DBA method also demonstrated strong performance, particularly with KNN, which achieved a precision of 97.22% and an F1-score of 97.56%. Similarly, the GA algorithm combined with Naïve Bayes produced competitive results, with an accuracy of 97.14%, precision of 97.22%, recall of 97.22%, and F1-score of 97.22%. These results suggest that while BEA leads in overall classification performance, both DBA and GA also offer robust alternatives when paired with appropriate classifiers.

On the other hand, RWA generated the poorest classification performances of all the classifiers, with accuracies between 58.00% and 72.00%, which means that its feature selection quality is inferior for this task. PSO and GA showed comparable performance, particularly when applied with Naïve Bayes and Decision Tree classifiers, which means that they offer good trade-offs between feature selection quality and model generalization.

In general, BEA and DBA proved to be the best feature selection methods for improving model performance, with RWA being less ideal in this situation.

Furthermore, as shown in Table V, the number of selected features varies across methods, with RWA selecting only 1 feature, PSO selecting 9, and other algorithms like DBA, GA, and BEA consistently selecting 4 features, demonstrating the impact of feature subset size on classification performance.

D. Computational Cost Analysis of Meta-Heuristic Feature Selection Methods

The objective of this experiment is to compare the computational efficiency of all algorithms used for feature selection in terms of feature selection time, classifier training and testing time, and total running time, as illustrated in Table VI.

RWA recorded the fastest total execution time (7.55 seconds) because of its relatively simple optimization process, but poor classification accuracy limits its practical applicability. PSO and DBA recorded moderate execution times (16.65 and 14.71 seconds, respectively) but excellent classification accuracy, making them good options where both efficiency and accuracy matter.

GA, although ranking well, took significantly more overall execution time (60.15 seconds) than PSO and DBA due mainly to the iterative nature of genetic operations. BEA, although showing the best classification performance, took the highest computational cost (451.39 seconds), which highlights a trade-off between predictive performance and computational resource usage. This substantial computational overhead is largely attributed to the ensemble-based nature and nested search operations within BEA, which, while improving feature selection quality, lead to increased time complexity.

From a practical standpoint, the high execution time of BEA raises concerns regarding scalability and real-time deployment feasibility, especially for edge devices or resource-constrained environments. For instance, in large-scale time series applications or streaming scenarios, such computational demand may hinder timely decision-making or exhaust device resources. In contrast, PSO and DBA strike a more favorable balance by offering competitive accuracy at a fraction of the computational cost, making them more viable for real-world deployment.

Therefore, while BEA may be suitable for offline analysis or batch processing tasks where accuracy is prioritized over speed, PSO and DBA are better suited for operational settings requiring rapid inference and low-latency processing. This analysis underscores the need to carefully match algorithm selection with deployment requirements and hardware constraints.

Briefly, although BEA offers higher classification accuracy, its deployment may be impractical in latency-sensitive environments. PSO and DBA are more balanced choices for scenarios where computational expense is a key consideration.

V. Conclusion

In this work, we have introduced an end-to-end deep learning architecture, Deep-CCNet, for detecting cotton leaf disease and

TABLE V
PERFORMANCE COMPARISON OF FEATURE SELECTION METHODS AND CLASSIFICATION ALGORITHMS

Feature Selection Algorithm	Classifier	# Selected Features	Accuracy	Precision	Recall	F1-Score
RWA	SVM	1	72.55	72.66	73.30	72.57
RWA	Naïve Bayes	1	72.55	72.80		72.58

TABLE VI
COMPUTATIONAL COST ANALYSIS OF FEATURE SELECTION METHODS.

Feature Selection Algorithm	Best Accuracy	Feature Selection Time (s)	Classifier Training and Testing Time (s)	Total Execution Time (s)
RWA	72.55	0.24	6.24	7.55
PSO	91.43	15.73	0.44	16.65
DBA	97.06	12.99	1.01	14.71
GA	97.14	58.92	1.02	60.15
BEA	97.66	448.65	2.61	451.39

have extensively analyzed the impact of various meta-heuristic feature selection techniques, including RWA, PSO, DBA, GA, and BEA, on classification performance and computational expense. The Deep-CCNet model has achieved high baseline accuracy (96.13% on unseen samples without feature selection), which is proof of its effectiveness for this task.

Through comprehensive experimentation, we found that the BEA achieved the highest classification performance among different classifiers, followed by DBA and PSO, providing a better balance between classification accuracy and computational cost. However, RWA, though having low computational cost, reported significantly lower predictive performance and was therefore less suitable for this application.

Aside from these promising results, there are several limitations to this work. First, the study is conducted on a single cotton leaf disease dataset; hence, the generalizability of the Deep-CCNet model and feature selection techniques to other crops and general plant pathology tasks has not been established. Second, while the study achieved high classification performance, it did not incorporate explainability techniques to interpret model predictions or feature selection outcomes, limiting the transparency and trustworthiness of the system for end users such as farmers and agronomists. Finally, the current approach uses traditional classifiers after feature selection; more advanced classifiers or ensemble techniques could further improve results.

Future work can extend this research in many directions. One direction would be to apply the Deep-CCNet model and feature selection steps to larger, multi-crop datasets for their scalability and robustness. Exploring light-weight models optimized for deployment on mobile and edge devices would also enhance the real-world usability of the system in actual agricultural settings. Last but not least, developing explainable AI (XAI) modules for model prediction and feature importances could provide actionable insights to farmers and agronomists and bring the study closer to the overall goals of interpretable and trustworthy AI in agriculture.

CODE AVAILABILITY

The source code used in this study is publicly available[1]. This facilitates reproducibility, enables validation of the results, and encourages further research and development in the field.

***Abstract*—The paper focuses on the problem of generating random numbers, which on the surface appears to be a very simple problem. However, Most software tools used for this purpose produce pseudorandom numbers. This means that, if certain conditions are met, it is possible to reproduce successive sequences of generated numbers. This paper addresses the problem by developing an IoT device to generate true random numbers based on selected physical properties. The device communicates with a server that provides a web service and an API for generating random values in multiple variations.**

I. Introduction

IN THE DIGITAL AGE, randomness plays a crucial role in a wide array of applications, ranging from cryptography and secure communications [4] to simulations of unexpected events [3], gaming, art and GUID or UUID [5]. The quality of randomness directly impacts the performance and reliability of these applications. True Random Number Generators (TRNGs) are particularly valuable in this context, as it derive their randomness from physical processes, ensuring a higher degree of unpredictability compared to pseudo-random number generators (PRNGs), which rely on deterministic algorithms.

Randomness, as a concept, has intrigued researchers and practitioners due to its wide-ranging utility in fields such as mentioned simulations, gaming, and also statistical sampling, and experimental design. While randomness is often associated with cryptographic applications, this project focuses on non-cryptographic use cases, where high-quality random numbers are equally essential but do not require the stringent security guarantees of cryptographic systems. This distinction allows for the exploration of randomness in a broader context, emphasizing accessibility, scalability, and ease of use.

Existing solutions for generating random numbers often come with limitations, such as high costs, restricted access, or reliance on pseudo-random number generators, which, while sufficient for many applications, lack the inherent unpredictability of true randomness derived from physical processes. This paper seeks to bridge this gap by developing a scalable, cost-effective, and user-friendly web service that leverages true random number generators to deliver high-quality random numbers for non-cryptographic purposes. By focusing on applications such as simulations, Monte Carlo methods, random sampling, and artistic content generation, the service aims to provide a reliable and accessible source of randomness for a global audience, fostering innovation and experimentation across diverse domains.

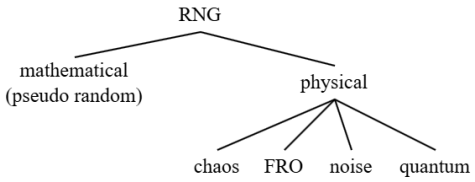

Fig. 1. Classification of random number generators.

Section II discusses how to generate random numbers. Section III describes the most important elements from the construction of the software and the device. Section IV presents and validates the system operation of the whole system and possible applications. The V section provides a summary of the work.

II. Generating random numbers

A. Classification

Random number generators can be divided into two major groups: Mathematical (pseudo random) and Physical. Pseudo random generators can be further divided into several categories based on the type of algorithm used, and physical random number generators are divided into 4 categories: noise based RNGs, free running oscillator (FRO) RNGs, chaos RNGs and quantum RNGs based on the entropy source [7].

B. Pseudo-random numbers

Pseudo-random number generators are algorithms that produce sequences of numbers approximating randomness using deterministic mathematical formulas. They rely on an initial state called a seed, which is processed into a longer sequence of values. PRNG output typically follows a uniform distribution, enabling transformations to other distributions (e.g., Gaussian) [6]. While not truly random, PRNGs are sufficient for applications like simulations, gaming, and randomized algorithms. Cryptographically secure PRNGs (CSPRNGs) enhance security by ensuring outputs are computationally indis-

tinguishable from true randomness, making them essential for cryptographic protocols [7], [8].

PRNGs excel in speed, generating millions of random numbers per second, far surpassing true random number generators limited by physical entropy sources. Their period, the length of the sequence before repetition, varies by algorithm. For instance, the Mersenne Twister has a period of $2^{19937}-1$, making it suitable for large-scale simulations, while simpler PRNGs like linear congruential generators (LCGs) have shorter periods. CSPRNGs feature periods so large that repetition is practically impossible, ensuring long-term reliability [7].

The advantages of PRNGs include low computational cost, ease of implementation, and reproducibility. By using fixed seeds, PRNGs enable consistent results for debugging and verification, making them indispensable in scientific and engineering applications [6], where repeatability is important.

There are a large number of PRNG algorithms implemented. The most popular are

1) **Middle-square method** [9]
   One of the earliest methods, presented by *J. von Neumann* in 1949 at a conference. Highly flawed, with very short period. The numbers are created by squaring the n-digit initial value, adding leading zeroes if the result has fewer than $2n$ digits and extracting middle n digits. The process can be repeated to generate more numbers.
2) **Linear Congruential Generator (LCG)** [10] One of the oldest and most widely used PRNGs, based on the Lehmer generator and published in 1958 by *W. E. Thomson* and *A. Rotenberg*. It is defined by the recurrence relation:

$$X_{n+1} = (aX_n + c) \mod m \tag{1}$$

   where:
   - X is the sequence of random values;
   - $m, 0 < m$ is the modulus;
   - $a, 0 < a < m$ is the multiplier;
   - $c, 0 \leq c < m$ is the increment;
   - $X_0, 0 \leq X_0 < m$ is the seed.

   LCGs are simple and efficient but suffer from lattice structures in higher dimensions, limiting their use in modern applications.
3) **Mersenne Twister** [11] Developed in 1997 by *Makoto Matsumoto* and *Takuji Nishimura*, this PRNG is renowned for its high-quality output and long period. Named after the Mersenne prime $2^{19937} - 1$, which defines its period length, the Mersenne Twister is widely used in simulations and statistical applications. It balances speed and statistical robustness, though its large state size can be a drawback in memory-constrained environments.
4) **Xorshift** [12] Created by *George Marsaglia*, a pioneer in random number generation, Xorshift is an extremely fast PRNG that produces sequences of $2^{32} - 1$ integers. It relies on repeated XOR operations with shifted versions of its state, making it lightweight and efficient. Variants like Xorshift+ and Xorshift* improve statistical properties while maintaining speed.
5) **WELL (Well Equidistributed Long-period Linear)** [13] An improvement over the Mersenne Twister, WELL generators offer better equidistribution and faster recovery from zero states. Developed by *F. Panneton, P. L'Ecuyer, and M. Matsumoto*, WELL variants are suitable for applications requiring high-quality randomness and long periods.
6) **PCG (Permuted Congruential Generator)** [14] A modern family of PRNGs designed by *M. E. O'Neill*, PCG combines linear congruential generators with permutation functions to enhance output quality. PCG variants are compact, fast, and statistically robust, making them popular in gaming and procedural generation.
7) **WELLDOC** [15] Aperiodic PRNGs based on infinite words techniques, developed by *L. Balkova, M. Bucci, A. de Luca, J. Hladky,* and *S. Puzynina* in 2013. These generators are theoretically interesting but less commonly used in practice due to their complexity.
8) **Blum Blum Shub** [16] A cryptographically secure PRNG based on quadratic residues modulo a product of two large primes. While highly secure, it is computationally intensive and rarely used outside cryptographic applications.
9) **Multiply-with-Carry (MWC)** [17] Developed by *George Marsaglia*, MWC generators combine multiplication and carry operations to produce long-period sequences. They are simple to implement and perform well in statistical tests.
10) **Philox and Threefry** [18] Counter-based PRNGs designed for parallel computing environments. They use cryptographic primitives to ensure high-quality randomness and are optimized for GPU and multi-core CPU architectures.

C. Physical random numbers generators

Random Number Generators that rely on physical phenomena generate inherently unpredictable and provably random outcomes. These hardware-based RNGs, often referred to as true random number generators, operate by exploiting naturally occurring random processes, such as electronic noise, quantum effects, or chaotic systems. Unlike pseudo-random number generators, which use deterministic algorithms to produce sequences that only appear random, physical RNGs are typically standalone devices connected to a computer via interfaces like USB or PCI. However, physical RNGs are not without limitations; they often exhibit bias and short-range correlations, meaning the output may not always be uniformly distributed. Bias, defined as the deviation in the probabilities of generating ones and zeros, is quantified by the equation:

$$b = \frac{p(1) - p(0)}{2} \tag{2}$$

where $p(1)$ and $p(0)$ represent the probabilities of generating a one and a zero, respectively. To mitigate these issues, post-processing techniques, such as von Neumann debiasing or

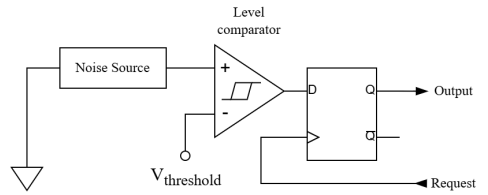

Fig. 2. The diagram shows a basic noise-based RNG comprising a noise source (e.g., thermal noise), a level comparator (with threshold $V_{threshold}$), and a D flip-flop (DFF) to sample and digitize the noise signal into random bits. This design leverages stochastic physical phenomena to generate true randomness.

cryptographic hash functions, are often applied to the raw output of physical RNGs. These methods help ensure the final output is both unbiased and suitable for applications requiring high-quality randomness, such as cryptography or secure communications.

Noise-based random number generators exploit stochastic physical phenomena to extract entropy for true randomness. These systems sample analog noise signals — unpredictable fluctuations inherent to electronic, optical, or quantum processes — and convert them into statistically independent bit sequences. Common noise sources include thermal agitation, quantum tunneling effects, and chaotic dynamics, each offering distinct advantages in entropy density and sampling rates [19], [7].

Thermal noise (Johnson-Nyquist Noise) arises from the random motion of electrons in conductive materials at equilibrium, as described by the fluctuation-dissipation theorem. Its power spectral density is given by:

$$S_V(f) = 4k_BTR \quad (\text{V}^2/\text{Hz}), \tag{3}$$

where k_B is Boltzmann's constant, T is the absolute temperature (K), and R is the resistance (Ω). This white noise exhibits a Gaussian amplitude distribution, making it a robust entropy source. Practical implementations sample thermal noise via high-gain amplifiers and analog-to-digital converters (ADCs), though challenges include mitigating $1/f$ noise at low frequencies and temperature-induced drift [7].

Zener noise (Avalanche Breakdown Noise) originates from quantum tunneling and impact ionization in reverse-biased Zener diodes operating near the avalanche breakdown regime. Individual electron-hole pair generation events produce discrete current spikes, yielding a shot noise process with Poissonian statistics. The noise current I_n follows:

$$\langle I_n^2 \rangle = 2qI_{\text{DC}}\Delta f, \tag{4}$$

where q is the electron charge, I_{DC} is the bias current, and Δf is the bandwidth. Zener-based RNGs achieve high bitrates (>100 Mbps) but require precise voltage regulation to stabilize the breakdown region and avoid deterministic oscillations [7].

Chaos-based random number generators leverage nonlinear dynamical systems governed by chaos theory to harvest entropy. These systems exhibit deterministic yet unpredictable behavior due to their sensitivity to initial conditions (the "butterfly effect") and topological mixing. Common implementations exploit chaotic phenomena in optical, electronic, optoelectronic, or mechanical domains, where small perturbations amplify exponentially over time, yielding outputs that are statistically indistinguishable from true randomness [21]. Other example of optical chaos-based RNGs employs distributed feedback (DFB) lasers with self-feedback mechanisms.

Free-Running Oscillators [7] (FROs) are a class of hardware-based random number generators that exploit the inherent jitter and metastability in electronic circuits to produce randomness. An FRO is a simple yet effective circuit that consists of a logical inverter whose output is fed back into its input, creating an unstable oscillatory state. The oscillation frequency is determined by the internal propagation delays of the inverter and the stray capacitances in the circuit. This unpredictability makes FROs a popular choice for generating random numbers in embedded systems and hardware security applications. The randomness in an FRO-based RNG is extracted by sampling the oscillating signal at irregular intervals or by comparing the phases of multiple FROs. One common approach is to use a pair of FROs with slightly different frequencies. The phase difference between the two oscillators drifts over time due to jitter, and this drift is sampled to produce random bits.

Quantum Random Number Generators (QRNGs) [8], [20] leverage the inherent unpredictability of quantum mechanics to generate true randomness. Unlike classical random number generators, which rely on deterministic algorithms or physical processes that may be predictable in principle, QRNGs exploit the fundamental indeterminism of quantum systems. This makes them ideal for applications requiring high levels of security, such as cryptography and secure communications. QRNGs operate by measuring quantum phenomena that are intrinsically random. One of the most common implementations uses photons, the elementary particles of light, and their quantum properties. For example, a photon in a superposition of states will collapse randomly into one of two possible states when measured. This randomness is used to generate binary bits (0s and 1s) [7], [8].

Spatial QRNGs [8], [7] rely on the physical path a photon takes after passing through a beam splitter. These systems use two detectors, one for each output port of the beam splitter. While conceptually simple, spatial QRNGs require careful calibration to ensure that the detectors are equally sensitive and that the beam splitter is perfectly aligned. Any imbalance in the system can introduce bias into the output, requiring post-processing to correct.

Temporal QRNGs [8], [7], on the other hand, exploit the randomness in the timing of photon arrivals. Instead of measuring the path a photon takes, these systems measure the time intervals between successive photon detections. For example, the system might compare two consecutive time intervals. This approach has the advantage of requiring only a single detector, simplifying the hardware design and reducing calibration requirements.

Another class of QRNGs exploits the randomness of radioactive decay [8]. In these systems, a radioactive source emits particles (e.g., alpha or beta particles) at random intervals. A detector registers the arrival of these particles, and the timing of the detections is used to generate random bits.

D. TRNG Type Comparison

The development and evaluation of TRNGs have been extensively studied in the literature. Quantum-based TRNGs, in particular, have gained significant attention due to their provable security based on the laws of quantum mechanics. Herrero-Collantes and Garcia-Escartin [8] provide a comprehensive review of quantum random number generators (QRNGs), highlighting their theoretical foundations and practical implementations. They emphasize the role of quantum phenomena, such as photon detection and vacuum fluctuations, in generating true randomness.

Cirauqui et al. [20] further explore the challenges and benchmarking of QRNGs, discussing the trade-offs between speed, security, and resource requirements. Their work underscores the importance of device-independent QRNGs, which offer enhanced security by minimizing assumptions about the underlying hardware.

Stipčević and Koç [7] provide a broader perspective on TRNGs, covering chaos-based, noise-based, and FRO-based designs. They discuss the sources of entropy, post-processing techniques, and security considerations for each type. Their work highlights the importance of environmental robustness and cost-effectiveness in practical TRNG implementations.

True Random Number Generators vary in design and application. Chaos-based TRNGs use nonlinear systems for high entropy but require complex calibration, making them suitable for cryptography. FRO-based TRNGs, leveraging electronic jitter, are simple and fast but require post-processing, which is ideal for IoT and FPGAs. Noise-based TRNGs rely on thermal or shot noise, offering reliability but requiring analog components, often used in hardware security modules (HMS) and military systems. Quantum-based TRNGs, exploiting quantum phenomena, provide ultimate security but are costly and sensitive, limiting their use to high-security applications. Each TRNG type balances performance, cost, and complexity for specific needs.

The choice of TRNG type depends on the specific application requirements:

- Chaos-based TRNGs are well-suited for cryptographic applications due to their high entropy and nonlinear dynamics. However, they are sensitive to environmental conditions and require careful calibration.
- FRO-based TRNGs are ideal for resource-constrained environments, such as IoT devices and FPGAs, due to their simplicity and low power consumption. However, they often require post-processing to improve randomness quality.
- Noise-based TRNGs offer a balance between reliability and security, making them suitable for hardware security modules and military systems. Their reliance on analog components increases the complexity of the design.
- Quantum-based TRNGs provide unparalleled security, making them ideal for high-stakes applications such as quantum communication and cryptography. However, their high cost and sensitivity to environmental factors limit their widespread adoption.

III. Implementation

A. Motivation

Randomness is seemingly underestimated, but it plays a key role in many areas: from simulations and Monte Carlo methods, through computer games, to statistical sampling and the generation of unique identifiers. The quality of random numbers directly affects the reliability of calculation results and system security, which is why generators based on real physical processes, rather than solely on deterministic algorithms, are increasingly being used. There is no common belief among programmers that it is necessary to use truly random generators. Popular libraries offer good-quality pseudo-random generators, but their deterministic nature makes it possible to reproduce the sequence if the initial state is known. True random generators, using the previously described thermal noise, quantum phenomena, or oscillator jitter, provide a higher degree of unpredictability. Building your own TRNG allows you to eliminate dependence on external services and gives you full control over the quality and availability of the entropy source.

The implementation of the true random number generator tool described below is a response to the needs of programmers. The basic access layer for this type of user is WebAPI, hence a lot of attention was paid to the preparation of the API and documentation when developing the solution. On the other hand, it is valuable to be able to test the solution in advance without having to use typical developer tools. In order to meet this requirement, a web interface was developed.

B. System architecture

The system must accommodate a moderate volume of simultaneous requests while maintaining low latency, high reliability, and scalability, ensuring robust performance under variable operational conditions. Additionally, the implementation will incorporate cryptographic protocols to secure data transmission and prevent adversarial manipulation during distribution.

Components presented in Fig. 3 work together in order to generate random numbers and serve them on the internet. The web app acts as a graphical interface for users. It displays the services available on the website as interactive forms that users use to send requests to the API and presents the results - the generated random numbers. The Hardware Random Number Generator is the source of random numbers. It generates random 32 bit words as quickly as possible and sends them over a WebSocket connection to the web API. The web API in pair with the database performs the back-end duties: converting random bits into numbers, processing user

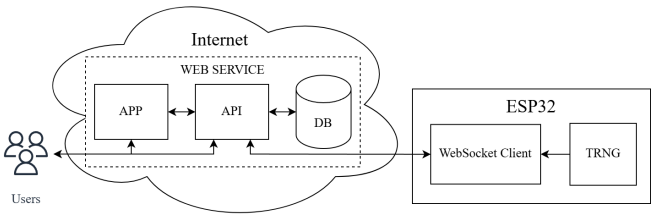

Fig. 3. The web service is a containerized application deployed in the cloud. The TRNG is a physical module connected to the internet. Users access the app through the internet.

requests, handling authorization, authentication and sending the results to users. The app, API and database components are deployed in a containerized environment in the cloud.

The development of the system utilizes a diverse set of tools and technologies tailored to each component. For the Web App, HTML structures web content, CSS handles styling, and JavaScript adds interactivity, while JQuery simplifies DOM manipulation and Bootstrap ensures responsive design. The Web API relies on Python and Django, with Django Rest Framework enabling RESTful API development, Open API providing standardization, and ASGI with Daphne supporting asynchronous communication. HTTP and WebSocket protocols facilitate seamless data exchange between the server and clients. The Database uses SQLite for its lightweight, high-reliability SQL engine, with SQL managing data manipulation and retrieval. For the TRNG, it use an IoT device [2], it means the ESP32 microcontroller with an embedded TRNG is programmed using the Arduino IDE and C++, ensuring efficient and secure random number generation. Together, these tools and technologies provide a robust foundation for the system's development. The ESP32 microcontroller was chosen because of its built-in Wi-Fi module (which simplified communication implementation), low purchase cost, and ease of programming in the Arduino environment. The IoT device can also be built on other microcontrollers that support Arduino programming, such as those from the AVR and NRF families.

C. Software

The web application's front end, which serves as the graphical interface accessible via a web browser, is integrated into the Python Django application using the Django templating engine. While the front end is primarily written using HTML, CSS, JavaScript and the Django Template Language (DTL), the Django templating engine dynamically renders the pages based on the context provided by the backend. This integration allows the front end to seamlessly interact with the Django framework.

The Web API is a distributed system designed to provide secure, scalable, and efficient access to random number generation services. It is composed of three interconnected applications, each responsible for a distinct functional domain. These applications work in concert to handle user authentication, random number generation and data delivery, ensuring a robust, modular architecture.

The Web API is organized into the following components:

1) **API (Application Programming Interface):** The core application responsible for handling user requests and delivering random number generation services. It implements the following modules:
   - **Views and Models:** Defines the endpoints and data structures for random tools, such as integer sequences, floating-point numbers, and custom distributions.
   - **Random Tool Functions:** Implements algorithms for transforming raw random bits into user-requested formats.
   - **OpenAPI Documentation:** Provides a standardized, machine readable specification of the API endpoints, request/response formats, and authentication mechanisms. This documentation is automatically generated using Redoc, ensuring clarity and consistency for developers integrating with the API. Available at https://trng.kacperochnik.eu/api/
2) **Auth (Authorization and Authentication Module):** A dedicated service for managing user identities, access control, and resource quotas. Key features include:
   - **User Authentication:** Implements Session and JWT-based authentication to verify user credentials and issue access tokens.
   - **Authorization:** Enforces role-based access control (RBAC) to restrict access to sensitive endpoints (e.g., administrative tools).
   - **Points System:** Tracks and deducts user points for each random number generation request, ensuring fair usage and preventing abuse.
3) **Trng (True Random Number Generator Interface):** A WebSocket-based service that interfaces with physical TRNG hardware to harvest entropy and deliver it to the API. Its components include:
   - **WebSocket Consumer:** Manages real-time connections with TRNG devices, enabling low-latency data transfer.
   - **Circular Buffer:** Stores incoming random bits in a fixed-size, ring-shaped buffer to ensure continuous availability and prevent data loss during high-throughput operations.
   - **Bit Disposal Interface:** Provides a standardized interface for delivering random bits to the API's random tool functions, ensuring compatibility with diverse TRNG hardware.

The system employs SQLite as its relational database management system (RDBMS), leveraging Django's Object-Relational Mapping (ORM) layer for data persistence operations. SQLite was selected for its minimal configuration requirements, serverless architecture, and atomic transaction support - characteristics that align with the application's need for simplicity and rapid development iteration.

D. Hardware

The Hardware Random Number Generator (HRNG) subsystem comprises an ESP32-WROOM-32D microcontroller configured as a dedicated entropy source. This IoT-enabled device leverages the chip's native True Random Number Generator peripheral to harvest physical noise, transmitting raw random data to the web API via secure WebSocket protocol. The complete design files and firmware are available in the project repository.[1]

The ESP32 incorporates a True Random Number Generator that generates 32-bit random numbers suitable for cryptographic operations [23]. The TRNG relies on physical entropy sources so that no number within the specified range is more or less likely to appear than any other. In terms of key characteristics, the generator obtains its entropy from thermal noise produced by the high-speed ADC and SAR ADC, as well as from an asynchronous clock mismatch provided by the RC_FAST_CLK (8 MHz internal RC oscillator). Its output rate can theoretically reach up to 5.2 Mbps, however, to ensure optimal performance, the recommended read rate is 500 kHz when using SAR ADC noise and 5 MHz when using high-speed ADC noise. The TRNG is accessed via the 'RNG_DATA_REG' memory-mapped I/O (MMIO) register at the address '0x3FF75144', and it incorporates built-in Von Neumann debiasing with a 2:1 bit compression ratio to remove bias from the raw entropy stream.

Functionally, the TRNG generates true random numbers based on two primary sources of entropy. The first source, Thermal Noise, is generated by both the high-speed ADC and the SAR ADC, when enabled, these ADCs produce bit streams that serve as random seeds for the TRNG. The second source, Asynchronous Clock Mismatch, is derived from the RC_FAST_CLK (8 MHz internal RC oscillator), which introduces timing jitter and clock drift. These sources are combined using XOR logic, as expressed in the following equation:

$$b_{out} = \bigoplus_{i=0}^{n} (s_i \oplus t_i) \tag{5}$$

where:

- s_i represents sampled oscillator states (e.g., from the SAR ADC or high-speed ADC).
- t_i represents timing jitter measurements (e.g., from the RC_FAST_CLK).

Regarding the entropy feed mechanism, the TRNG uses two distinct noise sources. SAR ADC Noise provides 2 bits of entropy per clock cycle of the RC_FAST_CLK (8 MHz), with a maximum recommended read rate of 500 kHz to ensure maximum entropy. In contrast, High-Speed ADC Noise offers 2 bits of entropy per APB clock cycle (typically 80 MHz) and has a maximum recommended read rate of 5 MHz to similarly ensure optimal entropy extraction.

The Arduino program is fairly simple, it sends generated 32 bit random words, over WebSocket, as fast as possible, in a loop. It uses esp32 random API function - *esp_random()* to retrieve random bits from the register. Source code are presented in example 3.1.

[1]Repository: https://github.com/TeriyakiGod/esp-arduino-trng

Example 3.1 (C++):

```
void loop() {
  webSocket.loop();// Maintain WebSocket conn.
  // Check if WiFi is still connected
  if (WiFi.status() != WL_CONNECTED) {
    Serial.println("WiFi lost connection");
    connectToWiFi();
  }
  // Gen. rnd. number and send over websocket
  uint32_t randomValue = esp_random();
  webSocket.sendBIN((uint8_t*)&randomValue(),
  sizeof(randomValue));
}
```

E. Security

The developed solution belongs to the class of IoT devices and is constantly connected to the Internet, so adequate security is required [2]. The Web API incorporates several integrated mechanisms to ensure both security and scalability. It encrypts all communications between clients and the API using TLS 1.3, which protects against eavesdropping and man-in-the-middle attacks. In addition, the API employs rate limiting with token bucket algorithms to throttle excessive requests, thereby preventing denial-of-service (DoS) [4] attacks and ensuring fair distribution of resources. Load balancing is also applied, as incoming requests are distributed across multiple API instances via round-robin or least-connections strategies to maintain high availability and fault tolerance. Complementing these measures, robust authentication is achieved through the use of session cookies (maintained via a 'sessionid') and API tokens supplied in the 'Authorization' header, while standard error responses—such as '403 Forbidden' for insufficient points or privileges, '503 Service Unavailable' when the TRNG is offline, and '429 Too Many Requests' when the rate limit is exceeded—provide clear feedback to users.

The device further implements a custom binary protocol over WebSocket Secure (WSS) that is optimized for both efficiency and security. This protocol defines its frame format using 32-bit little-endian unsigned integers and supports a transmission rate of around 20 KB/s. Error handling is addressed by incorporating an exponential backoff strategy for connection failures, and security is reinforced by using TLS 1.3 in conjunction with the ESP32's root certificate bundle. Moreover, additional security considerations include physical isolation through a Faraday-shielded enclosure, runtime protection ensured by secure boot with flash encryption, and enhanced transport security via Perfect Forward Secrecy (PFS) using ECDHE-RSA. Together, these strategies result in an implementation that achieves 128-bit security under the Dolev-Yao threat model, provided that there is no physical access to the TRNG unit.

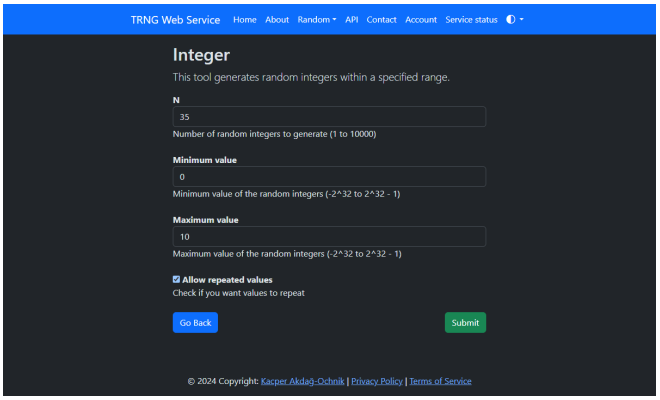

Fig. 5. Integer generator form filled with values.

IV. Verification

A. Access via GUI and API

Users begin by visiting the web service through a browser, where the homepage presents a selection of random number generators. To generate random integers, the user navigates to the integer generator using a button on the homepage, as shown in Fig. 4. Once on the integer generator page, the user can configure the tool to their preferences. For example, to generate 35 integers in the range from 0 to 10, the user sets N (the number of random integers) to 35, the minimum value to 0, and the maximum value to 10, as illustrated in Fig. 5. After submitting the form, the application returns the generated random integers. The distribution of these integers is visualized in a histogram in Fig. 6, showing a roughly uniform spread of random values across the specified range.

For programmatic access, users can send a GET request to the API endpoint[2]. The API responds with a JSON object containing the generated random integers, a timestamp, and the number of bits used, as shown in the code listing 4.1. The histogram in Fig. 7 visualizes the distribution of the integers generated via the API.

[2]https://serveraddess/api/rand/int?n=35&min=0&max=10&repeat=True

Example 4.1 (JSON):

```
"values":
    [4, 8, 2, 9, 8, 9, 10, 10, 5, 3, 1, 0,
    10, 6, 10, 3, 6, 10, 7, 1, 10, 3, 4,
    2, 10, 6, 8, 5, 3, 0, 9, 0, 0, 6, 7],
"timestamp": "2025-03-20T17:14:12.492409",
"bits": 1120
```

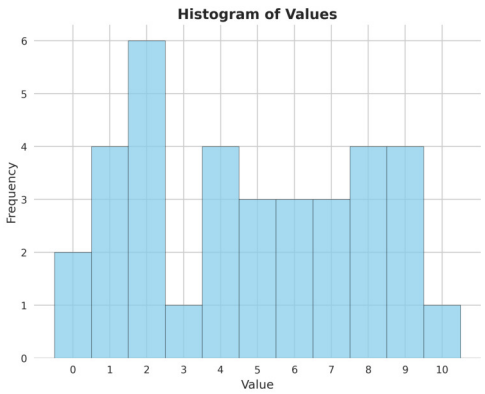

Fig. 6. Histogram of the first result

The application provides a seamless experience for generating random numbers, whether through the intuitive UI or the programmatic API. The histograms in Figs. 6 and 7 demonstrate that the generated integers are roughly uniformly distributed and random each time, validating the effectiveness and reliability of the random number generator. This ensures that users can trust the application to produce unbiased and balanced results for their needs. All functions are listed in the V appendix section.

B. Statistical Testing with Dieharder

The randomness of the TRNG output was evaluated using the Dieharder test suite, a comprehensive collection of statistical tests designed to assess the quality of random number generators. Dieharder analyzes the output for patterns,

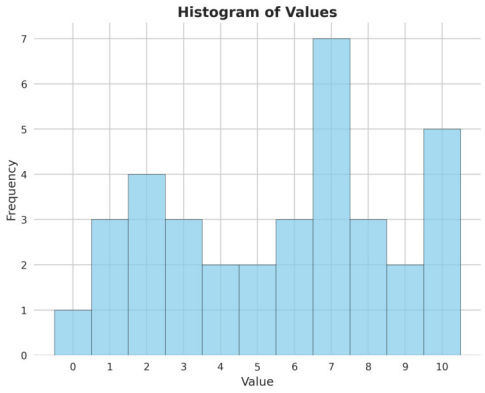

Fig. 7. Histogram of the second result

TABLE I

biases, and correlations that could indicate deviations from true randomness. The TRNG output was subjected to a variety of tests, and the results are presented in table I.

The Dieharder test results confirm that the TRNG output behaves as expected for a high-quality random sequence. Most tests passed with p-values within acceptable confidence intervals, indicating no significant biases or correlations. However, a few tests, such as rgb_bitdist (for bit distances 4 and 6) and rgb_lagged_sum (for lag 24), returned weak results. The weak result of the two tests is caused by insufficient variability in the sequences of consecutively generated zeros or ones. This may be due to suboptimal threshold alignment in the thermal noise signal digitization circuit, leading to correlation between consecutive samples.

C. Possible applications

The proposed self-hosted true random number generation system addresses diverse applications requiring high-quality, statistically robust, and verifiably unbiased randomness. The scientific field can make use of the web service in many ways, eg. Monte Carlo Simulations, Diffusion Models and Statistical Research.

Large-scale computational models in fields such as quantum chemistry, particle physics, and financial mathematics rely on entropy-rich seeds to minimize correlation artifacts. For instance, lattice Boltzmann simulations of fluid dynamics and option pricing models in quantitative finance demand randomness with certified uniformity to ensure convergence accuracy. The system's post-processing algorithms, which suppress residual biases in raw entropy sources, enhance the reproducibility of results across distributed computational clusters.

Modern generative artificial intelligence frameworks, including stochastic differential equation (SDE)-based diffusion models, utilize random noise sequences to synthesize high-fidelity images or molecular structures. A TRNG-backed service guarantees that the latent space sampling process remains free from deterministic patterns, which could otherwise introduce perceptual biases or reduce generative diversity in outputs.

Randomized controlled trials (RCTs), bootstrap sampling, and permutation tests require auditable randomness to preserve methodological integrity. By providing cryptographically signed random streams, the system enables researchers to verify the provenance of experimental data, mitigating concerns about inadvertent selection biases or adversarial tampering in peer-reviewed studies.

There are multiple applications in the field of gaming.

1) **Multiplayer Games:** Massively multiplayer online (MMO) platforms and blockchain-based play-to-earn ecosystems necessitate transparent randomness for procedural content generation, loot box mechanics, and non-fungible token (NFT) attribute assignment. Centralized pseudorandom number generators often face skepticism from users; outsourcing to an independently audited TRNG service enhances player trust and regulatory compliance.
2) **Lotteries and Raffles:** Public or decentralized systems conducting randomized prize allocations require algorithmic transparency to demonstrate impartiality. Integrating the TRNG system with blockchain-based smart contracts or verifiable computation frameworks ensures that draw outcomes derive from non-deterministic physical entropy, enabling participants to independently audit the randomness generation process. This eliminates skepticism toward algorithmic fairness, particularly in decentralized or distributed systems where trust in centralized authorities is limited.
3) **Casino Gaming:** Digital gaming platforms depend on unpredictability for mechanics such as shuffling virtual decks, generating roulette ball trajectories, or determining slot machine payouts. Hardware-backed TRNGs mitigate vulnerabilities inherent to algorithmic pseudorandomness—such as state reconstruction or seed manipulation—by anchoring outcomes to physically irreproducible entropy sources. This ensures that game mechanics cannot be reverse-engineered or biased, even by privileged insiders with access to the software stack.

The web service can be applied to create art.

1) **Generative Art:** Algorithmic art platforms (e.g., Art Blocks) and fractal geometry engines depend on entropy to drive procedural variations. High-dimensional randomness ensures that procedurally generated artworks—such as those minted as NFTs—exhibit unique traits without deterministic repetition, thereby preserving artistic value and collector interest.
2) **Algorithmic Music:** Stochastic composition tools, such as Markov chain-based melody generators or granular synthesis systems, leverage random parameters to explore unconventional harmonic structures. TRNG-derived sequences facilitate organic, non-repetitive soundscapes, distinguishing outputs from those produced by conventional PRNGs with limited cycle lengths.
3) **Interactive Installations:** Immersive environments and augmented reality (AR) experiences use real-time randomness to adapt narrative pathways or visual elements based on user interactions. A low-latency TRNG service enables dynamic, audience-responsive installations while maintaining statistical unpredictability across prolonged exhibitions.

While the system is unsuitable for high-throughput cryptographic operations like TLS handshakes (handling a single request takes almost 380 ms, for example from section IVa), it may supplement key derivation for non-real-time applications, such as creating master keys for offline data vaults and random vectors [1]. However, dedicated hardware security modules remain preferable for latency-sensitive tasks.

However, in production use, the scalability issue can be solved by duplicating instances through containerization and implementing a load balancer. Compared to competing solutions, it is worth highlighting the open-source approach and documentation of all endpoints. In addition, the proposed solution meets functional security requirements, including TLS and JWC.

V. Summary

Generating true random numbers is often underestimated by programmers. However, it turns out that a great deal depends on it, and it should be as random as possible. The paper demonstrates a software and hardware solution for generating such numbers. The IoT device developed uses noise, which serves as the basis for the generation. The generator's functions are then accessed via an API and GUI on a website.

The randomness of the generated numbers was verified using automatic tests, manual tests (histograms presented earlier) and a dedicated randomness verification solution, Dieharder. The results obtained show that the whole in the sense as a system generates data with a high level of randomness. Functional tests confirm that the system as a whole generates and provides numbers in accordance with user requirements and handles errors correctly. Performance tests show that the selected architecture (cloud containers, WebSocket, rate limiting) ensures low latency and high scalability. Statistical tests show that bit strings from TRNG do not exhibit significant deviations from randomness: no bias, appropriate distribution, no autocorrelation. As a result, they can be considered "truly random."

Obtaining a high level of randomness makes it possible to excavate the solution in many areas of IT. However, it should be pointed that the speed of data generation is average (less than 3 requests per second), so it cannot be used in real time. The solution to this problem is to multiply the IoT device, which, thanks to the use of ESP32, will not be expensive. Other risks arise from the analog circuit and the analog-to-digital converter. There is a risk that after generating a strong and steady signal, the system will receive the same grain all the time, hence work on improving the analog part is being considered. Other developments are related to expanding the software layer to generate random data for sharpening in artificial intelligence tools. Future work also could involve testing larger datasets to ensure the TRNG's performance scales appropriately. Additionally, other statistical test suites, such as the NIST Statistical Test Suite [22] or TestU01, could be used to further validate the TRNG's randomness.

Appendix

The system performs following functions:

1) Generating random numbers:
   a) Generating n random integers in range $[a, b]$.
   b) Generating n random floating point numbers in range $[0, 1]$ with p precision.
   c) Generating n random bytes represented in selected positional numeral system:
      i) Binary
      ii) Octal
      iii) Hexadecimal
      iv) Decimal
   d) Generating n random strings m long, with options:
      i) With repeating characters.
      ii) Without repeating characters.
      iii) With character set selection:
         A) Letters
         B) Digits
         C) Special characters
   e) Generating a random permutation of integers in range $[a, b]$
   f) Generating n coin tosses.
   g) Generating n, m sided dice throws.
   h) Generating n lottery tickets.
   i) Generating a random bitmap with dimensions x by y in PNG format, with the following types:
      i) Monochrome (1 bit per pixel)
      ii) Grayscale (8 bits per pixel)
      iii) Color (24 bits per pixel)
   j) Generating n random HEX color codes.
2) Ability to communicate with True Random Number Generator Modules using WebSocket protocol.

3) Ability to exchange data with users using HTTP protocol.
4) Encrypted connections using SSL/TLS.
5) Access to the service through the Web App or Web API.
6) Access control.
7) Anonymous user access with IP registry.
8) Web API keys for registered users.
9) Credit system allowing users to exchange points for random numbers.

***Abstract*—Attended Home Delivery is a last-mile distribution paradigm in which the customer must be present at home to receive the goods in person. In this context, we study a vehicle routing and scheduling problem in which the customers' availability is given as a time-dependent probability profile, and the company incurs a penalty cost proportional to the probability of not finding the customer at home during the selected timeslot for delivery. Using an efficient Mixed-Integer Linear Programming formulation for the problem as a black-box tool and lexicographic optimization procedures, we develop an economic analysis to support the company in exploiting the trade-off between basic optimization and the possibility of increasing the customer presence probabilities by paying additional costs. Managerial insights are derived from the change in the value and structure of optimal solutions under different budget levels allocated to improving customer availability profiles.**

I. Introduction and literature review

SINCE the advent of e-commerce, the delivery of goods purchased online directly to customers' homes has rapidly become the leading business model for retail companies and, in turn, one of the most important logistics operations within urban areas, and beyond. The largest share of deliveries performed in e-commerce consists of parcels, small packages, food, and groceries. The volume of this business is impressive and continues to grow rapidly. Over the past 10-12 years, the global e-commerce market has grown tenfold, reaching a value of 3.3 trillion dollars in 2022, approximately 22% of total retail sales. The COVID-19 pandemic significantly boosted this trend: the share of online retail rose from 15% in 2019 to 21% in 2021, exceeding even the most optimistic forecasts (see, e.g., [11]). Experts now agree that the sector still holds considerable long-term growth potential, with projections estimating it could reach 5.4 trillion dollars within the next 3–4 years [21].

Despite being very convenient (and sometimes necessary) for customers, home delivery services pose significant logistical challenges for companies and municipalities, in particular concerning last-mile deliveries. Last-mile delivery refers to the final stage of the distribution process, in which goods are transported from a local hub or depot to the end customer's address. From an economic point of view, last-mile operations represent by far the most expensive part of the fulfillment chain, accounting for more than 50% of the total shipping costs. On average, companies charge the consumers up to 80% of the shipping cost per package to cover them, taking the rest from the profit margins of sold products. Given the costs and the high impact in terms of emissions [8][15] and social implications [19], there is a considerable amount of literature devoted to the evaluation of alternative ways of handling the last mile, from parcel lockers [5] to drones [13], from autonomous robots [7] to crowd-shipping [2][3][12][22]. However, home delivery is one of the predominant delivery paradigms in the industry, whether because it is necessary given the types of goods being purchased (grocery, high-value items) or because customers perceive value when goods are delivered directly to their home. In this paper, we focus on a specific implementation of home delivery operations known as Attended Home Delivery (AHD). In the AHD setting, unlike standard home deliveries, the presence of the customer at home is required when the courier arrives. This requirement prominently brings the time dimension into the delivery operations, since couriers and customers must be synchronized with each other.

From a practical perspective, delivery synchronization is typically managed at the time of ordering by collecting not only the customer's location, but also a *time window* (*timeslot*) on a specific day for the expected delivery. While, in principle, the width of a customer's service time window can be arbitrarily chosen, it is intuitive that narrower time windows result in higher delivery costs for companies [18], which are often passed on to customers through additional delivery fees. Moreover, the delivery company needs to maintain a certain level of control over the time windows schedule available for its services, i.e., it is not realistic to leave an arbitrary choice to the online customer. For this reason, AHD services are often based on a discrete set of available time windows from which customers can select their favorite one. This way, the company still provides customers with a certain degree of flexibility while allowing itself the possibility of finding, at a tactical level, the best schedule to propose. An active stream

This work has been supported by "ULTRAOPTYMAL - Urban Logistics and sustainable TRAnsportation: OPtimization under uncertainTY and MAchine Learning", a PRIN2020 project funded by the Italian University and Research Ministry (grant number 20207C8T9M).

in the literature has addressed the optimization of this AHD tactical aspect, using approximated or explicit evaluation of the corresponding routing costs (see, e.g., [1][9][23]).

A recent alternative to use multiple time windows (thus avoiding the need to solve tactical timeslot assignment and pricing problems) is the introduction of Customer Availability Profiles (CAPs), presented in [10]. After partitioning a working day into timeslots, a CAP assigns to each timeslot the probability that the customer will be at home. This framework grants the company full flexibility in planning delivery routes and schedules, at the cost of potentially incurring a penalty when a delivery is attempted in a timeslot during which the customer is actually not at home. For the company, such a penalty may represent an estimation of the costs to sustain for the recovery of the service missed (e.g., re-delivery at a different time or day) and/or a compensation to the customer for having lowered the quality of their service. Since the customer presence in a timeslot is not deterministically known a-priori but just estimated through a probability, then it makes sense to calculate the penalty as proportional to the probability of not finding the customer at home in the timeslot selected by the company.

AHD optimization problems that explicitly include CAPs are more tailored to support a company in the decision-making process at a day-ahead tactical level (see, e.g., the multi-attribute approach proposed in [4]). They can better assess the trade-off that derives from simultaneously minimizing the traveling cost and maximizing the so-called service *hit rate* (equivalent to minimizing the corresponding penalty cost). The total hit-rate cost reflects the quality level of the delivery service and should be considered by the company together with the operating costs. However, in practice, the company may adopt additional strategies, such as offering discounted fees or other forms of compensation to encourage customers to be available during timeslots that are operationally desirable but associated with low presence probabilities. To the best of our knowledge, this integrated approach, where CAPs are treated with a certain degree of flexibility, has not yet been explored in the context of AHD problems. Hence, in this work, by developing mathematical tools including Mixed-Integer Linear Programming (MILP) models and tailored lexicographic solution methodologies, we provide a detailed economic analysis on the trade-offs related to investing in customers' behavior modification along with classical routing and scheduling decisions.

A. Contribution

Building on the current state of the art, this paper provides three main contributions:

- We propose a novel integrated problem in the AHD context, along with its mathematical formulation, that extends existing settings by allowing the company to actively invest a budget to improve customer presence probabilities. In this framework, availability profiles are no longer treated as fixed inputs but as strategic decision variables within the optimization process.
- We develop a multi-step analytical methodology based on lexicographic optimization that enables a structured economic analysis of the trade-offs involved, first by determining a maximum budget for influencing customer availability and then by systematically evaluating the impact of investing partial amounts of that budget.
- We conduct an extensive computational analysis on a large set of instances to derive actionable managerial insights. In particular, we quantify the strategic trade-off in which the company accepts higher penalties on some deliveries to obtain significant savings in travel costs, making the *price of customer presence* a clearly identifiable and decision-relevant concept.

B. Structure of the paper

The remainder of the paper is organized as follows. Section II introduces the optimization problem and provides its mathematical formulation. Section III describes the improved decisional setting in which the company has additional flexibility regarding the CAPs. Section IV details our experimental campaign, describing both the adopted methodology and the instances used, while Section V shows the results obtained and comments on them, deriving managerial insights on the process. Conclusions are drawn in Section VI.

II. Problem statement and mathematical formulation

In this section, we state the optimization problem addressed in this work by building upon an analogous framework presented in the literature [6]. We then formulate the problem as a Mixed-Integer Linear Programming (MILP) model.

A. Problem definition

We consider the problem of addressing daily delivery operations for a set P of geographically dispersed customers. The deliveries are performed by a uniform fleet of vehicles, $K = \{1, \dots, \lambda_K\}$, which originates from and returns to a central depot $\mathcal{D}$. Each vehicle has a uniform capacity, Q, and all routes must be completed within a maximum operational period, t_{max}. For each customer $p \in P$, there is a specific demand d_p, and a constant service time s is required for every stop. The road network defines the feasible routes along which vehicles can travel, both from the depot to each customer and between any two customer locations. Let t_{ij} denote the travel time between any two locations i and j, where each location may be either the depot or a customer. To incorporate customer availability profiles, the planning horizon is discretized into a set of sequential, non-overlapping timeslots, $T = \{1, \dots, \lambda_T\}$. Each timeslot $t \in T$ is defined by a start time a_t and an end time b_t. Let ρ_{pt} represent the likelihood that customer p is available at home during timeslot t. A key assumption is that $0 < \rho_{pt} < 1$ for all customers and timeslots, ruling out complete certainty of presence or absence. If a delivery attempt fails, a penalty is incurred. This penalty is calculated as the product of a failure cost parameter α_p, potentially different for each customer $p \in P$, multiplied by the probability $(1 - \rho_{pt})$

of the customer p not being home during the delivery during timeslot $t \in T$. The failure costs are assumed to be calculated in time units, thus representing the additional time spent by the courier to recover the service (e.g., by scheduling a second visit or by moving the goods to a collecting point) and/or the additional time spent by the customer to retrieve their parcel (e.g., roundtrip from the house to the collecting points where the goods have been left), which must be compensated by the company as well. Finally, while in many operational settings the failure costs can be seen as constant for all the customers, in this work we prefer to consider the general case in which they depend on the customer (e.g., on their distance to the depot, fidelity program, or delivery priority). The optimization objective is to determine a set of vehicle routes, along with their corresponding delivery schedules, that minimizes a composite cost function. This function aggregates the total vehicle travel costs with the overall penalty cost arising from potential synchronization failures (i.e., missed deliveries).

Unlike some prior studies that incorporate numerous operational details (see [6][10][24]), our model focuses solely on the core features of the optimization problem to keep the analysis clear and concise. For this reason, some simplifying assumptions are made concerning, e.g., the homogeneity of the vehicle fleet, the constant service time for all the customers, and the presence of a unique depot where all the vehicles depart and come back. Note, however, that these assumptions are realistic in many AHD services, as the e-grocery ones.

B. Problem formulation

The problem is modeled on an *extended* directed graph $G = (V, A)$. The ordered node set V is constructed from three distinct subsets:

- the ordered set $N_P = \{1, \ldots, \lambda_N\}$ of λ_N nodes, each representing a customer.
- the ordered set $N_S = \{\lambda_N + 1, \ldots, \lambda_N + \lambda_K\}$ of λ_K nodes, each being a replica of the unique depot $\mathcal{D}$. This duplication allows us to have one starting node per vehicle, thereby distinguishing each vehicle's route without the need to introduce additional vehicle-indexed arc variables.
- a single node $e = \lambda_N + \lambda_K + 1$, representing the common terminal node for all the routes of the vehicles. This node is a further replica of the unique depot $\mathcal{D}$, and its presence allows us to model vehicle routes as elementary paths.

The arc set A is defined as the set of all feasible connections, i.e., $A = \{(i,j) : i \in N_P, j \in N_P\} \cup \{(i,j) : i \in N_S, j \in N_P\} \cup \{(i,e) : i \in N_P\}$. A weight corresponding to the travel time t_{ij} is assigned to each arc $(i,j) \in A$. For those arcs starting or arriving in a replica of the depot, the corresponding travel time is replicated as well. Given the above graph, the problem asks for a set of λ_K directed elementary paths, one for each vehicle $k \in K$, which originate at the corresponding starting depot node $\lambda_N + k$ and terminate at e. Figure 1 shows an example of the creation of our extended graph starting from a standard network. The total travel time of a vehicle is the sum of the weights of the arcs along its path, and the total travel cost is the aggregate travel time of all vehicles.

The following decision variables are defined to model the problem:

- x_{ij}: a binary variable that is equal to 1 if the direct arc from node i to node j is part of a vehicle's route, and 0 otherwise;
- z_{ij}: a continuous variable denoting the time of arrival at node j, when it is reached directly from node i via arc (i,j);
- y_{it}^k: a binary variable that is equal to 1 if vehicle k services node i during timeslot t, and 0 otherwise.

Then, the problem under study can be efficiently formulated through the following MILP model, in which, given a subset of nodes $\bar{V} \subset V$, $\delta^-(\bar{V}) = \{(i,j) \in A : i \notin \bar{V}, j \in \bar{V}\}$ and $\delta^+(\bar{V}) = \{(i,j) \in A : i \in \bar{V}, j \notin \bar{V}\}$ represent the set of arcs entering and leaving the set of nodes $\bar{V}$, respectively:

$$\min \sum_{(i,j)\in\delta^-(\{e\})} z_{ij} + \sum_{p\in P}\sum_{t\in T}\sum_{k\in K} \alpha_p\,(1-\rho_{pt})\,y_{pt}^k \quad (1)$$

subject to

$$\sum_{(i,j)\in\delta^+(\{h\})} x_{ij} \le 1, \quad h \in N_S \quad (2)$$

$$\sum_{(i,j)\in\delta^-(\{e\})} x_{ij} = \sum_{k\in K}\sum_{(i,j)\in\delta^+(\{\lambda_N+k\})} x_{ij} \quad (3)$$

$$\sum_{(i,j)\in\delta^+(\{h\})} x_{ij} = \sum_{t\in T}\sum_{k\in K} y_{ht}^k, \quad h \in N_P \quad (4)$$

$$\sum_{(i,j)\in\delta^-(\{h\})} x_{ij} = \sum_{t\in T}\sum_{k\in K} y_{ht}^k, \quad h \in N_P \quad (5)$$

$$\sum_{k\in K}\sum_{t\in T} y_{ht}^k = 1, \quad h \in N_P \quad (6)$$

$$y_{\lambda_N+k,1}^k = \sum_{(i,j)\in\delta^+(\{\lambda_N+k\})} x_{ij}, \quad k \in K \quad (7)$$

$$y_{e,\lambda_T}^k = \sum_{(i,j)\in\delta^+(\{\lambda_N+k\})} x_{ij}, \quad k \in K \quad (8)$$

$$\sum_{t\in T}\sum_{p\in P} d_p y_{pt}^k \le Q, \quad k \in K \quad (9)$$

$$\sum_{t\in T}\sum_{k\in K} a_t y_{ht}^k \le \sum_{(i,j)\in\delta^-(\{h\})} z_{ij} \le \sum_{t\in T}\sum_{k\in K} b_t y_{ht}^k, \quad h \in N_P \quad (10)$$

$$\sum_{(i,j)\in\delta^+(\{h\})} z_{ij} - \sum_{(i,j)\in\delta^-(\{h\})} z_{ij} = \sum_{(i,j)\in\delta^+(\{h\})} (s + t_{ij}) x_{ij}, \quad h \in N_P \quad (11)$$

$$z_{ij} = t_{ij} x_{ij}, \quad h \in N_S, (i,j) \in \delta^+(\{h\}) \quad (12)$$

$$(t_{\lambda_N+1,i} + t_{ij} + s)x_{ij} \le z_{ij} \le (t_{max} - t_{je} - s)x_{ij}, \quad (i,j) \in A \mid i,j \notin N_S \cup \{e\} \quad (13)$$

$$\sum_{t\in T} y_{jt}^k \ge \sum_{t\in T} y_{it}^k + x_{ij} - 1, \quad (i,j) \in A, k \in K \quad (14)$$

$$x_{ij} \in \{0,1\}, \quad (i,j) \in A \quad (15)$$

$$y_{it}^k \in \{0,1\}, \quad i \in V, t \in T, k \in K \quad (16)$$

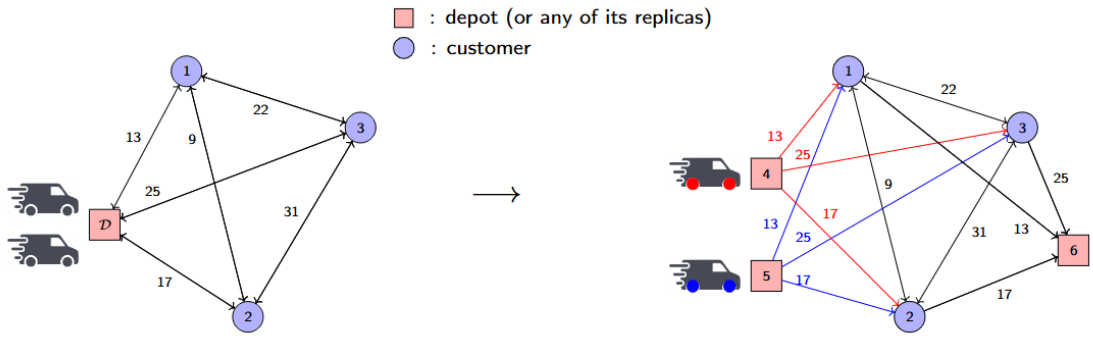

Fig. 1: Example of creation of our extended graph (on the right) starting from a standard network (on the left) involving a single depot, three customers, and two vehicles. In the extended graph, some arcs can be traversed only by a certain vehicle (red and blue arcs), while some others are in common (black arcs). Each vehicle starts from its own depot node, but they both arrive at the same final depot node e.

$$z_{ij} \geq 0, \quad (i,j) \in A. \tag{17}$$

The objective function (1) minimizes the total cost for the company, which is composed of the overall traveling time of the vehicles (first term) and the overall penalty cost paid for visiting customers in timeslots where there is a non-null probability of missing them (second term). Note that, for the sake of simplicity, this cost function is expressed in terms of time units as the scheduling variables and, therefore, also the penalties are measured in time.

Constraints (2) and (3) impose that all vehicle tours must originate from their specified start nodes and end at the common depot, e. The requirement for each customer in the set N_P to be visited exactly once is established through the flow conservation constraints (4) and (5). Constraints (6) guarantee that each customer visit is assigned to a single vehicle $k \in K$ and occurs within a single timeslot $t \in T$. If a vehicle $k \in K$ is used, constraints (7) and (8) ensure its corresponding start (i.e., $y^k_{\lambda_N+k,1} = 1$) and end (i.e., $y^k_{e,\lambda_T} = 1$) depot timeslots are activated. Furthermore, vehicle capacity limits are handled by constraints (9), which prevent the total demand of customers on any given route from exceeding the vehicle capacity, Q. The temporal feasibility of the routes is governed by the set of constraints from (10) to (13). Specifically, (10) enforces the arrival time within the time window $[a_t, b_t]$ for each service performed within timeslot $t \in T$, while (11) defines the progression of time between consecutive visits to customers i and j, accounting for service and travel times. The initial arrival time for each route's first customer is set by constraints (12). Constraints (13) introduce instead lower and upper bounds on the start of the service in a specific node j. This time has to be greater than the time required to reach the previous node from the depot, plus the time needed to reach j from the previous node, plus the service time in the previous node. The start of the service in node j also needs to make a return to the depot feasible, i.e., it needs to be lower than the maximum working time minus the time to serve the node minus the time to return to the depot. Together, these temporal constraints also serve the crucial function of eliminating subtours. Finally, the link between the routing variables (x) and the vehicle assignment variables (y) is established by constraints (14), to ensure that any two consecutively visited nodes are served by the same vehicle. These last constraints are needed since our formulation determines vehicle assignments without needing an explicit vehicle index on the x variables, a feature enabled by the unique starting depot for each vehicle. The domains of decision variables are defined in constraints (15) through (17).

The above formulation is similar to that presented in [4] and adopts a perspective that differs from that previously available in the literature [10][14][20][24]. In particular, the presented extended graph allowed us to obtain a more compact and more efficient MILP model through the introduction of:

- two-indexed binary variables for arc selection, which embed vehicle-specific route information without requiring a third index, similar to the method in [16];
- continuous scheduling variables to enforce time-based subtour elimination, drawing inspiration from modeling techniques for ordering problems [17].

The model efficiency obtained allows us to adopt state-of-the-art MILP solvers to find optimal solutions for real-world instance sizes.

III. An Improved Decisional Setting Including CAPs Flexibility

As stated in the introduction, the above formulation assumes that customer availability profiles are fixed input data and cannot be modified. However, in practice, companies often have the opportunity to foster some specific customer behavior of interest by offering some form of incentives (e.g., a discount on delivery fees). Assuming that the company has a budget B to support such modifications and a communication channel to reach the customers (e.g., email), it becomes possible to evaluate when and to what extent it is convenient for the company to implement such an influence on the customers' behavior.

To this aim, let us introduce an additional continuous decision variable γ_{pt} representing the increment (induced by the company) with respect to ρ_{pt} of the presence probability of customer $p \in P$ during timeslot $t \in T$[1]. Then, it is possible to create a new optimization model by modifying the one already presented in Section II-B, namely model (1)–(17). More precisely, the objective function (1) is substituted with the following one

$$\min \; f_{TC} + f_{HRC} - f_{HRI} \tag{18}$$

where

$$f_{TC} = \sum_{(i,j)\in\delta^-(\{e\})} z_{ij} \tag{19}$$

$$f_{HRC} = \sum_{p\in P}\sum_{t\in T}\sum_{k\in K} \alpha_p \; (1-\rho_{pt}) \; y^k_{p,t} \tag{20}$$

$$f_{HRI} = \sum_{p\in P}\sum_{t\in T} \alpha_p \gamma_{pt} \tag{21}$$

and the following inequalities

$$0 \le \gamma_{pt} \le (1-\rho_{pt}) \sum_{k\in K} y^k_{pt}, \quad p \in P, t \in T \tag{22}$$

$$\sum_{p\in P}\sum_{t\in T} \alpha_p \gamma_{pt} \le B \tag{23}$$

are added to the system of constraints (2)–(17).

The new objective function (18), in which the overall traveling cost is named f_{TC} and the overall hit-rate cost based on the pure CAPs initially given by the customers is named f_{HRC}, now incorporates a third term representing the saving on the hit-rate cost when considering the CAPs modified by the company investment, which is named f_{HRI}. In constraints (22), the new decision variables are allowed to take non-negative values up to the residual presence probability of a customer in a certain timeslot. However, since it makes sense to pay for improving presence probabilities only for timeslots included in the visiting schedule, constraints (22) set to 0 the corresponding variables γ when it is not the case. Finally, constraint (23) limits the company's investment in the modification of the CAPs to a certain budget B.

With respect to the model just stated, it is important to clarify two points:

- despite the definition of the decision variables γ, in reality, the company cannot directly adjust the customers' probability profiles. The model instead quantifies the amount of additional presence probability the company is aiming for and returns the proportional compensations to be offered to the customers for being at home during the selected timeslot. While the customers still have the freedom to choose what to do, the offered compensation is meant to convince them to stay at home during the desired timeslot.
- the third term of objective function (18) represents a saving only for the problem as it is modeled, not on the actual overall cost for the company, which is of course made up by the total objective function value plus the amount invested to influence the customers, i.e., the same amount of the saving. Hence, the company wants to evaluate the possibility of investing more than the traveling and expected hit-rate costs to better balance them.

From now on, we will refer to the MILP model (18) subject to constraints (2)–(17) and (22)–(23) as the *Attended Home Delivery Problem with CAPs Flexibility* (AHDP-CF).

IV. Experimental setting

This section describes the experimental setup adopted to evaluate how the budget constraint affects the optimization problem considered. Section IV-A outlines the generation of benchmark instances, while Section IV-B and Section IV-C describe the analytical methodology developed and the corresponding implementation details, respectively.

A. Instances generation

To obtain statistically meaningful results, our experiments consider a very large set of benchmark instances, in which many of their characteristics are randomly varied. More precisely, we generated 500 instances involving 10 customers (i.e., $|P| = 10$) and 3 vehicles (i.e., $\lambda_K = 3$). Customers are randomly distributed within a 20000×20000 m^2 area. Euclidean distances are computed between each node[2], assuming a constant speed of 11.11 m/s (i.e., 40 km/h). They are then truncated to integer values. Customer demands d_p range from 5 to 30 units, with a fixed service time of 7 minutes. Vehicle capacity is set to $Q = 3 \cdot \frac{\sum_{p\in N_P} d_p}{\lambda_K}$ to align total fleet capacity with aggregate demand. Each vehicle's work shift is limited to $t_{max} = 14400$ seconds (i.e., 4 hours), while the time horizon is divided into 8 equal timeslots (i.e., $\lambda_T = 8$). This time horizon has been chosen to mimic the typical half-day shift of many couriers; however, the model can tackle wider time horizons and denser timeslot division of the shift. Each customer is assigned to one of seven CAPs, each representing different customer presence behaviors during the day. Six profiles are adapted from [10] and eventually discretized, namely, *V-shape*, *A-shape*, *M-shape*, *W-shape*, *Linear-Increase*, and *Linear-Decrease*, whereas the last profile is randomly generated. A detailed visualization of the six non-random profiles is reported in Figure 2. Clearly, each profile is intended to mimic a peculiar behavior of a customer during the time horizon. Failure costs α_p are drawn from a Normal distribution with mean equal to the service time s and standard deviation equal to $s/2$, truncated in $[2, 15]$ minutes.

The generated instances are publicly available at https://or-dii.unibs.it/instances/AHDPCF.zip.

[1]Note that this variable represents an increment and not a free variation with respect to ρ_{pt} since it never makes sense for the company to pay for diminishing the presence probability of a customer during a timeslot.

[2]While real distances between customers seldom correspond to Euclidean ones, the absence of a real street map and the randomness used to generate the customer locations justify the adoption of this simple metric.

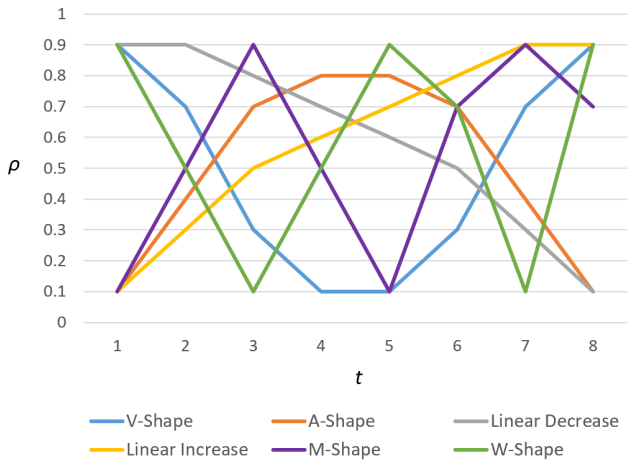

Fig. 2: A plot of the six non-random discrete Customer Availability Profiles adopted, across 8 timeslots.

B. Analytical methodology

The methodology adopted for our quantitative analysis is mainly based on the possibility to solve the MILP model AHDP-CF proposed in Section III and a two-step lexicographic approach that interprets the proposed multi-attribute optimization problem as an actual multi-objective one. The analysis includes a systematic change of the available budget B. To this aim, let B_{max} represent the maximum sensible budget that the company can consider and let β be a real value in $[0, 1]$. Then, let us define $B = \beta B_{max}$ as the available budget. In our analysis, β is used as a sensitivity parameter to evaluate the behavior of the optimal solution for the company against different budgets. The value of B_{max}, instead, which is instance-dependent, is calculated during the optimization process described below.

More precisely, for each of the generated instances, the following optimization steps are implemented:

- **Step 1:** A lexicographic optimization is performed on AHDP-CF where, first, the priority is given to the minimization of the overall objective function (18) and, then, the sole minimization of the hit-rate investment is pursued. This second optimization step is needed since there could be multiple optimal solutions, all with the same objective function value but different proportions of the three objective function terms f_{TC}, f_{HRC}, and f_{HRI}. Among these solutions, the one with the lowest possible value of f_{HRI} is of our interest. More in detail:
  - **Step 1.a**: The MILP model AHDP-CF is solved to optimality without considering the budget constraint (23). This way, the model returns a solution in which the presence probabilities of interest (i.e., those corresponding to the timeslots visited) are increased at least up to the most convenient value with respect to the traveling time minimization. Let us call $f^{Step1.a}$ the value of the optimal solution just obtained.
  - **Step 1.b**: The MILP model AHDP-CF is solved to optimality again without considering the budget constraint (23) but with the new objective function

$$\min \ f_{HRI} \tag{24}$$

and with the following additional constraint

$$f_{TC} + f_{HRC} - f_{HRI} \leq f^{Step1.a}. \tag{25}$$

Constraint (25) ensures that the value of the primary objective function obtained in the previous step is not deteriorated. Let us call $f_{HRI}^{Step1.b}$ the value of f_{HRI} calculated in the optimal solution.

- **Step 2**: The value of B_{max} is set to $f_{HRI}^{Step1.b}$, since it does not make sense to consider larger budgets for the current instance.
- **Step 3**: The parameter β is set to a value in $[0, 1]$ and the actual budget B is calculated.
- **Step 4**: The MILP model AHDP-CF is solved to optimality, now including also the budget constraint (23). Let us call sol_β the optimal solution obtained. This solution is the one analyzed in the later discussion of the results.

C. Implementation and resolution details

Experiments were performed on a machine equipped with an *Intel Xeon Gold* 6140x (18 physical cores, 36 logical threads) CPU, 64GB RAM, and running a *Windows 11* 64-bit operating system. The solution framework, including the lexicographic procedure and MILP models, was implemented in Java 16. Gurobi v12.0.0 was adopted for solving the MILPs; the default parameter setting is used, and no time limit is imposed on the resolution, thus ensuring termination only upon optimality.

V. Results and Discussion

This section presents and discusses the results of the computational experiments conducted to evaluate the impact of investing a certain budget for improving the expected hit-rate (representing the quality of the delivery service) on our AHDP-CF. Our analysis focuses on the trade-offs between the investment in higher customer presence probabilities and the resulting operational costs and solution structure. To provide clear managerial insights, we always compare the solutions sol_β obtained by using an increasing budget (from $\beta = 0.05$ up to $\beta = 1$, with a 0.05 increment) against solution sol_0, which represents the baseline scenario where no budget is available (i.e., when $\beta = 0$).

Our analysis is designed to provide quantitative insights into how different budget levels β reshape the optimal solution. In each part of the discussion, results are reported as sequences of boxplots, one for each β value that has been tested, thus aggregating the results obtained over all the 500 instances generated. In a boxplot, the cross denotes the average value, while the thick line indicates the median. The upper part of the colored box corresponds to the 75th percentile, while the lower one is associated with the 25th percentile. Moreover, the whiskers span from the minimum to the maximum value,

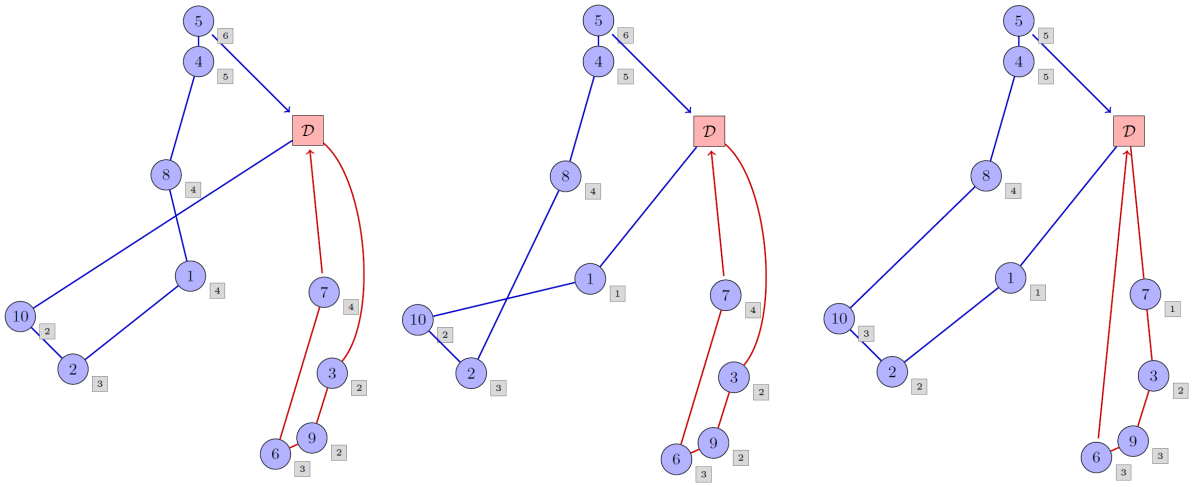

Fig. 3: Solution examples for different β values: $\beta = 0$ (left), $\beta = 0.50$ (center), $\beta = 1.00$, (right). The number in a gray square near each node indicates the timeslot selected for the corresponding visit.

excluding the outliers (which are reported as simple dots). Finally, we want to assess the impact of the available budget from several perspectives, each of which is related to a different Key Performance Indicator (KPI) that can be calculated on the solutions obtained by implementing the analytical method proposed in Section IV-B. In this discussion, we decided to focus on the following KPIs of interest:

- CSS (change in start times): represents, averaged over all the customers, the absolute value of the difference in seconds between the service start times scheduled in sol_β and those scheduled in sol_0.
- PCT (percentage of changed timeslots): represents the percentage of customers for which the timeslot scheduled for the delivery in sol_β is different from that scheduled in sol_0.
- PAC (percentage of affected customers): represents the percentage of customers in sol_β for which the company has invested at least something greater than 0 (clearly, in sol_0 where the budget is null, the baseline comparison value is always 0).
- PCTC (percentage change in traveling cost): represents the difference between the traveling cost of sol_β and that of sol_0, as a percentage of the traveling cost of sol_0.
- PCHC (percentage change in hit-rate cost): represents the difference between the hit-rate cost f_{HRC} of sol_β and that of sol_0, as a percentage of the available budget B.

To illustrate how investment drives structural changes in a single instance, Figure 3 compares the routes obtained with three different β values, namely, 0.0, 0.50, and 1.00. Although node-to-vehicle assignments remain fixed, increasing β reorders visits. The solution with $\beta = 1.00$ corresponds to the solution that could be obtained by solving a standard VRP with travel time minimization. The other solutions show more complicated routes, since the cost of visiting customers in less favorable timeslots cannot be fully compensated by the budget.

Figure 4 illustrates the distribution of the change in the service start times (CSS) for customers across various budget levels. A noticeable trend emerges, characterized by three

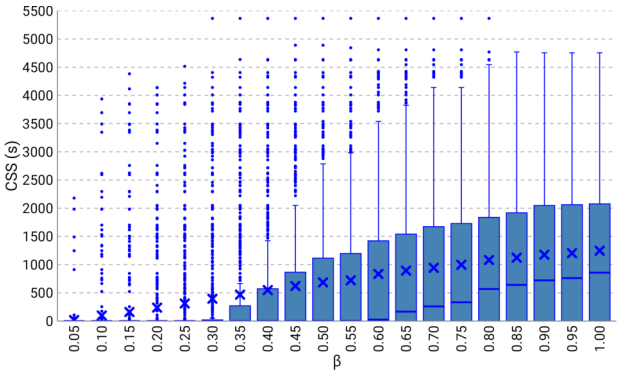

Fig. 4: Change of the start of the service (CSS), averaged over all customers.

distinct phases. Initially, for low budget levels ($\beta \leq 0.30$), CSSs are negligible, as the median, 25th, and 75th percentiles are all concentrated close to zero. As the budget increases into the intermediate range of $0.35 \leq \beta \leq 0.60$, the median CSS remains at zero, but the distribution skews significantly upward. This indicates that, while the start time for more than half of the customers is unaffected, a growing portion of them experiences a substantial shift, as seen in the 75th percentile progressively increasing to a value of nearly 1500 seconds. For the highest budget levels ($\beta \geq 0.65$), a different operational behavior emerges where the entire distribution shifts upwards. In particular, the median CSS itself starts to increase, reaching nearly 900 seconds for $\beta = 1$, signifying that the investment now alters the start times for the majority of the customers. This tripartite behavior is a pattern that can be noticed in most analyzed KPIs, indicating a fundamental shift in the solution's

characteristics based on the amount of budget invested. In contrast to such a behavior of the median, the average CSS has an almost linear increase from 0 to around 1250 seconds.

Figure 5 presents the distribution for the percentage of customers (PCT) whose selected timeslot changes with respect to the zero-budget baseline. The analysis reveals the same clear

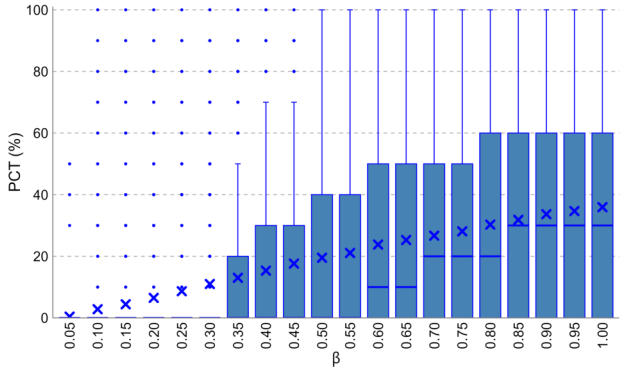

Fig. 5: Percentage of customers for which the timeslot selected by the company changes (PCT).

threshold-based behavior as in the previous KPI. The average PCT still increases linearly across β values, going from 0 to about 35%. The median's behavior, however, is more distinctly segmented. In the first segment ($\beta \leq 0.30$), the median PCT is null, thus indicating that most customers are unaffected. A sharp transition then occurs at $\beta = 0.35$ where the 75th percentile rises while the median stays at 0. For $\beta \geq 0.60$, the median increases in three steps and stabilizes at 30% for $\beta \geq 0.85$.

To understand the mechanism driving these outcomes, Figure 6 illustrates the investment strategy identified in the optimal solutions, by showing the percentage of customers (PAC) for which the company invests in changing their behavior. In

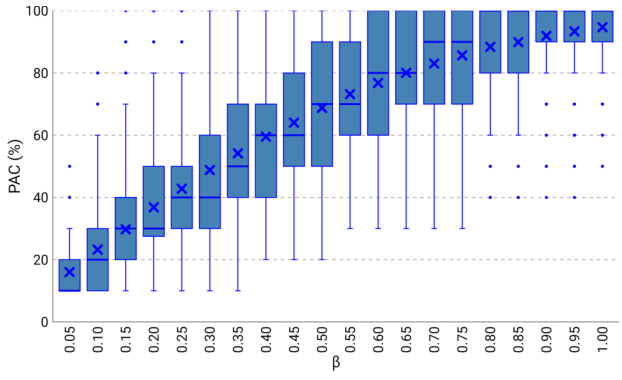

Fig. 6: Percentage of customers on which the company invests its budget (PAC).

contrast to the complex, threshold-based behavior seen in the previous KPIs, the application of the budget is remarkably direct and nearly linear. As β increases, the percentage of affected customers also rises monotonically and with relatively low variability. The median and average PAC values remain closely aligned throughout the entire range, starting near 15% and climbing steadily until they approach 100% for higher investment levels. A notable insight emerges when comparing this strategy to its impact on rescheduling (Figure 5), i.e., the percentage of customers receiving investment is considerably higher than the percentage whose timeslot is changed. For instance, if we consider median values at $\beta = 0.70$, the budget is invested in a 90% of the customers, while the percentage of customers with an altered timeslot is just 20%. This implies that, for a significant portion of customers (around 70%), the budget is invested not to change their assigned timeslot, but to increase the likelihood of delivery success for the scheduled timeslot in sol_0.

Figure 7 evaluates the impact of the budget on the routing decisions by showing the percentage change in traveling costs (PCTC). Note that, differently from the previous ones, this KPI

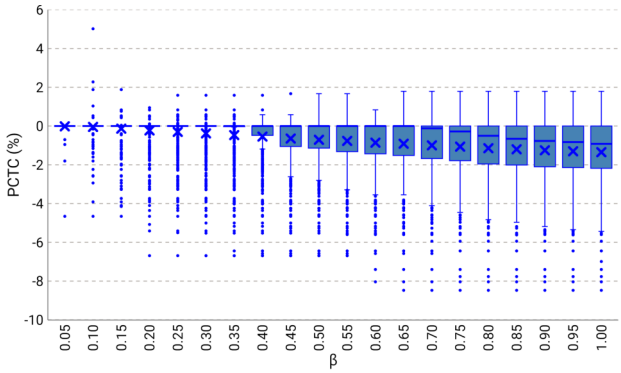

Fig. 7: Percentage change in traveling costs (PCTC).

may result in both negative and positive values. When they are negative, the f_{TC} derived from the solution including some investment is lower than the no-budget solution. This is the more frequent behavior. The resulting trend reveals a complex behavior that strongly mirrors (even if horizontally specular) the tripartite behavior of the first two KPIs analyzed rather than the linear investment strategy itself. Such a behavior appears, in this case, with thresholds at $\beta = 0.40$ and $\beta = 0.70$. The average PCTC decreases linearly from 0% to -1.4%, while the median PCTC value reaches a minimum of about -1%. Interestingly enough, there are some cases in which the budget investment increases the traveling cost, meaning that the model favors some decrease in hit-rate cost at the expense of a smaller increase in traveling cost. These situations correspond to noisy results, due to the possible existence of multiple optimal solutions for the problem. In fact, when a certain non-null budget is available, it is never optimal to invest in changing the solution structure without improving the traveling cost, since the hit-rate saving must always be compensated by the budget investment. This means, for every solution with an increase in traveling costs, there must be an equally optimal solution in which the traveling cost remains the same or improves compared to sol_0. Anyway, across all

the β values, these cases fall beyond the 75th percentile, and, therefore, they do not disrupt the validity of our analysis.

The final analysis, presented in Figure 8, examines the portion of the budget dedicated to compensating for changes in the objective function component f_{HRC}, as a percentage of the available budget to invest (PCHC). As before, this KPI may

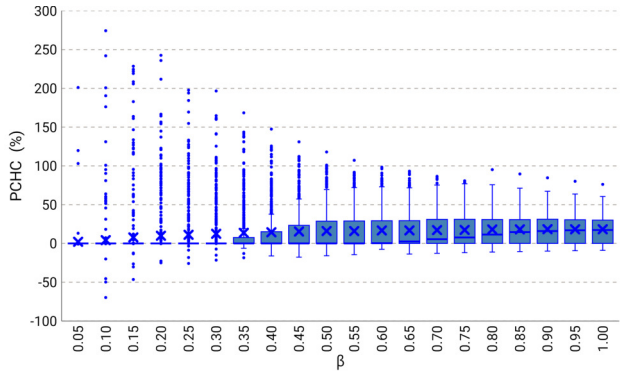

Fig. 8: Percentage change in hit-rate cost (PCHC).

result in both negative and positive values. Here, a positive value means that the value of f_{HRC} when a budget is available is greater than that obtained with zero budget. This is the more common situation. The trend follows a clear phased pattern, like in most previous KPIs. The median PCHC is initially zero, becomes positive and rises through the mid-range of β values, and finally stabilizes just under 20%. Notably, the high variability observed at low-to-moderate investment levels decreases significantly as the solution stabilizes. Interpreting these results provides a deeper insight into the solution's trade-offs. When the median PCHC value is close to zero, it suggests that the budget is primarily used to increase success probability within the timeslots scheduled for visits in sol_0. Instead, when the median PCHC stabilizes just under 20% for high β values, it indicates that roughly a fifth of the budget is now used to offset the corresponding increase in the hit-rate cost. This increase reveals a strategic selection of different timeslots for the visits that allows the traveling cost reduction seen previously for the same β values. The PCHC distribution also reveals a wide range of outcomes. Extreme cases show that the PCHC can reach almost 275%, where the hit-rate cost increase is 2.75 times the available budget. Conversely, very few times, negative values may also occur. These situations reveal the presence of multiple optimal solutions, as seen for the previous KPI. Again, the frequency of these cases does not affect the insights derived.

VI. Conclusions

In this paper, we studied the Attended Home Delivery problem with Customer Availability Profiles and introduced a novel and managerially relevant dimension, namely, the ability for a company to invest a budget to actively influence customer presence probabilities during certain timeslots of interest. We proposed the corresponding new optimization setting together with its MILP formulation, called the Attended Home Delivery problem with CAPs flexibility (AHDP-CF). Through a structured analytical methodology based on lexicographic optimization, we conducted an extensive computational study to quantify the impact of the possible investment. Our analysis revealed that the relationship between the investment in service quality and the resulting operational outcomes is characterized by two distinct thresholds that define three different ranges in which the invested budget has different impacts. We showed that small, incremental investments (within the first range) yield negligible changes to the solution, whereas substantial budgets (within the third range) enable a fundamental restructuring of the delivery routes and schedules. The primary managerial insight derived is the possible quantification of a strategic trade-off. Many times, it is optimal for the company to leverage the budget to accept higher penalties on some customer visits in exchange for significant savings in overall traveling costs. This work, therefore, provides a clear and quantitative understanding of the *price of customer presence* in AHD logistics. The framework and insights presented can serve as a valuable decision-support tool for logistics companies, allowing them to move beyond treating customer availabilities as fixed data and instead see them as a strategic lever that can be priced and optimized.

Future research could extend this work in several directions. Developing scalable heuristic or metaheuristic algorithms would allow the AHDP-CF to be applied to larger, real-world instances. Moreover, exploring dynamic settings where investment decisions can be adjusted during the operational day presents another promising avenue for future investigation. Finally, one may also want to incorporate into the problem the *willingness to accept* of a customer against the company's offers by adopting more sophisticated models specifically tailored for individual choices.

***Abstract*—The Subset Sum Problem (SSP) is one of those combinatorial problems that are very easy to understand (take a bunch of integer numbers and verify whether there exists a subset of these numbers which sums up to a given target integer), but it can be very difficult to solve. The SSP is actually an NP-complete problem, but it is "weakly" NP-hard, implying that there are instances of SSP that can be solved in polynomial time. For this particular problem, the instance hardness can be measured by evaluating the so-called "density" index, which basically compares the number of involved integer numbers to the number of bits we need for their binary representation. In our preliminary study on the use of adiabatic quantum computing for the SSP, we investigate the actual feasibility in solving hard instances of the problem. In fact, hard SSP instances are those requiring a large number of bits for the representation of the integers, while the analog nature of the quantum computer does not allow us to ensure highly accurate integer representations. Some preliminary computational experiments performed on D-Wave quantum annealer are presented and compared to standard solvers for classical computers.**

I. Introduction

GIVEN a set $\mathcal{A}$ of n positive integer numbers and a positive target t, the Subset Sum Problem (SSP) asks whether there is a subset $\mathcal{S}$ of $\mathcal{A}$ such that the elements of $\mathcal{S}$ sum up exactly to t. The original set $\mathcal{A}$ may be a *multiset*, but in this work we assume, for simplicity, that it contains no repeated elements. In a typical problem variant, the SSP asks to enumerate *all* possible solutions (i.e. all subsets) of a given SSP instance. But again, for simplicity, we make the assumption in this work that only one solution is required.

The SSP is one of the famous Karp's NP-complete problems [12]. It is considered to be *weakly* NP-hard, because there exist large classes of SSP instances for which algorithms admitting a pseudo-polynomial complexity have been proposed [6]. In order to find out the actual hardness of a given SSP instance, the so-called *density* index can be employed:

$$\rho := \frac{n}{\ell(n)},$$

where

$$\ell(n) = \log_2 \max_{a \in \mathcal{A}} a.$$

SSP instances having a density index ρ equal to 1 are the hardest to solve, and indeed, to date, no pseudo-polynomial algorithm for these instances have been found. In these instances, the number of bits necessary to represent the integers in $\mathcal{A}$ equals the number of integers in $\mathcal{A}$. In this work, we will focus our attention on these density-1 instances.

There is a large scientific literature on the SSP. A large review of the existing literature is out of the scope of this short paper, so that we will limit ourselves to cite only a few recent works aiming at improving the performance of SSP algorithms for hard "density-1" instances. The algorithm that has been considered to be the *fastest* for these instances for a very long time is one proposed by Horowitz and Sahni in 1974 [11], which has, however, an exponential theoretical complexity. In more recent times, the works presented in [3] and [19], for example, showed that there exist algorithmic solutions which can exhibit better performance. It is important to remark that the research is progressing in parallel in both areas of deterministic algorithms (such as in [3]) and heuristics (such as in [19]). The most recent effort in the former category of algorithms was presented in the pre-print [18]. To date, however, algorithms having polynomial complexity have not been found yet for solving density-1 instances (a discovery that could imply that **P**=**NP**, which is unlikely).

Many researchers are exploring nowadays alternative approaches for tackling the SSP. Some of us are for example currently working on a novel approach in optical computing [10], where the use of the spatial properties of light allow us to speedup the solution of hard SSP instances (very recently, moreover, the same optical circuit has been adapted to perform single-key cryptography in [7]). Even if these optical circuits are not "quantum devices", they exploit physical phenomena normally used in quantum computing, such as interference.

Some recent theoretical studies aiming at exploiting the potential "quantum advantage" of modern quantum technologies for solving the SSP can be found for example in [2], [5], [9].

In this work, we study the feasibility of solving hard density-1 instances of the SSP by adiabatic quantum computing. To the best of our knowledge, this alternative approach to the SSP was only a little studied in recent times. One example of such studies can be found in [20], where a mathematical model similar to ours is introduced, whose solution is however attempted in a different manner. Moreover, in our study, we will focus our attention on the analog nature of the considered quantum computer, and on the consequent representation issues for the elements of $\mathcal{A}$ (as well as for the target t). We also point out that several of the publications cited above are mostly theoretical and provide no computational experiments.

The rest of the paper is organized as follows. Two general methods for the SSP are briefly presented in Section II, because they will be involved in the performance comparisons presented with our computational experiments. Section III will briefly describe the physics behind the quantum annealer implemented by the D-Wave quantum processing units, and propose a reformulation of the SSP as a Quadratic Unconstrained Binary Optimization (QUBO), a problem format that can handled by D-Wave quantum computers. Finally, our experiments will be reported in Section IV, and Section V will conclude the paper.

II. Methods for the SSP

A. The BP algorithm

We begin this section by presenting a generic algorithm whose worst-case complexity is exponential, but that is suitable for all kinds of SSP instances, including the hard ones. This algorithm is presented in different guises in textbooks about NP-complete problems, and under different names. We make the choice to refer to it as the Branch-and-Prune (BP) algorithm [15]: this is the name of an algorithm for a more general problem, the Discretizable Distance Geometry Problem (DDGP) [17], which can be reduced to the SSP under special conditions. The DDGP has several important applications in various research fields [16].

The BP algorithm is based on the idea to construct a binary tree, where every path from the root to one of the leaf nodes represents a possible subset $\mathcal{S}$ of the original set $\mathcal{A}$. Every layer of the tree is related to one of the integers in $\mathcal{A}$: if the subsets "opting" for the left-handed branch at a given level do not contain the corresponding integer, then this same integer would instead be contained in all other subsets where the right-handed branch is selected. The tree grows regularly by doubling its nodes as we step from one layer to the next. The full tree contains therefore 2^n nodes, but they do not need to be all explored. Some tree branches can in fact be *pruned* by verifying some feasibility tests. If the integers that are selected in the current branch sum up to a value that is larger than the target t, for example, then we can prune the current branch. Also, if the sum of all remaining (i.e. not yet considered) integers at the current tree layer does not allow the current partial sum to reach the desired target t, then the branch can also be pruned.

An implementation in C programming language of the BP algorithm for the SSP is publicly available on the GitHub[1].

B. MILP formulation

Given the set $\mathcal{A} = \{a_1, \ldots, a_n\}$ and the target t, the SSP can be cast as the following boolean linear equation:

$$\sum_{i=1}^{n} a_i x_i = t, \tag{1}$$

where $x \in \{0,1\}^n$. Since, in principle, the SSP instance at hand may be infeasible, we need to take into consideration the case where the equation above may admit no solutions. For this reason, we introduce a slack variable $z \in \mathbb{R}$ and formulate the following optimization problem:

$$\begin{aligned} \min_{x,z} \quad & |z| \\ \text{s.t} \quad & \sum_{i=1}^{n} a_i x_i + z = t, \\ & x \in \{0,1\}^n, z \in \mathbb{R}. \end{aligned}$$

If the optimal value for the problem above is zero, then the SSP has a solution given by the binary decision variables x_i, where $x_i = 1$ indicates that a_i is a member of the solution subset $\mathcal{S}$.

In order to make the objective function linear, we can represent $z = \Delta^+ - \Delta^-$, where Δ^+, Δ^- are non-negative real variables. Then, we have the following Mixed Integer Linear Program (MILP):

$$\begin{aligned} \min_{x,\Delta^+,\Delta^-} \quad & \Delta^+ + \Delta^- \\ \text{s.t} \quad & a^T x + \Delta^+ - \Delta^- = t, \\ & \Delta^+ \geq 0, \quad \Delta^- \geq 0, \\ & x_i \in \{0,1\}, \quad i = 1, \ldots, n, \end{aligned} \tag{2}$$

where

$$a^T x = \sum_{i=1}^{n} a_i x_i.$$

Such a formulation is ideal for MILP solvers (as for example Gurobi [22], which we will use in our computational experiments) that implement branch-and-bound techniques for MILPs.

III. Quantum Annealing

Quantum annealing is an optimization technique used to find the ground state of a given Hamiltonian through the adiabatic evolution of the quantum system [1]. The problem to be solved can be encoded in the time-dependent Hamiltonian:

$$H(\tau) = A(\tau)H_I + B(\tau)H_F,$$

where the time-dependent coefficients $A(\tau)$ and $B(\tau)$ satisfy the condition $A(0) \neq 0$, $B(0) = 0$ and $B(T) \neq 0$, $A(T) =$

[1] https://github.com/mucherino/DistanceGeometry

0, with T being the total evolution time, which corresponds to the computation time. Following the proposal of quantum annealing in the transverse field Ising model [13], the initial Hamiltonian for n qubits is described by

$$H_I = -\sum_i^n \sigma_x^i$$

and the final one by

$$H_F = \sum_i^n h_i \sigma_z^i + \sum_{i,j}^n J_{i,j} \sigma_z^i \sigma_z^j.$$

In these equations, h_i denotes the bias field acting on the i-th qubit and $J_{i,j}$ is the coupling constant between the qubits i and j. Besides of being an easy-to-prepare Hamiltonian, whose ground state is

$$|\psi(0)\rangle = \left(\frac{|0\rangle + |1\rangle}{\sqrt{2}}\right)^{\otimes n},$$

H_I acts as a driver Hamiltonian, which is responsible for mixing the states in the computational basis. Therefore, if initially the physical system starts in the ground state of the Hamiltonian H_I and is adiabatically driven until the final configuration determined by H_F, then, by performing measurements in the computational basis, we can find the solution to our problem as a string of bits.

The strategy described above is the one implemented by the quantum computers produced by the D-Wave Systems Inc. company. In practice, the quantum system is working on 20 mK [21], so there is a no null probability of finding the system outside the ground state, indicating the probabilistic character of the solution of the computation. This implies that, in order to solve a given problem using the D-Wave's quantum processing units, it is necessary to run the calculations several times.

Instead of formulating the problem in terms of the Ising Hamiltonian, it is possible to write it in the form of a Quadratic Unconstrained Binary Optimization (QUBO) problem [8]. The mapping of Pauli operators (σ^i) to QUBO operators (q^i) is obtained by $\sigma^i = 2q^i - I$, where I is the identity matrix. Therefore, the QUBO Hamiltonian becomes:

$$H_F = \sum_i^n Q_i q^i + \sum_{i,j}^n Q_{i,j} q^i q^j,$$

where the operators q^i have eigenvalues 0 or 1, provided that the eigenvalues of the Pauli matrices are -1 and 1. From a practical point of view, the problem is in general written in the QUBO formulation and then translated to the Ising model, which is the natural physical formulation.

In order to obtain a QUBO formulation for the SSP, we remark that $x \in \{0,1\}^n$ solves equ. (1) if it is a zero for the quadratic function:

$$q(x) = (a^T x - t)^2, \tag{3}$$

where a is a column vector with elements a_i, and the same goes for $x \in \{0,1\}^n$. We can therefore re-write:

$$q(x) = x^T a a^T x - (2ta)^T x + t^2 = x^T Q x + b^T x + c,$$

with $Q = aa^T$, $b = -2ta$ and $c = t^2$. By ignoring the constant term c, we have a correspondence with the QUBO Hamiltonian where

$$Q_i = -2ta_i, \quad Q_{i,j} = a_i a_j,$$

are its coefficients.

IV. Computational experiments

A. Generating hard SSP instances

In order to generate hard SSP instances, we make sure that its density index is as close as possible to 1. To this end, we define the very first integer to be included in the original set $\mathcal{A}$ as 2^n, where n is the desired size of the instance. All other integers, used to fill the set $\mathcal{A}$ until it reaches the desired size n, are generated by randomly choosing integers with a uniform distribution in the (open) interval $(1, 2^n)$.

In order to control the hardness of our instances, we also follow some additional recommendations given in [4] when generating our instances. The range of the target t is constrained and taken between

$$(n/2 - \sqrt{n}) \cdot 2^{n-1} \quad \text{and} \quad (n/2 + \sqrt{n}) \cdot 2^{n-1},$$

while approximately half of the original integers in $\mathcal{A}$ are chosen to take part to one pre-constructed SSP solution, which needs to satisfy the selected target t.

Our method for a random generation of hard instances begins by selecting the maximum integer in the set, as described above, and then selects the target t in the bounds given above. Only at this point does the random generation of the other integers begin, and the decision on whether or not to include each generated integer (with chance 1/2) in one associated solution is randomly made. However, the probability of defining a valid solution in this way is extremely unlikely (the randomly chosen integers should sum up exactly at t), and therefore a *correction* step is implemented in our generation algorithm, where the values of the integers selected to form an SSP solution are modified in order to have their sum correspond to the pre-defined target t.

Before delivering the generated instance, our method double-checks that the number of integers forming the constructed SSP solution actually concerns exactly the half of the integers in $\mathcal{A}$ (the only tolerated approximation is the one implied by an odd n). When this is not the case, integers belonging to the SSP solution are either randomly split or fusioned, while other integers (not belonging to the solution) may be erased or added in order to keep the cardinality of $\mathcal{A}$ equal to n.

TABLE I
SOME COMPUTATIONAL EXPERIMENTS WHERE THE GENERATED SSP INSTANCES ARE SOLVED BY A C IMPLEMENTATION OF THE BP ALGORITHM, BY GUROBI (MILP MODEL), BY THE SA SIMULATION PROVIDED BY D-WAVE, AND FINALLY BY D-WAVE ITSELF. THE VALUES OF THE TARGETS, FOR THE 4 INSTANCES, ARE $t_1 = 1024$, $t_2 = 3145728$, $t_3 = 5368709120$, AND $t_4 = 7696581394432$. THE VALUE OF ϵ INDICATES THE OBSERVED ERROR WITH THE RESPECT TO THE KNOWN SOLUTIONS. THE COMPUTATIONAL TIME IS GIVEN IN SECONDS.

Size/target	10	t_1	20	t_2	30	t_3	40	t_4
	ϵ	time	ϵ	time	ϵ	time	ϵ	time
BP	0	0.00	0	0.00	0	0.07	0	9.36
Gurobi	0	0.01	0	0.31	0	1.53	0	1138.00
SA	0	2.00	-8	4.00	-249	8.00	21959	15.00
D-Wave	0	0.02	11	0.25	20926	1.1	173294	2.80

B. Preliminary experiments

We provide some preliminary computational experiments where we solve 4 hard instances of the SSP, having 4 different sizes: 10, 20, 30 and 40. We limit ourselves to instances having size 40 because we have soon noticed that we had already hit the limits of the quantum computer when using instances having this relatively small size. Since our instances all have density equal to 1, the number of bits necessary to represent the elements of $\mathcal{A}$ in the 4 instances is 10, 20, 30 and 40, respectively. On standard 64-bit machines, therefore, standard primitive types, in the majority of programming languages, can hold values that are sufficiently large for our purposes. This is, however, not the case in the analog environment of D-Wave QPUs (Quantum Processing Units).

Our experiments are reported in Table I. The value of ϵ indicates the absolute error with respect to the known solutions, while the computational time is given in seconds. All experiments have been performed on a laptop computer equipped with an 11^{th} Gen Intel(R) Core(TM) i7-1185G7 @ 3.00GHz, running Linux. We used Gurobi version 11, with default parameters except for `IntFeasTol` $= 10^{-9}$ and `NumericFocus` $= 1$. Concerning D-Wave QPUs, we considered two topologies, ZEPHYR and CHIMERA, and varied `num_reads` in $[2000, 4000]$ and `annealing_time` in $[40, 80]$. The results reported in Table I are the best over all the variations considered and over 10 runs/jobs.

We can remark that the BP algorithm, in spite of its worst-case exponential complexity, performs quite efficiently on a standard computer: it is able to solve *exactly* all SSP instances in a reasonable time. Gurobi applied to (2) also solved all instances but its drawback is the computation time. The Simulated Annealing (SA) meta-heuristics [14], implemented in the D-Wave standard Python package, appears to be slower than BP and faster than Gurobi, and provides solutions affected by large errors. This tendency is then amplified when running the experiments on D-Wave. The analog quantum computer is able to output its solution quickly (it is even faster than BP on the largest instances), but the given solutions are affected by much larger errors.

One interesting remark is that most of the solutions found by D-Wave are "local" minimizers, in the following sense. The concept of neighbouring, and hence the one of *locality*, makes sense in the context of the SSP only if we take into account the discrete nature of the search space. When we talk about local solutions, we make reference here to solutions that can be obtained from a provided solution x by performing only one bit flip: in other words, the solutions that are considered to be in the neighbourhood of x are those for which only one integer is added or removed from the current subset. We consider all D-Wave solutions to be local minimizers because they cannot be improved (with respect to the loss function (3)) by one single bit flip.

On D-Wave QPUs, the biases h_i and coupling parameters J_{ij} have specific physical ranges that the hardware can implement. These are typically floating-point numbers rather than integers, and they are restricted to a relatively small range: typically $h_i \in [-2.0, 2.0]$ and $J_{ij} \in [-1.0, 1.0]$. Besides, the D-Wave software interface has an automatic scaling feature which scales the problem data in order to fit in these intervals. Thus, if the problem data has a very large range, scaling them all down can make the smaller differences less distinguishable by the noisy analog hardware, potentially affecting solution quality.

We conjecture that, when D-Wave is actually not able to find the correct solutions, it is because of the representation errors implied by its analog nature. Part of our future works will be devoted to further studying this conjecture.

V. CONCLUSIONS

This paper focuses on the SSP, one of the most important, well-known and largely studied NP-complete problems. We have briefly surveyed two basic methods for the solution of SSP instances, provided a QUBO formulation of the problem, which we have then used for performing some preliminary computational experiments on D-Wave.

The main point in this work is the following: can we actually represent hard SSP instances on the quantum computer? Or is this rather possible only for some of the "easy" SSP instances? Our experiments show that an important difficulty is related to the accuracy in the representation of the integers in the set $\mathcal{A}$. As the number of bits necessary for representing the integers increases, it becomes harder and harder to have an error-free representation in the analog quantum computer. Our preliminary experiments seem to indicate that the primary impediment to quantum advantage in this domain is not algorithmic design but rather the limitations in representation in the analog computer.

Work is currently in progress to design methods for overcoming this representation issue. We will also study the possibility to represent and solve more general problems on D-Wave, such as for example the DDGP mentioned in the Introduction.

ACKNOWLEDGMENTS

This work was partially supported by the ANR project EVARISTE, which financed in May 2025 a visit of AM to the other co-authors at the Federal University of Santa Catarina. This paper is the result of the work performed during the visit. The authors are also grateful to the 5 reviewers for their fruitful comments.

***Abstract*—Peer assessment is widely used in higher education, yet the cognitive demands placed on student assessors, particularly under conditions of overload and repetition, remain poorly understood. We examine how two cognitive factors, information overload and what we term assessment fatigue, influence evaluation behavior and user experience. Assessment fatigue is defined as cognitive strain resulting from repeated evaluative tasks. The study draws on data from a university-level deployment of a structured peer evaluation system. We applied Structural Equation Modeling (SEM) to analyze how behavioral data and self-reported perceptions of overload and fatigue relate to overall system satisfaction. Results reveal a significant indirect pathway from information overload to system satisfaction, mediated by fatigue. Based on these findings, we propose design recommendations for cognitively-aware assessment systems that adapt to students' cognitive constraints, contributing to the development of AI-supported educational tools that are more robust and human-centered.**

I. Introduction

PEER ASSESSMENT is widely used in higher education to enhance learning and promote critical thinking [14, 19]. As educational platforms increasingly integrate automated or semi-automated assessment tools, peer evaluation systems are becoming candidates for AI-supported enhancement [7, 8]. While the design of aggregation methods and elicitation strategies has recently received some attention [18, 21], the *cognitive experience* of the assessors—specifically the effects of overload and fatigue—has been largely overlooked. The cognitive demands placed on student assessors when reviewing multiple peer projects—remain poorly understood. As students progress through a sequence of evaluations, they may experience information overload and fatigue, which can affect the consistency of their ratings and their overall satisfaction with the process. This paper addresses that gap by focusing on two cognitive factors that may degrade the quality of peer evaluations over time: information overload (IOL) and what we term assessment fatigue. There is no single definition of information overload (see e.g., the survey paper by Bawden and Robinson [2]). A commonly accepted definition is that information overload occurs when a user has insufficient cognitive capacity to handle the presented information. IOL has been linked to decreased decision quality and increased inconsistency [9, 11]. These cognitive factors do not only impact the user experience—they may also compromise the accuracy of peer evaluations. Under high cognitive load, students may fail to distinguish between projects, default to repeated ratings, or reduce the depth of evaluative effort, potentially affecting the fairness and validity of assessment outcomes.

We introduce the term assessment fatigue to describe cognitive depletion stemming from repeated evaluative tasks within peer review sessions. While information overload is well established in cognitive psychology and organizational behavior, its role in peer assessment systems remains underexplored. The concept of fatigue in this context has received even less scholarly attention.

We study these phenomena using data collected from the R2R peer assessment platform [8], deployed in a university course on data analysis. In this setting, students assessed peer projects using a structured interface that combined Likert-scale ratings with pairwise comparison queries. Figure 1 illustrates the R2R system flow. Specifically, we ask: (1) What is the impact of information overload on peer assessment? (2) What is the impact of assessment fatigue on peer assessment? (3) How satisfied are users with the R2R peer assessment system? Our goal is to model the relationships between these cognitive factors and evaluation patterns, and to consider how future systems might be designed to account for such effects.

In addition to collecting behavioral data such as score patterns and tie frequency, we administered a post-assessment questionnaire that measured perceived information overload (IOL), assessment fatigue, and satisfaction with the system. To model the relationships among these subjective constructs and evaluation behavior, we applied Structural Equation Modeling (SEM), treating each construct as a latent variable.

We use the results of our behavioral analysis to motivate several design recommendations for improving peer assessment systems. These include incorporating fatigue-sensitive prompts and weighting inputs based on behavioral reliability. The goal is to help future systems better support assessors under cognitive strain and improve the overall consistency and fairness of evaluations. By combining behavioral modeling with system-level implications, this work contributes to the development of human-centered, AI-supported educational

This work was supported by the Ministry of Innovation, Science & Technology, Israel

technologies that account for the cognitive limitations of student evaluators. Specifically, our contributions are threefold:

- We define and estimate assessment fatigue as a latent variable using behavioral and self-report data.
- We apply Structural Equation Modeling (SEM) to analyze the relationships between information overload, assessment fatigue, and peer evaluation behavior.
- We propose design recommendations for peer assessment systems that address cognitive strain during evaluation.

II. Related Work

Peer assessment has been widely used in educational settings to support evaluation and feedback among students. Many systems have been developed to structure this process, aiming to improve reliability, fairness, and ease of use [19, 20, 14]. However, persistent challenges include strategic grading [18], inconsistency among assessors [21], and score inflation [15]. Rating-based systems are vulnerable to calibration issues and leniency bias [8], while systems that rely only on rankings can impose high cognitive demands on students [16].

The R2R platform addresses some of these limitations by combining Likert-scale ratings with pairwise comparisons, triggered only when students assign the same score to multiple projects [8]. This approach collects informative input while keeping the evaluation task manageable. The present study builds on this framework to examine how assessors' cognitive states—specifically overload and fatigue—affect their rating behavior and system satisfaction.

Information overload has been studied in decision-making, education, and organizational behavior [1, 6, 9], but its relevance to peer assessment remains underexplored. We also introduce the concept of assessment fatigue, defined as cognitive strain from repeated evaluation tasks. Although well-studied in cognitive psychology, fatigue has not been explicitly modeled in the peer assessment context. This study examines both constructs and their relationship to behavioral patterns and subjective user experience.

Previous studies in large-scale peer review, such as in MOOCs, have documented variability in rater performance over time [13, 17]. However, such work typically treats inconsistency as noise, rather than exploring its cognitive origins. In contrast, our study models cognitive factors as latent constructs and uses Structural Equation Modeling (SEM) to analyze their connection to evaluation behavior.

Recent work in educational AI explores how systems can adapt to learners' cognitive and emotional states [7], including adaptive pacing [22], feedback support [5], and scaffolding [10]. However, most peer assessment platforms still treat all students as equally capable reviewers. We argue that behavioral indicators of cognitive strain—such as reduced variability, scoring decay, or rushed evaluations—can inform the design of more responsive peer assessment systems.

III. Methodology

The study was conducted in an undergraduate data analysis course at Ariel University. Students participated in a structured peer assessment exercise using the R2R platform [8]. Each student viewed and evaluated 9–12 peer presentations. Evaluations began with assigning 1–5 Likert-scale scores to each project based on predefined rubrics. When multiple projects received the same score, the system triggered pairwise comparison queries to elicit ordinal preferences among them. This hybrid approach—combining cardinal ratings with selective ordinal input—yields a partially ordered set of preferences per student.

Once all data were collected, the system aggregated the individual inputs into a full ranking over all projects. For each median score level, it computed an internal ranking among the tied projects using either Borda or Copeland voting rules. The final output was a global project ranking that preserved both score-based judgments and fine-grained pairwise distinctions [8].

To capture students' evaluation behavior over time, we computed a set of behavioral indicators derived from their interactions with the R2R system. These included the mean score each student assigned across all evaluated projects, as well as a decay coefficient—defined as the difference between the mean of the first third and the last third of scores in the session—to estimate whether students' ratings declined over time. We also recorded the proportion of ties (i.e., repeated scores across projects). Another variable tested is response latency—measured as the average time between rating actions—was also extracted as a behavioral indicator. However, it did not show a significant association with any of the cognitive variables (overload, engagement, or satisfaction), and was therefore excluded from the final model.

Upon completing their peer assessments, students filled out a questionnaire including validated items on information overload, perceived fatigue, and system usability. Responses were measured using a five-point Likert scale and aggregated into three latent constructs: Information Overload, Assessment Fatigue, and Satisfaction. The full questionnaire can be found in the Appendix VI.

A total of 231 students participated in the study. Some did not rate all projects in their session, or failed to complete the questionnaire. We were thus left with a total of 194 students.

We employed Structural Equation Modeling (SEM). The model was pre-specified based on the theoretical assumptions on the relationships between cognitive factors (fatigue and overload), behavioral patterns, and subjective experience (satisfaction with the system). The SEM was implemented in R using the `lavaan` package, with maximum likelihood estimation. Model fit was assessed using standard indices: CFI, RMSEA, and SRMR. The latent variables were modeled as predictors of observed behavioral features to understand how cognitive strain manifests in evaluation patterns.

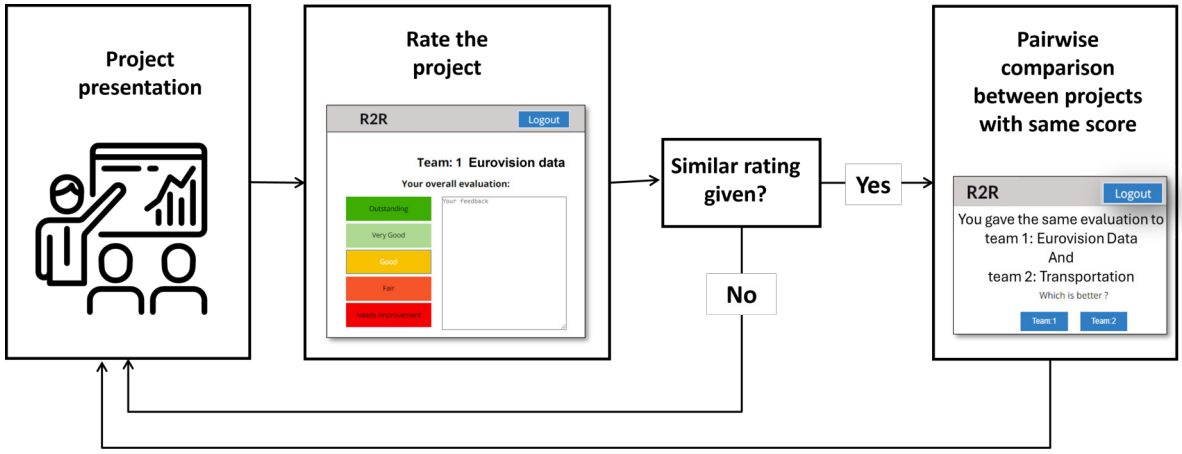

Fig. 1. R2R system flow. Students view project presentations and then rate the projects. If a student assigns the same rating to two or more projects, a series of pairwise comparison queries is executed.

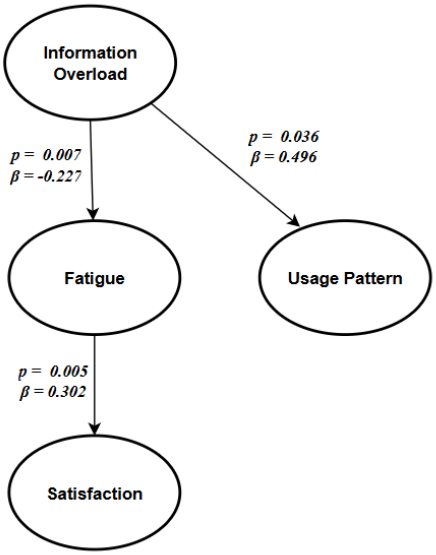

Fig. 2. Structural model results. Information overload predicts both assessment fatigue and usage patterns. Fatigue in turn predicts system satisfaction. A significant indirect effect from overload to satisfaction is mediated through fatigue.

IV. Results

The SEM demonstrated an acceptable to good fit with the data. The scaled chi-square test was marginally significant, $\chi^2(112) = 139.24$, $p = .041$. Additional fit indices supported the model: CFI = 0.934, TLI = 0.921, RMSEA = 0.035, and SRMR = 0.063.

Figure 2 presents a simplified diagram of the structural paths estimated in the model. The most robust finding was a positive and significant path from the latent fatigue construct to system satisfaction ($\beta = 0.302$, $p = .005$). Although labeled as fatigue, the items comprising this factor reflect cognitive engagement (e.g., active reflection and effort). Thus, higher scores indicate lower fatigue or greater evaluative involvement. Interpreted accordingly, the result suggests that students who were more cognitively engaged during the peer assessment process reported higher satisfaction with the system—a pattern consistent with prior findings on self-regulated learning and intrinsic motivation.

Information overload significantly predicted assessment fatigue ($\beta = -0.227$, $p = .007$), indicating that students who reported higher overload tended to also report greater fatigue. However, the direct path from information overload to system satisfaction was not statistically significant ($\beta = 0.012$, $p = .912$), suggesting that the relationship between overload and satisfaction operates indirectly, through its effect on fatigue.

The significance of the indirect path from information overload to satisfaction through fatigue ($ab_3 = -0.048$, $p = .019$) supports a partial mediation model. Fatigue acts as a conduit through which perceived overload affects downstream user experience. This finding aligns with cognitive theories that emphasize the cumulative toll of high information load and the importance of affective and physical strain in shaping task satisfaction [9, 1].

In the context of peer assessment, these mechanisms may help explain how students' evaluative consistency and system satisfaction decline as cognitive demands accumulate over the course of repeated assessment tasks.

In addition to the latent variables, the model incorporated behavioral measures. Information overload significantly predicted the mean rubric usage pattern ($ab_3 = 0.496$, $p = .036$), indicating that cognitive strain manifests not only in subjective reports but also in measurable changes in evaluation behavior. Students experiencing higher overload engaged differently with the interface, suggesting that behavior traces may offer real-time or asynchronous indicators of cognitive state.

Several additional paths were included in the model for completeness but were not statistically significant. These included the direct path from information overload to satisfaction

($ab_3 = 0.012$, $p = .912$), as well as paths from behavioral pattern indicators to satisfaction ($ab_3 = -0.053$, $p = .548$) and fatigue ($ab_3 = -0.070$, $p = .315$).

In summary, the model confirms that perceived information overload predicts fatigue, and that fatigue, in turn, positively predicts system satisfaction. The direct path from overload to satisfaction was not significant, indicating that fatigue mediates this relationship. These findings answer our core research questions and highlight the value of modeling cognitive constructs such as overload and fatigue as latent variables. The use of SEM allowed us to capture latent constructs that are not directly observable, such as perceived fatigue and overload, and to examine their relationships with both self-reported satisfaction and system-logged behavioral patterns. This modeling approach made it possible to detect indirect effects and account for measurement error, offering a more accurate view of how cognitive states shape peer assessment experience.

V. Design Recommendations

Assessment fatigue, i.e., cognitive fatigue during peer assessment, can be addressed through real-time detection mechanisms that rely on unobtrusive behavioral signals. Because the assessment environment already logs granular student actions—such as response times, ratings, and tie-breaking decisions—it is feasible to infer signs of strain or disengagement as students work through their evaluation tasks. Specifically, indicators such as repeated use of a single score (e.g., consistently assigning the highest rating), low variance across rubric dimensions, skipping optional comment fields, or evidence of scoring decay over time may suggest cognitive overload or reduced attentional engagement. The latter can be quantified using a decay coefficient, defined as the difference in mean scores between the first and last segments of a student's evaluation sequence. A consistent downward trend in scores, relative to how other assessors rated the same projects, may reflect increasing fatigue or diminished evaluative attention as the session progresses.

When such patterns are detected in real time, the system can scaffold the rating process to reduce cognitive load. Instead of allowing students to proceed with rapid, unreflective scoring, the interface can present brief prompts encouraging deeper engagement. For example, when repeated use of the same score is detected, the system might ask: "Consider pacing your next few ratings more slowly to ensure accuracy" or "Before submitting, consider whether this score reflects the project's clarity, originality, and completeness." Other prompts might invite rubric-based reflection, such as: "Did this project meet expectations for structure, argumentation, or use of data?". These light-weight nudges are designed to trigger evaluative reappraisal without interrupting workflow. Drawing on principles of adaptive scaffolding and self-regulated learning, such prompts can help students maintain attentional focus and calibrate their ratings more accurately, even under conditions of assessment fatigue.

In addition to in-the-moment interventions, cognitive strain can be addressed retrospectively through post-hoc adjustments to aggregation. After the evaluation session concludes, the system can compute a reliability score for each assessor based on fatigue-related behavioral signals. This score, scaled between 0.1 and 1.0, reflects the inferred trustworthiness of the student's inputs. These weights can then be used to adjust both rating-based and ranking-based aggregation methods. In the case of ratings, a student who assigns the same score to all projects or shows minimal rubric variance may have their evaluations down-weighted in the final average. For ranking-based aggregation, methods such as Borda or Copeland can be adapted to incorporate these weights directly. The adjusted Borda score for a project c_j would be computed as:

$$\text{AdjustedBorda}(c_j) = \sum_{i=1}^{n} w_i \cdot \text{BordaRank}_i(c_j)$$

where w_i is the reliability weight for student i, and $\text{BordaRank}_i(c_j)$ is the rank assigned by that student to project c_j. This post-hoc adjustment strategy requires no change to the frontend interface or assessment process.

VI. Discussion

Real-time scaffolding and reliability-based weighting support student wellbeing by recognizing and mitigating the cognitive toll of extended evaluation tasks. These adaptive mechanisms may also enhance fairness, by reducing the influence of assessors operating under strain. Thus, integrating fatigue-sensitive design into peer assessment systems carries not only cognitive and pedagogical value, but also reflects human-centered AI principles—namely, respect for cognitive limits, equitable treatment, and minimal intrusion.

Several directions remain open for extending this work. One promising avenue is the integration of large language models (LLMs) to enhance feedback analysis and detect signs of fatigue or disengagement through natural language patterns. While the present study focuses on rating behavior and assessment structure, written feedback can offer a complementary signal of cognitive strain. For example, LLMs can be used to analyze comment length, sentence count, lexical richness, or syntactic complexity. Qualitative shifts such as sentiment flattening ("nice job") or use of generic, non-specific phrases ("good project," "well done") may indicate reduced engagement or cognitive effort. Detecting such patterns at scale could enable a multi-modal fatigue detection pipeline that combines behavioral and textual indicators.

A second line of future work involves implementing the design recommendations proposed in this paper within a live peer assessment platform. This includes integrating fatigue-sensitive prompts, real-time scaffolding for ratings, and post-hoc reliability-weighted aggregation. Controlled experiments can then evaluate the effectiveness of these interventions in improving evaluation quality and fairness of outcomes.

APPENDIX: QUESTIONNAIRE

Students completed a questionnaire immediately after finishing the peer assessment tasks. It included two demographic questions, six items from a validated satisfaction scale [4], four items from an information overload scale [3], and five items on fatigue adapted from Krieglstein et al. [12].

Response Scales:

- **5-point scale:** 1 = Strongly Disagree, 2 = Disagree, 3 = Neither Agree nor Disagree, 4 = Agree, 5 = Strongly Agree
- **7-point scale:** 1 = Strongly Disagree, 2 = Disagree, 3 = Somewhat Disagree, 4 = Neither Agree nor Disagree, 5 = Somewhat Agree, 6 = Agree, 7 = Strongly Agree

General Information

- Age
- Gender

Satisfaction [4] *(5-point scale)*

- R2R was more efficient for peer and self-evaluation than paper-and-pencil methods would be.
- The operation of R2R evaluations was easy and convenient.
- I tried to grade my peers appropriately and not to be picky or hypocritical.
- I worried that my classmates would give me low grades intentionally.
- I think the instructor's comments and grading would be more professional than my classmates'.
- I felt that I received biased low scores from peers.

Information Overload [3] *(7-point scale)*

- I cannot effectively process all the information I read.
- I am overwhelmed with the information I read.
- I feel anxious that I might have missed an important piece of information I read.
- I cannot assimilate all the information I read.

Fatigue [12] *(7-point scale)*

- The learning content was difficult to understand.
- The learning content included much complex information.
- I actively reflected upon the learning content.
- I made an effort to understand the learning content.
- I was able to expand my prior knowledge with the learning content.

***Abstract*—Survival analysis focuses on modeling the time until a specific event occurs, often in the presence of censored observations. While classical methods like the Cox model are widely used, modern machine learning (ML) approaches offer greater flexibility and predictive power. This paper compares classical and ML-based survival models on both real-world and simulated datasets. We demonstrate that techniques like CoxBoost and penalized Cox regression outperform tree-based models like Random Survival Forests in most settings. Explainable Artificial Intelligence (AI) tools are applied to improve the transparency and interpretability of model predictions.**

***Index Terms*—Survival analysis, machine learning, Cox proportional hazards model, random survival forests, CoxBoost, penalized Cox model, ICU patients, explainable artificial intelligence**

I. Introduction

SURVIVAL analysis is a branch of statistics concerned with the time until an event of interest occurs. The event of interest can be, for example, the death of a patient or the time until the failure of a machine. In this situation, a phenomenon called data censoring is often present, as typically, not all units experienced an event of interest during the monitoring period.

The most widely used model in survival analysis is the Cox model, introduced in 1972 by [1]. The Cox model does not make assumptions regarding the hazard function, which provides necessary flexibility, but makes parametric assumptions about the effect of the covariates on the hazard function. The assumptions of the model are relatively strict and may lead to biased results if violated. This is often pointed out as a potential drawback.

Machine learning is a subfield of artificial intelligence that leverages knowledge from statistics and computer science. In the last decades, it has established itself as a highly flexible and powerful tool capable of solving a wide variety of problems. In general, machine learning requires little to no assumption to be made and is able to discover complex relations in the data. This raises an important question: How can survival analysis benefit from incorporating machine learning methods. Addressing this question is the primary focus of this work.

This paper presents a comprehensive evaluation of six models: Cox proportional hazard model, Cox model with elastic net regularization, CoxBoost, Random Survival Forests (RSF), Conditional Inference Forests (CIF), and Oblique RSF. We evaluated their performance on a real-world Intensive Care Unit (ICU) dataset as well as on simulated datasets with known ground truth.

II. Related work

The use of machine learning and statistical methods for survival analysis has been attracting a lot of attention in recent years. Survival clustering analysis for time-to-event data was proposed in [2], robust nonparametric survival curves comparison in [3], [4], while support vector machines in [5], [6], together with implementation in R. All the above mentioned approaches offer rather a methodological framework on usage the ML in survival analysis.

Another approach how to utilize machine learning in survival analysis appeared in a publication [7], where the authors decomposed the dependent two-dimensional time-event variable into two components. Thereafter, the authors separated

the analysis into two parts, the occurrence of the event being a classification task and time-to-event estimation being a regression task. This approach was later improved and used for the prediction of a COVID-19 blood antibody decrease, which could help to identify individuals who should receive boosting vaccination when a new variant of COVID-19 would appear [8].

Furthermore, the use of deep learning techniques in the field of survival analysis started to seem promising and become one of the main topics for research. In an article [9], the authors utilized neural networks in order to create a personalized treatment recommender system. Authors in an article [10] employed deep learning techniques for competing risk analysis. A comprehensive review about deep learning algorithms used in survival analysis was lately given by [11], which also discusses deep learning algorithms capable of handling time-dependent covariates. Additionally, the review outlines how deep learning can be used to integrate multimodal data – including image, text, and tabular inputs – into survival modeling.

III. Methodology

This section outlines the analytical framework used in our study. We detail the specific traditional and machine learning survival models evaluated, the metrics employed for assessing their predictive performance, and the explainable AI techniques used to interpret their behaviour.

A. Survival and ML Models

We evaluated six survival analysis models from both traditional and machine learning families:

- **Cox Proportional Hazards (Cox PH)**: The most popular model for the analysis of survival data is the Cox proportional hazards model (in literature, it often appears as the Cox PH model or simply the Cox model). The Cox model is a semiparametric model, it makes no assumptions about the hazard function but makes a parametric assumption regarding the effect of the covariates on the hazard function. The fact that the hazard function is not needed provides a significant advantage, as in many situations the true form of the hazard function might be unknown or too complex [12].
  The Cox model is most often stated in the following form,
  $$h(t|\mathbf{x}) = h_0(t)\exp(\mathbf{x}\boldsymbol{\beta}), \tag{1}$$
  where
  - $h(t|\mathbf{x})$ is the hazard function at time t given covariates $\mathbf{x}$,
  - $h_0(t)$ is the baseline hazard function at time t,
  - $\mathbf{x}$ is the vector of covariate (i.e., it is eventually a matrix),
  - $\boldsymbol{\beta}$ is the vector of regression coefficients.
- **Random Survival Forests (RSF)**: Random survival forests (RSF) is a method introduced in article [13], and it presents modification for analysis of right-censored survival data of the popular random forest algorithm. The authors argue that extending the random forest algorithm for the purpose of analyzing survival data is of great value as with traditional methods, nonlinear effects of variables must be modeled by transformations, and ad hoc approaches are often needed. On the other hand, random forests handle these difficulties automatically.
  The RSF algorithm, as described in [13] is as follows:
  (i) Draw B bootstrap samples from the original data. Each bootstrap sample excludes, on average, 37% of the data, these data are called out-of-bag data (OOB data).
  (ii) Grow a survival tree for each bootstrap sample. At each node of the tree, randomly select p variables as candidates for the splitting. The node is split using the variable that maximizes the survival difference between the child nodes.
  (iii) Grow the tree under the constraint that each terminal node should contain at least one unique event of interest.
  (iv) Calculate a cumulative hazard function (CHF) for each tree. Obtain the ensemble cumulative hazard function by averaging across all trees.
  (v) Use the OOB data to compute the prediction error for the ensemble CHF.
- **CoxBoost**: CoxBoost is an extension of the Cox model that incorporates boosting algorithm introduced in [14]. Boosting is a popular, iterative ensemble method that builds a strong predictive model by sequentially combining multiple weak models. The boosting algorithm initially sets equal weights to all observations, then for each successive (m-th) iteration, where $m \in \{2, 3, \ldots, M\}$, the weights for each observation are modified. At each (m-th) step, the misclassified observations have their weights increased, whereas correctly classified observations have their weights decreased. As the algorithm proceeds, observations that are difficult to classify correctly gain greater influence [15].
- **Penalized Cox (Elastic Net)**: As the amount of collected data rapidly grows, supported by advancements in detection techniques, high-dimensional settings are becoming increasingly common across most domains. For classical cases, with significantly more observations than predictors, the Cox model tends to work well. However, in situations where the number of predictors is close to or even exceeds the number of observations, the Cox model tends to output degenerate behavior, as all parameters β_j are converging towards $\pm\infty$, [16].
  To address this challenge, Simon et al. [16] proposed an algorithm that incorporates the elastic net penalty as
  $$\lambda\left(\alpha\sum_{i=1}^{p}|\beta_i| + \frac{1}{2}(1-\alpha)\sum_{i=1}^{p}\beta_i^2\right), \quad \alpha \in [0,1], \tag{2}$$
  which is to be minimized by the algorithm and is a mixture of the L_1 (LASSO) and L_2 (ridge regression) penalties. LASSO tends to work well for sparsity problems, as it tends to choose only a few nonzero coefficients. On the other hand, in the presence of correlations between the predictors, ridge regression tends to perform better, but sets no coefficients to exactly zero. The elastic net combines the strength of both approaches and as α changes between 0 and 1, the approach is changing to be more ridge-like or more LASSO-like [16].

- **Conditional Inference Forests (CIF)**: Conditional inference trees were introduced in [17]. The authors argue that the majority of recursive partitioning algorithms, such as CART [18], have fundamental problems in overfitting and selection bias towards covariates with many possible splits [17].
  To address these concerns, conditional inference trees adopt a more statistically principled approach that takes into account the distributional properties of the data. The core of this approach lies in determining the association between covariates and the response, which allows for an unbiased selection of variables, irrespective of their scale or the number of categories they might have [17].
- **Oblique Random Survival Forests (ORSF)**: A potential modification of the random survival forests described above is extending the splits to allow a linear combination of the predictors instead of using only a single predictor. This extension is applied in oblique random survival forests, as described in [19]. Authors argue that the described approach might improve the random survival forests especially when the predictors are correlated and some are irrelevant to the survival outcome, which is often the case when working, for example, with large medical databases.

B. Model Evaluation

In order to assess model performance, there is a need for metrics that can quantify the prediction performance of the survival models. A commonly used measure is *Harrell's concordance index* [20], which measures how well the model ranks two random individuals in terms of survival time. It is defined as a ratio of concordant pairs (correctly ordered pairs) to all comparable pairs. In order for the random pair i and j to be comparable, the sample with lower observed time y had to experience an event, i.e., $y_j > y_i$ and $\delta_i = 1$, where δ_i is a binary event indicator. A pair is concordant if the estimated risk predicted by the survival model is higher for observations with lower survival time (in other words, if the survival time is in general low, the risk had to be high because it shortened the survival time). Otherwise the pair is called discordant. The concordance index is then computed as

$$C = \frac{\text{number of concordant pairs}}{\text{number of all comparable pairs}}. \tag{3}$$

C. Explainability

With the introduction of machine learning methods into survival analysis, there emerged a need to deepen our understanding of these algorithms. As stated in [21], the successful adoption of machine learning in healthcare critically depends on techniques that enhance our ability to interpret model outputs.

In response to this challenge, an entire subfield has developed, commonly known as Explainable AI (XAI). This subfield focuses on creating techniques that make machine learning and artificial intelligence solutions more transparent and provide better understanding of the process behind decision making of the model [22].

However, until recently, these techniques were not designed to handle censoring and provide explanations for survival models. To fill this gap, [23] proposed a `survex` framework implemented into R, with the goal of empowering stakeholders with model understanding and building trust in machine learning models. The `survex` framework is designed to be model agnostic and, hence, can be applied to any survival model that returns predictions in the form of survival or cumulative hazard function [23].

Furthermore, methods dedicated to explain survival models such as SurvSHAP(t) [24] or SurvLIME [25] are also incorporated in the `survex` package along with explanations tailored to incorporate the time dimension. Moreover, local explanations that refers to prediction as well as global explanations regarding the whole model are provided [23].

D. Real-world data

Real-world dataset chosen for the purpose of the practical application of survival analysis methods, was MIMIC-III [26]. MIMIC-III is a large relational database consisting of 26 tables containing information about 38,597 adult patients and 7,870 neonates that were admitted to critical care units (ICU) to the Beth Israel Deaconess Medical Center in Boston, Massachusetts, between 2001 and 2012. Information about patients' demographics, diagnoses, laboratory tests, physiological measurements, drug codes, and many more are collected. Different types of information are kept separately in different tables [26].

The dataset underwent extensive preprocessing, the details of which are beyond the scope of this paper but are reproducible and available upon request. The final dataset contained 11,435 unique patients out of which 5,036 experienced an event of interest (i.e., death resulting from a severe health condition). This equals to a censoring level of roughly 56 %.

E. Simulated data

The goal of the analysis in the simulated dataset was to further assess the qualities of the individual algorithms in simulation settings that represent different scenarios. Another objective was to examine how well the models were able to recognize variables that have a real impact on the outcome and which models are more likely to get confused by variables representing only random noise. This can be done only under the simulation study, where these variables are known ahead.

The simulated dataset was created using standard Weibull distribution, which incorporates time-dependent effects of the variables. For simplification, a formula of how such a generating model can look for one covariate is illustrated in equation (4). In this example, it is assumed that the time-dependent effect of the covariate is induced by interaction with log time [27],

$$h_i(t) = \gamma \lambda t^{\gamma-1} \exp(\beta_0 X_{i,j} + \beta_1 X_{i,j} \cdot \log(t)), \tag{4}$$

where

- $h_i(t)$ is the hazard function for the i-th individual at time t,
- γ is the shape parameter of the Weibull distribution,
- λ is the scale parameter of the Weibull distribution,
- $X_{i,j}$ is the j-th covariate value for i-th individual,
- β_0 is log hazard ratio for the j-th covariate,
- β_1 specifies the amount by which the log hazard ratio changes for the j-th covariate, for every unit increase in $\log(t)$.

To test model robustness in noisy environments, a dataset containing 32 variables was created, with only 8 of these variables having a real impact on the outcome. The values of each variable were simulated from common probability distributions such as normal, log-normal or Bernoulli.

IV. Results and Discussion

A. Real-world data

For the analysis of real-world data, 80/20 train/test split was conducted and patient's diagnosis and demographics were used as predictors.

On the test set, RSF performed slightly better initially, but Cox-based models (especially CoxBoost and Cox with elastic net regularization) showed better or equal performance over the long term. Overall, performance was very similar.

Fig. 1 display comparison of the performance, using concordance index, over all used models. We observe that performance stability, particularly at later time points (when only a smaller number of individuals who have not experienced the event of interest remain, making prediction more difficult), is achieved by the CoxBoost and Penalized Cox models, whereas the traditional Cox proportional hazards model demonstrates poorer predictive performance.

Traditional Cox model found age, gender (males having 11.5% higher risk), admission type (emergency/urgent increasing risk), and diagnosis (sepsis being most dangerous, increasing risk by 33.8 % vs. Altered Mental Status (AMS)) to be significant predictors.

Random Survival Forest identified age, diagnosis, and admission type as most important, but ranked ethnicity/insurance higher than gender, unlike Cox model.

For better understanding of the model's behaviour, we used the R package `survex` [23] and displayed the predicted survival function for a new patient for different values of the variable of our interest (diagnosis). In this case, we identified the most typical patient who experienced the event of interest (death) as a 73-year-old female who, in reality, was diagnosed with congestive heart failure and died 71 days after the first admission. The practical implications of this explainable finding are straightforward – a newly admitted patient who is a 73-year-old female should be treated with maximum care, as she is at the highest risk of death given this diagnosis.

This demonstrates how powerful the machine learning algorithms could be in understanding complex relationships, which are often present in real-world data.

As was mentioned in the methodology section, the Cox model is constrained by strong assumptions – one of which being the proportional hazard ratios. This constraint is evident in Fig. 2, where the survival curves for individual diagnoses do not intersect. In contrast, the Random Survival Forest (RSF) model imposes no such assumption, enabling more flexible modeling of time-dependent effects. This flexibility is illustrated in Fig. 3 – for example, pneumonia initially presents lower risk compared to seizure or intracranial hemorrhage, but its predicted risk eventually exceeds both over time.

B. Simulated data

The algorithms used in the simulation part were the same as the algorithms used in real-world data analysis. Model performance was evaluated by concordance index on the test set after splitting 80 % of the data for training and 20 % for testing, can be seen in Table I. The size of the dataset before splitting is denoted by n. The best performance under each setting is bolded.

Initially, a dataset with only 100 observations was created, leaving only about 80 for training and 20 observations for

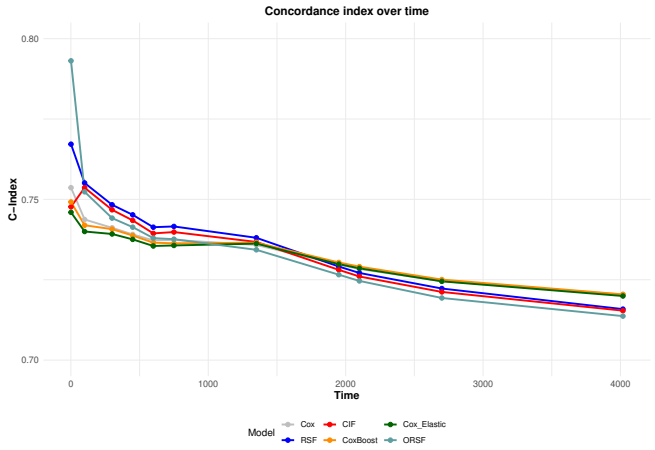

Fig. 1. Concordance index over time for all models.

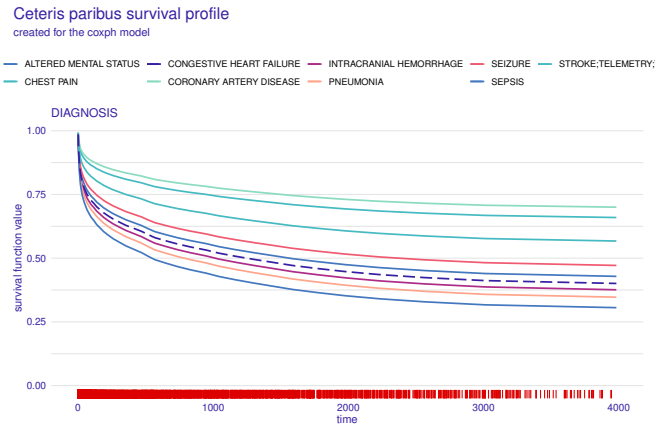

Fig. 2. Predictions for patient 16680 under different diagnoses – Cox PH model.

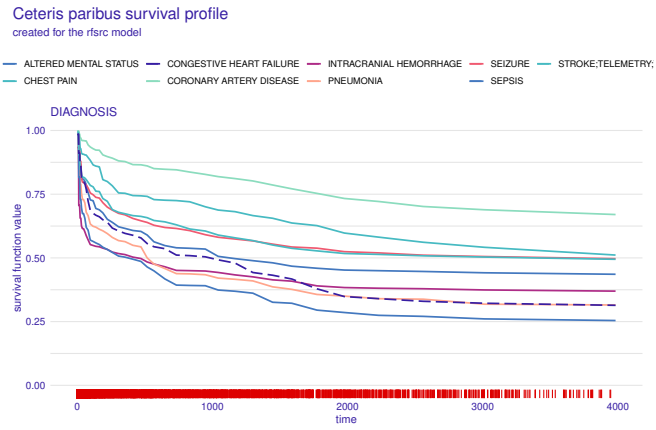

Fig. 3. Predictions for patient 16680 under different diagnoses – RSF.

testing. Under the Weibull distribution with scale 0.025 and shape 1.0, the Cox model with elastic net regularization performed the best on the test set. However, as the Weibull distribution was changed, presenting more risky environments with less censoring, the traditional Cox model surpassed the Cox model with regularization. Moreover, it is interesting to note that under the Weibull distribution with a parameter of scale 0.070 and shape 1.1, the conditional inference forests, the CoxBoost and the oblique random survival forest all had concordance index below 0.5, meaning that it was worse than random guessing (!).

Subsequently, the number of instances was increased to 2500 in order to see how a bigger dataset would influence the performances of each algorithm and also to see if the level of censoring would still be as influential as it was with the small dataset. First of all, from Table I, it is visible that once the size of the dataset is significantly increased, the influence of the censoring is decreased, and the performances of the algorithms do not tend to differ that much among different distribution settings. The best performing models, under this size of the dataset, were the CoxBoost and the Cox model with elastic net regularization.

TABLE I
CONCORDANCE INDEX FOR EACH OF THE ALGORITHM UNDER EACH SETTING

Weibull parameters	W(1.0, 0.025)	W(1.0, 0.060)	W(1.1, 0.070)
n=100			
Cox	0.788	**0.701**	**0.625**
RSF	0.765	0.591	0.554
CIF	0.671	0.468	0.391
CoxBoost	0.782	0.552	0.489
Cox_elastic	**0.882**	**0.701**	0.620
ORSF	0.647	0.565	0.467
n=2500			
Cox	0.619	0.641	0.647
RSF	0.623	0.641	0.635
CIF	0.608	0.628	0.632
CoxBoost	**0.633**	0.634	**0.654**
Cox_elastic	0.620	**0.642**	0.649
ORSF	0.621	0.638	0.640
n=5000			
Cox	0.638	0.627	0.626
RSF	0.629	0.618	0.614
CIF	0.636	0.625	0.619
CoxBoost	0.640	0.633	0.627
Cox_elastic	**0.641**	**0.634**	**0.630**
ORSF	0.628	0.627	0.622

Finally, the size of the dataset was even more increased to 5000 observations. This was done in order to see whether adding more instances would result in better model performance. In comparison with the setting, where only 2500 observations were generated, the performances improved only a little and, in some cases, got even a little bit worse. From that we can conclude that beyond a certain point, adding additional observations, which come from the same distribution, is bringing smaller and smaller value. The Penalized Cox model appears to be the best-performing model for large datasets, which aligns with our expectations, as penalization can effectively address the imbalance between the number of observations and covariates.

Additionally, we assessed each model's ability to distinguish between informative variables and random noise under different simulation settings. Under the settings of only 100 observations, algorithms like the RSF or the traditional Cox model tended to struggle in recognizing important variables and were only able to do better once the number of observations was significantly increased. On the other hand, the *Cox model with elastic net regularization was able to recognize the majority of important variables even under the setting of only 100 observations*. This likely contributed to its superior performance under that setting.

V. CONCLUSION AND FUTURE RESEARCH IDEAS

Overall, machine learning approaches demonstrated promising performance that was at least competitive with the traditional Cox model on both real-world and simulated data. Moreover, machine learning models offer valuable flexibility in capturing complex, non-linear relationships between covariates and survival outcomes. Applying techniques such as elastic net regularization combined with the Cox model under a penalized framework proved especially effective in scenarios with limited data availability or an imbalance between observations and covariates.

Future research could explore deep learning and multimodal data integration, which may enhance performance by providing richer patient information. Additionally, leveraging time-dependent covariates could reveal important patterns from measurements collected during a patient's stay. Moreover, future work should incorporate formal statistical testing (e.g., bootstrapped confidence intervals for the concordance index) to enable more rigorous model comparisons. While this study focused on a single ICU dataset, evaluating models across multiple real-world datasets would help assess generalizability across healthcare settings.

***Abstract*— Establishment surveys are essential for gaining well-founded insights into company structures and developments, whereby representativeness ensures that the results can be reliably transferred to the population and enable bias-free conclusions. Company surveys in Germany are often based on the company file of the Federal Employment Agency (BA), which, however, only allows limited links to other data sources. The free online service OpenStreetMap (OSM) could serve as an alternative, publicly accessible data source. This article analyses the extent to which OSM is suitable for drawing a representative sample of companies. It is hypothesised that OSM covers a large proportion of businesses, especially in metropolitan areas, and that customer-oriented sectors are better covered than industrial or B2B businesses. To verify this, establishments are identified in OSM and compared with the BA establishment file, differentiated by region and sector. The results show a high but not complete coverage with regional differences in favour of metropolitan areas. There are limitations in terms of data quality and contactability of the establishments.**

***Index Terms*— OpenStreetMap (OSM), Company level data, Sectoral Coverage, Survey Methodology.**

I. Introduction: New approaches in Business Research: Computational Approaches with OpenStreetMap and Supplementary Digital Data Sources

DATA on companies is of central importance for social science research, as it provides insights into economic structures, labour markets, regional development and social dynamics. An establishment refers to a social workplace. Many analyses restrict the definition to establishments with at least one employee subject to social insurance contributions. This therefore excludes solo self-employed persons. Establishments in this sense are to be distinguished from companies, which may consist of several establishments.

Information on location, size, sector and company structures makes a significant contribution to understanding employment processes, innovation, education and social inequality. Both found data from sources such as OpenStreetMap (OSM) and data from systematic company surveys offer different, complementary perspectives: While found data can provide up-to-date and widely available information, targeted surveys enable a deeper analysis of specific company characteristics and contexts. The combination of both approaches significantly expands the potential for well-founded social science analyses and evidence-based policy advice.

The availability of large, freely accessible digital data sets such as OSM opens up new opportunities for interdisciplinary research in the social sciences, economics and humanities. As a first step, the data from OSM itself can be used to analyse companies in Germany, for example. There is also the potential to link additional data from company websites, job advertisements and company valuations. Finally, the company addresses available in OSM can be used to conduct new company surveys that are as representative as possible.

This article is positioned in the context of computational approaches that utilise digital methods for theoretical, methodological and applied questions. It looks at the extent to which OSM is a suitable data source for the representative mapping of businesses in Germany. On the one hand, this applies as a source for a complete survey (use of the OSM data itself) and as an applied approach as a basis for drawing representative establishment samples. In particular, the article examines the potential of OSM for the applied generation of representative firm samples and critically reflects on the quality, reliability and representativeness of such digital resources.

The article thus addresses the central challenges of linking heterogeneous data sources such as crowdsourcing data with regard to the methodological integration of quantitative and qualitative information (e.g. OSM data with big data analyses of job advertisements or company evaluations).

It will also discuss how computer-aided methods such as web mining can contribute to systematically accessing digital resources and critically reflecting on their use for social science, economic and humanities issues.

II. State Of Research: Quality of OpenStreetMap

Found data refers to data that was not collected specifically for research purposes but was originally generated for other purposes, while the opposite is primary data collected specifically as part of scientific studies. OpenStreetMap (OSM) can be regarded as "found data" in the context of firm data collection, as the information about firms is not systematically

obtained through structured surveys, but is collected through diverse, often uncoordinated contributions from different sources.

The mapping of businesses in OpenStreetMap (OSM) is based on a variety of data sources, which together determine the diversity and depth of the information available. A significant proportion of the entries come from volunteers who use their local knowledge to record points of interest (POIs) such as shops, service providers and offices directly on site and add them to the OSM database. These personal on-site surveys are complemented by the mapping of freely available aerial and satellite imagery, utilising high-resolution imagery from services such as Bing Maps to determine the exact location and structure of businesses. In addition, mass imports of open government and company data are carried out, which are integrated into the database in compliance with the OSM import rules. Such imports can include, for example, data from local authorities or other public bodies ([1]). Last but not least, organised mapping initiatives, for example by companies or non-governmental organisations, contribute to the expansion and updating of operational data in OSM through targeted collection campaigns.

Each of these sources has specific strengths and potential biases that must be taken into account when using the data for scientific analyses. The reliability of OSM in capturing and mapping firms in Germany has been the subject of numerous scientific studies (e.g. [2], [3]). These studies show that the data quality of OSM strongly depends on the geographical location: In urban areas, the completeness and accuracy of the data is generally higher than in rural regions. For example, a study by Zielstra and Zipf ([4]) found that in German cities, the coverage of OSM is comparable to proprietary geodata, while in rural areas there may be differences.

The completeness of the businesses recorded in OSM also varies. While larger retail chains and well-known establishments are often well documented, smaller or less publicised businesses are often missing. One of the reasons for this is that the collection of such data is heavily dependent on the local community and there is no systematic survey. A study by Neis et al. ([5]) emphasises the importance of active user participation for the data quality of OSM.

Various tools and methods have been developed to assess the data quality of OSM. For example, the Heidelberg Institute for Geoinformation Technology (HeiGIT) launched the "ohsome" platform in 2018, which enables a structured analysis of OSM data quality ([6]). This platform takes into account quality characteristics such as completeness, thematic accuracy and logical consistency in accordance with ISO 19157 standards.

III. Theoretical Background And Hypotheses

OpenStreetMap (OSM) is a collaborative project in which voluntary contributors collect and record geodata and make it available to the general public. These contributors - also known as mappers - are individuals or organisations who are active with different interests: from improving local map content to scientific purposes and commercial applications. While some specifically want to map their own environment in detail, others participate for altruistic or public interest motives. At the same time, there are also regions where few or no contributors are active, which can lead to uneven data coverage.

OSM is classic Volunteered Geographic Information (VGI): Data collection depends on the voluntary commitment of the population, but also on institutional imports and technical constraints. Goodchild's concept of "Citizens as Sensors" ([7]) describes precisely this area of tension between supply (data and contribution potential) and demand (benefits for user groups).

Agency districts of the Federal Employment Agency are regional areas of responsibility of the employment agencies that divide the German labour market into administratively delimited units. They are relevant for company analyses in Germany as they provide a geographical structure that can be used to systematically record company data, evaluate it in a regionally differentiated manner and link it to labour market indicators. The theoretical mechanisms originate from VGI research (participation and digital divide theories) and geodata governance. They provide hypotheses to systematically explain why some agency districts of the Federal Employment Agency in Germany (AAB) are significantly better covered with company POI in OSM than others. A combination of individual factors (digital competence, community size) and structural contexts (urbanity, open government data, economic profile) is likely to explain most of the variance.

The quality and completeness of company data in OSM varies considerably between different AAB. These differences can be explained by socio-demographic and economic structural characteristics of the regions. The following section presents a theory-based derivation of five hypotheses that address these differences. Empirical studies show that data density correlates strongly with the number of active mappers and that social and economic differences ("digital divide") limit regional participation. On this basis, the following hypotheses can be derived for the AAB:

Hypothesis 1: The more people live in an employment agency district, the better the coverage of businesses in OpenStreetMap.

The number of OSM contributions correlates positively with the population of a region. In regions with a higher population, there are more potential contributors, which leads to better data coverage. Herfort [3] show that the completeness of OSM data is higher in densely populated areas.

Hypothesis 2: The more businesses there are in the primary sector in an agency district, the poorer the coverage.

The primary sector includes businesses involved in the extraction of raw materials, the secondary sector in processing and the tertiary sector in services. Businesses in the primary sector, such as agriculture and forestry, are often located in rural areas, which tend to be mapped in less detail in OSM. This may be due to the fact that businesses with little customer contact are less likely to be the focus of mapping initiatives.

Hypothesis 3: The more businesses there are in the secondary sector in an agency district, the poorer the coverage.

Although the secondary sector is often present in urban areas, certain industrial establishments may be less well mapped in OSM due to access restrictions or low visibility to the public.

Hypothesis 4: The higher the population density in the agency district, the better the coverage.

High population density increases the probability that a location is known to mappers. This can facilitate mapping in OSM.

Hypothesis 5: The lower the average age in the agency district, the better the coverage.

Younger population groups tend to be more tech-savvy and more willing to participate in digital platforms such as OSM. A higher level of OSM contributor activity can therefore be expected in regions with a lower average age, which leads to better data coverage.

IV. Data Basis, Operationalisation and Model

A. Data basis

Empirically, a comparison has now been made of how many companies are found per AAB in the official statistics on the one hand and in OSM on the other. The Federal Employment Agency (BA) determines the number of companies with employees subject to social security contributions on the basis of employers' social security notifications. This information forms the BA's so-called company file. The notifications are required by law and are used to compile government employment statistics. It is therefore a complete survey with a high degree of reliability.

To analyse the data from OSM, it was downloaded as a file as of 2025-05-25T20:21:00Z (https://download.geofabrik.de/europe/germany.html). The query was programmed using Python by integrating libraries for processing OSM data (osmium), tabular data (pandas) and geographical data (geopandas).

In OSM, all companies with employees subject to social security contributions were also researched as far as possible. After a previous random search, all so-called nodes from OSM in Germany are selected for which one of the following tags is filled with content: 'shop', 'amenity' (maintenance, education, …), 'office', 'craft', 'industrial'. In OSM, a "node" refers to a single point, defined by its geographical coordinates (latitude and longitude).

The companies found with geo-coordinates were then assigned to the AAB. A so-called shape file from the Federal Employment Agency was used for this purpose. The BA file "Deutschland_Agenturbezirke.shp" contains the geographical boundaries and associated information of the 150 AAB in Germany. The file can be downloaded from the BA statistics website in SHP format. (https://statistik.arbeitsagentur.de/DE/Navigation/Grundlagen/Klassifikationen/Regionale-Gliederungen/BA-Gebietsstruktur-Nav.html) It was then compared which companies are located in which AAB. The number of establishments per AAB was determined and stored in a file..

B. Operationalisation

- To empirically examine the question of the extent to which OSM is suitable for drawing a representative sample of businesses, the registration rate of businesses in OSM is defined as the dependent variable. On the one hand, this rate results from the nodes or points of interest (POI) registered in OSM for businesses (see above). This number is set in relation to the number of official business census of the Federal Employment Agency (BA) statistics. In OpenStreetMap (OSM), points of interest (POIs) are specific nodes to which specific attributes are assigned in order to characterise locations of particular importance.
- Various predictors are used to explain this coverage rate. These include regional structural characteristics from the BA's regional data, including population figures and economic indicators. For the analyses, characteristics of the individual AAB were taken from tables provided by the BA on its website. These include the proportion of employees in the primary, secondary and tertiary sectors, population density, the average age of the population and the number of employees per company. Table 1 provides an overview of the key figures per AAB used in the following. Most employees work in the tertiary sector. The majority of people are over 50 years old. On average (self-calculated index from the age groups), people are 44 years old. The population density varies greatly between the AAB, ranging from 47 to 7339.5 inhabitants/km2. On average, 16 people are employed per firm.

C. Model

A linear regression model (OLS) is used for the analysis in order to quantify the influence of these predictors on the recording rate (log. number of firms according to osm per aab in Germany) in order to identify systematic differences in the recording quality between the AAB. M1 includes Log. Number of employees in official BA-statistics (1), Number of employees in primary sector, Number of employees in secondary sector and Pop. Density (2). M2 additionally includes the Index of Average age per AAB. M3 adds an interaction term between (1) and (2).

V. Results

A. Descriptive results

In order to assess the suitability of OpenStreetMap (OSM) as a data source for recording businesses, a quantitative comparison of the businesses recorded in OSM with the official register data of the Federal Employment Agency (BA) is first carried out, supplemented by an analysis of regional differences and a modelling of relevant influencing factors.

TABLE 1: KEY FIGURES FOR THE INDIVIDUAL AGENCY DISTRICTS IN GERMANY
SOURCE: OWN CREATION. BASED ON: BA STATISTICS ON THE INDIVIDUAL AGENCY DISTRICTS. N = 147 AGENCY DISTRICTS (BERLIN IS MISSING)

Variable	Mean	Std. dev.	Min	Max
% Companies prim. sector	1,0	0,8	0,0	3,6
% Secondary sector Sector	29,8	8,6	9,5	51,4
% Companies tert. Sector	69,2	8,6	48,4	90,4
Persons under 25 years of age	136361	65758	44806	476924
Persons aged 25 to under 50	177142	100968	55786	716246
Persons 50 years and older	250959	99757	99536	716990
Index Average age	43,7	1,1	40,6	46,4
Population density (inhabitants/km2)	588,6	936,5	47,2	7338,5
Employees per company	15,8	2,7	10,8	26,6

TABLE 2: COMPARISON OF THE NUMBER OF REGISTERED COMPANIES (PER DISTRICT) ACCORDING TO BA AND OSM IN GERMANY. SOURCE: OWN COMPILATION: OFFICIAL BA STATISTICS (CUT-OFF DATE 31/12/2023) AND OSM QUERY (CUT-OFF DATE 25/05/2025). N = 147 AGENCY DISTRICTS.

Variable	Mean	Std. dev.	Min	Max	Total
Number of companies according to official (BA) statistics	14443,94	10049,79	5350	99550	2.137.703
Number of businesses according to OSM	5503,13	2745,02	2143	20471	824.738

In total, approximately 39% of all firms in Germany can be identified in OpenStreetMap (OSM), assuming that the matched entries refer to the same entities. (see Table 2). This shows that, as expected, less establishments are found than are recorded in the official statistics.

However, it must be noted that this comparison is conducted at the macro level. It remains unclear whether there are false positives or false negatives in the assignments of firms at the employment agency district level. For example, establishments may be recorded that have no employees subject to social security contributions.

To assess the potential of using OSM data for social science research, a more detailed examination of the identified firms is undertaken. For follow-up surveys, the availability of identifying information – such as postal address, email address, or telephone number – is particularly important. In addition, company websites play a key role in enabling further data enrichment. The following table 3 provides an overview of the proportion of firms for which these attributes could be retrieved.

TABLE 3: % OF FIRMS IN OSM WITH. N = 824.738 FIRMS TOTAL = NUMBER OF REGISTERED COMPANIES IN GERMANY. SOURCE: OWN COMPILATION: OSM QUERY (CUT-OFF DATE 25/05/2025).

	% firms with…
Name	95
Address: city	56
Address: postcode	57
Address: street	59
Address: house number	59
Phone	27
Email	13
Fax	4
Website	29

The analysis of business entries in OpenStreetMap (OSM) reveals varying levels of detail across different attributes.

Nearly all firms (95%) are identified by name, indicating a high degree of basic recognition in the dataset. Address-related information is moderately well-represented, with 56–59% of firms including details such as city, postcode, street, and house number. In contrast, contact information is less frequently available: only 27% of firms list a phone number, 13% provide an email address, and a mere 4% include a fax number. Websites are linked in 29% of cases. These findings suggest that while core identification and location data are commonly present in OSM business entries, contact details are comparatively sparse.

In the next step, the number of firms recorded in OSM will be compared, at the level of employment agency districts, with the number of firms that should be present according to official statistics. If one looks at the correlation between the values from the official statistics and the data from OSM, you can see a clear linear correlation across the AAB (see Figure 1). The dispersion is moderate, which indicates a good mapping.

A graphical analysis shows that regions in west Germany, central Germany and north-east Germany are more likely to ikely have a higher coverage rate of firms in OSM. No data is available for Berlin due to a different data structure (see Figure 2). Some of these regions are particularly rural.

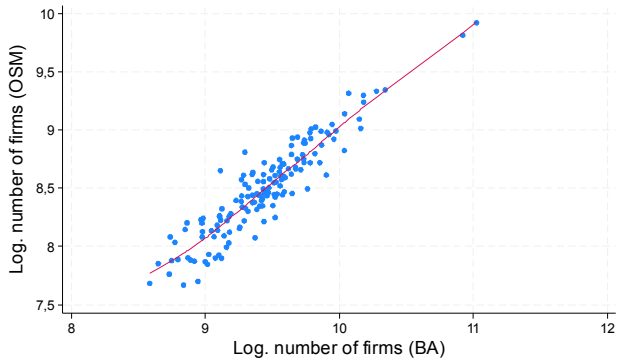

Fig. 1: Log. Number of firms per AAB according to OSM and BA in Germany, Source: Own compilation. Variables logarithmised due to skewness. n=147 agency districts.

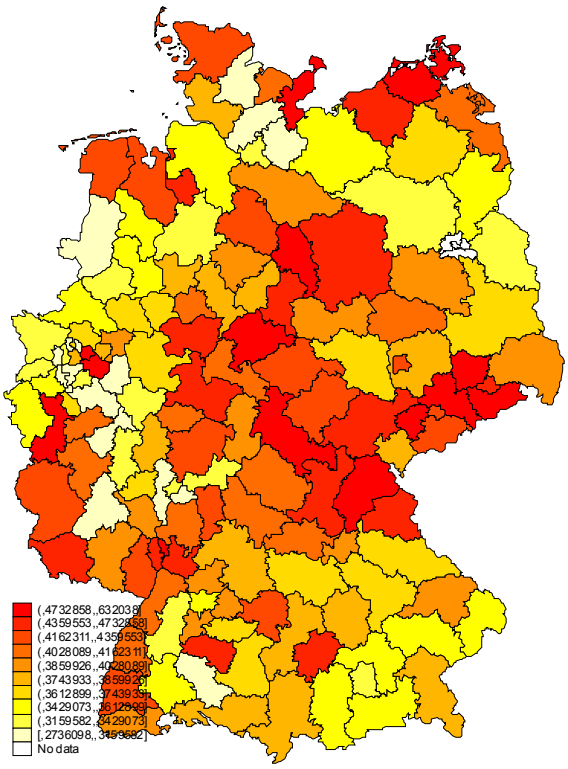

Fig. 2: higher (red) and lower coverage rate of firms (white) in OSM compared to BA in the agency districts in Germany.
Source: own compilation. The totals of the figures per agency district are compared. Berlin: no data.

B. Multivariate results

A regression model is calculated for further analysis. The dependent variable for each AAB is the logarithmised number of firms according to the OSM. The number of firms according to the BA is controlled for (Table 4).

Overall, the results show that both demographic and economic-structural characteristics have no significant influence on the completeness of voluntarily created geodata. The analysis shows no regional differences in the recording of businesses in OSM. Firstly (H1), a higher population size in the AAB does not improve the capture rate. Secondly (H2), a high proportion of firms in the primary sector, such as agriculture and forestry, does not correlate with the capture quality. Thirdly (H3), there is no correlation for the secondary sector. Fourthly (H4), a higher population density does not indicate a poorer coverage rate. Finally, there is no significant correlation between the average age of the population in the AAB and a better coverage rate.

VI. CONCLUSION

This study shows that OpenStreetMap (OSM) offers moderate coverage of businesses in Germany (about 39%). The total number of establishments recorded in OSM is not comparable to the official establishment file of the Federal Employment Agency (BA), although not necessarily the same establishments are recorded.

It was all the more important to examine whether the coverage is randomly distributed or follows a systematic pattern. The analysis shows that there are no significant regional and sectoral differences: Larger populations and lower average ages seems not to be associated with better coverage quality, while establishments in the primary and secondary sectors and regions with high population density seems not to tend to be better represented. These results illustrate both the potential and limitations of OSM for firm-related research.

Despite the limitations observed, OSM offers a fundamental advantage over traditional official registers: Because the data from the Federal Employment Agency's establishment file (BA establishment file) is based on mandatory social security data, it is generally subject to the requirements of the GDPR. Data on companies from OSM generally has no personal reference and can therefore be linked more easily with other digital resources. In addition, OSM opens up new opportunities for analysing "found data", for example by linking it to company websites, job advertisements or company valuations. These approaches enable deeper insights into company structures and dynamics that are difficult to capture with traditional surveys or register data.

For future research, an in-depth analysis of the validity and accessibility of the businesses recorded in OSM is recommended, for example by enriching the datasets with business email addresses, business websites, job adverts or telephone numbers - if these are missing. Companies could then be contacted for company surveys using contact information. Enrichment with qualitative information and text data can provide a new in-depth insight into the behaviour of companies. Improved procedures could help to systematically identify false-positive entries or the allocation of establishments as such and further increase data quality. In particular, approaches for the automated linking of OSM data with other open sources - such as knowledge graphs or web mining/web scraping of company websites - should be developed. At the same time, critical reflection is essential, particularly with regard to data protection, anonymisation and potential distortions, in order to ensure the validity and

TABLE 4: REGRESSION MODEL: LOG. NUMBER OF FIRMS ACCORDING TO OSM PER AAB IN GERMANY. SOURCE: OWN COMPILATION. N=147. MISSING AAB (MAX. 150): BERLIN (OTHER DATA COLLECTION) MODEL M2 ADDITIONALLY WITH AGE INDEX, MODEL M3 ADDITIONALLY WITH INTERACTION TERM.

	M1	M2	M3

***Abstract*—The growing demand for efficient video compression solutions underscores the increasing significance of research into coding optimization on multi-core systems.**

This paper presents the implementation and performance analysis of a multithreaded video encoder developed in Java and optimized for modern multi-core processors. The encoder performs intra-frame compression of raw YUV 4:2:0 video using a frame-based parallelism approach. This method maximizes CPU core utilization while minimizing thread management overhead.

Tests were conducted on five platforms equipped with multi-core processors from Intel and AMD. The application's execution time was measured for varying numbers of frames. The obtained results demonstrate effective scalability of the encoder as the number of processed frames increases, confirming that Java can be an effective tool for implementing parallel video compression on multi-core systems.

I. Introduction

THE INCREASING demand for efficient video processing continues to test the limits of contemporary computing platforms. Video compression is a computationally intensive task, particularly for high-resolution, high frame rate content, and achieving real-time or near-real-time performance is often essential in applications such as live streaming, video surveillance, or large-scale media processing pipelines. While dedicated hardware accelerators like GPUs are often used for such workloads [1], many real-world applications, especially in server environments, rely on general-purpose CPUs [2]. Numerous studies have explored video encoding algorithms and performance optimization techniques, providing valuable insights into how encoding efficiency can be improved through software and hardware-level enhancements [1], [3], [4].

This paper presents a performance-oriented evaluation of multithreaded video compression on modern server-grade processors using a custom-built encoder implemented in Java. Java was selected for its platform independence and robust support for multithreading, which facilitated the implementation of parallel processing using native concurrency constructs and stream-based data pipelines [5]. The encoder performs intra-frame compression on raw YUV 4:2:0 video and supports both single-threaded and multithreaded execution. Frame-based parallelism was used instead of block-based parallelism to more effectively leverage the high thread counts available on the test machines. This approach ensures sufficient workload distribution across all cores, avoiding granularity limitations that arise when the number of parallel tasks is too low. It also reduces overhead associated with thread management, allowing the encoder to scale efficiently with increasing core counts. Our evaluation measures the total encoding time, starting after the video data is fully loaded into memory and ending once the encoded file has been written to disk. As such, the performance results reflect not only the efficiency of parallel computation, but also task distribution overhead, thread synchronization, and serial operations such as output handling.

Five multicore platforms were tested, representing a range of CPU architectures and core counts. By comparing execution time and speedup across varying frame counts, we explore the strengths and limitations of each system in handling a realistic, mixed-parallelism workload. Rather than isolating idealized, parallel-only scenarios, our measurements reflect the practical end-to-end behavior of CPU-based encoding workflows.

This article is organized as follows. Section II begins with an introduction to video encoding and compression, describing the basic concepts and challenges of reducing video data while maintaining visual quality. It explains how video encoders convert raw video images into a compressed format through algorithmic steps. It also highlights the computational requirements of these processes and the importance of parallelization for performance. Section III presents the main video compression algorithms such as discrete cosine transform (DCT), quantization and motion estimation. It explains how these techniques reduce redundancy and achieve efficient compression. Section IV describes the architecture and internal structure of the encoder, detailing the modular design, block-based processing and the implementation of parallelization at the frame level using multithreading in Java. Section V describes the test environment and methodology, followed by an analysis of the performance results on different systems, comparing single-threaded and multithreaded execution. Section VI presents the conclusions from the experiments and possible directions for further research.

II. Video encoding and compression

Video encoding is a computationally demanding process that transforms raw, high-resolution video data into a compressed format suitable for storage and transmission [6]. This transformation typically involves a series of algorithmic

steps designed to reduce redundancy and preserve perceptual quality.

At the core of most intra-frame compression schemes lies a block-based pipeline consisting of the following operations [7]:

1) **Block partitioning:** the input frame is divided into fixed-size macroblocks (e.g., 16×16 pixels).
2) **Transformation:** each macroblock is converted into the frequency domain using the Discrete Cosine Transform (DCT), enabling more efficient compression by concentrating signal energy into fewer coefficients.
3) **Quantization:** DCT coefficients are scaled and rounded to reduce precision, effectively discarding less perceptually significant data.
4) **Entropy coding:** quantized coefficients are compressed using techniques such as run-length encoding (RLE) to eliminate statistical redundancy.

These stages are computationally expensive, particularly at high resolutions and frame rates. As a result, the performance of a video encoder depends not only on the efficiency of these individual algorithms, but also on how well they are integrated into a scalable execution model. Our approach focuses on frame-based parallelization, where individual frames are processed concurrently across multiple threads.

III. Transform coding of video data and reduction algorithms

TRANSFORM coding is one of the more computationally demanding steps in the encoding pipeline. This process converts visual data from the spatial domain — where it's represented as individual pixel values — into the frequency domain. It is used to isolate the components that carry the most visual weight from those that can be discarded with minimal impact on perceived quality [7]. After the transformation, we reduce the precision of the less important frequency components using quantization. This lossy compression step shrinks the file size drastically, without noticeably affecting how the video looks [8]. The specific technique we rely on for this transformation is the Discrete Cosine Transform (DCT).

A. Discrete Cosine Transform (DCT)

DCT represents a block of an image as a weighted sum of cosine waves oscillating at different frequencies. This shift from pixels to frequency components reveals a useful pattern: most of the important visual information tends to concentrate in just a few low-frequency coefficients, while the high-frequency components — often corresponding to fine detail or noise — can be compressed more aggressively or discarded entirely [9].

In a typical implementation, the process begins by dividing each video frame into smaller blocks, usually 8×8 pixels. Each of these blocks is then transformed using the 2D DCT. The result is a matrix of coefficients that describe the contribution of each frequency component within that block — the top-left corner of the matrix holds the DC (average) value, while the remaining entries describe increasingly fine detail as you move outward. This structure allows us to perform quantization more intelligently. Because human vision is more sensitive to low-frequency information, we can preserve those coefficients with higher precision and apply more aggressive compression to the less perceptible high frequencies.

Mathematically, the 2D DCT (type II, $O(N^4)$) for a block of size $N \times N$ is defined as follows:

$$Y(u,v) = \frac{1}{4} \cdot c(u) \cdot c(v) \sum_{x=0}^{N-1} \sum_{y=0}^{N-1} f(x,y) \cdot \cos\left(\frac{(2x+1)\cdot u \cdot \pi}{2N}\right) \cdot \cos\left(\frac{(2y+1)\cdot v \cdot \pi}{2N}\right) \tag{1}$$

where:

- $Y(u,v)$ is the resulting DCT coefficient at frequency indices (u,v),
- $f(x,y)$ is the input pixel value at position (x,y),
- $c(k) = \frac{1}{\sqrt{2}}$ when $k = 0$, and $c(k) = 1$ otherwise,
- N is the block size, typically 8.

One practical advantage of DCT is its separability. The 2D transform can be broken down into a 1D DCT applied first along the rows, and then along the columns (or vice versa). This significantly reduces the computational complexity ($O(N^3)$) [10].

B. DCT quantization

Once each image block has been transformed via DCT, we're left with a set of frequency-domain coefficients. While many of these coefficients — especially the ones representing higher frequencies — contribute little to the perceived visual quality, they still occupy space. Quantization reduces this burden by simplifying these values.

The process involves dividing each coefficient by a corresponding value from a quantization matrix and then rounding the result:

$$Q(x) = \text{round}\left(\frac{x}{Q_{i,j} \cdot S}\right) \tag{2}$$

Where:

- $Q(x)$ is the quantized coefficient,
- x is the original DCT coefficient,
- $Q_{i,j}$ is the value from the quantization matrix at position (i,j),
- S is a scaling factor that adjusts the compression strength.

The quantization matrix controls how much detail is kept in different parts of the image. Lower numbers in the matrix correspond to low-frequency components, which capture the general structure and smooth areas of the image—these are preserved more accurately. Higher numbers are assigned to high-frequency components, which represent fine details or noise; these are compressed more aggressively.

A commonly used quantization matrix from the JPEG standard is shown below.

$$\begin{bmatrix} 16 & 11 & 10 & 16 & 24 & 40 & 51 & 61 \\ 12 & 12 & 14 & 19 & 26 & 58 & 60 & 55 \\ 14 & 13 & 16 & 24 & 40 & 57 & 69 & 56 \\ 14 & 17 & 22 & 29 & 51 & 87 & 80 & 62 \\ 18 & 22 & 37 & 56 & 68 & 109 & 103 & 77 \\ 24 & 35 & 55 & 64 & 81 & 104 & 113 & 92 \\ 49 & 64 & 78 & 87 & 103 & 121 & 120 & 101 \\ 72 & 92 & 95 & 98 & 112 & 100 & 103 & 99 \end{bmatrix}$$

C. Motion estimation and compensation

To further improve compression efficiency, modern video encoders utilize the similarity between consecutive frames through motion estimation and compensation - processes that analyze changes between frames and predict what future frames will look like based on the movement of visual elements.

Step 1: Motion estimation. This step works by comparing two consecutive frames to identify macroblocks that have shifted in position. This is usually done by searching within a defined area of the reference frame to find the best match for each block in the current frame. Metrics such as the Sum of Absolute Differences (SAD) or Mean Squared Error (MSE) are used to evaluate how well blocks match. The result of this process is a set of motion vectors, which describe how far and in which direction each block has moved.

Step 2: Motion compensation. This step then uses these vectors to shift corresponding blocks in the reference frame to approximate the content of the current frame. Instead of encoding the full frame, the encoder stores only the difference (residual) between the predicted and the actual frame. This residual typically contains less information than the original frame.

IV. Encoder architecture

The encoder was developed in Java with a modular, object-oriented structure, centered around the core classes `VideoObjectPlane`, `Macroblock`, `Bitstream`, and `VOPHeader`. Each video frame is divided into 16x16 pixel macroblocks, which are then processed using DCT, quantization, and run-length encoding (RLE).

The encoder supports two execution modes: sequential and multithreaded. In the multithreaded version, the `ExecutorService` from `java.util.concurrent` package is used to create a thread pool that matches the number of available CPU cores. This allows each video frame to be processed independently in a separate thread, significantly improving encoding performance. Synchronization is handled through `Future` objects, which act as placeholders for the results of asynchronous tasks and allow results to be collected in order. .

Two levels of parallelism were considered during implementation: frame-level and block-level. Frame-level parallelism was chosen and implemented, with each frame processed in a separate thread. This approach aligned well with the hardware characteristics of the testing environment. While block-level parallelism was explored as a finer-grained alternative, it proved to be significantly slower, and thus not integrated into the final encoder.

The encoder processes raw video data stored in a YUV 4:2:0 file with a resolution of 1920x1080 pixels. This format represents color using separate planes for luminance (Y) and chrominance (U and V), with chrominance subsampled by a factor of two in both horizontal and vertical dimensions. Video frames are loaded using the `loadYUVFrames` function, which reads the raw data from disk, partitions it into individual frames, and converts them to `BufferedImage` objects in RGB color space. Each frame is then encoded as an `I_VOP` object, that then segments the image into individual macroblocks and compresses each block.

Each `Macroblock` object stores pixel data in the same 4:2:0 structure, with luminance represented by 256 samples and each chrominance channel by 64 samples, corresponding to the 16×16 luminance block and its associated 8×8 chrominance blocks. These values are stored in separate one-dimensional arrays for Y, U, and V components and are extracted during macroblock construction from the input RGB image via internal color space conversion. Internally, the pixel data is converted from RGB to YUV, then further processed into 8x8 sub-blocks for DCT and quantization. The DCT implementation uses separable 2D transformation with precomputed cosine values for efficiency and relies on double-precision arithmetic to maintain numerical accuracy during computation.

The result of the encoding process is stored in a binary file, written using the custom `Bitstream` class. The output maintains the original block order thanks to the use of `Future.get()`. This ensures deterministic output even when block processing completes in a different order.

The entire encoder was developed using standard Java libraries, including `java.util.concurrent` for parallelism and `java.awt` for image handling. Due to its modular architecture, the system can be extended in the future with additional features, such as motion estimation for inter-frame coding or dynamic encoding strategies based on scene characteristics like `Video Objects`.

V. Performance analysis and test environment

To evaluate the performance of the implemented video encoder, a series of experiments were conducted on five different computing platforms, each equipped with a distinct server-grade processor, selected to cover a range of architectures, core counts, and generations:

- **C1 (2 x Intel Xeon E5-2670 v3)** – 12 cores / 24 threads, Haswell-EP architecture (22 nm), released in 2014. An older platform with limited performance compared to modern standards.
- **C2 (2 x Intel Xeon Gold 5218R)** – 20 cores / 40 threads, Cascade Lake Refresh (14 nm), released in 2020. A mid-range server CPU offering a good balance between core count and clock speed.

- **C3 (2 x Intel Xeon Gold 6342)** – 24 cores / 48 threads, Ice Lake-SP architecture (10 nm), released in 2021. With improved single-core performance and memory bandwidth support.
- **C4 (2 x Intel Xeon Platinum 8358)** – 32 cores / 64 threads, Ice Lake-SP architecture (10 nm), released in 2021. High core density suited for parallel workloads.
- **C5 (2 x AMD EPYC 9654)** – 96 cores / 192 threads, Zen 4 (Genoa) architecture (5 nm), released in 2022. A high-end processor optimized for massive parallelism and throughput.

Each system processed a standard YUV 4:2:0 1920x1080 video file, with frame counts ranging from 250 to 2000 for the multithreaded (MT) version[1] and from 250 to 1500 for the single-threaded (ST) version[2].Depending on the number of frames, the size of the test files ranged from approximately 741 MB (250 frames) to 5.79 GB (2000 frames). This setup allowed for the analysis of both raw execution time and scalability with increasing frame counts.

To quantify the performance gain achieved through parallelization, the speedup factor was calculated as the ratio of the single-threaded execution time to the multithreaded execution time:

$$S = \frac{T_{\mathrm{ST}}}{T_{\mathrm{MT}}}. \tag{3}$$

The performance data collected across all tested platforms is summarized in Table I, which lists the minimum measured processing times for both single-threaded and multithreaded executions, along with the computed speedup values. The results are presented for increasing frame counts, illustrating how processing time scales with input size. Speedup values were calculated using equation 3. Figures 1 and 2 visualize the speedup and multithreaded processing times across all systems, respectively, providing a comparative view of scalability and performance gains with increased threading and workload.

In general, all platforms demonstrate substantial performance improvements from multithreading, with speedup tending to increase as the number of processed frames grows. However, the magnitude and consistency of these gains vary across systems. Notably, some platforms—particularly `C2` `C3`, and `C4` —exhibit a plateau or even slight dip in speedup around mid-range workloads (750 to 1250 frames), indicating that the platforms either have, or are close to reaching their maximum effective scaling and additional workload does not significantly improve parallel efficiency.

Among the tested systems, the AMD-based `C5` platform initially shows comparatively modest speedup at lower frame counts, which can be attributed to the overhead of managing its high core count when the workload is too small to fully utilize the available resources. As the workload increases, `C5`'s scalability becomes clear: by the 1500-frame mark, it surpasses all other platforms in speedup and achieves the shortest absolute multithreaded processing time at 2000 frames.

Interestingly, `C1`, despite having the poorest absolute processing times, consistently achieves the second highest speedup among all platforms. This indicates that while its baseline single-threaded performance is limited, it benefits strongly from multithreading, scaling efficiently with increasing workload size. In contrast, `C2`, which also features fewer cores, shows more consistent but lower speedup values, plateauing around 12 to 13× speedup across moderate to larger frame counts, and is eventually outperformed by more scalable systems at higher workloads. `C3` and `C4` occupy a middle ground, maintaining solid and relatively stable speedup improvements that exceed those of `C2`, yet do not quite match the top-end performance and scalability of `C5` at larger frame counts.

VI. Conclusion

This work aimed to design, implement, and evaluate a multithreaded video encoder in Java, capable of leveraging the parallel processing capabilities of modern multicore architectures. In pursuit of this goal, the encoder was developed using a modular, object-oriented structure in Java, incorporating key compression techniques such as the Discrete Cosine Transform (DCT), quantization, and run-length encoding (RLE). The implementation included both single-threaded and multithreaded execution modes, enabling a comparative analysis of encoding performance across different hardware platforms and workloads. A series of experiments were conducted using five server-grade systems with varying core counts and architectures, focusing on the encoding of high-definition video data in YUV 4:2:0 format. The objective was to assess the scalability and performance benefits of multithreading for video encoding tasks.

The results demonstrate that all tested CPUs benefit substantially from multithreading, with speedups ranging from approximately 9x to over 24x depending on the system and workload. Among them, `C5` achieved the highest ultimate acceleration, peaking above 24× speedup at larger frame counts, demonstrating superior scalability on high concurrency workloads despite initially modest gains at lower frame counts. Notably, `C1`, despite having the slowest absolute processing times, consistently achieved the second highest speedup, indicating efficient scaling relative to its baseline single-threaded performance. `C3` and `C4` maintained solid and relatively stable speedup improvements, exceeding `C2`'s generally lower but consistent gains, which plateaued around 12 to 13× at moderate to large workloads.

Importantly, our measurements suggest that raw core count alone does not fully explain observed performance. Differences in scaling behavior—especially how speedup grows with frame count—highlight the role of thread orchestration overhead and single-threaded efficiency in managing output and coordination. For example, while `C5` initially showed lower speedup at small workloads, it ultimately surpassed

[1]A total of 2000 frames were used for testing. This value was chosen as the maximum that could be reliably loaded across all systems, given their varying available memory.

[2]Due to long processing times, the single-threaded encoder was only tested up to 1500 frames.

TABLE I

several peers as the workload increased, indicating superior multithreaded scalability at higher concurrency levels.

These findings validate the need to assess full-system performance for parallel workloads, not just isolated parallel execution paths. In practice, the total encoding time is shaped by how well a CPU balances parallel computation with effective scheduling and sequential operations. This is especially relevant in environments without GPU acceleration, where CPUs must take on end-to-end responsibility for video processing.

Future research may explore extending the encoding model to include inter-frame prediction, introducing more complex dependencies across frames, or benchmarking hybrid CPU-GPU configurations. Nevertheless, this work offers a grounded perspective on CPU capabilities in a realistic, high-throughput encoding pipeline, and serves as a foundation for further exploration of CPU-bound multimedia processing.

***Abstract*—Vision-Language (VL) models have gained significant popularity in recent years for tasks involving data extraction and image recognition. In this paper, we introduce reVISION, a large-scale Polish benchmark for evaluating such models, comprising over 39k questions extracted from Polish national exams. We assess both the models' general knowledge and their ability to handle tasks that go beyond plain text, including tables and the recognition of specialized visual objects. Our study also examines the effects of image resizing and the inclusion of additional context via OCR-extracted text. To explore the correlation between human and model performance, we compare their results across multiple exam years.**

I. Introduction

FROM the very beginning, Large Language Models have been evaluated using exam-like tests based on multiple-choice questions, as exemplified by the MMLU benchmark created specifically for assessing capabilities of GPT-3[7]. MMLU was popular among LLM practitioners despite its inconsistencies and even outright errors [6]. A more principal way to build LLM benchmarks was proposed by [8], where the benchmark was created using Polish national exams.

Currently, many LLMs are actually not only about language, but they are multi-modal models, handling both language and vision. Again, a natural need to evaluate them in a systematic manner and an idea to use real-life exams remains valid, as actually a significant part of exam questions uses 2D layout and images (tables, graphs, diagrams, etc.). In this paper, we extend the ideas put forward by authors [8] to the bimodal (text and vision) domain, by preparing reVISION, a new comprehensive benchmark for measuring the quality of VL models.

Figure 1 shows an example of a difficult physics question extracted from the 2014 high school exam, which both Qwen2.5-VL-72B-Instruct and GPT-4.1 failed to answer correctly. In contrast, Figure 2 presents an easier question from the 2020 professional exam, which was correctly answered by both models.

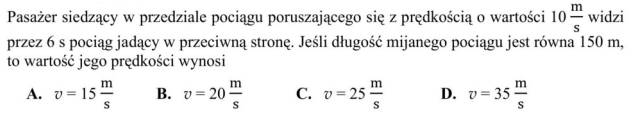

Fig. 1: Example of a difficult question from the 2013 high school physics exam. The question states: A passenger sitting in a train compartment moving at a speed of 10m/s sees, for 6 seconds, a train traveling in the opposite direction. If the length of the passing train is 150m, what is its speed?

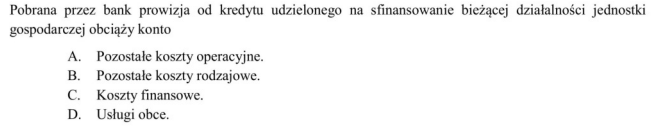

Fig. 2: Example of an easy question from the 2020 professional exam. The question states: The commission charged by the bank on a loan granted to finance the current operations of the business entity is recorded under the account: A. Other operating costs. B. Other cost types. C. Financial costs. D. External services.

Our contributions consist in stating and answering the following questions:

- How effectively do vision–language (VL) models answer Polish exam questions?
- How do VL models compare to human performance?
- How do visually grounded questions differ from text-based questions?
- Does resizing images to reduce computational cost affect model performance?
- Does providing additional context in the form of OCR-extracted text improve model accuracy?

II. Related work

Ever since the introduction of the first vision-language (VL) models [12], their performance has been continually challenged using a variety of benchmarks. Assessing their capabilities is

crucial for selecting the appropriate model for the task at hand. These evaluations range from testing object, attribute, and relation recognition [16] to performance on multi-disciplinary tasks [14]. Despite the diversity of tasks, all benchmarks share a common goal: to identify and compare models in order to determine which performs best in a given category.

LLMzSzŁ [8], a previous work that relied heavily on Polish exam questions, addressed the need for Polish-language benchmarks in the research landscape. It demonstrated the importance of academic datasets and benchmarks that capture the linguistic specificity of languages like Polish. By incorporating visual information, we aim to support the development and evaluation of multimodal models in the Polish-language context, extending the capabilities of previous text-only benchmarks.

Previous work such as EXAMS-V [4] emphasizes the need for benchmarks that assess curriculum-specific knowledge. The EXAMS-V dataset consists of thousands of multilingual exam questions. The authors highlight the dataset's difficulty, noting that even the most advanced models, such as GPT-4V and Gemini, struggle with it. While Polish professional exams are included in the benchmark, they account for just over 2.5k questions. In this paper, we focus on expanding the number and variety of questions while narrowing the language scope to a single language, while using clear criteria for inclusion and future extensions. Similarly, M3Exam [15] provides a multilevel benchmark composed of human exam questions. The study demonstrates that models face challenges when processing multilingual texts, particularly in low-resource languages.

III. Dataset

A. Data sources

Each year in Poland, three types of national exams are conducted to assess the knowledge of Polish students: the eighth-grade exam, the high school exam, and professional exams. The middle school exam, which was part of the Polish education system prior to recent educational reforms, was also considered when preparing the data sources. After each exam session, the exams are published by the Polish Central Examination Board (Pol. CKE, Centralna Komisja Egzaminacyjna). These archives provided us with access to both questions and answers from a reliable source, ensuring the high quality of our dataset.

B. Data selection

The primary constraint considered when selecting documents for dataset preparation was the number of closed-ended questions with a single correct answer. This approach eliminated the need for a larger model or human annotators as judges, enabling us to focus solely on extracting one type of question while ensuring objectivity by removing emotional bias and personal preferences. Since many types of exams were heavily focused on open-ended answers, we decided to exclude them from further processing. This strict elimination process resulted in the following categories: math, natural sciences, biology, physics, and the Polish language for pre-high school questions, and arts, mechanics (including mining and metallurgy), and agriculture (including forestry) for professional exams.

C. Dataset preparation

The preparation of the dataset began with downloading the exams that were made public over the years. We automated this stage using basic web scraping methods and Python scripts. All exams were published in PDF format, with their answers in separate files, making it crucial to track which question file corresponds to which answer file.

To extract all the questions from a single PDF file, we first had to determine the accurate X-axis positions of each question. We took a single page of the file in order to test the techniques for position extraction. Our initial approach was to prompt a multimodal model with an image and have it extract the bounding boxes of entire questions. However, this proved ineffective as multimodal models, although good for OCR text extraction, cannot accurately pinpoint and return text positions even on small images. Having this in mind, we decided to use an OCR engine, specifically PaddleOCR[1], that can extract text, precisely draw its bounding boxes, and return their positions. In this way, we identified the text indicating the beginning of a question. For most exams, the keyword was 'Task' (Pol. *Zadanie*). If the word appeared above the actual task, we used the lower X-axis of 'Zadanie' as the starting position of the task; otherwise, we used the upper X-axis. The upper X-axis of the next question was used as the ending position. The images were then cropped along those axes.

When initially testing on entire exam documents, we attempted to convert the entire PDF file into a single long image and then used an OCR engine to detect text. However, this approach proved ineffective, as the engine was unable to detect any text in the image. The issue arises primarily due to the extreme aspect ratio of the images. OCR engines are typically optimized for standard-sized documents and conventional aspect ratios. A more effective approach was based on the fact that each question had to be contained on a single page, making it possible to split the document into individual pages, convert them into images, and then detect tasks within them. After fine-tuning the detection and splitting process to match each exam type, we were able to extract almost 40,000 images, each containing exactly one question. This figure reflects the results after a cleaning process, which involved removing approximately 30% of the original questions, primarily due to duplication, with a smaller portion removed for issues such as poor cropping. The cleaning process was fully automated, involving the removal of duplicate images by comparing the OCR-extracted text from each image. Images containing no text or lacking answer options labeled A, B, C, and D were also removed. To ensure the accuracy of the cleaning process, random samples were extracted from the dataset for manual verification.

The second-to-last step in the preparation of the dataset was to match the questions with their corresponding answers. We

[1]https://github.com/PaddlePaddle/PaddleOCR

used a simple PDF text extraction tool and cleaning scripts to extract answers from Professional Exams files, as the format of the answer key has remained consistent over the years. For other exam types, the answers were manually extracted.

Once the dataset was nearly complete, we decided to add more metadata, specifically indicating whether a task requires additional data, such as an image or table, to answer the question, or if it is entirely text-based. To automate this task, we utilized the Qwen2-VL-7B-Instruct[2] model to analyze and classify the questions. We used the system and user prompt shown below.

```
System prompt:
    You will see a picture of a Polish
    task.If there is more than just a
    text in the image, like an image,
    table, etc, return true. Otherwise
    return false. Respond ONLY with
    'true' or 'false'.

User prompt:
    Does this task need an image
    for context?
```

Table I presents the hardest professional exams categories. A more detailed analysis of these categories is provided in Section V-C.

D. Documents cropping as a tool for building text-based datasets

Dividing a set of questions into individual items can be useful not only for creating image-based datasets but also for constructing textual datasets. When using an OCR engine to extract text from questions that do not require visual context for understanding, the post-processing effort can be significantly reduced compared to standard text extraction techniques, as the data is already segmented into more manageable chunks.

The growing popularity of using multimodal models as a means for data extraction, particularly with the use of Structured Outputs[3], opens up the possibility of generating structured datasets that require minimal or no post-processing. Feeding data to a model in smaller units, rather than entire document pages, can improve the accuracy of data extraction and analysis.

E. Dataset summary

To better understand the finalized dataset, a numerical representation of its potential size and actual results will be given now. Starting with the lowest extraction rate, the 8th-Grade Exams achieved a 27.5% extraction rate. This was followed by the High School Exams at 42.9%, the Middle School Exams at 61.7%, and the Professional Exams with the highest rate of 67.7%. Until 2012, Mathematics and Nature were combined in the middle school exams, resulting in a joint discipline. Table III presents the exact number of questions for each exam and discipline, while Table IV presents the distribution of answer options in the dataset.

F. Dataset availability

The dataset will be publicly available on the Hugging Face page.

IV. Evaluation

A. Evaluation harness

The tool we used to assist with model evaluation was lmms-eval [5] [10], a fork of LM Evaluation Harness[6] [5] framework. Each model was prompted with the following task (in English) in addition to being shown the image:

```
Answer the Polish exam question from
the image. Answer with the good answer
letter only. Possible answers are
A or B or C or D.
```

The evaluation was carried out using two different approaches. The first approach involved resizing the images so that their longest side was 512 pixels, while preserving the aspect ratio and readability. This resizing was performed not only to save memory and reduce computational overhead, but also to evaluate the consequences of image resizing, which are discussed later in the paper. In the second approach, models were evaluated using full-size images to assess their full capabilities. All analyses presented later in the paper are conducted using the outputs from full-sized images.

A common approach for selecting a model's answer involves extracting the log-likelihoods—or probabilities—of each possible option. However, this functionality was not implemented for all of the models evaluated. Therefore, we generated the answers in text format and processed them post hoc by stripping any punctuation or extraneous content beyond the answer letter.

Questions with answers other than A, B, C, or D were excluded from the evaluation. This prompting strategy also simulates a more realistic usage scenario, reflecting how such models are often used in everyday applications.

B. Evaluated models

For the general evaluation on resized images (the 1st approach), we selected 18 different open-weight models across 7 model families, with sizes ranging from 2 billion to 72 billion parameters. We also included one closed-weight GPT model in the evaluation.

GPT 4.1: gpt-4.1-2025-04-14 [7]

Qwen: Qwen2.5-VL (3B-Instruct, 7B-Instruct and 72B-Instruct) [2], Qwen2-VL (2B, 2B-Instruct, 7B and 7B-Instruct) [13]

Answer Option	Count	Percentage (%)
A	9,564	24.3
B	10,235	26.0
C	10,075	25.6
D	9,457	24.0
Other	15	0.04
Total	39,346	100.0

Llava-HF: 1.5 (7B and 13B), v1.6 (Mistral-7B and 34B), NeXT (Llama3-8B and 72B) [11]

Phi: Phi-4 [1]

Idefics2: Idefics2 (8B and 8B–chatty) [9]

InstructBLIP: Vicuna-7B

C. Cropped images results

The general accuracy of the evaluated models on resized images is summarized in Table V.

As shown in the table, the Qwen models dominate this part of the evaluation, despite being trained primarily on English and Chinese data. All other models tend to hover around the 25% random-guess baseline. The Qwen2-2B model began generating random tokens instead of answering the questions, which explains its low accuracy score.

The LLaVA models, even in their largest 72B variant, demonstrate that model size alone is insufficient; the quality and relevance of the training data are the primary determinants of performance. These models, trained on English data, achieve at most 28.06% accuracy.

TABLE V: Performance of models on images resized to 512px

Model	Size	Acc. (%)
Qwen/Qwen2.5-VL-72B-Instruct	72B	60.56

D. Full image results

As seen in Table VI, model accuracy approaches practical usefulness only for larger models, such as GPT-4.1 and Qwen2.5-VL-72B-Instruct. Other models, even those that performed above the guess rate of 25%, still yield unsatisfactory results. These findings highlight the need for benchmarks like this one to rigorously evaluate model performance on real-world tasks. Moreover, they underscore the substantial room for improvement in smaller or mid-sized vision-language models.

E. To resize or not to resize

Depending on the model version, the performance gains from using high-resolution images vary. The Qwen2.5 models show modest improvements of just over 10%, while the Qwen2 models demonstrate increases approaching 40%. Notably, models that perform poorly on resized images tend to see limited improvement even when image quality is not altered.

These findings suggest that when image downscaling is necessary, newer model versions should be preferred to mitigate the negative effects of reduced image quality.

V. Results Analysis

A. Confusion analysis

To better understand the models' "thinking" processes—that is, the sequence of statistical and text-processing steps they use to generate answers—a deeper analysis of their answer choices is required. Each confusion matrix in Figure 3 illustrates the relationship between the true answers (y-axis) and the answers predicted by the models (x-axis). This enables a granular examination of how frequently the top three performing models confuse specific answer options.

One of the most notable insights from these matrices is the visual representation of the models' uncertain guesses. While

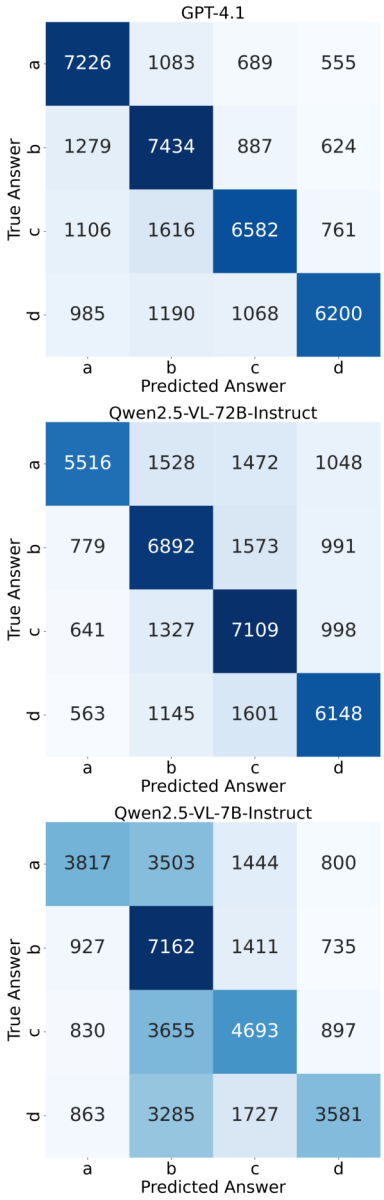

Fig. 3: Confusion matrices for different models.

the GPT model demonstrates the best overall performance across most answer classes, it is slightly outperformed by the 72B Qwen model on questions with "c" as the true answer. When uncertain, GPT exhibits a bias toward selecting earlier answer options, with the likelihood of selection decreasing progressively across the choices. Notably, it appears to almost avoid choosing the furthest option, "d", under uncertainty.

The Qwen models tend to favor the middle answer choices when in doubt. The larger 72B model most frequently guesses "b" or "c" under uncertainty, reflecting a moderate central bias. In contrast, the smaller 7B model exhibits a strong preference for answer "b," even to the extent that it accidentally outperforms the larger model in predicting this specific answer.

TABLE VII: Performance of vision-language models on visual- and text-based tasks.

Model	Visual Acc. (%)*	Text Acc. (%)*
GPT-4.1	65.47	73.07
Qwen/Qwen2.5-VL-72B-Instruct	59.09	69.98
Qwen/Qwen2.5-VL-7B-Instruct	44.72	52.19
Qwen/Qwen2-VL-7B-Instruct	42.74	49.71
Qwen/Qwen2.5-VL-3B-Instruct	38.35	43.32
Qwen/Qwen2-VL-7B	36.21	43.92
Qwen/Qwen2-VL-2B-Instruct	30.55	32.64
microsoft/Phi-4-multimodal-instruct	28.33	29.11
OpenGVLab/InternVL2_5-8B	28.37	28.71
llava-hf/llava-next-72b-hf	27.14	29.09
llava-hf/llava-v1.6-34b-hf	24.87	26.88

llava-hf/llava-v1.6-mistral-7b-hf	23.72	24.71
llava-hf/llama3-llava-next-8b-hf	23.21	24.95
Qwen/Qwen2-VL-2B	23.42	17.47

*Task classification is based on automated labeling with an estimated 12.2% error rate. See Section V-B for details.

This pronounced bias suggests a reliance on heuristics or a limited ability to disambiguate between options in uncertain scenarios.

B. Visual vs. Text-Based Tasks

To confirm the accuracy of Qwen's classification of images that require additional context, such as a picture or table, a random sample of 1,000 images was selected for manual verification. The verification revealed that 122 of the 1,000 images were misclassified, with the vast majority being false positives (120 out of 122). This disproportion may indicate that the prompt did not sufficiently guide the model to identify tasks requiring additional context. All subsequent tables that report model results based on the image-context grouping should be interpreted in light of an estimated 12.2% labeling error, with a 95% confidence interval ranging from approximately 10.2% to 14.2%. While this level of error is acceptable for exploratory analysis and broad grouping, it is not sufficiently accurate for training downstream models. We therefore emphasize that findings based on this stratification are preliminary and should not be overinterpreted without more precise annotation.

Out of 39,331 questions considered when calculating the accuracy of the models, 17,058 were marked as visual-based and 22,273 were marked as text-based. Table VII shows results of each model both on visual- and text-based tasks.

With few exceptions, most of the tested models exhibit higher accuracy on text-based questions compared to those requiring visual context. This discrepancy stems from the fact that vision-language models are still primarily trained on textual data and are less focused on the deep analysis of figures, tables, or the recognition of specific and highly niche objects. Visual tasks often demand fine-grained perception, complex reasoning, and the integration of visual features with language understanding. Even the most advanced models evaluated remain far from achieving human-like reasoning and multidimensional understanding. This performance gap underscores the limitations of current multimodal training approaches and highlights the need for more diverse, richly annotated datasets that better capture the complexities of visual reasoning.

C. Professional Exams categories analysis

This analysis was conducted on the top 10 best-performing models, as it required a level of domain knowledge sufficient to demonstrate informed responses rather than mere guessing. There are 150 unique category codes, and for the easiest and hardest analyses, the codes that appeared most frequently among the top 20 easiest and hardest categories for the selected models were identified. The proportion of visually-based tasks was also considered when assessing question difficulty, as text-based tasks were generally easier for the models to answer as shown in Section V-B. This led to the exclusion of categories with more than 70% visual tasks among the hardest categories, and less than 30% visual tasks among the easiest categories. These thresholds were selected to create a clear contrast between predominantly visual and predominantly text-based categories, while also preserving a sufficient number of categories to support a robust and meaningful analysis. These thresholds were selected to create a clear contrast between predominantly visual and predominantly text-based categories, while also preserving a sufficient number of categories to support a robust and meaningful analysis.

The most challenging categories were closely tied to the limited availability of widely accessible resources for model training, particularly those that are highly niche and vocational. Eight categories fell into this group, the most difficult of which were *Protection and Management of Forest Resources* and *Exploitation of Underground Deposits*.

The knowledge required to become one of these specialists is heavily underrepresented in training corpora and typically demands extensive hands-on experience and practical training.

In contrast, most of the easiest categories belonged to the broader domain of mechanics. Notably, Shipbuilding works—a subcategory within this domain—appeared among the top 20 easiest categories in nine models. With approximately 1.64 billion cars in the world, mechanical data is widely available and has certainly been included in model training. The second easiest domain was *Environmental Protection*, a highly discussed topic, particularly in today's context of increasing global awareness and concern.

VI. Comparison against humans

Comparing the accuracy of Multimodal Language Models to exact human performance is not feasible, as human results are published only for entire exams rather than individual questions for all but the High School exams. All exams, except for the Professional exams, contain a significant number of open-ended questions, which were not included in our dataset.

Additionally, some closed-ended questions may have been excluded from the dataset due to the postprocessing described earlier. Data on human performance in professional exams were extracted from the WaszaEdukacja website[8], which is not affiliated with the Central Examination Board (CKE). Therefore, the exam content presented on the site may not fully correspond to the official questions used in the models' evaluation. The purpose of this section is not to compare human knowledge to model performance directly, but rather to evaluate whether the difficulty reflected in human performance for a given year aligns with the general performance of the models—even if the exact questions differ. This type of analysis applied to textual exams dataset has been proposed and shown to correlate well with human performance in [8]. For the visualized models performance, the top 3 performing models were chosen: GPT-4.1, Qwen2.5-VL-72B-Instruct and Qwen2.5-VL-7B-Instruct.

A. Eighth-grade exam

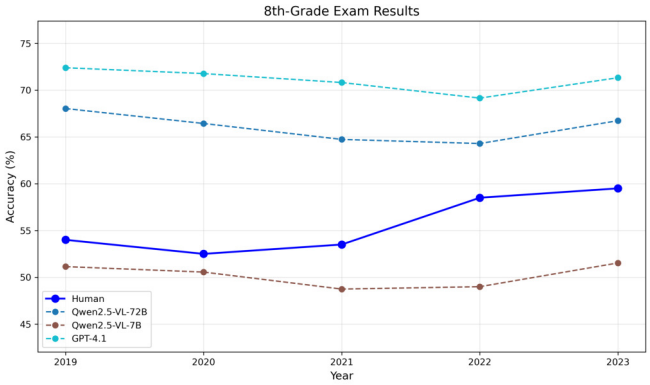

Fig. 4: 8-th grade selected models results compared to average human results.

In the combined results from all 8th-grade question categories—grouped due to the limited number of questions available for individual analysis—the GPT model emerges as the top-performing model. All models exhibit similar year-to-year fluctuations in accuracy, differing primarily in their overall performance levels. GPT achieves an average accuracy of 69.87%, while the Qwen models follow with 64.48% and 48.99%, respectively. A notable divergence between human and model performance occurred between 2020 and 2022, where the average human accuracy improves compared to the previous years, all the evaluated models experience a decline in performance.

[8]https://waszaedukacja.pl/egzaminy/zawodowy

B. Middle school exam

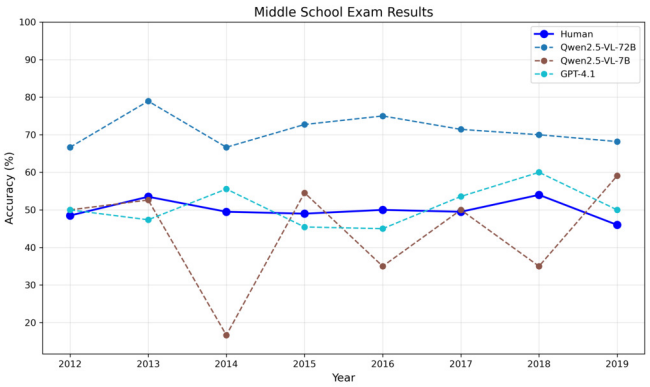

Fig. 5: Middle school selected models results compared to average human results.

Qwen2.5-VL-72B performs exceptionally well on the Middle School exams, achieving an impressive average accuracy of 77.14%, clearly leading among the evaluated models. In contrast, GPT-4.1 achieves a more modest average accuracy of 58.02%, aligning more closely with the smaller Qwen2.5-VL-7B model, which scores 51.98%. Interestingly, the performance of the 72B Qwen model mirrors the trend of human results across the years, with the exception of 2018, where a noticeable deviation occurs. GPT-4.1 maintains accuracy levels generally comparable to human performance, while the Qwen 7B model exhibits high variability—ranging from below 20% to as high as 60%—indicating inconsistency in its performance across exam years.

C. High school exam

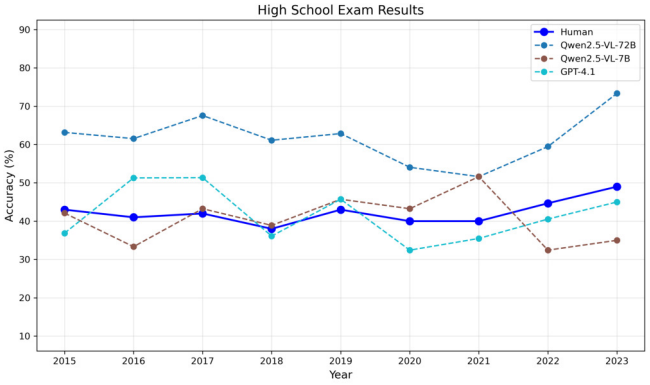

Fig. 6: High school subjects selected models results compared to average human results.

For the high school exams, the Qwen2.5-VL-72B model's performance mirrors the overall trend of human performance over the years, with rises and declines occurring in parallel, though at a different absolute level of accuracy. In contrast, the other two models hover around the human performance baseline, with GPT-4.1 achieving an average accuracy of 53% and Qwen2.5-VL-7B scoring 47.34%.

D. Professional exam

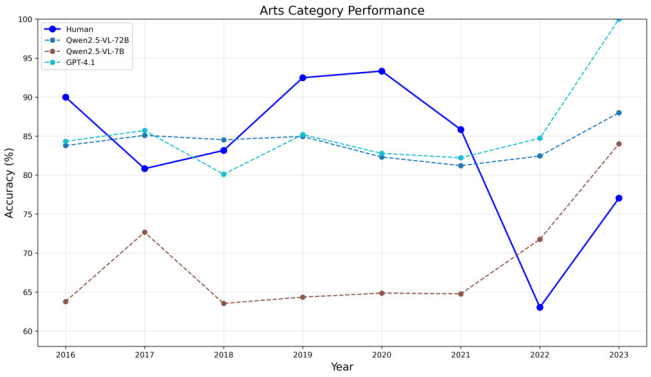

Fig. 7: Arts selected models results compared to average human results.

1) Arts: In contrast to the models' performance, fluctuations in human accuracy are particularly noticeable in the arts professional exams. The two best-performing models consistently maintain accuracy above 80%, while human performance occasionally drops below 65%, highlighting a significant performance gap in this category.

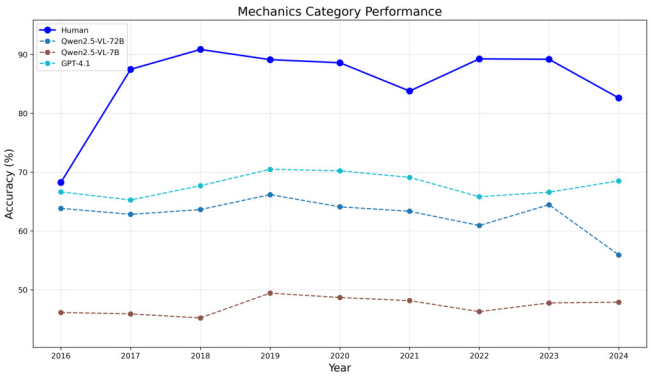

Fig. 8: Mechanics (including mining and metallurgy) selected models results compared to average human results.

2) Mechanical, Mining and Metallurgical: In the mechanical category, human performance significantly surpasses that of the models, indicating that in highly specialized domains, models still underperform and have considerable room for improvement. All models exhibit similar trends of rising and falling performance over time, though at different levels of average accuracy. This consistent fluctuation pattern across models suggests a correlation between model size (i.e., number of parameters) and overall performance, with larger models achieving higher accuracy while following the same performance trajectory.

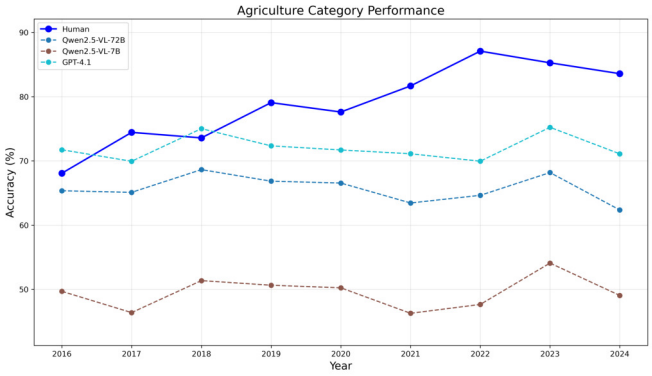

Fig. 9: Agriculture (including forestry) selected models results compared to average human results.

3) Agriculture and Forestry: The accuracy trends for models and humans on agricultural exam questions appear to move in opposite directions: while human performance steadily improves over the years, model performance consistently declines. This contrast highlights the limitations of using vision-language models as a benchmark for assessing exam difficulty. It suggests that what may seem harder for a model may, in fact, be easier for a human—and vice versa—underscoring the fundamental differences in reasoning strategies and domain familiarity. This emphasizes the need for caution when relying on model-based metrics in educational evaluation or exam design.

VII. Additional OCR context

In this section we will try to answer the question if prompting the model with additional context from the image—in the form of Optical Character Recognition (OCR)-extracted text—can improve its accuracy and overall performance. Including OCR-extracted text from the image in the prompt itself can enhance model performance by providing additional context that may not be captured through visual input alone, bridging the gap between modalities. To encourage the model to utilize this additional information when answering the question, we appended the following text to the prompt:

```
Use the OCR text as well as the image
to answer the question. OCR text:
```

The following models were selected to evaluate the benefits of additional context: **Qwen2.5-VL-7B-Instruct**, **Qwen2-VL-7B**, **Qwen2-VL-7B-Instruct**, **Llama3-llava-next-8b-hf**, **Phi-4**.

For the OCR engine, EasyOCR [9], was used, as it handles Polish characters more effectively than the previously used PaddleOCR. The text indicating the beginning of each question did not contain any Polish letters, so the earlier use of PaddleOCR did not result in processing errors. The extracted text was provided in the prompt verbatim, without any post-processing. The OCR was performed on the original, pre-resize image.

[9]https://github.com/JaidedAI/EasyOCR

A. Results

Across the tested models, only the Phi-4 model exhibited notable improvements when prompted with additional OCR context. This outcome may be attributed to its modular architecture, which employs separate adapters (LoRAs) for vision, speech, and text. Phi-4 processes each modality independently and integrates them later, enabling more effective fusion of external textual input with visual features.

Interestingly, the Qwen2-VL-7B-Instruct model showed a decrease in performance with the additional OCR context. This suggests that the injected text may have conflicted with the model's internal visual interpretation, potentially leading to confusion or interference during reasoning. Unlike Phi-4, Qwen models use a single vision encoder that processes visual inputs and aligns them with textual representations via rotary embeddings before feeding the combined data into a unified Transformer stream.

The overall results suggest that, while promising in theory, incorporating OCR context when processing images of questions does not consistently improve model performance and may, in some cases, degrade it. Nevertheless, the observed gains in Phi-4 underscore that, when properly integrated, OCR context can enhance performance. Therefore, it is important to continue exploring modality-specific architectures and training strategies.

TABLE VIII: General performance of selected models with additional OCR context

Model	Acc.	OCR Acc.	Increase
Qwen2.5-VL-7B-Instruct	48.95	50.24	+2.64%
Qwen2-VL-7B	40.58	40.84	+0.64%
Qwen2-VL-7B-Instruct	46.69	46.16	-1.14%
Llama3-llava-next-8b-hf	24.19	25.07	+3.64%
Phi-4	28.77	31.46	**+9.35%**

VIII. Limitations

While this benchmark is a necessary step toward assessing a model's knowledge, it evaluates only the model's final answers to closed-ended questions and does not account for the reasoning process behind those answers. Although the provided responses may be sufficient for tasks such as assisting a student in finding a correct answer, they fall short in educational contexts where the underlying reasoning is also evaluated. In such scenarios, a model might provide the correct answer but fail to justify it coherently, potentially misleading users about its understanding. Additionally, the dataset used in this benchmark represents idealized conditions in which all questions are fully visible and neatly typewritten. As a result, the benchmark assesses visual recognition only within these controlled parameters and does not reflect the broader variability encountered in real-world visual inputs, such as handwritten notes, partially obscured text, or classroom environments.

One of the previously mentioned issues is the error rate in Qwen's visual-context task recognition. Although the classification was sufficient for simple comparisons and provided some insight into the increased difficulty compared to text-only tasks, the error rate may render the data unsuitable for other applications.

***Abstract*—This survey reviews AI goals and tools for: (1) preparing educational materials, (2) interacting with teachers and students, and (3) assessing the results and providing feedback with (semi-)automatic methods. As a summary, we provide the crucial challenges to be tackled and discuss the associated ethical concerns.**

***Index Terms*—Artificial Intelligence, Automated Assessment, Higher Education, Large Language Models, Learning Analytics**

I. Introduction

RECENT advancements in Artificial Intelligence (AI) and Natural Language Processing (NLP), particularly the rise of Large Language Models (LLMs), have transformed human-computer interaction across domains. Significant changes are evident in education, where artificial intelligence supports students in their everyday studies and helps teachers deliver material more engagingly and effectively [1].

A recent survey indicates that teachers now use AI more often than students [2]. Our complementary survey reviews NLP methods for course design, delivery, and personalised assessment, including technical details and their implementation. We discuss how these solutions are designed, integrated into higher-education workflows, and evaluate their effectiveness for both students and teachers. The listed solutions form a strong basis for fully integrated, technology-aided education, and we present an example AI-driven engineering course.

Our research questions are:

- What current approaches apply NLP to course design and delivery?
- How do these methods fit educational settings?
- How can they be integrated into different course aspects?

The survey follows the class flow. Section II reviews NLP for course-content creation; Section III examines technology that enhances live teaching. Section V covers automated assessment, proctoring, and anti-cheat tools, and Section VI, explores personalised learning systems. Finally, we outline implementation challenges and ethics.

II. Course Content Creation & Modification

Designing a university course involves transforming ideas into course materials that are engaging, academically sound, and easy-to-follow [3], [4]. AI now supports instructors in this process. Designing teaching material must consider principles that support learning [5], [6], and how students learn and are assessed [7]. In practice, a course is split into several lectures – seminar, frontal, or interactive. While face-to-face teaching remains dominant, innovative educational technologies reduce student passivity, enabling them to interact and actively learn the class material [8]. Student assessment remains delicate and error-prone. Modern methods emphasize continuous homework and assignments, a mid-term checkpoint, and a final written, oral, or project-based exam [9]. At course launch, instructors draft a syllabus, a "contract" that defines objectives, lecture sequence, assessment, and permitted tools [10]. Some universities now ban student use of generative AI for homework [11]. Rather than prohibiting evolving tools, we advocate channeling them, e.g., letting chatbots handle low-stakes assessment to save instructor time. AI already cuts preparation time: a 2024 survey of 144 instructional designers found that 67% reported moderate-to-significant efficiency gains, and 64% let ChatGPT draft objectives or quizzes first [12].

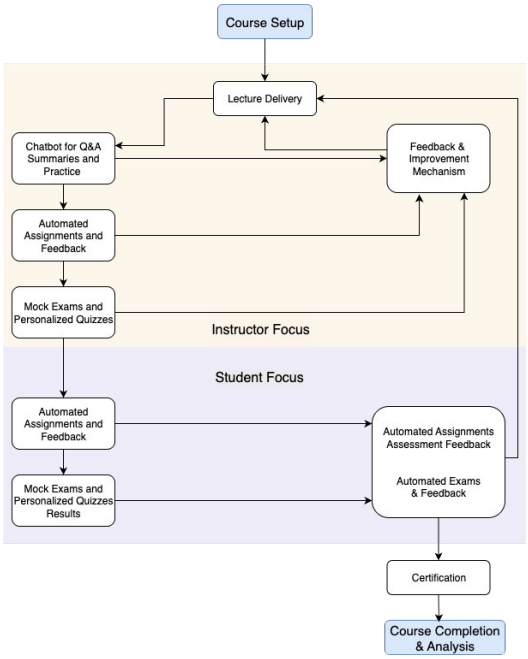

Fig. 1. Flowchart of subsequent steps in educational academic course delivery and students' assessment, up to the final certification. Note: light yellow are boxes more in the focus of the instructor, and grey ones are more for students

Figure 1 summarises the course flow. In an AI-enhanced version, instructors become supervisors and facilitators, while AI acts as a coach, evaluator, and feedback provider [13]. We will touch especially on the important ethical aspects and challenges while working on the creation of educational tools. The crucial questions here are:

1) How can AI/LLMs generate lecture materials and exercises?
2) How can technology structure the course and each session?
3) How can automated tools improve grading and feedback?
4) How do we evaluate the quality of AI-prepared material?
5) What are the pros and cons of teacher–AI collaboration?

A. How can AI/LLMs generate lecture materials and exercises?

AI tools can now draft lesson plans aligned with standards [14], [15], [16]. By specifying duration, lesson count, learner profile, and desired outcomes, instructors obtain varied analogies, examples, and explanations. Prompt engineering is continually refined [17], and multiple versions can be generated to suit individual students or fresh perspectives [18].

B. How can we use AI for detailed lesson planning and time allocation?

ChatGPT-style assistants quickly produce weekly and daily plans – topics, activities, assignments, assessments [19]. They can also recommend external videos and readings and link them to objectives, ensuring self-directed study complements the course [20]. Beyond text, AI can seed graphic-novel tasks, game-based projects, and debate topics to deepen engagement [21], [22], [23].

C. Grading and feedback generation

Timely, actionable feedback is hard at scale [24]. AI can create individualized quizzes and instant comments, drawing on prior performance, while human oversight preserves fairness and limits bias [25], [26].

D. Materials quality evaluation

AI-generated content still requires a documented two-pass human review: a subject-matter expert checks accuracy, then an instructional designer ensures pedagogy and accessibility [27], [28], [29]. Automated fact-checkers, readability analyzers, and rubric-based scores (e.g., AIGDER $\geq$ 85/100) flag issues for revision [30], [31], [32], [33]. Student "muddiest-point" feedback pinpoints residual confusion for rapid remediation [34], [35], [36], [37], [38].

E. Interaction between instructors and AI

Instructors work in cycles—prompt, review, refine, and embed pedagogy—when collaborating with AI. Attitudes range from scepticism about bias and deskilling [39] to enthusiasm for efficiency and creativity [40]. Empirical studies show that training and guided use shift beliefs and improve outcomes [41], [42].

III. Teaching

Generative AI tools can create diversified and personalised teaching materials and even automate routine "paper work" such as emails, deadline checks and consistency control [43]. Yet quality is essential; recent studies stress rigorous evaluation, from re-using credible sources [46] to iterative assessment protocols [44], [45].

Beyond content creation, AI supports real-time observation of teaching and learning. A design study [47] foregrounds learning-analytics dashboards -single screens aggregating key indicators- for ongoing improvement. Surveys classify multiple dashboard types and confirm they mainly serve teacher supervision [48]

A. Interactive content generation

Automatic content or question generation hinges on carefully crafted LLM prompts that spell out context, audience, and difficulty. Retrieval-Augmented Generation can instead feed the model verified knowledge before output [38].

B. Engaging lecture delivery

During lectures, AI can act as a creative co-teacher—suggesting analogies or examples [49], powering avatar instructors that field questions [50], and turning text into images, videos or podcast teasers for multimedia slides [51], [52]. Students can critique AI answers to hone critical thinking and visualise experiments via dynamic images.

C. Real-time learning process supervision

Real-time supervision captures how, not just what, students learn. AI dashboards visualise engagement and performance from digital environments [53]; open-learner models update each learner's knowledge profile [54]. Dashboards must stay interpretable to be actionable [55], [56], [57]. Predictive analytics within these dashboards can flag at-risk or low-engagement students for prompt support [58], [59], [60], [61].

D. AI chatbot Q&A summaries and practice

LLM-powered chatbots have spread rapidly across higher education. Surveys find enthusiasm tempered by doubts: ease of use is clear, but cognitive gains are still debated [62], [63]. When offered as optional study partners, chatbots can scaffold distance or dyslexic learners through personalised encouragement, summaries and practice prompts [64], [65].

IV. Aid in Academic Activities

A. Coding assistance

One of the core competencies acquired by engineering and computer-science students is coding. Programming is indispensable for many assessed projects. Requirements vary—Mathematical Computation students code in R, Computer-Science majors in Python or Java, Robotics students in low-level hardware languages—but all must solve complex problems. AI-powered coding assistants (ChatGPT, Gemini, Claude, Grok) now provide instant code generation, refactoring, explanations and debugging via LLMs plus web search.

Recent work compared ChatGPT-assisted learners with self-directed peers: final scores were similar, but ChatGPT users debugged more, refined AI code and, citing ease-of-use, planned to keep using the tool [66].

These findings show how AI tools scaffold programming at every level, offering step-by-step guidance and fast debugging. Effectiveness, however, hinges on good prompts and critical evaluation; instructor-led prompt training markedly boosts outcomes [67]. LLMs still struggle with large code-bases, may hallucinate and often default to generic patterns. Over-reliance can erode academic integrity, so institutions need guardrails that balance tool use with independent problem-solving.

B. Academic writing aids

A review [68] groups modern AI writing tools into literature management, drafting, plagiarism checks, data analysis and other features. They accelerate brainstorming by mining vast corpora and adding predictive analytics throughout the research workflow.

V. Assessment

A. Assessment generation

Automated assessment is now a popular NLP topic because it saves teachers time and money. Its goal is to achieve scores similar to human graders with far less effort and cost. Many methods exist (e.g., semantic similarity), but large language models (LLMs) currently dominate. Their chief flaw is hallucination—inventing incorrect information, which undermines reliability. One mitigation is retrieval-augmented generation (RAG): a standard LLM linked to a vetted knowledge base. Retrieving evidence relevant to each question reduces hallucination and equalises scores [69], though irrelevant hits can still occur. LLMs further support AI-assisted grading [70]; yet their human-like prose raises doubts about assessment validity. Human oversight, therefore, remains essential [71].

LLM-generated assessments can still be inconsistent. The "LLM-as-a-judge" pattern—a second model auditing the first—adds a control layer that flags misgraded answers and outliers with high accuracy [72].

B. Automated final exam / exam proctoring

AI-driven NLP already handles full exams—multiple-choice and essay tasks. Studies confirm feasibility [73] but show score distributions can narrow, and domain-knowledge gaps (e.g., biomedical items) cut accuracy [74]. Essay scoring benefits from LLM text processing [75], yet quality hinges on prompt tuning: focusing on different rubric points shifts grades [76]. Performance also depends on language coverage [77], and research now extends LLM scoring to oral exams [78]. Item-response theory (IRT) frameworks could anchor AI scoring, replacing today's opaque heuristics [**?**].

C. Anti-cheat solutions

Anti-cheat tools remain vital [79]. Traditional detectors such as Turnitin catch plagiarism [80], while stylometric authorship checks compare writing style [81]. These methods falter on short answers. GPT-based classifiers now spot AI-generated text but still produce false positives. The most reliable—though intrusive—approaches monitor cursor or keystrokes during exams [82], [83].

VI. Personalized Learning

Personalized learning represents a fundamental shift in the educational process, aiming to replace the singular, standardized educational experience with a customised, learner-centred one delivered via intelligent tutoring systems, content recommendations or adaptive assessments.

A. Adaptive assessments

This protocol first creates a large RAG-based question bank, each item labelled for difficulty and topic. The instructor sets the time window, duration, item count and proctoring; the system then randomises—or adaptively selects—questions for every student. Learners log in while camera, safe-browser and image-recognition tools safeguard integrity. Built-in timers show time left and auto-submit; real-time alerts flag suspicious activity. After all submissions, RAG compares answers with a rubric, awards partial credit and exports grades to the LMS. Plagiarism scans and on-the-fly follow-up questions protect originality, while analytics refine subsequent tests.

Considerably less research views these tests from the learner's side. Co-designing AI-based assessments with students can boost critical thinking and creativity [**?**], and meta-awareness that items are machine-generated maps to Bloom's highest levels—analysis, synthesis and evaluation [85].

B. Personalized feedback

Providing reasonable feedback is a crucial part of the whole AI-supported exam-conducting ecosystem. It helps students fill gaps in knowledge, focus on the right areas, and understand the material faster. Research shows that the best feedback is timely, specific, and actionable [86]. Equally important is wording it pedagogically so it truly motivates learning. The most common solution today is a data-driven approach: transformer models (e.g., BERT) can evaluate many aspects of an answer through their understanding of context [87]. Yet merging expert knowledge with AI feedback is challenging; LLM comments are often generic and miss key details [86]. LLMs may also hallucinate—studies report that about 15% of feedback can be totally incorrect [86]. Prompt design, therefore, matters: telling a model to "behave as a teacher," giving step-by-step instructions, and asking it to analyse first and comment second all raise quality.

Despite these gains, the model is still far from perfect, so retrieval-augmented generation (RAG) can further improve performance. RAG combines an LLM with local data sources such as presentations or notes, ensuring feedback stays strictly aligned with course material [88]. A complementary method splits the task among several specialised agents, each handling a smaller part; this helps catch mistakes and adjust tone [88].

Feedback during learning is tentative diagnostic information, so a relationship of mutual trust between learner and instructor is essential. When automation intervenes, its effect on that relationship must be monitored; simple chatbots can bore users and discourage sustained dialogue.

LLM-based feedback systems have now been piloted in real courses, and learner perceptions are being evaluated [89]. Careful messaging can promote reflection on one's learning situation [90], and design choices—topic coverage, timing, tone—must be optimised for each activity [91].

VII. Challenges & Future Directions

In recent years, many studies have explored the possibilities, challenges and threats of AI tools in education. Yet most merely list what AI can do; few run carefully designed experiments to test usability and reliability. The key task now is to conduct comparative studies—contrasting AI-based recommendations, testing, grading and feedback with long-standing practices. For instance, we should compare LLM resources with earlier crowd-sourcing platforms used by students before chatbots.

We must also continuously measure how well up-to-date, fine-tuned and well-prompted LLMs acquire and refresh knowledge.

Moreover, ethical challenges loom large; automated tools must remain especially sensitive to educational contexts. As AI is introduced, we must be aware of data and algorithmic biases. Models trained on large corpora can mirror societal, cultural or institutional prejudices, prioritising students by past performance or learning style and producing unfair outcomes tied to race, language, socioeconomic status or disability. Thus transparency and explainability are needed for every recommendation or assessment, yet remain elusive because LLMs are inherently opaque.

Student privacy is also at stake, particularly under learning surveillance. Over-reliance on automation, coupled with inadequate informed consent, can erode professional judgement on both sides of the classroom. Unequal digital access—whether through language or technology—may widen existing educational gaps.

Mitigation demands careful design: human-in-the-loop oversight, informed student choice, and channels for learner voice. Done well, AI frees teachers to spend more quality, personalised time with each student.

Towards the automated classification of German job titles according to KldB

Ralf Dorau*, Kristine Hein*

Email: dorau@bibb.de, kristine.hein@bibb.de

***Abstract*—The automated classification of occupational titles is a pivotal component of labor market analysis, survey research, and administrative data processing. This paper explores the viability of mapping German job titles to the German Classification of Occupations (KldB) by employing conventional machine learning methodologies to examine the challenges and limitations inherent in the data itself. To this end, the present study leverages two complementary datasets—manually annotated survey data and a dataset of occupational synonyms—to assess the performance of established classifiers under varying levels of taxonomic granularity. The methodological challenges inherent to this study include class imbalance, semantic ambiguity, and linguistic variability, which are all characteristics of German job title expressions. The findings of the study suggest that while coarse-level classifications can be addressed with relatively simple models and text representations, finer-grained distinctions remain challenging to resolve using title-based features alone. The findings indicate that more expressive models and richer contextual information may be necessary for high-resolution occupational coding.**

I. Introduction

THE automated classification of job titles is an important topic in research, but also for practitioners in the field of labor market research. For example, in questionars people may answer the question about their occupation. However, this needs to be matched to a certain occupation, for example the German Classification of Occupations (Kldb) or the International Standard Classification of Occupations (ISCO). Other tasks include the classification of online job advertisements (OJAs) or the matching of other occupations, e.g., from online platforms like Kununu [1]. Other researchers try to tackle the question of identifiying occupations in textual data, for example in parliamentary debates [2]. The German language has several challenges, as occupational titles are not only single nouns but may also be a combination of nouns and may also contain additional data like the examining institution (e.g., 'IHK'). Next, different forms for male, female, gendered or neutral titles may exist. For generic texts, another challenge is that surnames may originate from (partly historical) professions, for example 'Bäcker' (baker).

Linking a variety of different sources on labor market is usually considered a very challenging task [3], however, in this paper, we limit the question to the mapping and automated classification of job titles in German language. Here, we find dictionary-based approaches which are widely used, but also other ML-based approaches. Training data was widely collected from survey data or job-titles from KldB, ESCO or other synonym data.

The main contribution of our paper is a large collection of novel training data and a systematical analysis of challenges to train classificators for German job titles according to KldB and in particular different levels of occupations and their level of performance.

This paper is divided into five sections. The first section provides an introduction, the second section gives the the state of the art, and related work. The third section describes the data and methodological background. The fourth section is dedicated to experimental results and evaluation. Our conclusions are given in the last section.

II. Related Work

A multitude of classification categories are recognized for occupations. The International Standard Classification of Occupations (ISCO) was developed by the International Labor Organization (ILO) and published in 1958, 1968, 1988, and most recently in 2008)[1]. The ISCO 2008 has also been utilized within the European Union (EU), with certain German-speaking countries (Germany, Austria, and Switzerland) developing a customized version of the classification. The International Standard Classification of Occupations (ISCO) is structured at a skill level and linked to the "European Skills, Competences, Qualifications and Occupations" (ESCO) ontology, which adds another hierarchy level to the data. In Germany, the Classification of Occupations (KldB) serves as the reference classification for the Federal Employment Agency (BA) and its research institute (IAB)[2]. In this organization, occupations are structured at a task level. The most recent version is the 2020 revision of the KldB 2010, which has undergone a comprehensive redesign, thereby rendering the previous versions from 1988 and 1992 obsolete. The development of this system was undertaken with the objective of ensuring compatibility with the ISCO-08 standard. The study of job titles and taxonomies has a long history, extending even before the advent of computer technology [4].

A portion of the research has focused on the classification of OJAs according to the O*NET framework [5]. This has included the application of normalization approaches [6] and

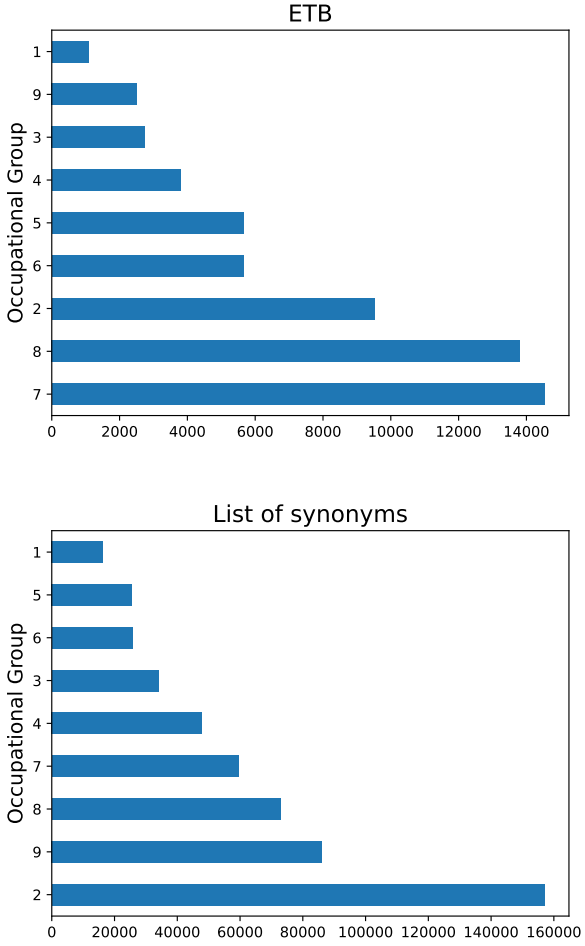

Fig. 1: Distribution of training data according to occupational groups

similarity-based methods [7]. The classification of job titles is also employed in the context of online job recruitment [8].

A limited number of publications have been published on the subject of German job titles, with a particular emphasis on the German KldB. For instance, a technical report based on OJAs [9] with challenges on level 4, but with promising results on level 1. Malte Schierholz's 2018 publication [10] introduced the concept of auxiliary classifications in the field of occupational coding. For further research on the subject of occupational coding in surveys, we refer to [11]. A master's thesis endeavors to predict KldB 5-digit job titles from survey data, thereby highlighting the persistent challenges associated with this endeavor, see [12]. In a similar vein, a scholarly article was published that compared the classification of survey data using BERT and GPT-3, see [13]. However, the absence of a standardized reporting methodology precludes the direct comparison of their results. Nevertheless, they evince analogous challenges to those observed in other studies. Consequently, both the classification of occupational areas and, in particular, the level of performance (5th digit) persist as arduous tasks.

III. Data and Methods

A. Data

The dataset aggregates 60,022 manually annotated occupational titles from the 2012, 2018, and forthcoming 2024 waves of the Erwerbstätigenbefragung (ETB; German Employment Survey)[3], each coded to KldB 2010. These representative surveys – conducted by BIBB and BAuA – target Germany's core workforce (employed individuals aged 15+ working $\geq$10 hours/week). While historical predecessor surveys (1979-1999 BIBB/IAB studies[4]) exist, their integration was precluded by fundamental incompatibilities between KldB versions, despite partial crosswalk feasibility.

[3]Main datasets: 10.7803/501.12.1.1.60 (2012), 10.7803/501.18.1.1.10 (2018). Supplementary variables: 2012: 10.7803/501.12.1.4.10 (full-text), 10.7803/501.12.1.3.20 (regional identifiers), 10.7803/501.12.1.5.30 (special variables); 2018: 10.7803/501.18.1.4.10 (full-text), 10.7803/501.18.1.3.10 (regional identifiers), 10.7803/501.18.1.5.10 (special variables).

[4]GESIS SUF: 10.4232/1.1243, 10.4232/1.12563, 10.4232/1.2565, 10.4232/1.12247

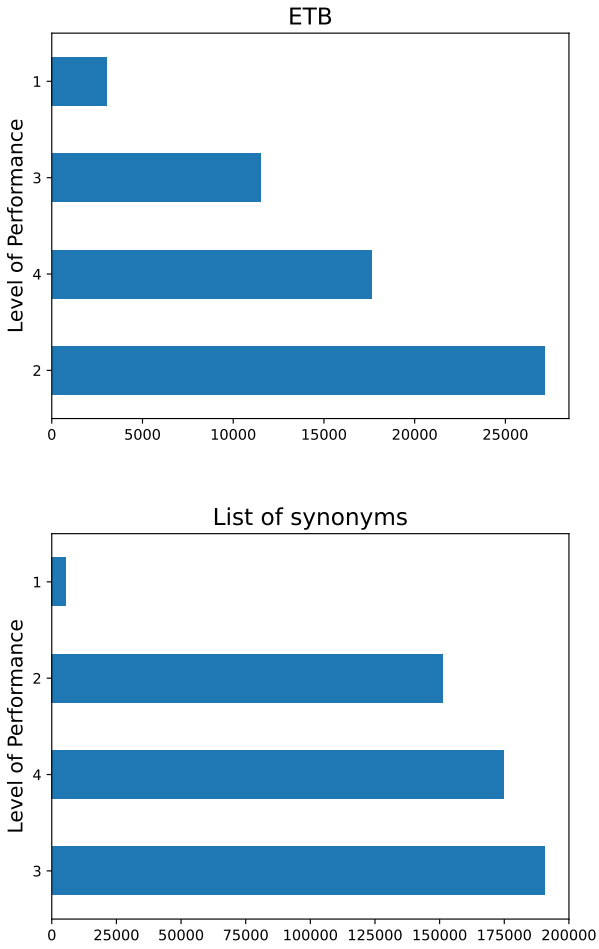

Fig. 2: Distribution of training data according to level of performance (5th-digit)

We use a second dataset comprising 526,535 synonyms and variants of male, female, and neutral job titles, provided by the German Federal Employment Agency (BA)[5]. Both datasets have their own biases, as can be seen in Figures 1 and 2: While in ETB dataset the majority of occupations are located in groups 7 and 8, they are in groups 2 and 9 for the list of synonyms. We find a similar bias with respect to the level of performance, coded in the 5th digit of KldB.

Data cleaning is an existentiell step. We remove occupational are 0 from the dataset as we omit military occupations. Second, we clean all data with errors, for example too large or small KldB numbers. In Dataset 1, 59,535 and in dataset 2, 522,197 entries remain.

B. Method

In this paper, we adopt the classification approach to labor market data presented in [14], [15]. The baseline model was trained using three standard classifiers with default values from the scikit-learn library [16] with logistic regression ($C = 10$), naive Bayes, and random forest. We split the data data so that 20% was used as test data and 80% as training data. As the main question is about specific challenges, we will apply traditional methods to identify the route for further research in this area.

However, another open question is the choice of text representation. As shown by this can significantly change the performance of classifiers. We can use the combination of term frequency and inverse document frequency as TF.IDF (term frequency–inverse document frequency). Another approach is the Word to Vector (W2V) which applies unsupervised learning to represent textual data and produces rather low-dimensional data. As we have seen, the later produces rather poor results and we will only showcase the results for Logistic Regression.

TABLE I: Results for 1-digit on dataset 1

Approach	Metrics (Macro/Weighted)		
	Precision	Recall	F_1 Score
Logistic Regression (Tf-idf)	0.88 / **0.86**	**0.79 / 0.84**	**0.83 / 0.84**
Logistic Regression (W2V)	0.45 / 0.47	0.26 / 0.46	0.26 / 0.38
Naive Bayes	**0.90** / 0.84	0.68 / 0.79	0.75 / 0.79
Random Forest	0.84 / **0.86**	0.76 / 0.79	0.78 / 0.81

TABLE II: Results for 1-digit on datasets 1+2

Approach	Metrics (Macro/Weighted)		
	Precision	Recall	F_1 Score
Logistic Regression (Tf-idf)	**0.92 / 0.91**	**0.89 / 0.91**	**0.90 / 0.91**
Logistic Regression (W2V)	0.61 / 0.57	0.35 / 0.51	0.38 / 0.47
Naive Bayes	0.91 / 0.89	0.84 / 0.88	0.87 / 0.88
Random Forest	0.91 / **0.91**	0.88 / 0.90	0.89 / 0.90

IV. Experimental Results

A. Occupational areas (1-digit)

Tables I and I present the outcomes for occupational categories with a one-digit classification, contrasting the utilization of Dataset 1 exclusively or Datasets 1 and 2 collectively. The results of this study are largely consistent with those reported in the extant literature. As previously discussed, the W2V model demonstrated substandard performance. A comparative analysis reveals that, while all other models demonstrate comparable performance, Logistic Regression consistently exhibits superior performance in various applications.

The findings of this study demonstrate that extending the dataset has a substantial impact on the quality of the results. For instance, the F_1 score increased from 0.84 to 0.91, a notable enhancement.

B. Occupational group (3-digit)

As illustrated in Tables III and III, the results for occupational group (3-digit) are presented. A direct comparison with occupational areas reveals that the performance is suboptimal. However, the employment of both datasets results in a substantial enhancement of the outcomes. However, a more thorough examination reveals that this approach is particularly ineffective for groups with limited data. A cursory examination of dataset 1 reveals that there is an absence of data points corresponding to area 114 (occupations in fishing), 213 (occupations in industrial glass-making and -processing), and 214 (occupations in industrial ceramic-making and -processing). For future research endeavors, there is a necessity for not only improved training data that is more balanced, but also for the evaluation of cross-validation approaches.

C. Level of Performance (5th digit)

The results of the classification of the level of performance (5th digit), as demonstrated in Tables V and VI, also exhibit a number of noteworthy outcomes. First, it is noteworthy that the extended dataset does not yield substantial improvements in the results. Secondly, we observe that different levels yield different F_1 scores. For Logistic Regression, a score of 0.86 is observed for both level 2 and level 4, while the level 1 (0.73) and level 3 (0.71) demonstrate inferior performance. A similar outcome is observed for all other methods, although level 1 and 3 demonstrate an even poorer performance. Therefore, it appears that the fifth digit is a significant factor in the classification of job titles. The available data from a job title alone is insufficient for effective classification.

V. Discussion and Outlook

The classification of German job titles according to the KldB taxonomy remains a complex task, particularly at the more granular levels such as the 3-digit occupational group and the 5th-digit level of performance. The findings of this study underscore the strengths and weaknesses of conventional machine learning methodologies in this context. While the utilization of TF-IDF features in conjunction with Logistic Regression yielded robust outcomes, particularly for the 1-digit classification, performance exhibited a substantial decline for finer-grained levels. This phenomenon underscores the inherent intricacy of occupational data, wherein minor linguistic and contextual variations can wield substantial consequences for classification.

The present study demonstrates the significance of high-quality, balanced training data. The incorporation of the synonym dataset led to a substantial enhancement in performance at more extensive classification levels. However, this augmentation was accompanied by the introduction of biases stemming from the unequal distribution across occupational categories. This phenomenon is especially evident among underrepresented categories. Furthermore, our analysis indicates that classical models rapidly reach their limits when tasked with inferring the level of performance from job titles alone. In this context, the available information frequently lacks the requisite depth to accurately differentiate between skill levels. This finding underscores the necessity for more comprehensive or even external input data, such as job descriptions, qualifications, or contextual metadata, to capture the subtleties that may be obscured by simplistic job titles.

TABLE III: Results for 3-digit on dataset 1

Approach	Metrics (Macro/Weighted)		
	Precision	Recall	F_1 Score
Logistic Regression (Tf-idf)	**0.81** / 0.80	**0.60 / 0.74**	**0.67 / 0.75**

Random Forest	0.84 / 0.84	0.77 / **0.85**	**0.81 / 0.85**

In terms of future research, several avenues emerge as potentially fruitful directions. Initially, the integration of extensive and heterogeneous datasets, encompassing historical KldB mappings or annotated survey data, could assist in mitigating class imbalance and enhancing generalizability. Secondly, the implementation of advanced language models, such as BERT, domain-specific transformers, or large language models (LLMs), has the potential to substantially improve classification accuracy, especially when fine-tuned on labor market data. Finally, methodological improvements, such as stratified cross-validation or ensemble learning approaches, have the potential to offer more robust evaluation and enhanced performance. While the present approach is both effective and stable, these insights serve as a foundation for more sophisticated future work in the automatic classification of job titles.

***Abstract*—This study investigates the potential of large language models (LLMs) to apply hermeneutical methods rooted in philosophy, theology, sociology and literary studies in a meaningful manner. Utilising a comparative experimental design, four LLMs were prompted to interpret a variety of texts, encompassing religious, philosophical, poetic, and conversational material. The findings indicate considerable variability, an absence of reproducibility, and a substantial reliance on prompt design, model type, and language. This suggests that LLMs do not employ coherent hermeneutical strategies. Despite the automation of formal features, limitations in context sensitivity, interpretive intentionality, and epistemic grounding render LLMs ill-suited to authentic hermeneutics. The study concludes that current LLMs are incapable of replicating the depth of human interpretive practice, and calls for further interdisciplinary research to define evaluation standards for machine-assisted exegesis.**

I. Introduction

IT IS evident that all perception and self-perception are founded on acts of interpretation, extending beyond the mere reception of auditory and written statements. The term 'hermeneutics' generally encompasses theories that address the possibility, necessity, conditions, challenges, and objectives of processes involving understanding and interpretation. Thus, it can also be seen as a 'theory of understanding' or 'theory of interpretation', see [1]. Despite the numerous endeavours to define hermeneutics, a comprehensive consensus remains elusive. Maier has highlighted two predominant tendencies in the understanding and definition of hermeneutics, see [2]. Firstly, a rather mechanical tendency, and secondly, a definition of understanding and comprehension that is more common in German-speaking countries. In theology, this is an essential basis for exegesis, i.e. the interpretation of texts.

In antiquity and the Middle Ages, hermeneutics served as the science and art of interpreting fundamental texts, especially the Bible and laws. In modern times, its field of application has expanded, developing into a general doctrine of the prerequisites and methods of proper interpretation and a philosophy of understanding, see [3], [2]. Hermeneutics are also widely discussed and applied in areas like study of literature, psychology, social sciences, history and medical research.

It is important to note that hermeneutical concerns are ubiquitous. In the analysis of data (exegesis), a certain form of data hermeneutics is essential, and communication is pervasive. Over the past several years, a new generation of generative AI tools has emerged. In Section II, we will demonstrate that researchers are concerned about which hermeneutics should be applied to AI-generated texts, or which tasks of hermeneutics can be carried out by LLMs. However, there is a paucity of research in this area, with only a small number of studies examining the hermeneutical capabilities of LLMs and generative AI in general.

The central research question guiding our study is as follows: Can contemporary LLMs apply hermeneutical approaches from Philosophy, Sociology, study of literature and Theology to textual data? Our research is particularly interested in methodological and technical reflections, while also raising novel questions that will serve as a foundation for a more robust theoretical framework in this field.

II. Literature Review

Some researchers argue to use hermeneutics on AI-generated texts [4], others propose hermeneutics as tool to optimize prompts [5]. However, there is a clear lack of hermeneutics for AI-generated texts as recognized in research [6], [7], [8]. While some researchers are generally positive on applying existing theory, e.g., by Heidegger or Lacan, to LLMs, see for example [9], there is no consent on this issue [10]. In general, researchers from non-technical domains seem to overestimate the features and capabilities of LLMs and AI in general, see for example [11]. Other researchers highlight the need for domain knowledge, for example in Bible teaching in confessional religious education using LLMs [12]. However, as our main research question is mainly concerned with whether LLMs can perform hermeneutical tasks, we will now turn to literature on this.

According to our best knowledge, there is only one preprint paper addressing this question directly [13] and being critical about hermeneutical and understanding capacities of LLms. Other research focuses more on technical limitations or the correct place of LLMs, for example by seeing LLMs as "AI-interns" as [14] proposes. Another paper by [15] focuses on the theological and ethical bias of LLMs for interpreting texts from the Hebrew Bible and finds a bias which aligns with "contemporary socio-political and environmental concerns". Some scholars work on hermeneutics within the medical domain. For example, Hans-Georg Gadamer [16] argues that

LLMs cannot take over patient interaction as it cannot take over moral practices. In general, we see the aspect of human interaction and experience as one of the key challenges in using LLMs for hermeneutical aspects. Although the aspect of machine relationships complementing human-human interactions was suggested [17] this does not solve any hermeneutical questions.

III. Methodological Approach

We will now discuss several methodological approaches from different domains. They all share a common foundation. For example, Körtner describes the reader as a central aspect of Biblical hermeneutics [18]. However, he also points at the connection between narrative approaches from literature and Biblical exegesis. Oeming describes some confusion about this approach and its naming. In general, we find this method as "New (Literary) Criticism, Literary Approach/Criticism, Holistic Approach, Rhetorical Criticism, Close Reading, Synchronical Approach, Narratology und Narrative Criticism" [19]. This approach tries to determine how biblical texts can be interpreted as literature, see [20]. In summary, "the literary critic looks at the text for what *it* says in itself by means of the patterning or shaping—the informing—of its content." [21] Thus, we will – after a philosophical approach – focus on a selection of theological approaches. This selection must be somewhat arbitrary, but we tried to bridge between the reformators Zwingli and Calvin and a rather contemporary approach, liberation theology, as a contextual theology. However, as there is a clear link to narrative analysis, we will also discuss narrative approaches [1].

There is also some discussion between hermeneutics and sciences. Wyss, for example, discussed about the experience of time and self [22]. Other scholars discuss the world of living ('Lebenswelt') as paradigm for hermeneutics in the world of qualitative and quantitative reserach [23]. Thus we include a hermeneutics from the domain of sociology, namely objective hermeneutics.

Objective Hermeneutics, sometimes also labelled structural hermeneutics, derives from cultural anthropology. [24] discusses its connections to theories by Berger and Luckmann, Mead, and Chomsky. The idea is that how entities see the world they live in is reflected in the speech. On an individual level this would relate to an expression of one persons perception of reality, its ordering and the connections between entities. Within sociological theory there are also broader levels of groups of persons or organisations (meso level) up to the level of states (macro level). The structures that can be found by applying objective hermeneutics can be communicated intersubjectively and are answers to objective problems of action [24, p. 12]. For every structure there are numerous situations that pose problems, or crises. In fact, every single action is at first a situation of crises. The structure devises some solution and tests it. The way to re-construct structures within objective hermeneutics is thus interesting in two ways in view of its application to LLMs. The first interesting aspect is a "layer of normality" ("Normalitätsfolie", [25, p. 136]). This is one of the starting points for reconstructing a structure and refers to ideal types of normal behaviour. The second interesting aspect refers to the logic of cognition. In objective hermeneutics researchers explicitely use abductive reasoning. This can be seen as an inference to the best explanation while at the same time only having assumptions about the laws and rules from which to infer. This is seen as a creative process and might as such be particularly challenging for LLMs. For the inclusion of objective hermeneutics in this experiment this leads to some assumptions: If the LLMs are capable of applying an objective hermeneutics approach, they should all come to the same conclusion. Even though generally structures are reconstructed, these all refer to specific situations that find expressions in text. Thus, characters, places, times, etc. of these situations can also be reconstructed and should be comparable between different analysts.

The interest in narrative and 'story' began with Richard Niebuhr in 1941, see [26]. After that, it was introduced in the 1970s[1]. While some scholars focused on 'text-oriented approaches', 'reader-oriented approaches' were also widely used. What they all have in common, however, is the usage of methods of criticism studies for the interpretation of narrative texts [29]. Different schools exists which are not only committed to different literary theories, but are also connected to different geographical areas, see [19] and in particular [30]. In narrative exegesis, the first step is to apply methods of text analysis: "The 'what' of a text (its content) and the 'how' of a text (its rhetoric and structure) are analyzed as a complete tapestry, an organic whole." [20] For this purpose, the text is examined with respect to its content layer and effect layer to find out which structure, order and content the text wants to convey. In order to refine the exegesis, different elements of the text are examined: time, locations, characters, perspective, plot or plot line, narrator, listeners, and readers, key words, repetitions and other structural elements and stylistic devices.

Narrative approaches can be applied to any narrative texts – religious texts, for example Biblical texts, are widely considered to be suitable. Bailey et al. argue: "A Gospel is a narrative, fashioned out of selected traditions, that focuses on the activity and speech of Jesus as a way to reveal his character and develops a dramatic plot that culminates in the stories of his passion and resurrection." [31] Other scholars emphasize the need to work with historical-critical methods, see for example [32] and [33]. Narrative approaches are also widely applied to biblical and theological texts [34], [35], [36], so the quintessential next step is to also consider hermeneutics in Theology, for example liberation theology [37] or the Swiss reformers Ulrich Zwingli and John Calvin [38], [39], [40], [41].

Despite having elected to examine only a limited number of approaches, it has become evident that, upon thorough discussion of the various hermeneutical approaches that have been posited, it can be concluded that all of them exhibit features that cannot be directly substituted with concepts that are quantifiable. However, our study reveals two fundamental

[1]See also [27] and the overview by [28].

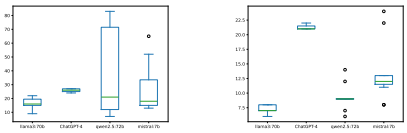

Fig. 1: Number of sections detected (direct) in Text 1 (left) and 2 (right)

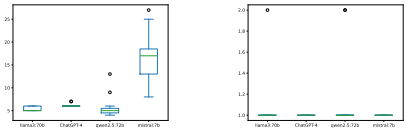

Fig. 2: Number of sections detected (direct) in Text 3 (left) and 4 (right)

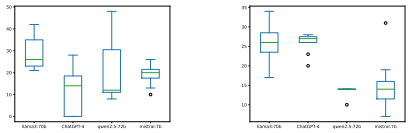

Fig. 3: Number of actors detected (direct) in Text 1 (left) and 2 (right)

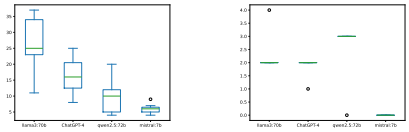

Fig. 4: Number of actors detected (direct) in Text 3 (left) and 4 (right)

aspects that all hermeneutics share: first, an understanding of human nature, and second, an understanding of language. While the question of whether AI can comprehend human nature remains a subject of ongoing discourse, the focus will be on the understanding of language. Danner summarizes: Hermeneutics is the study of interpretation, with a focus on comprehending meaning. The concept or phenomenon that is being understood is inherently present within the linguistic medium or can be articulated through it. The fundamental question, therefore, is: What is the origin of language? The fundamental question, therefore, is: what does precede language? The fundamental nature of language is predicated on its capacity to articulate elements of reality, that is to say, to "speak" of a reality that is already "out there" in the worldLLMs are unable to substitute the following aspects due to their inability to comprehend the context of reader and writer in a broader sense: (a) The reader and his perception or the listeners (unless we define LLMs as reader) (b) The context of a reader (unless we define LLMS as reader and define its context) (c) The author or narrator (d) With respect to both: Creator and created. Or the influence of the Holy Spirit (per Definition, as Luther and Zwingli described it), or Christ as hermeneutical principle (Calvin). In summary, it is evident that LLMs can only be utilized for the automation of fundamental principles of language understanding. However, as evidenced by our study of various hermeneutical approaches, different hermeneutics emphasize distinct aspects of language. Nevertheless, it is possible to identify several formalized structures that are, or may be, studied by hermeneutics. These include: (a) Plot as a broader concept, e.g., by selecting sections or units of meaning (b) Characters, e.g., the directly or indirectly acting persons (c) Space, while no single definition can be given. For example, according to Lefebvre and Soja [42] space can be defined as follows: "(Social) space is a (social) product." [43]. They differ between the *firstspace*, which includes physical space, the *secondspace* as mental space, and the *thirdspace* as social space. This, in turn, redirects the focus back to the question of which social actor a LLM is. (d) The concept of perspectives or points of view is also crucial in this analysis. However, it is crucial to acknowledge that an individual's understanding of points of view is significantly influenced by the context of the reader. This reiterates the necessity for a comprehensive examination of the social actor in question.

Consequently, an initial approach to assess the capabilities of LLMs in applying hermeneutics entails a concentration on plot and characters, as this method facilitates the introduction of objectivity to the inquiry. It is imperative to establish the following assumptions: The assumption is made that a single LLM is capable of interpreting a text employing a specific hermeneutical approach. Conducting a repeated experiment should, under these conditions, yield a consistent result or at least a reasonably proximate outcome. Secondly, it is hypothesized that different models will yield analogous results. The number of actors in a text is a subject that merits discussion; however, especially in narrative texts, this number should be nearly fixed. Furthermore, if two models yield divergent units of meaning or sections, they are likely to employ different perspectives and, consequently, divergent hermeneutical methods.

Our approach is as follows: We will study four different texts from various backgrounds and repeatedly query a LLM ($n = 10$) to select sections or units of meaning in a text and to return the number of actors in a text. For a detailed exploration of different prompting strategies, we refer to Appendix A.

IV. Experimental Results

To that end, the present study will examine four different texts. Initially, we examine a renowned German poem entitled "An die Freude" ("Ode to Joy", 1785) by Friedrich Schiller. Subsequently, we examine a biblical text comprising three narratives (Acts 8:1-25), having both a narrative and theological dimensions. Finally, we turn to a section of the philosophical text by the German philosopher Immanuel Kant, titled "Beantwortung der Frage: Was ist Aufklärung?" (Answering the Question: What Is Enlightenment?, 1784). The final text is a concise sentence: "Guten Abend, meine Damen und Herren" (Good evening, ladies and gentlemen).

Reconstructing a structure from one sentence with objective hermeneutics is challenging, but entirely possible. The least

a model should arrive at is to reconstruct personen (one speaking, more than one being spoken to), possible places (a theater, a lecture room, a TV setting) and times (evening). There are at least two sequences within this sentence, on referring to people being adressed, the other to a time. There is a published example of such an analysis by Oevermann himself [44]. All texts can be found online and there are likely references to them being analysed with one or another of the included hermeneutics. Selecting LLMs to test is a another challenge. We followed [45] by choosing the most widely used ChatGPT-4 and llama3:70b which are widely compared and discussed, see e.g. [46], [47], [48]. In addition, we choose qwen2.5:72b as another large model and, to compare with a rather small model, mistral:7b.

A. Plot

As illustrated in Figures 1 and 2, the boxplots depict the range of detected sections within the text corpus. For a more detailed analysis, please refer to Table tab:sections. It is noteworthy that the ChatGPT 4 and llama3 models demonstrate the greatest consistency in their output. However, for text 2, which comprises three stories, the output is particularly

problematic, though it should be noted that no model partitions every verse (25). This phenomenon is also evident in Text 4, which essentially comprises a single sentence, particularly in instances where two sections have been identified. In such instances, the LLM has demonstrated an inability to distinctly delineate the boundaries of the two sections. Consequently, the outcomes for the poem "An die Freude" and Kant's text appear somewhat arbitrary. The discrepancy in the analysis of different languages, as demonstrated in Text 2 and Text 3, is equally perplexing. These alterations, far from being mere nuances, introduce divergent interpretations.

The inconsistency of models in their own perspectives is evident, and the inability to compare different models is apparent. The application of a hermeneutical perspective appears to be both unclear and erratic. This discrepancy persists when employing an alternative prompting strategy, as evidenced in Table II. However, the number of suggested sections does undergo a substantial change. However, the value ranges do not offer any possible explanations within the text itself. In summary, three factors appear to influence the output: the model, the prompt, and the language.

B. Actors

As demonstrated in Figures 3 and 4, the boxplots illustrate the range of detected actors within the text corpus. For a more detailed analysis, please refer to Table [tab:personen]. The ensuing results proffer illuminating insights from a variety of perspectives. For instance, it is noteworthy that Texts 3 and 4 do not explicitly mention any actors, yet they do implicitly refer to actors through the use of language such as "Ladies and Gentlemen." However, the models detect a multitude of actors. The detection of more than 35 actors in a philosophical text is substantial, and the identification of four actors in a single sentence of greeting appears implausible. It is noteworthy that models can exhibit disagreement in their estimation of the number of actors mentioned in a narrative text or poem (texts

1 and 2). It is important to note that modifying the input language can substantially alter the output.

The lack of comparability and inconsistency of these models to other LLMs, as previously discussed in the context of plot, further complicates the analysis. It is evident that modifying the prompting strategy leads to alterations in the output, as illustrated in Table IV. It is important to note that none of these numbers are directly connected to the text itself. LLMs exhibit deficiencies in addressing fundamental hermeneutical elements that are essential for text exegesis.

V. Conclusions and Outlook

This study critically examined the extent to which large language models (LLMs) are capable of engaging in hermeneutical analysis, drawing from traditions in philosophy, theology, sociology, and literary theory. The present study evaluated the consistency, interpretive depth and methodological coherence of LLM outputs by testing multiple models on a range of textual genres, including poetic, theological, philosophical and conversational texts. The findings indicate that current LLMs exhibit significant variability and lack reproducibility in the application of hermeneutical principles. Across a range of models and prompting strategies, the interpretation of plot structures and identification of actors demonstrated inconsistency, both within and across iterations. This variability suggests that LLMs are not applying coherent hermeneutical frameworks, but rather relying on surface-level linguistic patterns that diverge significantly depending on language, prompt design, and model architecture.

Nevertheless, this is at odds with some of the recent literature that has been published, which has asserted that LLMs "can analyze nearly any textual statement." [49] The experimental results obtained in this study appear to be in alignment with the arguments set forth by researchers who posit that LLMs are deficient in their capacity to perform even rudimentary logic-based tasks, such as counting and identifying general substructures in graphs [50], [51]. Therefore, it is debatable whether LLMs could offer any technical assistance with textual analysis, against, for example [52].

It has been demonstrated that there is a discernible discrepancy between certain components of LLM output and hermeneutical procedures. These components include, but are not limited to, text segmentation and the identification of narrative elements. The models demonstrate an inability to comprehend text, see [53], and their apparent lack of understanding of context, intentionality, and reader-writer dynamics. These components are fundamental to traditional hermeneutics. In other words: "Should our interpretation capabilities be engaged? If yes, under what conditions? The rules of the language game should be spelled out; they should not be passed over in silence." [54] Moreover, the validity of conventional hermeneutical principles is also open to question. For instance, the assumption that hermeneutics necessitates the interpretation of a human being with consciousness, engaging with interpretive dimensions involving principles, historical consciousness, praxis, or – in the context of theological hermeneutics – the influence of the Holy Spirit, is not necessarily indisputable. The assumption that an LLM could act as an exeget is not, in itself, sufficient to ensure that it will be able to identify all the important aspects of context necessary for the application of hermeneutics. It appears improbable that LLMs will ever be capable of this [55].

It is recommended that future work concentrate on the development of evaluation criteria for the purpose of assessing interpretive coherence in the context of machine-generated text analysis. This is a common debate also in the field of AI-generated text detection, see [56]. Furthermore, it is recommended that interdisciplinary frameworks be explored, with a view to more accurately reflecting the limitations of computational models within the domain of humanities or theological understanding. Moreover, the integration of insights from phenomenology and semiotics has the potential to provide supplementary conceptual foundations for the assessment of interpretive capacities of AI systems.

Appendix A
Prompts

In the process of designing the prompts, adherence was observed to the general principle for success when engineering a prompt with clear and concise, step-by-step reasoning, as outlined in [45]. TThe direct approach posed a question that was explicit in its formulation.The 'Single Explanation' (SE) strategy is a rhetorical device that functions to provide an illustration of a concept or idea.

***Abstract*—Clothing production is an important sector within manufacturing. It includes the sewing, knitting and leather industries. It is important for a manufacturer to organize the production process well. This organization includes personnel allocation, machine loading, and material allocation. The goal is to complete the given order in the shortest time and, if possible, at the lowest cost. This paper addresses the task of producing knitted shirts. An ant colony optimization algorithm has been proposed to solve the problem. The objective is to complete the order in the shortest possible time.**

***Index Terms*—Feshion production, Optimization, Scheduling**

I. Introduction

OPTIMIZING knitted garment production is a special part of job shop scheduling problem. Job shop scheduling problem is an important problem arising in manufacturing and industry. The production consists of producing various elements/parts on different machines. Sometimes it matters in what order the individual elements are produced. Individual machines may have some specialization, as well as different productivity. Therefore, it is important to find the optimal distribution of the production across machines so that the final product can be produced in minimal time or within a certain period of time and, if possible, at a lower cost. There is a wide variety of job shop scheduling problems, depending on the specific production processes, requirements, and constraints. A survey was conducted in about the various job shop problems and algorithms solving them [1]. This is a typical machine scheduling problem. For the first time, an algorithm for solving a variant of this problem, with machine setup time included, was made in 1954 in [2]. Next years other variants of the problem called flow shop scheduling problem is solved in [3], [4]. These publications solve small-sized problems. There are 1 to 4 operations that are performed on 2 to 4 machines. Exact methods are used to solve the problem. The term job shop was first used by Sisson in 1959 [5].

In general, the job shop scheduling problem can be defined as follows:

There is a set of m machines $M = \{M_1, M_2, \ldots, M_m\}$.

There is a set of n jobs $J = \{J_1, J_2, \ldots, J_n\}$.

The job J_i has a set of operations $O_i = \{O_1^1, O_2^i, \ldots, O_{n_i}^i\}$. The operations have predefined technological sequence.

The operation O_i^j has an operation time p_{ij} and is assigned on machine M_k from the set of machines M.

The solution is a scheduling of the jobs on the machines. The aim is to minimize the completing time of all the jobs.

When the problem is large, it is difficult to solve it in a reasonable time using exact methods. For this reason, metaheuristic methods are applied, which find an approximate solution in a short time.

In this article, we solve a variant of the job shop scheduling problem, related to the production of knitted clothes. To solve the problem, we propose an algorithm based on the ant colony optimization.

The organization of the rest of the paper is as follows. Section 2 gives literature review of the variants of job shop scheduling problems and methods to solve them. Section 3 provides the definition of the considered variant of the job shop scheduling problem. Section 4 describes the algorithm for solving the problem. Computational examples are given in Section 5. Section 6 gives some concluding remarks and direction for future work.

II. Literature Review

When manufacturing a product, we have various measures and constraints. There may be a requirement that jobs be completed in a minimum time or within a given interval. Another requirement may be minimizing the cost of the production, and others. The problem may relate to optimizing one of the measures or to meeting a maximum number of criteria.

In [6] scheduling considers flexible manufacturing system. They solve the problem by applying an adaptive genetic algorithm. Machine flexibility is the focus of the problem solved in [7], [8]. They consider energy efficiency too. Job shop scheduling problem is applied on semiconductor production [9], manufacturing of machines [10], automobile industry [11], metallurgical industry [12].

Wang [13] solves robust job shop problem with a specific structure. Dynamic flexible job shop problem is solved in [14]. Biogeography-based optimization algorithm for solving flexible multi-objective job shop problem has been proposed in [15].

Anghinolfi [16] apply a split greedy heuristic for parallel machine scheduling. In [17] has been proposed a hybrid genetic algorithm for energy adaptive production. Scalia [18]

proposed mixed integer programming model for solving job shop scheduling problem. In [19] is applied implementation in Python using *pyomo* library for solving the problem. A review of flexible job shop scheduling problem is done in [20].

III. Knitwear Production Problem

In this article, we consider the problem of optimizing the production of knitted garments. This is a variant of job shop scheduling problem. Suppose there is an order to produce knitted shirts. The shirts come in $s = 3$ sizes: M, L and XL. $N_{i,j}$ units of type i and size j must be produced, where $i = 1, \ldots, d$ and $j = 1, \ldots, s$. Each shirt consists of $d = 4$ types of parts: front, back, collar and two sleeves. t_{ij} is the time for manufacturing part i of size j, $i = 1, \ldots, d$ and $j = 1, \ldots, s$. There is a set M of m machines available. $M_{i,j,k}$ is the number of parts of type i and size j that are manufactured on machine k, $i = 1, \ldots, d$, $j = 1, \ldots, s$ and $k = 1, \ldots, m$. All machines are identical. The material used to make the shirts is the same and therefore does not require recharging.

The time during which machine k operates is:

$$T_k = \sum_{i=1}^{d} \sum_{j=1}^{s} M_{i,j,k} * t_{i,j} \tag{1}$$

We assume that all machines start working on the order at the same time. Thus the order completion time is:

$$T = \max_{k=1}^{m} T_k \tag{2}$$

or this is the time by which all the machines will have finished working.

The objective is to minimize T, or to find the minimal order completion time, $\min T$. The solution is described by the matrix M with elements $M_{i,j,k}$, indicating which parts will be manufactured on which machine.

The mathematical description of the problem is as follows: We look for:

$$min \left(max_{k=1}^{m} \left(\sum_{i=1}^{d} \sum_{j=1}^{s} M_{i,j,k} * t_{ij} \right) \right) \tag{3}$$

fulfilling the conditions:

$$\textstyle\sum_{k=1}^{m} M_{i,j,k} = N_{i,j} \quad i = 1, \ldots d \quad j = 1 \ldots s \tag{4}$$

The aim is to finish the order for the minimal time.

IV. Production Scheduling

The job shop scheduling problem is NP-hard combinatorial optimization problem. This type of problem requires a large amount of computer memory and an exponential number of calculations. For this reason, when the size of the problem is large, it could not be solved by an exact method or traditional numerical method. In such cases, metaheuristic algorithms are applied. Metaheuristic methods are iterative stochastic methods, based on random searches or searches with probability and statistical feedback from the results of previous iterations. Prior knowledge of the task and estimates, if any, are also used to improve and guide the search.

One of the most successful method for solving combinatorial optimization problems is Ant Colony Optimization (ACO) [21], [22]. In the early 1990s, Marco Dorigo proposed a stochastic method for solving combinatorial optimization problems, based on observations of the behavior of ants in nature [23]. The main thing is how ants manage to find the shortest path to a food source, marking the paths with pheromone and following the one with the highest concentration of pheromone. In order for ants to be imitated, the problem to be solved must be reduced to finding the shortest path. This is done by representing the problem in terms of a graph. A shortest path is searched in the graph under certain conditions, using numerical information (weight) on the edges or nodes of the graph, imitating the pheromone in nature. Ants use a combination of pheromone and random search to improve their path.

Artificial ants move to a new node in the task graph using a transition probability. This consists of heuristic information and the pheromone corresponding to that transition.

$$P_{i,j} = \frac{\tau_{i,j}^{a} \cdot \eta_{i,j}^{b}}{\sum\limits_{k \in Unused} \tau_{i,k}^{a} \cdot \eta_{i,k}^{b}}, \tag{5}$$

where P_{ij} is the transition probability to go from node i to node j, η_{ij} is the heuristic information related to the problem and τ_{ij} is the quantity of the pheromone, $Unused$ is the set of nodes which are not used yet in the solution.

It starts with a small positive pheromone value, the same for all elements of the graph τ_0, $0 < \tau_0 < 1$. After each iteration, the pheromone is updated depending on whether the corresponding vertex belongs to a solution and how good this solution is compared to the other solutions found. The main pheromone update rule is:

$$\tau_{i,j} \leftarrow \rho \cdot \tau_{i,j} + \Delta\tau_{i,j}, \tag{6}$$

ρ mimics evaporation in nature, which reduces the amount of pheromone over time. Then, a new pheromone is added $\Delta\tau_{i,j}$, which depends on the quality of the solution and is inversely proportional to the value of the objective function.

The iteration ends when all ants have built their solutions, i.e. the transition probability is 0. The algorithm ends its work when: it has performed its predetermined number of iterations; when there is no improvement in the result for a fixed number of iterations; when the value of the objective function is sufficiently close to a predetermined lower bound.

One of the important elements in applying the ant method is the description of the problem with a graph. The graph we use to describe the problem we are solving is three-dimensional, and node (i, j, k) corresponds to element i of size j manufactured on machine k, $i = 1, \ldots, d$, $j = 1, \ldots, s$, $k = 1, \ldots, m$. This node is assigned a value $M_{i,j,k}$, which indicates how many units of element i of size j to be manufactured on machine k. So if on machine k produces parts of type i, size j, then $M_{i,j,k} > 0$. If on machine k

does not produced parts of type i, size j, then $M_{i,j,k} = 0$. This means that a single part and size can be manufactured on several machines, and different parts with different sizes can be manufactured on one and the same machine.

Graph of the problem is completely connected. An ant begins building the solution from a random node in the graph. At the begining the value of $M_{i,j,k} = 0$, $i = 1, \ldots, d$, $j = 1, \ldots, s$, $k = 1, \ldots, m$, because the distribution of the parts along the machine is not fixed. When the ant passes through node (i, j, k), the value of $M_{i,j,k}$ increases by 1 or $M_{i,j,k} \leftarrow M_{i,j,k} + 1$. The ant can go through the same vertex (i, j, k) multiple times adding 1 to $M_{i,j,k}$. The important thing is not to violate the constraints of the problem.

The pheromone will be associated with the nodes of the graph. It indicates the importance of the node to the solution. Thus, pheromone $\tau_{i,j,k}$ corresponds to node (i, j, k) and its value indicates how important it was for the solutions of the previous iteration. So, the quantity of the pheromone $\tau_{i,j,k}$ indicates how significant the node was for the decisions of previous iterations.

At the beginning, we randomly select one of the elements to be manufactured and assign it to a randomly selected machine. Every time an element i of size j is assigned to machine k, we increase the value of $M_{i,.j,k}$ by 1.

To assign the next elements for fabrication, we select element i of size j at random and we calculate the transition probability to assign it to one of the machines. The transition probability is a product of the amount of pheromone and the heuristic function uses prior knowledge of the problem to guide the search for a good solution. We propose the following heuristic function:

$$\eta_{i,j,k} = \frac{1}{T_k} \tag{7}$$

where the value of T_k is calculated for the current values of the elements of the matrices M by increasing the value of $M_{i,j,k}$ by 1. We calculate the transition probability for the selected element i of size j for all possible machines k. We choose the node (machine) with maximum probability. If there are two or more nodes $(i, j, k_1), \ldots, (i, j, k_s)$, $1 \leq s \leq m$, with the same transition probability value, then we choose one of them randomly.

After an element i of size j is selected to be manufactured on machine k, we increase the value of $M_{i,j,k}$ by 1, $M_{i,j,k} \leftarrow M_{i,j,k} + 1$. At the same time we decrease the value of $N_{i,j}$ by 1 $N_{i,j} \leftarrow N_{i,j} - 1$. The current value of $N_{i,j}$ shows how many items of type i and size j have not yet been assigned to the machines for the production.

The algorithm repeats until $N_{i,j} = 0$, for all $i = 1, \ldots, d$ and $j = 1, \ldots, s$. This means that all the parts have already been assigned for the production on the machines, i.e. the ant has built the solution. The matrix M shows for each type and size of parts on which machine and how many are produced.

The order of the production of the parts is not important, so for each machine k it is possible to produce first all the parts of type 1 and size 1, then all the parts of type 1 size 2 and so on, and at the end all the parts of type d and size s.

When all the ants have built their solutions, we calculate the value of the objective function, i.e. the time to complete the order. Then we update the pheromone. After reducing/evaporating the pheromone with the evaporation parameter ρ, we add a new pheromone.

$$\begin{array}{lll} \Delta\tau_{i,j,k} = & (1-\rho)\frac{1}{T} & \text{if} \quad M_{i,j,k} \neq 0 \\ \Delta\tau_{i,j,k} = & 0 & \text{if} \quad M_{i,j,k} = 0 \end{array} \tag{8}$$

This concludes the current iteration. The algorithm performs a predetermined number of iterations or there is a fixed number of iterations without updating the results. In our problem, updating the results occurs when the time for filling the document is reduced.

V. Computational examples

The organization of the production is very important for its success. Given a variety of elements and a fixed number of the production machines, the elements must be distributed so that the order can be completed in the shortest possible time. In the task of producing knitted garments, there are knitting machines that can produce each of the elements. The material used to make the garments is the same for the entire order. Therefore, there is no delay in moving from one item to another because there is no need to load new material. The garments produced come in three sizes: *M*, *L*, *XL*. The machines available for the production are identical and the same item is produced on each of the machines in the same amount of time. Each garment consists of four parts/elements, a front, a back, a collar and two sleeves. The individual elements can be manufactured on different machines. It is important that for each size the number of fronts is equal to the number of backs, is equal to the number of collar and the number of sleeves is twice as large as the number of other elements. This is a necessary requirement so that the garments can then be assembled. Let the time for making the individual elements be as indicated in Table I.

TABLE I: Knitted shirt production time

element	size M	size L	size XL
front	17 min	18 min	19 min
back	13 min	14 min	15 min
sleeve	10.5 min	11 min	12.5 min
collar	3 min	3 min	3 min

The data on the production time for each element was taken from a Bulgarian company producing knitted garments.

Let the company have 3 machines. The machines are identical and each of them can knit each of the elements. Let an order be received for the production of knitted shirts as noted in Table II.

TABLE II: Knitted shirt order

shirts	size M	size L	size XL
	10 pieces	20 pieces	10 pieces

Each size could be produced on a separate machine. This is one possible solution, but not optimal. If the production of

the parts is distributed in this way, each of the machines will complete its assigned work in the following time Table III.

TABLE III: Knitted shirt production time solution 1

shirts	machine 1	machine 2	machine 3
shirt quantity	10M	20L	10 XL
front	10M	20L	10XL
back	10M	20L	10XL
sleeve	20M	40L	20XL
collar	10M	20L	10XL
production time	540 min	1140 min	620 min

With this distribution of work, the order will be completed in 1140 minutes, which is 19 hours. This is the time by which all machines will have finished working. The machine 2 finished last and it determines the order execution time.

Another valid solution is to have machine 1 produces all 10 risques of size M and only 4 of size L. Machine 2 produces 13 risques of size L, and machine 3 produces all 10 risques of size XL and 3 risques of size L. This way, the distribution of work across machines will be almost even. The machines will complete its assigned work in the following time Table IV.

TABLE IV: Knitted shirt production time solution 2

shirts	machine 1	machine 2	machine 3
shirt quantity	10 M + 4 L	13 L	3 L + 10 XL
front	10M, 4L	13L	10XL
back	10M, 4L	13L	10XL
sleeve	20M, 8L	20L	10XL
collar	10M, 4L	13L	10XL
production time	768 min	741 min	791 min

With this distribution of work, the order will be completed in 791 minutes, which is 13 hours and 11 minutes, which is shorter than previous solution. The machine 3 finished last and it determines the order execution time.

Let's apply the ant colony optimization to solving the problem of making knitted shirts. We use 2 ants. Every ant constructs his own solution and after we compare them and choose the better and it will be the iteration best solution. We compare it with the current global best solution and if it is better it is the new global best solution. The ant chose randomly an element from the order and assigns it to randomly chosen machine. After the ant chose randomly other element from the order and calculates the transition probability to be assigned to every one of the existing machines. The element is assigned for the production to the machine with a higher probability. This procedure is repeated till all elements from the order are assigned. After several iterations our ant algorithm achieves following solutions, see Table V and Table VI.

TABLE V: Ant's solution 1

element	machine 1	machine 2	machine 3
front	10M, 4L	14L, 1XL	2L, 9XL
back	10M, 4L	14L, 1XL	2L, 9XL
sleeve	20M, 8L	28L, 2XL	4L, 18XL
collar	10M, 4L	14L, 1XL	2L, 9XL
time	768 min	760 min	770 min

With this distribution of work, the order will be completed in 770 minutes, which is 12 hours and 50 minutes, which is shorter than previous solution. The machine 3 finished last and it determines the order execution time.

TABLE VI: Ant's solution 2

element	machine 1	machine 2	machine 3
front	10M, 4L	14L, 1XL	2L, 9XL
back	10M, 4L	14L, 1XL	2L, 9XL
sleeve	20M, 8L	28L, 2XL	4L, 18XL
collar	10M, 3L	16L, 1XL	1L, 9XL
time	765 min	766 min	767 min

With this distribution of work, the order will be completed in 767 minutes, which is 12 hours and 47 minutes, which is shorter than previous solution. The machine 3 finished last and it determines the order execution time. We observe that the time during which the machines work to fulfill the order is almost the same. The difference in time is within 1 to 2 minutes, which is less than the time for producing any of the elements. Therefore, if we move a part from one machine to another, the total order execution time will not be reduced any further. This gives us reason to assume that the proposed algorithm, based on the ant colony optimization, has found the optimal solution for this example.

VI. Conclusion

This paper proposes an ant colony optimization algorithm for solving the knitwear production scheduling problem. This is a problem coming from the industry. The simplest variant of the task is solved, where we have a single type of machine and the manufactured parts are of the same type and differ only in size. In our future work, we will test the algorithm with large examples with a range of several hundred numbers of elements. We will include the creation of clothes in different colors, which will require a recharge of the machine, which takes time , but it will not require a reconfiguration. Another variant of this problem involves producing multiple types of garments, which would require machine reconfiguration time.

***Abstract*—This paper examines the challenges in distributing AI models through file transfer mechanisms. Despite advancements in security measures, vulnerabilities persist, necessitating a multi-layered approach to mitigate risks effectively. The physical security of model files is critical, requiring stringent access controls and attack prevention solutions. This paper proposes a novel solution architecture that protects the model architecture and weights from attacks by using Moving Target Defense (MTD), which obfuscates the model, preventing unauthorized access, and enabling detection of changes to the model. Our method is shown to be effective at detecting alterations to the model, such as steganography; it is faster than encryption (0.1 seconds to obfuscate vs. 18 seconds to encrypt for a 2500 MB model), and it preserves the accessibility of the original model file format, unlike encryption. Finally, our code is available at https://github.com/ArielCyber/AI-model-MTD.git.**

I. Introduction

THE swift evolution of Artificial Intelligence (AI) technology has made it a top priority for cybercriminals looking to obtain confidential information and intellectual property or cause damage in different ways. These malicious individuals may try to exploit AI systems for their own gain, using specialized tactics alongside conventional IT methods. In particular, attackers may wish to gain access to a trained AI model for any number of reasons: to exfiltrate valuable data from victims, including stealing trained AI model data, to tamper with the model, for example, implanting backdoors [1], etc. Given the broad spectrum of potential attack strategies, safeguards must be extensive.

While adversarial AI model security [2], [3], privacy [4] and operational security aspects of AI receive much attention [5], [6], it's equally important to address the physical file security aspects of AI models. In this day and age, an AI model is a valuable asset; training AI models is a long and extremely expensive process, hence, the resulting trained models are the sole artifacts that carry the effort put into the training process.

Figure 1 shows the simplified AI model architecture. Inside the model, we have the architecture metadata (in some cases), model weights (numeric parameters such as weights/biases), and optional metadata such as labels and notes. The model weights essentially carry the frozen state of the model after training, they represent the model's "knowledge" of the task it was trained on. Therefore, deploying trained AI models necessitates protecting the model file, and in particular, the trained weights. The model might be exposed to danger in different scenarios: in training, transit, deserialization, and inference.

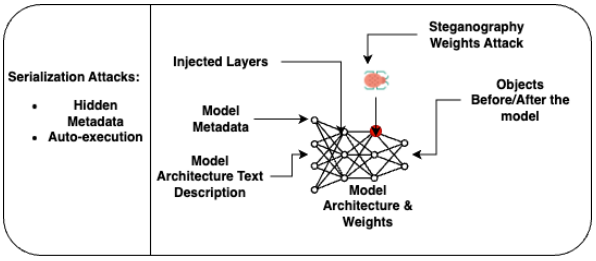

Fig. 1. Simplified AI model file architecture, and serialization attacks and steganography attacks that utilize the AI model file.

The National Security Agency (NSA) recently released a Cybersecurity Information Sheet (CSI) [5]. The CSI is intended to support National Security System owners and Defense Industrial Base companies deploying and operating AI systems designed and developed by an external entity. The CSI illustrates the steps to protect the deployment and two main points directly related to this work. The first is to validate and test the AI model. The second is protecting AI model weights. The NSA CSI suggests the following protection steps:

- Harden interfaces for accessing model weights to increase the effort it would take for an adversary to exfiltrate the weights.
  - Implement hardware protections for model weight storage, disable unnecessary hardware communication capabilities, and protect against emanation or side-channel techniques.
  - Aggressively isolate weight storage. For example, store model weights in a protected storage vault or enclave

The Open Web Application Security Project (OWASP) has been at the forefront of web application security for years. Recognizing the burgeoning significance of machine learning, OWASP introduced the "Top 10 Machine Learning Risks"

[7], a compilation that categorizes and outlines the most prevalent threats targeting AI systems, specifically about the content of the model and the threats around it. Examples of the discussed attacks are inference attacks and poisoning attacks. Of all the discussed threats, the AI Supply Chain Attacks are the most relevant to this work, while the other attacks are related to the content and integrity of the model. In the AI supply chain attack use case, an attacker modifies or replaces a machine learning library or model used by a system. This can also include the data associated with the machine learning models. MITRE Adversarial Threat Landscape for Artificial-Intelligence Systems (ATLAS™) [8] is a comprehensive knowledge base. It's designed to document adversary tactics, techniques, and case studies pertinent to machine learning (ML) systems. These details are amassed from real-world observations, demonstrations by ML red teams and security groups, and academic research. In terms of this research, ATLAS helps to understand the attack surface, but it is not a cyber solution. This work is positioned in MITRE ATLAS as a solution against user execution of unsafe ML Artifacts (AML.T0011.000) [9].

While growing, the literature on physical AI model security is still in its early stages [10], [11], [12], [13]. As the adoption of AI and Machine Learning (ML) technologies continues to rise, the need for robust security measures becomes increasingly critical. This work focuses on providing a secure solution to train, transfer, and ingest AI models.

In this work, we propose model weight separation based on Moving Target Defense (MTD) of model weights. Our MTD also provides verification and authentication mechanisms to guarantee the model's validity. By adopting an agreed-upon framework of obfuscation of serialized models and verifying models upon deserialization, model receivers can ensure they ingest models safely, whether as part of a supply chain or directly using the model.

The paper is organized as follows: Section II summarizes the paper's contribution. Section III reviews the related work. Section IV presents the MTD solution architecture. Section V describes our threat model. Section VI offers a detailed description of our dataset. In Section VII, we present our research evaluation and validation methodology. Subsequently, in Section VIII, we discuss our limitations. Finally, Section IX provides our conclusions.

II. Contribution

This work reviews the state-of-the-art physical Artificial Intelligence (AI) model security solutions. For the first time, as far as we know, we suggest a novel zero-trust solution based on MTD for AI model weights.

- We suggest a novel zero-trust MTD solution designed to bolster the robustness and security of AI models against potential threats. This approach ensures protection throughout the entire model life cycle, from its initial training phase to its final distribution. Consequently, it provides a strong defense against physical file-based attacks on the model weights and prevents unauthorized use of the trained model by obfuscating the model weights.
- We fully publish our code [14].

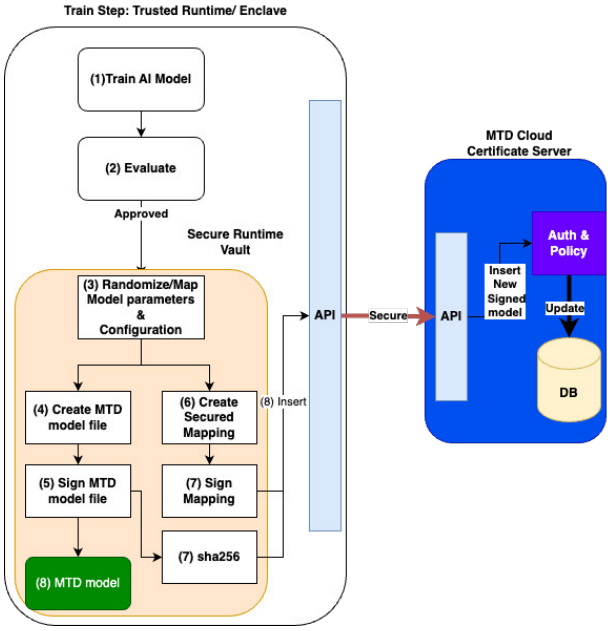

Fig. 2. MTD model creation inside a secure enclave

III. Related Work

Moving Target Defense (MTD) [15] is a proactive cybersecurity strategy that increases the complexity and cost for attackers by continuously changing the attack surface. Unlike traditional defense mechanisms, MTD introduces variability and unpredictability into the system, making it more challenging for attackers to exploit vulnerabilities. MTD encompasses techniques like IP address hopping [16], port rotation [16], virtual machine migration [17], code diversification [18], software obfuscation [19], memory randomization [20], and data randomization [21]. It is helpful in network and software security and represents a paradigm shift in cybersecurity by emphasizing dynamic and adaptive defense mechanisms. Our AI model MTD uses model weight randomization and reconstruction to prevent all model weight attacks and report an attempt of an attack.

IV. Architecture & Solutions

In this section, we describe our MTD methodology, which provides comprehensive protection against physical attacks on the model weights and prevents unauthorized use of the trained model. It is used to save and load models.

The architecture is divided into two parts: MTD creation (Fig. 2) and MTD loading (Fig. 3). If the model is not MTD protected, a fallback step optionally uses Content Disarm and Reconstruction (CDR) methods that were discussed in previous works [22] (Fig. 3).

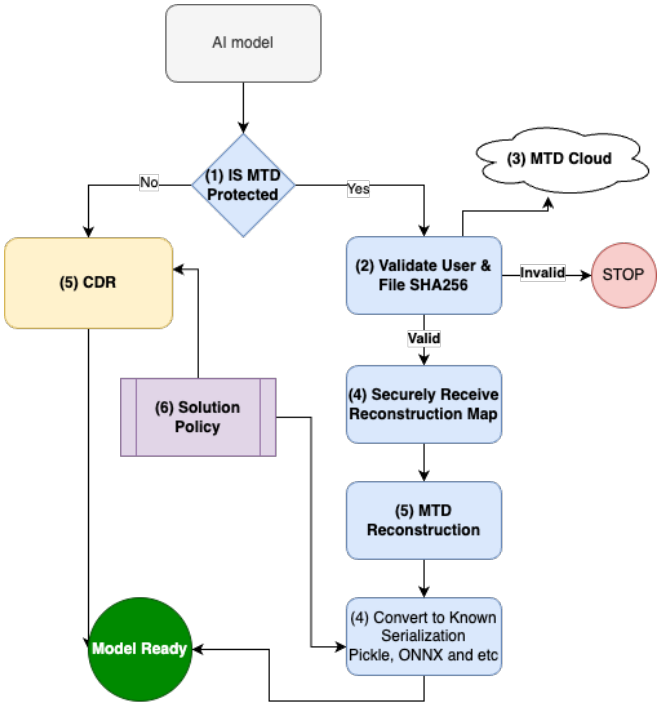

Fig. 3. MTD model loading and fallback to CDR

The model training process powered by MTD is demonstrated in Fig. 2 and occurs within a secure runtime environment or enclave [23]. Once the training is complete (1) and model evaluation passes (2), the MTD process (3) begins. The NSA [5] recommends separating the model and its weights. Therefore, the MTD algorithm randomizes the model weights, separates the model mapping from the randomized weights, and prevents unauthorized use of the trained model. To provide additional security, the MTD model's weights can be encrypted. This produces a file (4) that is protected by MTD. We sign and send this file to the cloud (5, 8) along with a mapping (6). We also sign and store the mapping in the cloud (6, 7). To further protect the model, upon saving the MTD model, we save a sha256 hash of the model weights and verify the hash on load.

Figure 3 shows how the MTD-protected model is loaded. First, it checks (1) if the model is MTD protected. If it's not, CDR (5) is used instead. If the model is protected, it's validated (2) with the MTD cloud API (3). If any modifications are detected, an alert is sent, and the process is stopped. If the model is valid, the mapping is received, and the model is reconstructed. Once the model is reconstructed, it can be saved to a file or kept in memory. It's important to note that this process assumes that if the user is compromised, it's already too late, and the focus is on securing the model and not the device. AI inference can also run inside a secure enclave. Our future work will focus on securing AI PC, which is expected to be the future of running large language models by utilizing a Neural Processing Unit (NPU) (see [24]).

V. Threat Model

To ground our security analysis, we first formalise the adversary we seek to resist, the assumptions we place on system components, and the boundaries of our evaluation. The threat model presented here guides the design choices in Section IV and underpins the evaluation in Section VII.

A. System Participants and Assets

We consider three roles:

- **Model Owner** - trains the network inside a trusted hardware enclave, applies the proposed Moving-Target Defense (MTD) to obfuscate the weights, and signs the resulting artefacts.
- **Distribution Service** - a cloud repository that stores the MTD-protected weight file and the corresponding reconstruction mapping, exposes a mutually-authenticated API, and returns the mapping only to authorised consumers.
- **Model Consumer** - fetches the protected file, verifies the signature, retrieves the mapping via the API, reconstructs the model, and performs inference.

The primary assets are: (i) the trained weights, (ii) the architecture/mapping that re-orders the weights, and (iii) the Model Owner's signing key.

B. Adversary Capabilities

The adversary ("*A*") is *active* and may:

1) Observe, intercept, replay, or tamper with any file transferred between participants (supply-chain attack, man-in-the-middle, malicious mirror).
2) Obtain *direct* read–write access to any storage location that holds the protected file at rest (e.g., compromise of a consumer endpoint or removable media).
3) Craft and deliver malicious model artefacts that embed steganography, hidden payloads, or altered weights in an attempt to bypass verification.
4) Deny or delay network access to the Distribution Service.

A cannot (by assumption):

- Break standard cryptographic primitives (digital signatures, SHA-256 hashes, authenticated encryption).
- Extract secret keys from the hardware enclave or the Model Owner.
- Compromise the integrity of the Distribution Service's authentication and access-control logic.

C. Trusted Computing Base (TCB)

Our TCB consists of:

- The hardware enclave used for training and MTD obfuscation, including its firmware and attestation chain.
- The Model Owner's private signing key and the correctness of the signature-generation process.
- The Distribution Service's storage and access-control mechanisms (but *not* its surrounding OS or network, which may be hostile).
- Standard cryptographic libraries and their implementations.

TABLE I
SUBSET OF PYTORCH MODEL ARCHITECTURES USED TO VALIDATE THE SUGGESTED MTD METHOD.

Model Type	Model Architecture	#Models	Size [MB]
Vision (Classification)	AlexNet [25]	1	230
	ConvNext [26]	4	110-750
	DenseNet [27]	4	30-110
	EfficientNet [28], [29]	12	20-450
	RegNet [30]	34	20-2460
Vision (Segmentation)	DeepLabV3 [31]	3	40-230
Vision (Detection)	Faster R-CNN [32]	4	70-160
Vision (Video)	SwinTransformer [33]	4	110-360
Text	BERT [34]	8	440-1440
Audio	Wav2Vec [35]	2	380-1270

D. Out-of-Scope Scenarios

The following are expressly excluded from this work:

- **Data poisoning, backdoor insertion during training, or adversarial-example attacks at inference time.** These alter model *behaviour* rather than the on-disk artefact and are orthogonal to file-level protection.
- **Full host compromise *before* MTD creation** (if the training environment is already under attacker control, any file- level defence is moot).

VI. DATASET

For evaluation of our suggested method, we create 2 datasets: benign AI models, and AI models attacked with steganography.

Dataset 1 - Benign PyTorch models: A dataset of benign pre-trained PyTorch models. We compile this dataset using the torchvision and HuggingFace APIs. Table I contains a subset of the pre-trained model architectures we used. In total, this dataset contains 129 vision, text, and audio models. We use this to validate our method on benign data, and it is used as a base for creating a dataset of models attacked with steganography (dataset 2) for further evaluation.

Dataset 2 - Attacked models for MTD method evaluation: We use LSB model weight steganography attacks [36] from our previous work on the benign models from dataset 1 to validate the MTD verification, ensuring that the MTD process works as intended with untempered models and also that the method successfully detects changes (i.e., physical attacks) in the model as intended.

VII. EVALUATION

This section evaluates our proposed AI model MTD method. The experiments are designed to prove that the method has practical value for protecting AI model ecosystems from physical attacks such as data exfiltration or unauthorized access to the trained AI model.

Experimental Setup: All experiments are run on a Ubuntu Linux 24.04 server, equipped with an Intel(R) Xeon(R) w5-2445 CPU (20 cores @ 3.10GHz), and 128 GB RAM.

Baseline Method: In terms of obfuscating the model to prevent unauthorized access, the immediate solution is to encrypt the serialized payload before transmission. This is also suggested by the NSA CSI [5] to ensure security of the model files. In our experiments, we compare our suggested MTD method to the Fernet encryption algorithm in terms of runtime. The MTD approach has the property of keeping the model file accessible, i.e., recognizable as the original model file, but the trained state is only available to the rightful owners of the model. This can be a benefit, for example, in scenarios such as model hubs that index the model and give an overview of its metadata, like HuggingFace does; with encryption, this won't be possible.

A. Experimental Results

We evaluate the MTD method for protecting training models with 2 main concerns: validity and runtime. Validity means we assert that the method prevents the attacks it's supposed to prevent and that the models stay intact after the whole process. We measure runtime to analyze the time overhead that the MTD methods cause. On the model sender side, there are the obfuscation and saving (serialization) methods, and on the model receiver side, there are the loading (deserialization) and the deobfuscation methods. We created automated Quality Assurance (QA) tests to check the method's validity. The tests check the following:

1) MTD model is the same after obfuscation and deobfuscation.
2) MTD model is the same after saving and loading.
3) Attack simulation: An MTD Model is constructed, obfuscated, and saved. Then the model weights are attacked, and we assert that the change is detected upon load.

For steps 1 and 2, we use the benign PyTorch models dataset (dataset 1, see Section VI); for step 3, we use dataset 2. All tests passed. Figure 4 plots the mean runtime of saving and loading MTD functions on all models in dataset 1, repeated 10 times. Additionally, we compare the runtimes to regular saving and loading to quantify the additional overhead our suggested method adds. Saving and loading were done with a virtual file since we are only concerned with the runtime overhead our method adds. We can see our MTD method adds approximately 4 seconds of runtime overhead to the serialization of a 2500 MB model; we feel this is within reason. Additionally, looking at Table II, we can see MTD obfuscation/deobfuscation has almost no runtime overhead, while the alternative method of encrypting the payload has a significant runtime overhead (about 17 seconds for a 2500 MB model). Therefore, in total, choosing our MTD method will be faster than using encryption. Finally, the MTD deserialization method has nearly identical runtime to regular runtime. In conclusion, the suggested MTD method is faster than encryption, especially as model size scales, and it also keeps the model file accessible in terms of metadata, structure, etc., which can be useful for sites like HuggingFace that give high-level overviews based on the model metadata.

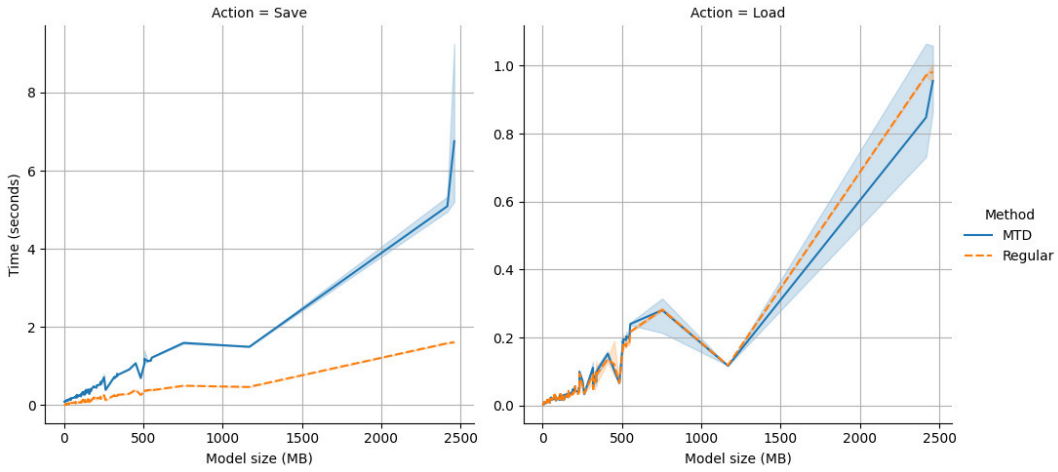

Fig. 4. Mean time (seconds) measurement vs. model size (MB) of saving/loading MTD actions. We show the MTD variant (solid blue line) and the regular variant (dashed orange line) for save and load. The action procedures were repeated 10 times with each model in the MTD datasets, and we show confidence intervals. We can see a linear increase in serialization (saving) runtime as the model size grows, and MTD has little to no overhead on loading the model after serialization.

TABLE II
RUNTIME (SECONDS) OF SERIALIZATION/DESERIALIZATION USING OUR SUGGESTED MTD METHOD, AND THE BASELINE FERNET ENCRYPTION METHOD.

	Model Serialization		Model Deserialization

VIII. LIMITATIONS

The proposed solution introduces a novel architecture for physically securing AI model files from malicious exposure. The architecture prevents all file alterations when the model is secured with the suggested MTD method. This builds upon previous work on CDR against steganography attacks [37] and steganalysis [36] (steganography attack detection). Since AI model file security is still in its early stages, we expect to see more sophisticated attacks and vulnerabilities in this domain. The proposed MTD architecture requires the user to fully use the various AI model functions, such as training and serialization within it, but widely-used methods like SafeTensors [38] do so too. Moreover, the proposed method adds a certain performance overhead that is added to all models since it works in a zero-trust manner. However, the performance overhead is small, as described in the results section. It is important to note that this work focuses solely on the security of the AI model's physical file. Other adversarial attacks exist, such as backdoors in machine learning models [1] and dataset poisoning attacks [39]. Dataset attacks are outside this paper's scope, but future work should view them as part of a holistic platform.

IX. CONCLUSIONS

Our work proposes a new solution for securing AI model files by preventing file modifications and unauthorized access through the use of MTD and authentication. This architecture aims to secure AI model file transfers from malicious attacks that threaten the industry. By incorporating MTD, we follow the NSA's [5] recommendation to separate the model architecture and its weights. This is accomplished by randomizing the model weights and separating the model from the deconstruction mapping. This ensures that only authenticated users can reconstruct and use the model when it is distributed. Based on our experimental results, the proposed architecture provides a 100% attack prevention rate (129/129 tampered models were correctly alerted) under the assumed conditions. In addition, we show that our method is significantly faster than using encryption (0.1 seconds to obfuscate vs. 18 seconds to encrypt

for a 2500 MB model), and contrary to encryption, it also keeps the model file in the original format, which can allow to get a high-level overview of the model, based on the metadata (e.g., number of parameters, etc.). Of course, users can also choose to use encryption on top of our suggested method if they wish to. Our method was evaluated on a wide range of data, which includes diverse benign models and steganography attacks from the literature and real-world scenarios found in HuggingFace [40]

***Abstract*—Artificial Intelligence (AI) adoption poses complex, multidimensional challenges for organizations that extend beyond technical implementation. While strategic interest in AI is rising, many initiatives struggle to scale sustainably. This paper addresses the fragmented state of AI adoption research by offering a theory-driven synthesis of the key management challenges organizations face. Based on a systematic literature review and grounded in the socio-technical systems (STS) perspective, the study identifies challenges across technological, organizational, and social domains—such as data governance, organizational inertia, skill shortages, and ethical ambiguity—as mutually reinforcing. The resulting framework highlights the systemic entanglement of these barriers, underscoring the limits of isolated interventions. This study contributes to Information Systems (IS) research by conceptualizing AI adoption as a socio-technical transformation and providing an integrative typology of adoption challenges. The findings offer a foundation for future empirical research and guide strategic decision-makers in navigating the organizational complexity of AI integration.**

***Index Terms*—AI Adoption, STS, Organizational Change, AI Challenges, Information Systems**

I. Introduction

ARTIFICIAL Intelligence (AI) has recently evolved rapidly into a strategic priority for organizations across industries. In a 2019 survey, already over 84% of 1,500 surveyed C-suite executives from high-profit international companies across various industries emphasized that AI is essential for achieving their growth targets [1]. Despite this ambition, the majority of organizations continue to face substantial barriers in scaling AI effectively to this day [1], [2], [3]. Many initiatives remain confined to isolated pilot projects, lacking cross-functional integration and strategic alignment [1], [4]. Even as AI tools become more accessible, only a minority of organizations have redesigned their core workflows accordingly, and governance responsibilities often remain unclear or underdeveloped [2]. These discrepancies reveal a deeper issue: AI adoption is not merely a matter of technology implementation but requires ongoing adaptation to complex structural, procedural, and human dynamics. This paper, therefore, aims to identify and systematize the management challenges organizations must overcome to successfully adopt AI, using a socio-technical systems (STS) lens to account for the intertwined nature of these challenges.

Although existing research has addressed various barriers to AI adoption, ranging from technical and infrastructural issues to strategic misalignments or cultural resistance, it has typically examined these challenges in isolation. Several studies investigate specific barriers through expert interviews, systematic literature reviews, or conceptual models (e.g., [5], [6], [7], [8], [9]). However, few contributions adopt an integrative, theory-driven perspective that accounts for the socio-technical entanglement of AI adoption management challenges in organizations. On the other side, scholars increasingly argue that technological, structural, and social dimensions of AI implementation are tightly coupled and mutually reinforcing [9], [10], [11]. Without a holistic understanding of these interdependencies, even advanced AI initiatives risk stagnation or failure to scale sustainably [10], [12]. This paper responds to this gap by proposing a structured, STS-based

synthesis of existing knowledge on AI management challenges in an organizational context. To do so, the paper addresses the following research questions:

RQ1: *What are the management challenges of AI adoption in organizations?*

RQ2: *How does existing literature consider the socio-technical entanglement of the challenges?*

By providing a structured overview of AI adoption challenges from a socio-technical perspective, this paper contributes to Information Systems (IS) research in two ways: first, by enhancing theoretical understanding of AI adoption as an entangled socio-technical process; and second, by offering a systematic categorization of challenges that can support both academic inquiry and practical decision-making. The findings aim to support researchers, strategists, and policymakers in navigating the complex landscape of organizational AI management.

The paper is structured as follows: Section 2 provides the theoretical background on AI adoption and socio-technical systems. Section 3 outlines the methodological approach used to identify and synthesize the relevant challenges. Section 4 presents the results of the systematic analysis. Section 5 discusses the socio-technical interdependencies and implications for research and practice. Section 6 concludes with a summary and outlines directions for future research.

II. Background

AI is broadly understood as the science and engineering of developing intelligent systems capable of replicating or augmenting human cognitive functions such as reasoning, problem-solving, and decision-making [13], [14], [15]. When it comes to technology, AI comprises a diverse set of approaches including machine learning, deep learning, natural language processing, and computer vision [6], [7], [15], [16]. Functionally, AI can be defined as the capacity of systems to autonomously interpret data, learn from experience, and apply that learning to achieve goal-oriented behavior [8], [12]. Due to its general-purpose nature [17], AI is increasingly integrated into organizational routines, enabling automation, augmentation, and innovation across industries. In contrast to traditional IT systems, AI is characterized by three interrelated properties: autonomy, learning, and inscrutability [10]. Autonomy refers to AI's ability to make decisions without human intervention; learning captures the system's capacity to evolve through experience; and inscrutability addresses the opacity of AI decision-making, particularly in complex models such as deep neural networks [12], [18]. These characteristics complicate organizational control and validation practices and contribute to uncertainty in implementation outcomes[19]. As a result, AI systems often act as semi-autonomous agents, embedded in decision-making contexts with significant organizational and societal implications [20].

While the concept of technology adoption has been widely studied in the IS field (e.g., TAM, TOE, DOI), AI adoption presents a new level of complexity [9], [21]. The unique characteristics of AI challenge traditional assumptions regarding transparency, accountability, and control, rendering many existing models insufficient [21]. AI adoption refers not only to the technical integration of AI tools but also to the organizational transformation required to generate sustained business value [9], [12]. This includes the alignment of strategic priorities, development of technical and organizational capabilities, stakeholder coordination, and iterative adaptation of business processes [10], [14]. Several studies have already contributed to identifying and categorizing challenges related to AI implementation, drawing on methods such as qualitative interviews (e.g., [22]), conceptual frameworks (e.g., [14]), and systematic literature reviews (e.g., [8], [19]). These works have yielded valuable insights into key barriers, including data governance, infrastructure limitations, skill gaps, and organizational inertia. Collectively, they have helped establish a rich foundation for understanding critical factors that affect AI adoption. However, despite these advances, most studies tend to examine these challenges in isolation or emphasize predominantly technological or organizational dimensions. While a socio-technical entanglement of these challenges is often implied or acknowledged in principle [12], [18], a systematic and theory-based integration that explicitly maps their interdependencies across functional and structural boundaries remains limited. This fragmented view is problematic. Given the socio-technical nature of AI, challenges cannot be addressed in isolation. A detailed understanding of these challenges supports more effective implementation by revealing organizational gaps and enabling proactive risk mitigation. Yet, there is limited research that systematically examines how challenges from different organizational levels and functional domains interact and reinforce each other [5], [7], [8], [11], [12], including no systematic STS-classification of AI management challenges of AI adoption in organizations.

III. Method

In order to identify and synthesize current academic discourse on challenges in managing AI adoption in organizations, we conducted a concept-centric literature review following the guidelines of [23] and [24]. The objective was to provide a structured overview of the key challenges associated with organizational AI adoption and to analyze their socio-technical interdependencies using a theory-informed framework. We followed the five-stage model of [23] for literature reviews: (1) problem formulation, (2) data collection, (3) data evaluation, (4) analysis and interpretation, and (5) presentation. Stages (1) and (5) are addressed in the introduction and results sections, respectively; this section covers stages (2) through (4).

A. Data collection and evaluation

For our data collection, we use Litbaskets.io, a curated and reproducible search tool optimized for IS research, covering over 1,000 IS-relevant journals indexed in Scopus. This tool allows dynamic filtering of the "medium bucket" of 51 core IS journals and conferences, mitigating risks of over- or under-inclusiveness often associated with traditional search

strategies [25], [26]. To define the search space, we applied the string ("artificial intelligence" OR "AI") AND "manag*" AND "challenge*" across abstracts, titles, and keywords, covering the period from 2000 to January 2025.

The initial result of 196 hits was filtered by applying multiple exclusion criteria. First, duplicates and non-English entries were removed. Second, only papers addressing AI management challenges within an organizational context were considered, excluding papers focused solely on technical or specific domain implementations (e.g., in healthcare, logistics, or mobility domains) without addressing overall organizational implications. Third, the search was extended via forward and backward snowballing, as suggested by [24].

By adopting the described method, a targeted yet inclusive identification of AI-related literature was achieved, ensuring that both high-impact contributions and emerging research trends were systematically captured. At the end of the entire process, 15 publications specifically included challenges of AI management on an organizational level.

B. Data analysis and interpretation

The final corpus of 15 contributions was analyzed using the six-step qualitative thematic analysis procedure from [27]. This approach is well-established in IS research and supports systematic and transparent theme identification. The goal was to extract, classify, and interpret explicit challenges regarding AI management in organizations. We employed a deductive coding strategy guided by the Socio-Technical Systems (STS) model [28], [29], which conceptualizes work systems as interactions between four components: technology, task, structure, and people (cf. Fig. 1).

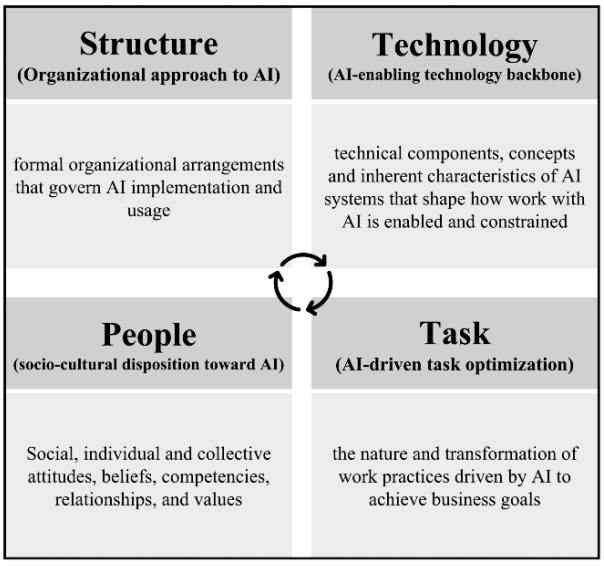

Fig 1 - STS perspectives applied on AI based on [28]

To explain the STS lens for AI adoption, we briefly outline the relevance of each of the four core perspectives. The *technology perspective* addresses the "AI-enabling technology backbone" and therefore refers to the technical components, concepts, and inherent characteristics of AI systems that shape how work is enabled and constrained. This includes, for example, physical infrastructure such as computing power and storage, as well as virtual resources such as pre-trained models, algorithms, training data, or IT-security efforts to keep the new technology safe. These elements determine not only the feasibility of AI deployment but also the system's autonomy, learning capacity, and opacity—factors which are central to how AI affects organizational routines (e.g., [8], [10]).

The *task perspective* considers the "AI-driven task optimization" and captures the nature and transformation of work practices driven by AI. It concerns the activities and processes through which organizational goals are pursued and how these are augmented, redefined, or automated by AI technologies. AI integration can shift task boundaries, introduce new dependencies, or alter performance criteria, thereby affecting both productivity and work design (e.g., [7], [19]). The *structure perspective* consolidates aspects of the "organizational approach to AI", which addresses the formal organizational arrangements that govern AI implementation and use. This includes decision rights, coordination mechanisms, and governance structures that define how responsibilities are distributed, risks are managed, strategies are defined, and AI capabilities are scaled across organizational units. As AI blurs traditional boundaries between human and machine decision-making, structural adaptation becomes a prerequisite for responsible and effective use (e.g., [22], [30]). Finally, the *people perspective* focusing on the "socio-cultural disposition toward AI" focuses on the human actors—such as employees, managers, and other stakeholders—and their perceptions, beliefs, competencies, and values. AI implementation is shaped by individual and collective attitudes, digital skills, trust in AI systems, and willingness to engage with algorithmic processes (e.g., [8], [12]).

This framework allows for theory-informed mapping of challenges and their systemic interrelations. The operationalization of the STS components was informed by prior IS research that applied similar socio-technical logics to technology and platform adoption (e.g., [26], [31]). Coding was conducted manually in Excel using a structured matrix and visualized on a collaboration board. One researcher initially coded all 15 papers, and afterwards the coding was refined across three iterative rounds in expert workshops with another 3 researchers. Disagreements in coding were resolved through discussion within the expert workshops until consensus was reached. During coding, no new categories emerged outside the STS framework, indicating thematic sufficiency. The final coding structure was thus stable and consistent with the four original dimensions. To ensure validity, definitions and representative indicators for each category were documented in a shared collaborative board and reviewed across the rounds.

IV. RESULTS

This section presents the identified management challenges in the literature that organizations face when adopting AI, answering RQ1 and visualizing the interdependencies regarding

RQ2 (cf. Table 1). It is oriented on the four STS model components and their derived categories.

A. Technology

The literature analysis resulted in 10 challenges related to the technology dimension of the STS model clustered by the categories AI security, AI infrastructure, AI characteristics, and data management.

In the context of the category **AI security**, addressing technical vulnerabilities emerged as a critical concern due to the growing deployment of AI systems in safety- and mission-critical domains. A key challenge lies in *mitigating security vulnerabilities* inherent to AI technologies, particularly those resulting from adversarial examples, data poisoning, or insufficient model robustness. These vulnerabilities present new attack vectors and expose AI systems to manipulation or malfunction, potentially leading to catastrophic outcomes in real-world applications [11], [32]. AI models, particularly those based on machine learning, are susceptible to inputs that are deliberately designed to cause misclassification while appearing benign to human observers —for example, when strategically placed stickers on a stop sign lead a vision model to interpret it as a speed limit sign [11]. This complicates the detection and mitigation of adversarial attacks. Furthermore, training data can be subtly manipulated to introduce harmful biases or reduce model performance, underscoring the urgency of robust data validation and attack-resilient learning algorithms [11].

In the category of **AI infrastructure**, *legacy integration* challenges persist as organizations attempt to embed AI within outdated or fragmented IT landscapes. Technical debt, rigid architecture, and incompatible data structures hinder seamless deployment and scalability. Consequently, AI implementation efforts are often delayed or limited in scope due to the inability of legacy systems to support dynamic and data-intensive AI functionalities [7], [9], [12], [16]. Beyond integration, infrastructure resilience has been identified as a prerequisite for the sustainable operation of AI systems [5], [7]. Ensuring resilience entails mitigating system downtimes, enabling rapid recovery, and maintaining consistent performance under stress [11], [16]. AI-specific demands, such as continuous learning and high-volume data processing, impose additional strain on traditional infrastructures [8], necessitating architectural adaptability and robust failover mechanisms [12]. Simultaneously, *ensuring infrastructure resilience* proves to be challenging, as there is a constant need to adapt to an increasingly volatile technological environment. Frequent shifts in tools, platforms, and vendor ecosystems place additional pressure on organizations to maintain flexibility without compromising reliability. A lack of strategic foresight or modularity in AI infrastructure design can result in systemic inefficiencies or incompatibilities when transitioning between rapidly evolving AI ecosystems [8], [9], [14].

The concerns within the category **characteristics of AI** stress the distinct challenges complicating its effective deployment and governance. A central issue arises from *the limited transferability of AI models*. Context-specific training and performance constraints hinder model generalization, thereby requiring resource-intensive retraining and calibration efforts when AI is applied across diverse domains or tasks [8], [10], [11], [16]. Compounding this is the difficulty of *understanding computable human cognition* within organizational settings. AI maturity is often overestimated, and the disparity between perceived and actual capabilities leads to misaligned expectations and strategic missteps in adoption efforts [7], [9], [14], [18], [19], [22]. Another key challenge lies in *handling probabilistic behavior*. AI systems frequently produce non-deterministic outcomes due to inherent stochastic modeling. This unpredictability can undermine user confidence, especially in critical applications requiring consistent and repeatable decisions [8], [11], [12]. Equally critical is the need to *address information processing bias*. Biases stemming from data selection, model assumptions, or systemic societal inequities can propagate through AI outputs, leading to skewed or unfair results that compromise ethical and operational standards [5], [8], [11], [14]. Finally, *handling the inscrutability* of advanced AI systems presents substantial governance risks. Complex architectures such as deep neural networks often lack interpretability, making it difficult to justify decisions or intervene in case of failure. This opacity impedes transparency and undermines accountability structures [8], [12], [14], [32].

Another category of **data management** addresses the management challenge of *ensuring a robust data foundation* as a critical prerequisite for the effective deployment of AI systems. Challenges arise when data is fragmented, incomplete, poorly structured, or inaccessible across organizational silos, thereby limiting model training quality and reliability. These limitations constrain the scalability and performance of AI applications and increase the risk of biased or unstable outcomes [5], [7], [8], [10], [16], [22]. Insufficient governance and weak integration between data sources further aggravate these problems. Inadequate metadata, inconsistent taxonomies, and a lack of data lifecycle management practices impede effective AI use and model interpretability. Moreover, the absence of real-time data pipelines delays responsiveness and undermines decision-making precision in dynamic environments [5], [7], [16]. As a result, building a solid data foundation not only requires a robust technical infrastructure but also strategic alignment between data stewardship, organizational objectives, and AI initiatives. Without such alignment, data management inefficiencies will propagate into model behavior, reducing trust, scalability, and business value across AI-driven systems [8], [10], [22].

B. Task

The literature analysis resulted in 4 challenges related to the task dimension of the STS model, all clustered within the category AI lifecycle management.

Within the category of **AI lifecycle management**, the *identification of valuable AI use cases* represents a persistent challenge. Strategic misalignment, lack of domain understanding, and unclear business objectives often hinder the selection of

use cases with real organizational impact. Without a systematic process to prioritize AI initiatives, resources risk being diverted to projects with limited value creation [5], [7], [8], [10], [12], [14], [30]. Once use cases are identified, *the optimization of AI solution design* becomes critical. Challenges emerge when requirements are poorly captured, stakeholder needs remain unstructured, or technical feasibility is not properly assessed. This leads to mismatches between designed systems and operational realities, reducing solution effectiveness and user acceptance [5], [8], [10], [12], [19], [22]. Equally complex is the *development of AI solutions*, where iterative prototyping, model training, and validation demand high levels of coordination and technical expertise. Challenges arise from data constraints, evolving requirements, and difficulties in transferring conceptual models into deployable systems, often resulting in extended timelines and reduced reliability [10], [11], [12], [14]. The *operationalization of AI solutions* further introduces barriers related to integration, scalability, and governance. Insufficient monitoring, unclear ownership, and a lack of standardized practices for maintenance and update cycles impede sustainable AI operations, placing long-term reliability and compliance at risk [8], [10], [12], [14], [16].

C. Structure

The literature analysis resulted in 10 challenges related to the structure dimension of the STS model clustered within the categories AI strategy, AI readiness, AI risk & compliance.

Within the category of **AI strategy**, the *alignment of strategic AI initiatives across organizational levels* presents a persistent challenge. Discrepancies between top-level vision and operational execution often result in fragmented initiatives, conflicting priorities, and inefficient resource use, undermining enterprise-wide AI coherence and effectiveness [6], [7], [10], [19], [30]. Closely related is the need to *align cross-domain collaboration for AI adoption*. Functional silos and disciplinary boundaries impede the integration of technical, business, and operational expertise, thereby restricting the co-creation of viable AI solutions and slowing organizational learning [5], [7], [9], [10], [18], [30]. Compounding these challenges is the difficulty of *identifying business value from AI integration*. Without clear mechanisms to assess and translate AI capabilities into measurable outcomes, initiatives risk remaining technology-driven rather than impact-oriented, limiting stakeholder support and long-term investment [5], [7], [8], [9], [10], [14]. A further obstacle lies in *clarifying the role of AI within the broader organizational vision*. Ambiguities regarding AI's strategic purpose or future role hinder commitment and direction, leading to ad hoc experimentation rather than coordinated transformation efforts [5], [6], [8], [18], [30]. Finally, the *navigation of resource constraints* remains a cross-cutting issue. Budget limitations, talent shortages, and technical debt constrain the scope, pace, and sustainability of AI initiatives, often forcing organizations to deprioritize foundational efforts in favor of short-term experimentation [5], [7], [8], [9], [14], [16], [19].

In the category of **AI readiness**, *ensuring transparency in information processing for organizational decision-making* has emerged as a critical concern. The opacity of AI-driven analytics impedes trust and accountability, particularly when decision outcomes cannot be traced back to interpretable data logic or model behavior, thereby limiting managerial acceptance and regulatory compliance [8], [11], [12], [14]. A further barrier is the *insufficient understanding of the organizational AI status quo*. Many firms lack a clear assessment of their current AI maturity, adoption level, and capabilities, which hinders strategic planning and investment prioritization, while also impairing the identification of internal gaps and alignment needs [7], [9], [14], [18], [19], [22]. Moreover, *managing the disruption caused by AI* constitutes a central readiness challenge. The transformation of workflows, redefinition of roles, and shift in decision authority induced by AI adoption frequently trigger organizational resistance, role ambiguity, and cultural friction, thereby complicating effective change management and sustainable implementation [5], [8], [12], [14], [18], [19].

Within the category of **risk and compliance**, the *management of AI-related risks* has emerged as a core organizational concern. Especially, in high-stakes environments, the inability to anticipate or explain AI behavior under attack undermines trust and usability. Therefore, increasing emphasis is placed on developing risk-aware AI systems capable of assessing, quantifying, and managing the multifaceted security threats posed by intelligent algorithms [11], [32]. Additionally, the probabilistic nature of AI systems, combined with limited transparency and unpredictable interactions, generates uncertainties that may result in unintended consequences, undermining both operational reliability and stakeholder trust [5], [8], [11], [16]. Closely connected to risk management is the challenge of *ensuring AI compliance*. Regulatory frameworks also increasingly demand transparency, fairness, and accountability in AI systems, yet technical opacity and unclear governance structures hinder compliance with standards such as the GDPR or emerging AI-specific regulations like the European AI Act [5], [8], [11], [12].

D. People

The literature analysis resulted in 3 challenges related to the people dimension of the STS model clustered within the categories AI competence development and AI workforce transformation.

In the category of **AI competence development**, *overcoming a lack of organizational AI competence* has been identified as a fundamental barrier to successful adoption. Deficits in technical skills, strategic understanding, and interdisciplinary collaboration inhibit the effective design, implementation, and governance of AI systems, leading to misaligned initiatives and underutilized potential [8], [9], [14], [19].

Looking at the category of **workforce transformation**, *facilitating human-AI collaboration* presents a significant challenge. Unclear role definitions, insufficient interface design, and a lack of trust impede effective interaction between employees and AI systems. Without structured integration and mutual augmentation, the potential of hybrid intelligence remains largely underexploited [6], [8], [12], [19], [22]. Moreover, *overcoming cultural distance toward AI* constitutes a critical barrier to transformation. Deep-seated skepticism, fear of replacement, and resistance to change create a climate of mistrust that slows down adoption and undermines engagement. Addressing these tensions requires not only communication and training, but also a shift in organizational mindset [5], [7], [8], [9], [18], [22].

V. Discussion

This section reflects on the findings, considering the two guiding research questions. First, we revisit RQ1 and summarize the identified barriers. Second, we address RQ2 by evaluating the extent and limitations of current research through the lens of the STS framework.

While the challenges identified—such as data bias [11], legacy infrastructure limitations [10], unclear strategic anchoring [30], or persistent skill gaps [7]— on their own are well-documented in the literature, their significance shifts when examined through a structured sociotechnical (STS) lens. The findings support and extend prior research by demonstrating that these issues do not merely coexist but are systematically interlinked across organizational levels. This multi-level mapping reveals not just the breadth but the vertical distribution of management challenges in the context of AI adoption. For instance, earlier studies have pointed to a misalignment between strategic intent and operational realization [7], whereas now results show how such misalignment frequently stems from disconnects between abstract ambitions and the concrete readiness of middle and technical layers. Moreover, it also becomes visible that, for example, technical-level data issues—such as infrastructure bottlenecks or lack of clean training data—can reverberate upward, fostering cultural skepticism toward AI and weakening governance capacity [12]. Although certain challenge areas are known previously from other contexts, our observations align with the broader literature, which increasingly acknowledges the systemic nature of AI adoption challenges. For example, [18] emphasizes that organizational readiness must be understood as a socio-technical configuration, not a purely technological state. Similarly, [19] stresses the need for integrated frameworks that bridge organizational, technical, and human dimensions. Our findings offer empirical reinforcement of these positions by illustrating how misalignments are often not incidental but structurally embedded, emerging from insufficiently coordinated transformation efforts across different layers of abstraction.

The second RQ examined how literature addresses the sociotechnical entanglement of AI management challenges. Our analysis shows that while many studies acknowledge interdependencies between technological, organizational, and human factors, few analyze them through a theory-informed lens. The application of the STS framework has demonstrated value not as a descriptive taxonomy but as a diagnostic tool. By revealing how challenges in one dimension—e.g., *inscrutability* (Technology)—can constrain *transparency* (Structure) and foster *mistrust* (People), the analysis substantiates the STS proposition that AI adoption is inherently a system-wide transformation rather than a technical integration exercise. The study confirms through the STS view that managing one subsystem effectively requires anticipating feedback from others. This insight also resonates with current literature from a perspective of organizational change management [33], which also posits that the four STS core components must be kept in dynamic balance for change efforts to succeed. Imbalances or unilateral interventions in one domain are likely to trigger unintended effects in others. Thus, managing AI requires more than technical readiness—it demands systemic alignment [34]. Nonetheless, the review also reveals blind spots. Some entanglements are better theorized than others. Vertical interconnections (e.g., from vision to implementation) are rarely articulated, pointing to a need for longitudinal research. Horizontally, identical challenges—such as AI governance—are framed differently depending on disciplinary or epistemic perspectives. While this study offers a structured and timely synthesis of AI adoption challenges, it has certain limitations. The final analysis draws on a relatively small set of 15 peer-reviewed papers, which—despite a broad search window (2000–2025)—mostly stem from recent years. This likely reflects the evolving discourse, shaped by the rise of generative AI and increasing accessibility. Still, the limited sample and primarily descriptive approach call for further empirical validation and broader literature inclusion. Future research should explore to what extent challenges are recognized across domains (e.g., medicine, agriculture) and functions (e.g., supply chain, finance), and how IS research can address such pluralism without fragmenting. Several implications emerge from this analysis:

Theoretical integration: To validate this work's diagnostic potential, future research should examine cross-dimensional dependencies in organizational contexts. This aligns with recent calls for theoretically grounded and empirically tested models of AI readiness and maturity (e.g., [7], [18])

Methodological pluralism: To address the complexity and context-specific nature of sociotechnical entanglements, we advocate mixed-method designs—e.g., comparative case studies combined with systems modeling. This reflects broader demands in AI research to integrate qualitative depth with quantitative generalizability (e.g., [8], [19]).

Constructive interdisciplinarity: Management challenges in AI adoption often reflect the disciplinary lens through which they are viewed. Future work should distinguish between "perspective-conditioned" and universally critical challenges. This supports calls for integrative frameworks bridging technological, organizational, and societal viewpoints (e.g., [6]).

Governance-focused modeling: Our results suggest that STS-informed maturity or capability models can help assess AI readiness systemically, beyond narrow metrics of technology or compliance. The need for such governance-oriented frameworks has also been underscored in recent work on sociotechnical envelopment [12], organizational AI capabilities [10], and risk-aware AI systems [11].

In summary, the recent literature increasingly acknowledges AI as a socio-technical transformation but stops short of treating it as such in analytical practice. Our study bridges that gap and opens a trajectory for more systematic analyses and empirical verifications.

VI. Conclusion

This study examined AI adoption challenges in organizations through the socio-technical systems (STS) lens. Addressing two core research questions, it synthesized fragmented literature and revealed interrelations across the STS dimensions of Technology, Task, Structure, and People.

To advance AI operationalization amid rising regulatory and strategic demands, this study is both timely and necessary. It shows that AI adoption is not merely technical, but a socio-organizational transformation. Key challenges do not occur in isolation—they reinforce each other. The study's novelty lies in its theory-driven, cross-dimensional mapping of entangled AI challenges. Unlike prior work treating obstacles as standalone, this paper highlights how misalignments across layers can hinder adoption. It thus extends the IS discourse beyond techno-centric models. The findings address multiple audiences: researchers gain a conceptual framework for empirical validation, practitioners a diagnostic lens for identifying coordination gaps, and policymakers criteria to expand governance beyond technical performance toward structural and cultural readiness.

Future research should empirically validate the proposed framework across sectors through case studies, develop STS-based maturity models for AI readiness, and explore governance mechanisms that account for cross-dimensional dependencies. These steps are critical for ensuring that AI is not just implemented—but implemented responsibly, strategically, and sustainably.

Acknowledgment

This research was partially funded by the Bavarian State Ministry for Science and the Arts (StMWK: Bayerische Staatsministerium für Wissenschaft und Kunst- StMWK) as part of the Project "CHIASM" (Chancenreiche industrielle Anwendungen für vortrainierte Sprachmodelle).

***Abstract*—In this contribution, the numerical solution of the spectral fractional elliptic equation with power $\alpha \in (1,2)$ is studied. After discretization, the problem is reduced to solving a system of linear algebraic equations. We apply the Best Uniform Rational Approximation (BURA) method and focus on the numerical aspects, related to its implementation. An extensive experimental study is conducted to evaluate the accuracy of the proposed approach. The numerical results confirm the theoretical analysis and demonstrate the effectiveness of using the BURA method for the fractional super-diffusion problems.**

I. Introduction

LET US CONSIDER the spectral fractional elliptic equation with power $\alpha \in (1,2)$, given by

$$\mathcal{A}^\alpha u(x) = f(x), \tag{1}$$

where $\mathcal{A}$ is a self-adjoint elliptic operator in Ω, satisfying homogeneous Dirichlet boundary conditions. The non-local operator $\mathcal{A}^\alpha$ is defined via the spectral decomposition of $\mathcal{A}$, namely

$$\mathcal{A}^\alpha u = \sum_{j=1}^{\infty} \lambda_j^\alpha (u, \psi_j)\psi_j,$$

where $\lambda_j > 0$ are the eigenvalues, respectively, ψ_j are the corresponding normalized eigenfunctions of $\mathcal{A}$, and $(.,.)$ is the L^2 inner product.

Let ω_h be a uniform rectangular mesh, while the Finite Difference Method (FDM) is applied to approximate the operator $\mathcal{A}$. In this case, the FDM discretization of (1) leads to a system of linear algebraic equations with respect to the mesh functions $\mathbf{u}$ and $\mathbf{f}$, in the form

$$A^\alpha \mathbf{u} = \mathbf{f}. \tag{2}$$

Here, $A \in \mathbb{R}^{N\times N}$ is a sparse, symmetric and positive definite (SPD) matrix, and

$$A^\alpha \mathbf{u} = \sum_{j=1}^{N} \lambda_{j,h}^\alpha (\mathbf{u}, \Psi_{j,h})\Psi_{j,h}. \tag{3}$$

As in the continuous case, $\{\lambda_{j,h}\}_{j=1}^N$ is the spectrum of A, and the eigenvectors $\Psi_{j,h}$ are normalized with respect to the Euclidean dot product $(.,.)$.

When $\alpha \in (0,1)$, the problem (1), corresponding to the fractional sub-diffusion, has been extensively studied in the past decade (see, for instance, [1]). When $\alpha \in (1,2)$, the problem (1) is related to the fractional super-diffusion [2], which is the focus of this study. Notably, many numerical methods developed for the sub-diffusion case rely directly on the condition $\alpha \in (0,1)$. Therefore they do not extend naturally to the super-diffusion case. For $\alpha \in (1,2)$, the BURA has one positive pole and one positive zero, making one of the resulting linear systems non-positive definite. To address this, we employ the BURA method, based on the Best Uniform Rational Approximation $r_{\alpha,k}(t)$ of degree k of t^α in the interval $[0,1]$. Specifically, we investigate the numerical behavior of the BURA method [3], [4] when applied to the fractional super-diffusion problems.

II. The BURA Method

The abbreviation BURA stands for Best Uniform Rational Approximation. Let us consider the min-max problem: find $r_{\alpha,k} \in \mathcal{R}(k,k)$ such that

$$\max_{t\in[0,1]} |t^\alpha - r_{\alpha,k}(t)| = \min_{r_k(t)\in\mathcal{R}(k,k)} \max_{t\in[0,1]} |t^\alpha - r_k(t)|, \quad \alpha \in (0,1), \tag{4}$$

where $r_k(t) = P_k(t)/Q_k(t)$, P_k and Q_k are polynomials of degree k. Then the error $E_{\alpha,k}$ of the k-BURA element $r_{\alpha,k}$ is defined as

$$E_{\alpha,k} := \max_{t\in[0,1]} |t^\alpha - r_{\alpha,k}(t)|. \tag{5}$$

A sharp estimate of $E_{\alpha,k}$ has been derived in [5] and has the form:

$$E_{\alpha,k} = 4^{\alpha+1} \sin(\alpha\pi) e^{-2\pi\sqrt{\alpha k}}. \tag{6}$$

Following [6] we introduce the approximation of $A^{-\alpha}$ in the form

$$A^{-\alpha} \approx \lambda_{1,h}^{-\alpha} r_{\alpha,k}\left(\lambda_{1,h} A^{-1}\right),$$

and then

$$\mathbf{u}_k = \lambda_{1,h}^{-\alpha} r_{\alpha,k}\left(\lambda_{1,h} A^{-1}\right)\mathbf{f}, \tag{7}$$

where $\mathbf{u}_k$ is the BURA numerical solution of the linear algebraic system (2). In other words, $\mathbf{u}_k$ is the BURA approximation of the solution $u(x)$ of the fractional elliptic equation (1). Scaling A^{-1} by $\lambda_{1,h}$, above, ensures that all eigenvalues of the matrix are in the interval $(0, 1]$ where the BURA error is uniform.

III. An application of the BURA method

In this work we consider the original problem (2) in the form:

$$A^{\alpha_1} A^{\alpha_2}\mathbf{u} = \mathbf{f},$$

where $\alpha = \alpha_1 + \alpha_2$, $\alpha_{1,2} \in (0, 1]$. Now, the BURA method can be used for solving the following sub-diffusion problems:

$$A^{\alpha_1}\mathbf{w} = \mathbf{f}, \tag{8}$$

$$A^{\alpha_2}\mathbf{u} = \mathbf{w}. \tag{9}$$

The application of the BURA method for solving such problems has been relatively well studied, during the last years.

In [2] the authors used similar approach where $\alpha = \sum_{i=1}^{l} \alpha_i$. In our study, we limit our analysis to the case $l = 2$, for the following reasons. First, using $l > 2$ requires solving larger number of linear systems, which increases the computational complexity, and reduces the efficiency of the solver. Second, for small values of α, a larger k must be used, to achieve good accuracy, which further increases the computational cost.

IV. Numerical experiments

The presented numerical experiments are designed to determine the optimal combination of parameters, balancing the numerical error and the computational time. Specifically, we consider the one dimensional problem (1) with the right hand side

$$f(x) = sin(\pi x) - sin(2\pi x) + sin(3\pi x),$$

where the computational domain Ω is the unit interval $[0, 1]$ and $\alpha = 1.25, 1.5, 1.75$. For this problem, it is possible to compute the exact solution of the problem (1). Therefore, the error in the numerical solution can be also precisely calculated.

The problem is discretized on a uniform mesh ω_h, $h^{-1} = n = 8000, 16000, 32000, 64000$, by applying the standard three point stencil. Next, the BURA method is applied with:

- $\alpha_1 = 1$;
- $\alpha_1 = \alpha_2 = \frac{\alpha}{2}$;
- $\alpha_2 = 1$.

Specifically, the additive BURA method (see [4]) is used, where

$$r_{\alpha,k}(t) = c_0 + \sum_{i=1}^{k} \frac{c_i}{t - d_i}. \tag{10}$$

In this case, the equation (7) can be rewritten as

$$\mathbf{u}_k = \left[c_0 \lambda_{1,h}^{-1} I + \sum_{i=1}^{k} c_i \left(A - \lambda_{1,h} d_i I\right)^{-1}\right]\mathbf{f}, \tag{11}$$

The BRASIL [7], [8] software, version 1.2.1, was used for the computation of the coefficients of the rational approximation $r_{\alpha,k}(t)$ in the interval $[0, 1]$.

The l_2 norm of the error was computed as:

$$\|\mathbf{u} - \mathbf{u}_{exact}\|_{l_2} = \sqrt{\frac{\sum_{i=1}^{n+1}(u_i - u_{exact}(x_i))^2}{n+1}}.$$

The code has been implemented in Python. (See the Appendix for the main part of the code.) The equation (11) requires a solver for the tridiagonal systems of equations. In the implemented solver, the LAPACK [9] subroutine DGTSV was used for solving these tridiagonal systems. Across the solver, double precision real numbers were used.

The code has been tested on a server which has Intel(R) Xeon(R) Silver 4309Y CPU with 16 cores at 2.8 GHz and 32 GB of RAM. However, it should be noted that no attempt was made to parallelize the solution process. This direction of research may be pursued in the future, when substantially larger problems are going to be solved.

V. Numerical results

The l_2 norm of the error for $n = 8000, 32000$ is presented in Tables I and II, the l_2 norm of the error for $n = 64000$ is presented in Fig. 1. Let us note that the error of the numerical solution, in the experiments, consists of a composition of several types of errors. First, the discretization leads to an error. Here, when the Laplace equation is formed, it can be estimated as $O(h^2)$. Second, the rational approximation has an error $E_{\alpha,k}$ and the sharp estimate of $E_{\alpha,k}$ is presented in (6). Thus, the error of the rational approximation depends on αk. For $\alpha \in (0, 1)$, a more accurate rational approximation for α close to 1, and for large k, is obtained. Third, there is also an error in the numerical solution of the systems of linear algebraic equations, in (11). It should be noted that increasing the size of these systems leads to a larger error in the solution. Finally, at every step of the numerical solution of the problem there are rounding errors. Unfortunately, there is no easy way to decouple these errors, and capture them independently.

From Tables I and II it follows that for the same α and the same k a better accuracy is obtained when $\alpha_1 = \alpha_2$. Next, as expected, for α close to 1, the accuracy is higher. However, higher accuracy comes at an additional cost. When $\alpha_1 = \alpha_2$, the BURA method is applied twice to solve (8–9). When $\alpha_1 = 1$ (or $\alpha_2 = 1$) the BURA method is applied only for solving equations (9) (or (8)). Thus, in total, for $\alpha_1 = \alpha_2$, $2k$ linear systems are solved, while for $\alpha_1 = 1$ (or $\alpha_2 = 1$) only $k + 1$ linear systems have to be solved. The practical realization of this comparison can be seen in Table III, where the average execution time (from multiple runs) for $n = 8000$ is presented in milliseconds.

The next observation that can be derived from Tables I and II is that the difference in the accuracy for $\alpha_1 = 1$ and $\alpha_2 = 1$ is less than one percent and thus can be neglected.

From the results represented in Fig. 1 it is possible to compare the error obtained for $\alpha_1 = \alpha_2$, $k = 10$ and for $\alpha_1 = 1$, $k = 19$. In both cases, in total, 20 linear systems

TABLE II
l_2 NORM OF THE ERROR FOR $n = 32000$.

k	(α_1, α_2)								
	(1, 0.25)	(0.625, 0.625)	(0.25, 1)	(1, 0.5)	(0.75, 0.75)	(0.5, 1)	(1, 0.75)	(0.875, 0.875)	(0.75, 1)
12	2.64e-6	1.97e-08	2.64e-6	3.07e-08	1.62e-09	3.07e-08	4.30e-10	3.10e-10	4.30e-10
16	4.91e-7	1.59e-09	4.91e-7	2.91e-09	1.11e-10	2.91e-09	4.08e-11	1.67e-10	4.08e-11
20	1.14e-7	1.42e-10	1.14e-7	2.85e-10	2.32e-10	2.85e-10	7.51e-11	3.21e-11	7.51e-11
24	3.06e-8	1.87e-10	3.06e-8	4.90e-11	1.94e-11	4.92e-11	8.93e-12	1.91e-10	8.91e-12

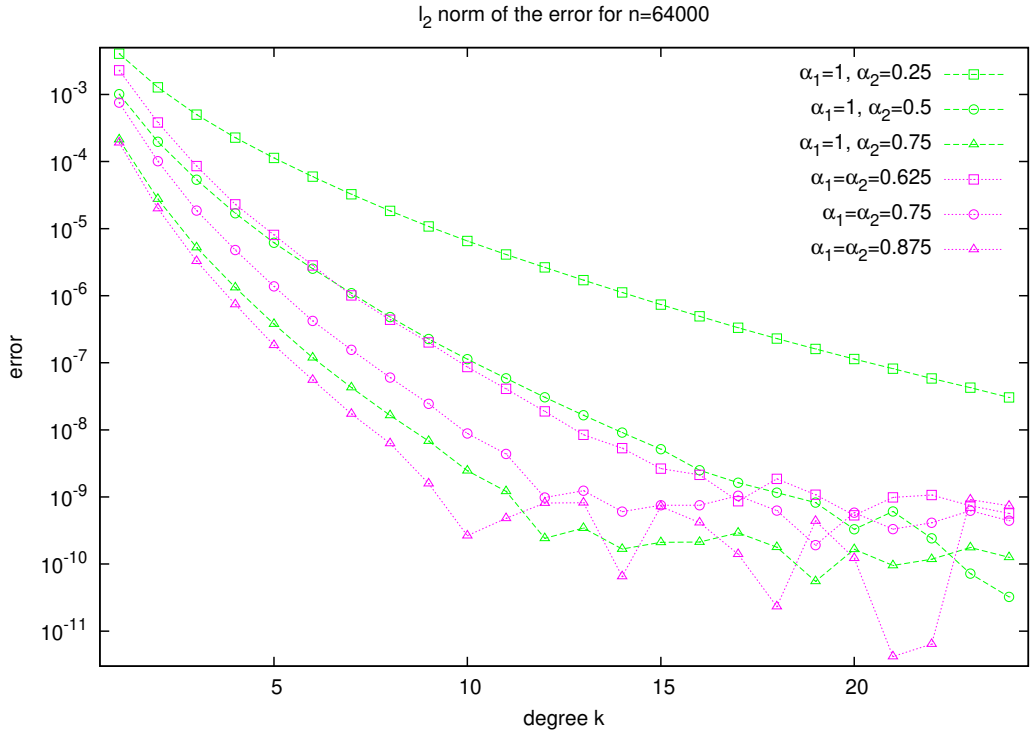

Fig. 1. l_2 norm of the error for $n = 64000$.

have been solved, and the execution time is almost the same. For $\alpha = 1.25$ the obtained errors are $\approx 9.10^{-8}$ and 2.10^{-7}, for $\alpha = 1.5$, the errors are $\approx 9.10^{-9}$ and 8.10^{-9}, for $\alpha = 1.75$ the errors are $\approx 3.10^{-10}$ and 6.10^{-11}. Therefore, it can be concluded that, depending on the value of α, it is possible to choose the optimal order k and the parameter α_1.

The next observation concerns the results depicted in Fig. 1. There, one can see the strange behavior of the error for $\alpha_1 = \alpha_2 = 0.875$ for large k. As noted above, the error consists (among others) of the discretization error and the rational approximation error. For $n = 64000$, the discretization error is $\approx 2.5 \times 10^{-10}$ and this error could not be improved for $k > 10$.

Finally, Fig. 2 shows the average execution time (from multiple runs) for $n = 8000, 16000, 32000, 64000$, in seconds. As noted above, for $\alpha_1 = 1$ the algorithm solves $k + 1$ linear systems of size $n + 1$, while for $\alpha_1 = \alpha_2$ — $2k$ systems of the same size. As expected, the execution time is proportional to $k + 1$ or to k and the linearity is clearly visible in the plot.

VI. CONCLUDING REMARKS

In this contribution, the numerical solution of the spectral fractional elliptic equation with power $\alpha \in (1, 2)$ was studied.

TABLE III
THE EXECUTION TIME FOR $n = 8000$ IN MILLISECONDS.

k	(α_1, α_2)								
	(1, 0.25)	(0.625, 0.625)	(0.25, 1)	(1, 0.5)	(0.75, 0.75)	(0.5, 1)	(1, 0.75)	(0.875, 0.875)	(0.75, 1)
12	2.82	5.09	2.79	2.82	5.09	2.79	2.83	5.09	2.79

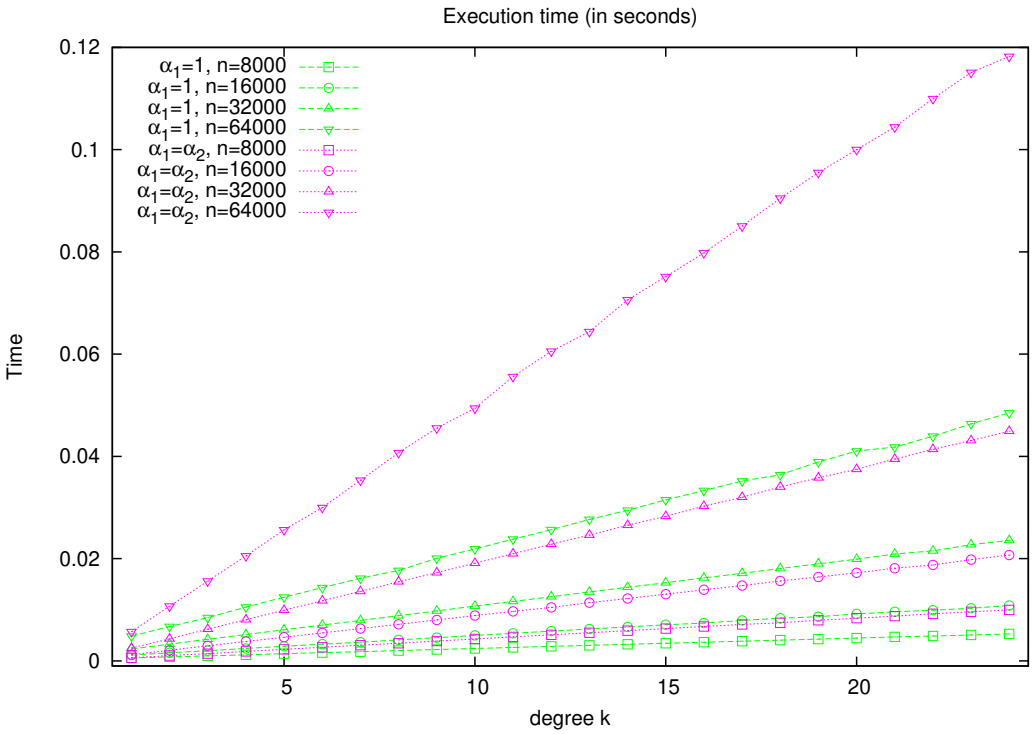

Fig. 2. Execution time in seconds for $n = 8000, 16000, 32000, 64000$.

Specifically, for the problem in question, the Best Uniform Rational Approximation method has been applied. Next a comprehensive set of experiments has been completed. The obtained results match the theoretical expectations. In particular, the fact that the solution error is composed of multiple components has been captured for large values of k and n. This may constitute the actual limit of applicability of the proposed approach (in its standard form).

***Abstract*—In this paper we describe an exact algorithm that constructs all Pareto optimal solutions of the biobjective minimum risk minimum length spanning trees problem. The method constructs directly the Pareto optimal spanning trees without constructing the entire classes of optimal spanning trees with respect to the length and with respect to the risk criterion.**

We formulate the theorems that prove the correctness and computational complexity of the proposed algorithms. Also, we illustrate the method using a comprehensive numerical example. The computational complexity of the algorithm that constructs the complete Pareto front of the problem is $O(s(m + n \lg n))$, where s is a constant that depends on the number of all Pareto optimal solutions and a predefined constant that can be used to limit the number of constructed solutions.

I. Introduction

THE minimum spanning tree (MST) problem is the problem to construct a single spanning tree in an undirected weighted graph that has minimum total weight. A spanning tree is an acyclic subset of the edges of the graph that connects all its vertices. In the standard single-objective case the weight of the spanning tree is defined as the sum of the weights of all edges that are contained in it (see for example [1]).

While in practice even the basic binary heap implementation gives a good performance of the Prim's algorithm [2], the advanced data structure Fibonacci heap [3] can result in even more significant speedup. In the general case, the Prim's algorithm implemented with Fibonacci heap runs in $O(m+n \lg n)$ computational complexity, where n is the number of vertices and m is the number of edges in the graph. In the case of sparse graphs for which $m = \Omega(n \lg n)$, the computational complexity is improved to $O(m)$.

On the other hand, by introducing of additional objective function to the MST problem, in specialized literature is reported that it results into a NP-hard problem [4], [5], [6], [7]. Also, in the case of multiple objective functions, we are no longer looking for a single optimal solution, but a whole set of non-dominated optimal spanning trees that are called Pareto optimal (see for example [8]).

Even though the NP-hardness of the biobjective MSTs problem suggests that exact methods are inefficient to apply, and heuristic or metaheuristic methods, like for example ant colony optimization [9], are more appropriate, our research shows that for particular objective functions the problem turns to be weak NP-hard. The latter means that an exact pseudo-polynomial or even polynomial algorithms can be formulated.

In this paper we describe an exact algorithm that constructs the complete Pareto front of the biobjective minimum risk minimum length spanning trees problem. The algorithm does not construct the entire classes of optimal spanning trees with respect to the length and with respect to the risk criterion and directly finds the Pareto optimal solutions of the problem with computational complexity $O(s(m + n \lg n))$, $s = \min\{M, |P|\}$, where M is a predefined constant that can be used to limit the number of constructed solutions, and P is the complete Pareto optimal set.

The paper is organized as follows. In the next section we provide definitions and problem formulation. Section III-A describes our algorithm that constructs the complete set of MSTs for the standard single-objective version of the problem. Section III-B describes our polynomial complexity algorithm that finds the minimum complete Pareto front. The algorithm that solves the main problem in this paper is given in section IV, and section V contains our conclusions.

II. Problem definition

We denote with $G = (V, E)$ a connected undirected graph with $n = |V|$ number of vertices and $m = |E|$ number of edges. The vertices of G are labeled with the first n natural numbers and $V = \{1, 2, \ldots, n\}$. The edges of the G are symmetric and we will denote each edge $(u, v) \equiv (v, u)$ as a pair of its endpoint vertices $u, v \in V$. We define two weight functions on the set of the graph edges: $f : E \to \mathbb{R}_+$ and $g : E \to \mathbb{R}_+$. The function f maps to each edge $(u, v) \in E$ the positive number $f(u, v)$ which we will call the *length* of (u, v). The function g maps to each edge $(u, v) \in E$ the positive number $g(u, v)$ which we will call the *risk* of (u, v).

The graph G together with the two weight function defines the network $N = (V, E, f, g)$ which is represented by the adjacency lists $N.Adj$ which is a vector of n elements, where each element $N.Adj[u]$ is a list of the adjacent vertices to the vertex u and corresponding edges weights:

$$\langle (v_{u_1}, f(u, v_{u_1}), g(u, v_{u_1})), (v_{u_2}, f(u, v_{u_2}), g(u, v_{u_2})), \ldots \rangle$$

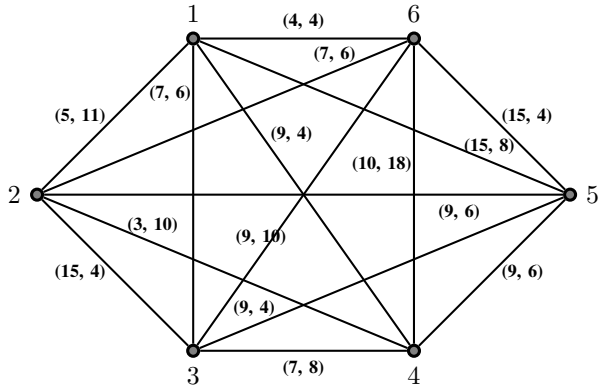

Fig. 1. Example complete network N_1

TABLE I
ADJACENCY LISTS OF EXAMPLE COMPLETE NETWORK N_1 GIVEN FOR EACH VERTEX $u \in V$

u	Adjacency list
1	$\langle(2,5,11),(3,7,6),(4,9,4),(5,15,8),(6,4,4)\rangle$
2	$\langle(1,5,11),(3,15,4),(4,3,10),(5,9,6),(6,7,6)\rangle$
3	$\langle(1,7,6),(2,15,4),(4,7,8),(5,9,4),(6,9,10)\rangle$
4	$\langle(1,9,4),(2,3,10),(3,7,8),(5,9,6),(6,10,18)\rangle$
5	$\langle(1,15,8),(2,9,6),(3,9,4),(4,9,6),(6,15,4)\rangle$
6	$\langle(1,4,4),(2,7,6),(3,9,10),(4,10,18),(5,15,4)\rangle$

This representation is illustrated with the adjacency lists given in Table I of the example complete network N_1 (see Fig. 1).

For each subset of edges $A \subseteq E$ we define the *length* of A:

$$x(A) = \sum_{i=1}^{|A|} f(u_i, v_i), \tag{1}$$

and the *risk* of A with:

$$y(A) = \max\{g(u,v) : (u,v) \in A\}. \tag{2}$$

We denote with W the set of all spanning trees in the network N. The set of all spanning trees with minimum length is W_f, where:

$$W_f = \{T' \in W : x(T') \leq x(T), \forall T \in W\}, \tag{3}$$

and the set of all spanning trees with minimum risk is W_g, where:

$$W_g = \{T' \in W : y(T') \leq y(T), \forall T \in W\}. \tag{4}$$

Definition 1. *We call the tree $T' \in W$ **Pareto optimal spanning tree** (POST) when there does not exist another tree $T \in W$, for which any of the following two conditions is fulfilled:*

- $x(T) < x(T')$ *and* $y(T) \leq y(T')$*;*
- $x(T) \leq x(T')$ *and* $y(T) < y(T')$*.*

We denote with P the set of all POSTs in the network N. P is the Pareto optimal set and is represented in the form:

$$P = \bigcup_{i=1}^{K} P_i, \tag{5}$$

where the subsets P_i satisfy the following two conditions.

1) All trees in P_i, $i = 1, 2, \ldots, K$, are equivalent.
2) For each $i = 1, 2, \ldots, K-1$ the following inequalities hold:
$$l_i < l_{i+1} \text{ and } r_i > r_{i+1}, \tag{6}$$
where l_i is the length, r_i is the risk of each tree in P_i.

The set P has an unique representation (5). We will call each subset P_i *class of equivalent POSTs*, and we will call the set P *complete Pareto front* (CPF).

Definition 2. *We will call each set $P_{min} = \{t_1, t_2, \ldots, t_K\}$, where $t_i \in P_i$, $i = 1, 2, \ldots, K$ a **minimum complete Pareto front** (MCPF).*

Let $e_1 = (u_1, v_1)$ and $e_2 = (u_2, v_2)$ are arbitrary edges in the network N. We will use the following edge relations.

- The edges e_1 and e_2 are *equivalent*, denoted $e_1 \sim e_2$, when $f(e_1) = f(e_2)$ and $g(e_1) = g(e_2)$.
- The edge e_2 is *dominated by* e_1 with respect the *length*, denoted $e_2 \prec_f e_1$ when: (i) $f(e_1) < f(e_2)$ or (ii) $f(e_1) = f(e_2)$ and $g(e_1) < g(e_2)$.
- The edge e_2 is *dominated by* e_1 with respect the *risk*, denoted $e_2 \prec_g e_1$ when: (i) $g(e_1) < g(e_2)$ or (ii) $g(e_1) = g(e_2)$ and $f(e_1) < f(e_2)$.

When $e_2 \sim e_1$ or $e_2 \prec_f e_1$ is fulfilled, we will denote it by $e_2 \precsim_f e_1$, and when $e_2 \sim e_1$ or $e_2 \prec_g e_1$ is fulfilled, we will denote it by $e_2 \precsim_g e_1$.

The aim of this paper is the solution of the problem given in Problem 1.

Problem 1. *(Main Problem) Let N be a connected network and let M be a natural number. Find a set of POSTs such that:*

1) *if $M \leq K$, then $|P'| = M$ and $P'[i] \in P_i$, for $i = 1, 2, \ldots, M-1$, and $P'[M] \in P_K$;*
2) *if $K < M \leq |P|$, then $|P'| = M$ and P' contains at least one MCPF;*
3) *if $|P| < M$, then $P' = P$.*

The solution of Problem 1 that we propose in this paper is given in Sec. IV. The proposed algorithm finds the list P' and determines which of the three cases of the problem is fulfilled. It also determines whether P' contains at least one MCPF. If P' contains a MCPF, the algorithm reports whether the CPF is found, and if it is not found, which classes of equivalent POSTs, given in equation (5), may contain elements that are not included in P'.

III. HELPER ALGORITHMS

A. Complete list of all minimum spanning trees

In this section we will solve the helper Problem 2.

Problem 2. *Let N be a connected network and let M be a natural number. Construct the list W'_f of MSTs in N that has the following properties:*

1) *if $M \geq |W_f|$, then $W'_f = W_f$;*
2) *if $M < |W_f|$, then $|W'_f| = M$.*

Algorithm 1 Function MSTLIST(N, r, M)

Input: network N, root vertex r, natural number M
Output: list of MSTs L, Boolean flag all

```
1: let S be an empty stack, L be an empty list
2: push into S the initial subproblem
3: while S ≠ ∅ and |L| ≠ M do
4:    X ← POP(S), (t, S) ← SUBPROBLEMS(S, N, X)
5:    if t ∉ L then
6:       PUSHBACK(L, t)
7:    end if
8: end while
9: if S ≠ ∅ then
10:   all ← false
11: else
12:   all ← true
13: end if
14: return L, all
```

The solution of Problem 2 is given by the function MSTLIST in Algorithm 1. The input of the algorithm are the network N, a root vertex of the constructed trees r and a natural number M. The output are the list of lists of parents of the constructed trees L that contains the set W'_f, and a Boolean value all. The set W'_f forms the solution of Problem 2. When $all = true$, it shows that $W'_f = W_f$, and when $all = false$, then $|W'_f| = M < |W_f|$.

The helper function SUBPROBLEMS is described in details in our work [10]. The computational complexity of MSTLIST is evaluated to $O(s(m + n \lg n))$, where $s = \min\{|W_f|, M\}$.

B. Minimum complete Pareto front

In this section we describe Algorithm 3 that solves the helper Problem 3.

Problem 3. *Let M be an arbitrary natural number. Find a subset P' of the set of POSTs P that has the following properties:*

1) $|P'| = \min\{M, K\}$, *where K is the number of classes of equivalent POSTs;*
2) $|P' \cap P_i| = 1$, *for $i = 1, 2, \ldots, |P'|$.*

Algorithm 3 uses the following two modifications of the Prim's algorithm.

1) Function MINTREERISK that finds a POST that has minimum risk. The pseudocode of the function is given in Algorithm 2.
2) Function MINTREELENGTH that finds a POST that has minimum length. In this case the algorithm is analogous to Algorithm 2, but the relation $\prec_f$ is applied.

Both functions MINTREERISK and MINTREELENGTH extend the greedy principle of the Prim's algorithm using the relations $\prec_g$ and $\prec_f$ respectively.

Theorem 1. *Let A is a tree that corresponds to the predecessor list t_{bar} calculated with* MINTREERISK. *Then A is a POST that has minimum risk among all POSTs.*

Algorithm 2 Function MINTREERISK(N, r)

Input: network N, root vertex r
Output: POST that has minimum risk t_{bar}

```
1: a ← [false, false, ..., false]
2: d ← [∞, ∞, ..., ∞], d[r] ← (0, 0), t ← [0, 0, ..., 0]
3: insert each u ∈ V into Q with key d[u]
4: while Q ≠ ∅ do
5:    u ← EXTRACTMIN(Q, ≺_g)
6:    a[u] ← true
7:    for all (v, f(u,v), g(u,v)) ∈ N.Adj[u] do
8:       if a[v] = false and d[v] ≺_g (u, v) then
9:          t[v] ← u, d[v] ← (f(u,v), g(u,v))
10:         DECREASEKEY(Q, v, (f(u,v), g(u,v)))
11:      end if
12:   end for
13: end while
14: E' ← ∅
15: for all e ∈ E do
16:   if g(e) ≤ y(t) then
17:      E' ← E' ∪ e
18:   end if
19: end for
20: E ← E', t_bar ← MSTList(N, r, 1)
21: return t_bar
```

Algorithm 3 Function MINCPF(N, r, M)

Input: network N, root vertex r, natural number M
Output: POSTs list L, barrier tree t_{bar}, integers c_{dif} and M'

```
1: let L be an empty list
2: M' ← M, t_bar ← MINTREERISK(N, r)
3: c_bar ← y(t_bar), c_dif ← 1
4: while M' > 0 and c_dif > 0 do
5:    t ← MINTREELENGTH(N, r)
6:    PUSHBACK(L, t)
7:    c ← y(t)
8:    E' ← ∅
9:    for all e ∈ E do
10:      if g(e) < c then
11:         E' ← E' ∪ e
12:      end if
13:   end for
14:   E ← E'
15:   M' ← M' − 1, c_dif ← c − c_bar
16: end while
17: return L, t_bar, c_dif, M'
```

If A is a tree with a predecessor list calculated with MINTREELENGTH, *then A is a POST that has a minimum length among all POSTs.*

Theorem 2. *The computational complexity of both functions* MINTREERISK *and* MINTREELENGTH *is* $O(m + n \lg n)$.

Algorithm 3 applies as a step also the restriction operation (lines 8-13) which separates a subnetwork N' of the input

network N. The resulting subnetwork N' has the same set of vertices, however it contains only these edges of the original network, which have a risk *strictly less* than the fixed risk value c.

Let the list L is a result of the calculations of Algorithm 3. We define the set of trees P' such that:

1) the number of elements of P' is equal to the length of the list, $|P'| = |L|$;
2) $P'[i]$ is the tree that has the predecessor list $L[i]$, for $i = 1, 2, \ldots, |L|$.

Then the following Theorem 3 holds.

Theorem 3. *The set P' is a solution of Problem 3.*

The proof of Theorem 3 directly follows from Theorem 1.

Corollary 1. *For the above defined set P', barrier tree t_{bar}, integers c_{dif} and M' that result from Algorithm 3, the following four statements hold.*

1) *The tree T_{bar} with predecessor list t_{bar} is a POST and $T_{bar} \in P_K$.*
2) *$P'[i] \in P_i$, for $i = 1, 2, \ldots, |L|$.*
3) *If $c_{dif} = 0$, then the set P' is a MCPF. In this case, if $T_{bar} \neq P'[K]$, then besides the MCPF P', Algorithm 3 have constricted a second tree in the class P_K.*
4) *If $c_{dif} > 0$ and $M' = 0$, then $M < K$. Then for each $j \in \{M+1, \ldots, K\}$ the inequalities $x(P'[M]) < l_j \leq x(T_{bar})$ and $y(T_{bar}) \leq r_j < y(P'[M])$ hold. In this case $M+1$ number of POSTs are constructed from the same MCPF. An additional verification is needed in order to determine whether the set $P' \cup \{T_{bar}\}$ is a MCPF.*

From Theorem 2 it follows that the running time of Algorithm 3 can be evaluated $O(\alpha(m + n \lg n))$, where $\alpha = \min\{M, K\}$. Because K cannot exceed the number of edges of the network m, we say that Algorithm 3 has polynomial complexity.

IV. Complete Pareto front

The helper algorithms, given in section III, are used in the definition of our algorithm for direct construction of all Pareto optimal biobjective minimum spanning trees, which is described in this section.

Let the CPF P of the network N is given by the equality (5). The solution of the main Problem 1 is given by the function DIRECTCPF, described in Algorithm 4. The algorithm stores the predecessor lists of the discovered POSTs in the list of lists C. Each list of lists in C corresponds to one class of equivalent POSTs. The algorithm itself implements the following **inductive procedure**:

1) **Base case.** Store in the list C the first MCPF. Complement C with the remaining POSTs from the class P_1.
2) **Inductive step.** Suppose that in C are stored all POSTs from the class P_j. The procedure complements C with the remaining POSTs from the class P_{j+1}.
3) The inductive procedure continues until all POSTs are constructed or until in C are stored M number of POSTs.

Algorithm 4 Function DIRECTCPF(N, r, M)

Input: network N, root vertex r, natural number M
Output: list of lists of POSTs C and seven indicators

let C be an empty list of lists of POSTs
$M' \leftarrow M$
$(L, c_{dif}, t_{bar}, M') \leftarrow$ MINCPF(N, r, M')
$k \leftarrow |L|$, $t_{last} \leftarrow L[k]$, $j \leftarrow 0$, $all \leftarrow false$
if $c_{dif} = 0$ **then**
  while $j < k$ **and** $M' > 0$ **do**
    $M' \leftarrow M' + 1$, $E' \leftarrow \varnothing$
    for all $e \in E$ **do**
      if $g(e) \leq y(L[j+1])$ **then**
        $E' \leftarrow E' \cup e$
      end if
    end for
    $E \leftarrow E'$
    $(L', all) \leftarrow$ MSTLIST(N, r, M')
    $M' \leftarrow M' - |L'|$
    PUSHBACK(C, L')
    $j \leftarrow j + 1$
  end while
  while $j < k$ **do**
    PUSHBACK$(C, \langle L[j+1] \rangle)$
    $j \leftarrow j + 1$
  end while
else
  for all $t \in L$ **do**
    PUSHBACK$(C, \langle t \rangle)$
  end for
end if
return C, c_{dif}, t_{last}, t_{bar}, M', j, k, all

The function DIRECTCPF takes as parameters the input network N, a root vertex r and a natural number M that defines the maximum number of POSTs. As a result of its calculations, the function returns the list of lists of POSTs C and the following indicators:

- c_{dif} shows whether a MCPF is constructed by the function MINCPF;
- t_{last} is the last POST contained in the list of the MCPF L;
- t_{bar} is the barrier tree that belongs to the class P_K constructed by MINCPF;
- M' shows if the number of discovered POSTs is M and if not, how many POSTs are required;
- j shows which is the last class of equivalent POSTs that is stored in C
- k shows whether in C is stored at least one MCPF;
- all is a Boolean flag that shows whether the last call of MSTLIST found all MSTs in the restricted network.

Theorem 4, given below, follows from Theorem 1, Theorem

3 and the correctness of algorithms in section III.

Theorem 4. *Algorithm 4 solves correctly Problem 1.*

Besides that, the following six properties hold.

Property 1. *Each element of C is a list of the predecessors lists of the same class of equivalent POSTs. For example, $C[1]$ is is a list of the predecessors lists of the class P_1.*

Property 2. *If $M' = 0$, then in C are stored exactly M number of POSTs. If $M' > 0$, then exactly M' number of POSTs are still required.*

Property 3. *The indicator k can take exactly two values. It is equal to 0, when C does not store any MCPF. It is equal to the number of classes of equivalent POSTs K, when in C is stored at least one MCPF.*

Property 4. *The indicator $j \in \{0, 1, \ldots, K\}$. If $j = 0$ then C stores at most one element of each class of equivalent POSTs. If $j \in \{1, 2, \ldots, K\}$, then the calculations of the algorithm terminated at the stage in which in C were included the predecessors lists of the POSTs of the class P_j. When $j \in \{2, 3, \ldots, K\}$, then $C[i]$ stores the complete classes P_i, for $i = 1, 2, \ldots, j-1$.*

Property 5. *If $M' = 0$ and $k = 0$, then M number of POSTs has been discovered before a MCPF was completed. The trees t_{bar} and t_{last} define the rectangular area in which are located the POSTs of the MCPF that are not stored in C.*

Property 6. *When $j \neq 0$ and $all = false$, then P_j may contain elements that are not stored in C. If $j \neq 0$ and $all = true$, then all elements of P_j are stored in C.*

From Theorem 2 it follows that the computational complexity of Algorithm 4 is $O(s(m + n \lg n))$, where $s = \min\{M, |P|\}$.

The calculations of Algorithm 4 are illustrated in Example 1. Because of the small size of the network used in the example, the above six properties can be directly verified.

Example 1. *Consider the example network N_1 given in Fig. 1 with adjacency lists in Table I. We select the vertex $r = 1$ for the root vertex of the POSTs that will be constructed. We will track the calculations of Algorithm 4 in the following four cases: (a) $M = 2$; (b) $M = 5$; (c) $M = 18$ and (d) $M = 25$.*

Solution. Before we solve the example, in order to illustrate graphically the results of the calculations, first we find all the spanning trees in the network N_1 using function MSTLIST given in Algorithm 1. The number of all spanning trees of N_1 which has number of vertices $n = 6$ is $n^{n-2} = 1256$. For each spanning tree t we store the pairs $(x(t), y(t))$, and we store only those pairs that does not coincide. For N_1 there are 116 such pairs, which means that the set of all spanning trees in N_1 is divided in 116 classes of equivalent trees. In Fig. 2 and 3 we illustrate all classes of equivalent trees with a black dot with the corresponding Cartesian coordinates.

(a) We solve Problem 1 with Algorithm 4 for $M = 2$. The

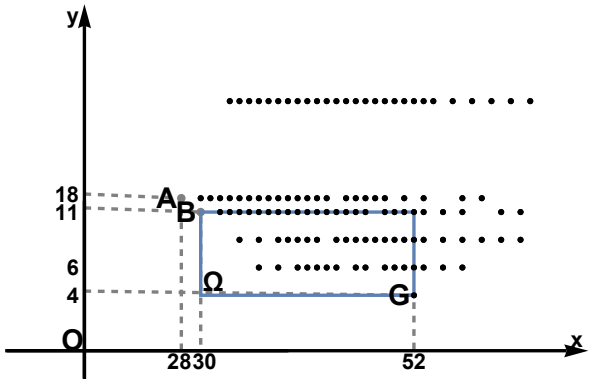

Fig. 2. Partial MCPF and the rectangle area Ω for the example network N_1. The POST that represent the class P_1 is denoted with A, and the POST that represent the class P_2 is denoted with B. The barrier tree is denoted with G

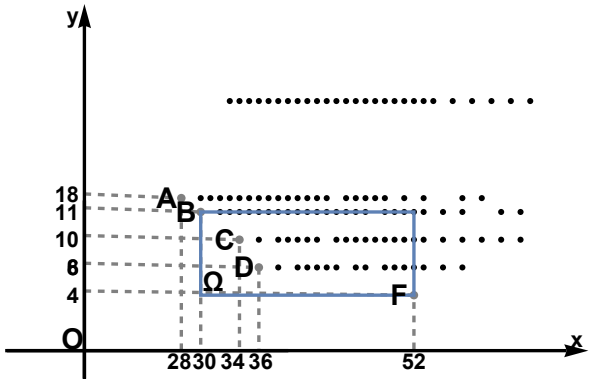

Fig. 3. MCPF for the example network N_1. The POSTs that represent the classes P_1 to P_5 are denoted with A, B, C, D and F respectively

resulting list is:

$$C = \langle\langle[0, 1, 1, 2, 3, 1]\rangle, \langle[0, 6, 1, 2, 3, 1]\rangle\rangle.$$

From the correctness of Algorithm 4 it follows that the two trees stored in C are POSTs and both of them are from a different class of equivalent POSTs. Since $k = 0$, from Property 5 it follows that the entire MCPF is not yet constructed. If we denote with T_1 the POST with predecessor list $[0, 1, 1, 2, 3, 1]$ and with T_2 the POST with with predecessor list $[0, 6, 1, 2, 3, 1]$, then $T_1 \in P_1$ and $T_2 \in P_2$. In this case $l_{last} = 30$ and $c_{last} = 10$ are respectively the length and the risk of the last tree T_2.

In Fig. 2 we denote the trees T_1 with the point A and T_2 with the point B. Also, the algorithm calculates the barrier tree T_{bar} with predecessor list t_{bar}. We denote with G the point with coordinates $(x(T_{bar}), y(T_{bar})) = (52, 4)$. From the correctness of Algorithm 3 it follows that POSTs that does not belong to P_1 or P_2 are contained into the rectangular area Ω with diagonal BG and sides parallel to the coordinate axes. From Corollary 1 we know that the barrier tree T_{bar} (illustrated by the point G in Fig. 2) is a POST from the last class of equivalent POSTs.

(b) We solve Problem 1 with Algorithm 4 for $M = 5$. After

the termination of the algorithm $M' = 0$ and therefore exactly $M = 5$ POSTs are found. In this case the resulting list is:

$$C = \langle\langle[0,1,1,2,3,1]\rangle, \langle[0,6,1,2,3,1]\rangle, \langle[0,1,1,2,3,1]\rangle, \langle[0,6,1,2,3,1]\rangle, \langle[0,1,1,2,3,1]\rangle\rangle.$$

Since now $k = 5 \neq 0$, from Property 3 it follows that C contains a MCPF and it is composed from exactly 5 POSTs. Besides that, $j = 0$ and from Property 4 it follows that for each class of equivalent POSTs a single element is included in the list C. Besides the trees T_1 and T_2 that were also calculated in the case (a), the list contains the trees T_3, T_4 and T_5 with predecessors lists respectively $[0,6,1,3,3,1]$, $[0,6,1,1,3,1]$ and $[0,3,5,1,6,1]$. The corresponding weights of these POSTs are $(34,8)$, $(36,6)$ and $(52,4)$. In Fig. 3 the POSTs T_3, T_4 and T_5 are denoted with the corresponding points in the Cartesian plane $C(34,8)$, $D(36,6)$ $F(52,4)$.

Also, in this case $all = false$ that gives us information that it is not clear whether in P_1 there is no more than one element. Besides that, it is directly verified that $T_5 = T_{bar}$ and in the class P_5 there is no second element that is discovered.

(c) We solve Problem 1 with Algorithm 4 for $M = 18$. After the termination of the algorithm, we get that $M' = 0$, and from Property 2 it follows that in the list C there are exactly 18 POSTs. It can be directly verified that in $C[1]$ there are 6 elements, in $C[2]$ there are 9 elements, and $C[3]$, $C[4]$ and $C[5]$ contain single element each.

Since $k = 5$, from Property 3 it follows that C contains at least one MCPF. Besides that, $j = 2$ and from Property 4 we get that the classes P_1 and P_2 are visited more than once by the algorithm and all elements of P_1 are stored in $C[1]$. Since $all = true$, from Property 6 it follows that all elements of P_2 are stored in $C[2]$. The POSTs stored in $C[3]$, $C[4]$ and $C[5]$ are the same as in the case (b).

(d) We solve Problem 1 with Algorithm 4 for $M = 25$. The algorithm returns $M' > 0$ and $k = 5 \neq 0$, and therefore the CPF is stored in C. The last class of equivalent POST that has been visited by the algorithm is defined by $j = 5$ and it is the class P_5. The classes P_1, P_2, P_3 and P_4 are stored respectively in $C[1]$, $C[2]$, $C[3]$ and $C[4]$. Since $all = true$, the entire class P_5 is stored in $C[5]$.

It can be directly verified that $|C[1]| = 6$, $|C[2]| = 9$, $|C[3]| = 3$, $|C[4]| = 5$, and $|C[5]| = 1$, and the CPF has totally 24 POSTs.

V. Conclusion

In the general case, the biobjective MSTs problem is widely considered an NP-hard problem, which means that an exact method will lead to exponential computational complexity. In our research we have shown that for particular objective functions, the problem is weakly NP-hard, and efficient exact algorithms can be found.

In this paper we have examined in details a version of biobjective MSTs problem in which the first objective function is linear (length), and the second objective function is non-linear bottleneck (risk). Our algorithm that finds the minimum complete Pareto front of the problem has polynomial complexity. The proposed algorithm in this paper that constructs the complete Pareto front has pseudo-polynomial complexity.

We have implemented and tested the described algorithms in this paper on complete random networks. The conducted experiments illustrate the effectiveness of Algorithm 4 that constructs the complete Pareto front. For example, for a complete random network with $n = 100$ number of vertices, the running time of the program written in Wolfram language is not more than 11 minutes on a standard computer configuration. In the particular case, the number of all spanning trees in the network are 100^{98}, the number of Pareto optimal spanning trees in the complete Pareto front are 4739, and it is distributed in 3986 number of classes of equivalent Pareto optimal spanning trees.

The results of the prototype program written in Wolfram language show that with a more optimized implementation (for example in C++ or Julia programming languages), we will be able to run the described algorithms with even bigger examples for much less running time. For example our Julia implementation of Algorithm 3 competes in 66.28 seconds on a complete random network with $n = 1000$ number of vertices.

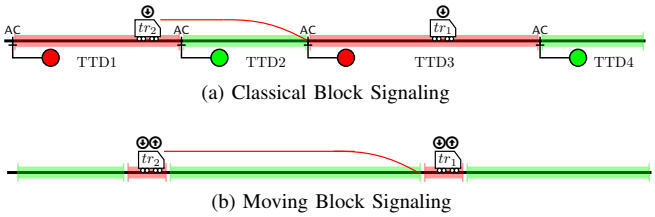
***Abstract*—The demand for sustainable railway transportation is increasing over time. At the same time, the capacity of railway networks is limited. Hence, efficient algorithms for generating optimal timetables are of great interest. Previous research focuses on trains being separated by classical fixed block signaling systems. With modern control systems based on moving block, e.g., within the *European Train Control System* (ETCS), the principles of safely separating trains change significantly. Only limited research on optimal routing on such modern railway networks exists. With this work, we propose a simulation approach tailored to be used with heuristic optimization algorithms to tackle this problem. Moreover, we show how such a framework can allow for more general inputs to jointly optimize what is usually planned sequentially as of today. The simulation framework is included within the open-source *Munich Train Control Toolkit* (MTCT) available on GitHub at https://github.com/cda-tum/mtct.**

I. Introduction

PASSENGER rail traffic in the European Union (EU) has increased by 35% in the last 30 years [1]. The main driver of this increase is high-speed rail traffic, which has risen on average by 6% per year. At the same time, freight rail traffic volume has stagnated, but, triggered by the European Green Deal, freight traffic should be prioritized to be transported by rail instead of road [2]. However, many railway lines are already operating at their capacity limit. A good planning process and traffic management systems are crucial to cope with the increasing demand. Some of the arising design tasks are introduced in [3].

The general railway planning process is commonly split into multiple sub-problems. Solving these sub-problems sequentially makes it possible to reduce complexity drastically. While mathematical modeling of these singular steps is feasible and widely implemented, an integrated approach remains out of reach [4], [5].

In this work, we focus on timetabling on a predefined railway network, or more precisely, how to optimally route trains through a railway network to fulfill certain conditions. The feasibility of a solution highly depends on the implemented control system. Since trains cannot operate on sight due to long braking distances, such signaling systems are crucial to prevent collisions and ensure safe operation. Classically, block signaling systems have been implemented. However, new train control principles have also been defined considering the increasing demand. One of these extensions is the introduction of *Moving Block* control systems, replacing classical block signaling with dynamic supervision. Relevant details on these systems are reviewed in Section II.



Much of the existing literature for train routing relies on the properties of fixed-block signaling. There is only limited research on optimally routing trains through networks equipped with modern moving block control systems [6], [7], [8]. They are based on Mixed Integer Linear Programming and do not (yet) scale well. We aim to close this gap by introducing an alternative heuristic approach based on simulation on a microscopic level, i.e., considering individual tracks. Existing simulation tools, such as OpenTrack [9] or OSRD [10], mainly focus on verifying and evaluating given solutions. Instead, our work focuses on applying a simulation framework already within the optimization process. Its architecture is built from the ground up with a moving-block approach, ditching old constraints. This allows us to apply novel techniques to encode solutions more efficiently to improve the performance of respective search algorithms applied to our simulation framework. Our approach can even include more complicated objectives. By doing so, it could be extended to combine multiple planning steps jointly in one optimization step. All work is integrated into the *Munich Train Control Toolkit* (MTCM) available open-source on GitHub at https://github.com/cda-tum/mtct.

For this Section II reviews the basic principles of train control systems, Section III describes the routing problem, Section IV introduces the underlying model and encoding with the aim of reducing the search space, Section V provides information on how this model can be used for optimization purposes, and, Section VI evaluates the approach by conducting a case study on a small benchmark set. Finally, Section VII concludes this work.

II. Train Control Principles

Train signaling has been based on splitting a line into discrete segments or blocks (fixed block), going back to the 19th century, Once a train enters a block, it is marked occupied, and access to other trains is forbidden. The status of a line segment is indicated to the driver via a mechanical display, called a semaphore, or later, an optical signal. This ensures mutual exclusion for track segments and thus prevents train collisions. *Trackside Train Detection* (TTD) uses electrical

*Corresponding author.

(a) Classical Block Signaling

(b) Moving Block Signaling

Fig. 1: Schematic drawings of signaling principles [8]

circuits embedded in the tracks or discrete sensors triggered by passing train axles to define the signal status.

Example II.1 (from [8]). *Consider two trains following each other on a single track as depicted in Figure 1a. Train tr_2 can only move until the end of $TTD2$. It cannot enter $TTD3$ because it is still occupied and, hence, might have to slow down in order to be able to come to a full stop before entering the occupied block section.*

With advances in communications technology, it has become possible to soften the traditional block structure into virtual and moving blocks. *Virtual Subsections* (VSS) obey the same principles as fixed blocks but can be arbitrarily defined. Position reporting relies no longer on trackside equipment but continuous bidirectional communication with the train. This alleviates the previously mentioned problems, especially with small or large block sizes, and allows for changing the block layout at any time.

Moving Block is a further evolution where blocks are abolished altogether. All trains in the network self-report and receive each other's position and speed. This allows them to calculate safe headway times dynamically, considering their individual braking curves. Moving Block has been taken up first on suburban railways, where risks are easier to manage. In metro lines, technical efficiency was improved by 11.5% by introducing moving block signaling and connected automation [11].

Example II.2 (from [8]). *In contrast to Eample. II.1, consider a moving block control implemented in Figure 1b. Because trains operate at the ideal absolute braking distance, tr_2 can move up to the actual end of tr_1 (minus a little buffer). In particular, it can already enter what has been $TTD3$ previously. Hence, trains can follow each other more closely.*

III. Train Routing under Moving Block Control

This work considers optimal train routing on a network equipped with a moving block control system. The *Train Timetabling Problem* (TTP) is part of the previously described planning process in Section I. It aims to find a feasible schedule and train routing under various constraints imposed by requirements on the desired timetable and safety conditions imposed by the control system as discussed in Section II. Train routing on a microscopic level consists of assigning trajectories and timings at the track level without imposing conflicts between different train movements.

In this work, we consider a part of a network that is equipped with a moving block control system, i.e., the problem is given as:

Problem III.1 (Train Routing under Moving Block Control). ***Given:*** *A railway network, a list of trains including relevant properties, and a set of demands for every train consisting of*

- *information on when and where the train enters the network,*
- *information on when and where the train exits the network, and*
- *a list of stations*[1] *the train should stop at.*

Problem: *Find a feasible train routing that minimizes overall travel time.*

IV. Simulation Model

This section describes the underlying model of our microscopic time-continuous simulator. First, we briefly discuss how the railway network and train in Sections IV-A and IV-B. Finally, an efficient solution encoding is discussed with the aim of preventing invalid solutions from being generated by the optimizers presented in Section V.

A. Network and Train Model

Our network model is based on [3]. At the same time, we allow trains to move on railway tracks in arbitrary directions. Thus, a railway network is an undirected graph $G = (V, E)$ with vertices $V = \{v_1, v_2, v_3, \ldots, v_m\}$ representing railway switches, signals or other points of interest and edges $E = \{e_1, e_2, e_3, \ldots, e_m\}$, $e_i = \{v_j, v_k\} \subset V$ representing railway tracks. Each edge e_i also has an associated positive weight l_{e_i} representing track length and a maximum permitted speed $v_{e_i}^{max,edge}$. Moreover, railroad switches can only be traversed in specific directions, which is also modeled within the railway network.

B. Train Model

Trains are objects of a certain length l^{train}, maximal velocity $v^{max,train}$, and maximal acceleration/deceleration[2] $a^{max,train}$. We allow negative velocity values to include directional information. If $v > 0$, the train moves forward; if $v < 0$, it moves backward. In contrast to previous work [6], [7], [8], this allows trains to also turn around if necessary, e.g., in stations where this commonly happens in practice. Without loss of generality, we define a train's position as its center point and denote by $e[t] \in E$ the edge at time t

C. Solution Encoding

Choosing a purely heuristic approach affords us freedom in the design of the entire optimization loop. This makes it possible to limit the search space by intelligently preprocessing our candidate solutions. We choose a representation

[1]This only includes the station. The platform is not yet fixed, but it is to be decided by the solving algorithm.

[2]For simplicity, the train's maximal acceleration and deceleration are equal. However, the model can also be extended to model that these are usually different since braking and accelerating behavior differ.

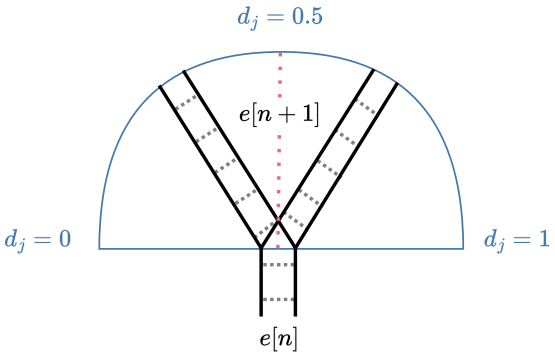


Fig. 2: Directional choice variable.

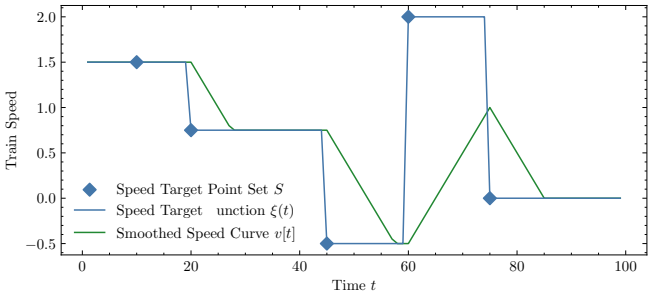
such that for each train, the decision variables map onto a physically possible train trajectory. This way, we eliminate solutions that contain overspeed, overacceleration, and invalid paths.

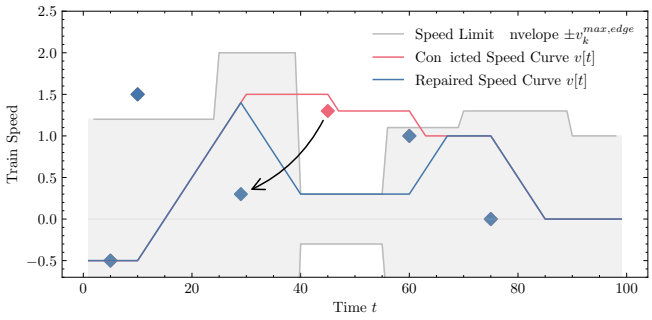
1) Railway Switches: Since trains in our model can reverse directions at any time, their trajectory describes an open, undirected walk. Instead of generating a valid graph walk for each solution, we compute it implicitly at simulation time with no additional cost. For this, we introduce directional choices $D = \{d_1, \ldots, d_{N^{max}_{transitions}}\}$, where each $d_j \in [0, 1]$ mimics a steering wheel for a given decision point. If $d_j = 0$, the train wants to move left; if $d_j = 1$, the train wants to move right; see Figure 2. Because $d_j \in \mathbb{R}$, this allows us to also choose middle tracks if a given switch allows for more than two options. At the first switch, the route is chosen according to d_1, at the second switch according to d_2, and so on. That means the route choice variables do not depend on time but are a list of decisions that are made in order whenever it is necessary to make a decision.

More precisely, assume that at time t, a train traverses a switch v_{trav} on edge $e[t]$ and has to make its kth decision. Assume that the list of possible successor edges allowed by the switch $\Gamma(e[t], v_{trav})$ is ordered and contains j elements $e_0, e_1, \ldots, e_{j-1}$. Then



$$e[t + \Delta t] = e_{\lfloor (d_k \cdot (j-1)) \rceil}, \tag{1}$$

where $\lfloor \cdot \rceil$ denotes rounding to the closest integer.



2) Speed and Acceleration: We do not directly encode each train's velocity (and acceleration) because modeling future speed limits (which might induce braking well in advance) would be challenging to model. Instead, we choose a set of speed target points S as decision variables, as time-velocity pairings. More precisely, any $s_i = (\tau_i, \nu_i) \in S$ consists of a time point $\tau_i \in [0, T_{max}]$ and a normalized velocity target $\nu_i \in [0, 1]$. From S we create a piecewise constant function $\xi(t)$ by previous-neighbor interpolation and scaling with $v^{max,train}$, i.e.,

$$\xi(t) = v^{max,train} \cdot \nu_{previous(S,t)}, \tag{2}$$

where $previous(S, t) := \max\{i \colon \tau_i \leq t\}$ is the most current speed target. From this, we induce the acceleration by attempting to reach the current speed target as quickly as possible, see Figure 3a, similar to a bang-bang controller known from optimal control theory. If $\left|\frac{\xi(t) - v[t]}{\Delta t}\right| \leq a^{max,train}$, then $v[t + \Delta t] = \xi(t)$, otherwise the train maximally accelerates toward its target.

(a) Transformation of speed decision variables into continuous curve.

(b) Single iteration of the track speed limit repair algorithm.

Fig. 3: Smoothing ξ to a feasible trajectory.

The track speed limit is much more difficult to encode since train speed $v[t]$ and edge position $e[t]$ are interdependent. Adjusting the speed can shift the time of an edge change or, when reversing, even the edges themselves. We leverage this by repairing $v[t]$ during the simulation using backtracking, a standard method for algorithmic constraint satisfaction as shown in Figure 3b. When encountering a constraint violation, the offending speed targets in S are removed and replaced with the maximum allowed speed for the track section. The simulation travels backward in time and applies just enough braking to avoid overspeed. Similarly, we can force the train to stop at a given point, e.g., at a station.

Encoding the target velocity curve as a set of discrete points in this way reduces the dimensions of the solution space. Any arbitrary curve in the solution space is still representable by increasing the number of points until every timestep is contained in S, amounting to a lookup table.

V. Optimization using Simulation

The combined encoding from Section IV-C gives us a space of decision variables consisting of speed target points S and direction choices D that map onto individually feasible train trajectories as previously discussed. Next, we evaluate the

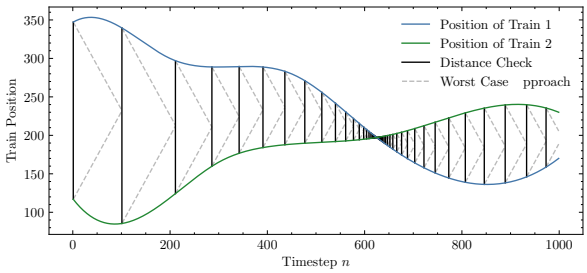


Fig. 4: Detection algorithm for headway constraint violations.

quality of each solution to define optimization criteria and apply various heuristic algorithms to find reasonable solutions.

A. Objective Function

The objective function is a composite of soft constraints $f_{headway}, f_{dest}$, and a global objective f_{stops}, which are explained next. They form the multi-objective minimization problem. Each objective can easily be normalized and weighted as desired.

1) Headway: Arguably, the most critical constraint is to avoid collisions, i.e., to apply long enough headways between two consecutive trains. It is introduced into the objective as a soft constraint $f_{headway}$ penalizing closeness beyond a minimum safety distance $h_{safe} \geq 0$.

Let $d_{i,j}(t)$ be the distance between tr_i and tr_jat time t. Additionally, a distance penalty function ω is chosen, which is zero for distances greater than h_{safe}, for example, a triangle function. The headway penalty can then be defined as

$$f_{headway} = \sum_{i=1}^{N_{trains}} \sum_{j=i+1}^{N_{trains}} \sum_{t} \omega(d_{i,j}(t)). \tag{3}$$

Using pre-computed all-pairs shortest paths for the entire network, the effort to find the distance between two trains is constant. The total number of necessary checks can be reduced by skipping time steps where a collision is physically impossible. For this, not that $d_{i,j}$ fulfills the following constraints:

$$\begin{aligned} & d_{i,j}(t) \geq 0, \\ & d_{i,j}(t) \leq longest\ distance\ in\ network, \\ & |d'_{i,j}(t)| \leq \left|v_i^{max,train}\right| + \left|v_j^{max,train}\right|, \text{ and} \\ & |d''_{i,j}(t)| \leq \left|a_i^{max,train}\right| + \left|a_j^{max,train}\right|. \end{aligned} \tag{4}$$

Using Equation (4), we can calculate a grace period for each distance check in which the trains cannot meet even when taking the shortest path towards each other at full speed. As seen in Figure 4, more checks are performed when trains are closer. Consequently, the computational effort for this objective varies based on the density and maximum speed of trains on the network. This method can be further improved by considering acceleration constraints in the grace period calculation and using a more efficient sampling of the distance function.

2) Destination: The problem specifies that each train enters and exits the network under consideration at some point in time with respective target velocities. The former constraint can be fulfilled by fixing the initial state of each train. Guidance toward a final destination is added through another soft constraint, penalizing the distance from the desired position and the difference in speed.

3) Intermediate Stops: Stops en route can be introduced by rewarding time spent with zero speed on scheduled edges. However, we can increase the prevalence of solutions with valid stops by encoding them using the repair algorithm described in Section IV-C. Each train passing an edge with a stop will be forced to halt for a minimum amount of time. In the objective evaluation, the fulfilled stops can be counted at minimal cost.

B. Optimizer

As described in Section IV, we are confronted with a general, non-linear, constrained optimization problem. In addition, the objective is non-convex and non-smooth, and its analytic form is unknown. We already defined an unconstrained version via relaxation using penalty functions; see Section V-A. This no longer guarantees solution feasibility for the combined objective. However, feasibility can be verified by evaluating the penalty functions.

The formulation gives rise to applying various heuristic approaches to find a good solution, which are described in the following paragraphs.

1) Random Search: A trivial baseline for search can be achieved by randomly assigning decision variables and keeping the best result. Such a method can be improved by introducing local search steps in each iteration. , e.g., using the Luus-Jakola method, a simple gradient-free local search algorithm [12]. An initial solution is randomly perturbed in a hypersphere with radius r. If the new candidate solution is an improvement, it replaces the old one as a starting point. The radius r contracts with each iteration by a contraction factor $c_{contract}$.

2) Greedy Search: It can be beneficial to mimic the behavior of human timetable planners when generating candidate solutions, as proposed in [13]. We, therefore, place trains sequentially using a limited random search for each instance in sequence. This approach breaks down the routing into subproblems. The order of train placement in our implementation is randomized. Classic asynchronous routing usually schedules trains by priority. Again, such an algorithm could be improved using local search, leading to the *Greedy Randomized Adaptive Search Procedure* (GRASP).

3) Genetic Algorithm: The use of genetic algorithms for timetabling is widespread [14], [15]. We implemented a primitive version, where crossover amounts to randomly choosing a trajectory for each train from the two parent solutions. Again, the iterations can be combined with local search. The population is sorted by objective score. Individuals are transferred from an elite set of top performers to the next

TABLE I: Search method comparison parameters.

Local Search and random+local and GRASP	Start Radius	$sr_{initial}$	0.4
	Stop Radius	sr_{final}	0.001
	Contraction Coefficient	$c_{contract}$	0.99
Greedy Search and GRASP	Per Train Stall Time		10ms
Genetic Search	Population	$\|P\|$	1000
	Elite Fraction	$n_{elite}/\|P\|$	0.01
	Mutation Rate		0.1
	Crossover Fraction	$n_{crossover}/\|P\|$	0.7

generation without modification. The crossover fraction determines the subset of individuals selected as parents for the next generation. Each offspring has a uniform chance to mutate, called the mutation rate; in this case, a random perturbation of all variables proportional to their maximum range is applied. The size of this perturbation is scaled down non-linearly as the generations progress. Our implementation uses the *openGA* library [16].

VI. Case Study

Due to their different model assumptions and significant limitations on publicly available data, the performance of timetabling tools is difficult to compare quantitatively. Ultimately, the most decisive measure is usefulness when applied in day-to-day planning. With this case study, we demonstrate the applicability of the proposed framework to the early stages of timetable planning.

A. Benchmark

For this, we solve three sample problems of varying size from [17]. These networks are included in the aforementioned *Munich Train Control Toolkit* (MTCT) available open-source. The first network, "Overtake," models a situation where faster trains must overtake slower ones. The second "SimpleNetwork" makes four trains cross at a central station. The last network, "Stammstrecke," is a full-sized replica of the Munich S-Bahn's core network passing through the city center.

Each train is defined with a fixed schedule for arrival and departure in the network and planned stops. In our test case, all objective functions are designed such that an objective score of zero indicates an optimal solution. This means all trains obey the distance minima, visit their scheduled stops, and reach their destination at the right speed and time. The collision objective is weighted roughly 10 to 1 against the two others.

Table I shows the parameters chosen to compare all search methods. They are a compromise across all test networks drawn from previous parameter measurements not reported in this paper due to space limitations. The numeric results for the search parameters we obtained are not universal since they depend heavily on problem parameters. However, we attempt to make generalized statements about algorithm performance wherever conclusive measurements allow.

B. Setup

Our C++ implementation is integrated into the open-source Munich Train Control Toolkit available on GitHub at https://github.com/cda-tum/mtct. Each optimizer instance was run on a single 4GHz core of a stock Intel i7-6700K processor using DDR4 RAM at 2133 MHz. For each algorithm instance, we record each improvement in objective score along with the expired search time. After collecting a statistically significant number of runs, we interpolate at 500 evenly spaced points over the runtime of the longest run. We then calculate the arithmetic mean score at each point. These mean score progressions can then be compared to assess algorithm quality.

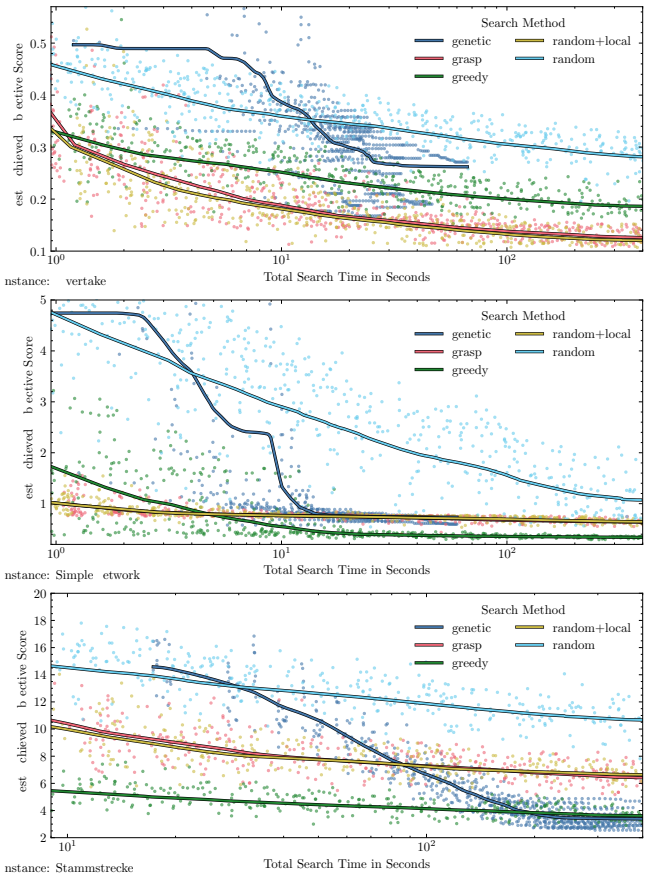

Fig. 5: Search Methods Effectiveness Measurement.

C. Evaluation

We compare the optimizers introduced in Section V-B. For the genetic algorithm, adding a local search step for each generation did not improve outcomes while increasing search time by an order of magnitude. For this reason, we excluded local improvement from the results. For our sample problems, all search methods stopped improving within the investigated time period. Thus, we focus on the best score before stalling, primarily reflecting solution quality.

Figure 5 pits all optimizers against each other. The random search baseline performed worst in all cases, as expected. The two local search methods dominated for the smallest instance. Focusing on refinement is more fitting for a smaller fraction of infeasible solutions. Greedy search was the overall best,

delivering both fast results and a low floor over time. It can efficiently generate many feasible solutions but will drop them immediately. The genetic algorithm showed progressively improved results for larger problem sizes, even overtaking greedy search in final solution quality for the Stammstrecke instance.

By tracking individual objectives and visualizing the train trajectories, we can assess the quality of the solutions for these candidates. The objective values are normalized to $[0, 1]$ or $[0\%, 100\%]$ respectively. The best solutions for the SimpleNetwork and Overtake instances exhibit no distance violations, an average destination penalty of 7% and 11%, and visit all reachable stops. The Stammstrecke solution does contain collisions, a 34% average distance penalty, and 27% average unfulfilled stops.

VII. Conclusions

We have reviewed current developments in railway planning and shown the need for modern, flexible, and accessible simulation platforms. We presented a new microscopic simulation framework for train timetabling on networks equipped with modern signaling systems based on moving block separation. This allows for more flexible train movements than previous approaches. We explained how architectural decisions and constraint encoding could be chosen to help heuristic algorithms find feasible trajectories quickly by implementing repair heuristics. Our approach allows for flexible objectives so that, e.g., line planning could be included in a joint optimization using the presented framework.

We tested multiple optimizer configurations on example timetabling problems to demonstrate functionality and gain insights into problem structure. Greedy and population-based search strategies proved superior to neighborhood-focused ones. For small instances, this trend was reversed. Overall, diversification, in combination with constraint satisfaction, dictated solution quality rather than local refinement. The smaller routing instances could be solved within a few minutes and withstand hard constraints even with limited hardware.

At the same time, this hints that the repair step introduced in the encoding to enforce feasible trajectories significantly helps the heuristics progress. Note that not all solutions firmly adhered to the headway constraints. Hence, the approach might improve from an enhanced solution encoding, which ensures safe distances by a backtracking repair step similar to the one proposed to ensure satisfying track maximum speeds. It is conjectured that this will highly benefit the quality of the solution.

Overall, this work constitutes a promising approach for using simulation frameworks to generate optimal timetables and microscopic routes on general railway networks equipped with modern moving block control systems. All code is available open-source within the *Munich Train Control Toolkit* (MTCT) on GitHub at https://github.com/cda-tum/mtct, which is still under active development.

***Abstract*— Smart city technologies aim to address urban challenges by leveraging digital innovation to contribute to livability. However, their acceptance by citizens remains a critical challenge. Technology acceptance models such as the Unified Theory of Acceptance and Use of Technology (UTAUT) assess individual benefits, overlooking community-oriented motivations. This study proposes expanding UTAUT by introducing perceived public value (PPV) as a new dimension that reflects collective benefits that individuals perceive for their community. Drawing on public value theory, we synthesize a concept of public value and evaluate UTAUT's capability to reflect resulting public value dimensions. Our findings suggest that integrating PPV as additional dimension in UTAUT could enhance understanding of technology acceptance in the smart city context and lays the groundwork for empirical validation. This research contributes to both research and practice by advocating for the inclusion of public value considerations in smart city development, aiming for more sustainable urban development.**

***Index Terms*—Smart city, technology acceptance, public value, UTAUT, sustainable development.**

I. Introduction

THE increasing development of smart city solutions is crucial for addressing urban challenges such as overpopulation, space shortages, and pollution, with the goal to provide a livable environment for citizens [1], [2], [3]. By leveraging the advantages of information and communication technology (ICT), these solutions can offer advantages across various domains, including smart economy, smart environment, smart mobility, smart governance, smart living, and smart people [4].

However, smart city applications can only fulfill their purpose if they are widely accepted and adopted by citizens [5]. The most commonly used models to evaluate technology acceptance are the technology acceptance model (TAM) and the unified theory of acceptance and use of technology (UTAUT) [6], [7], [8], [9]. However, these models are primarily used in the context of private organizations and focus on evaluating personal utility and use. In contrast, smart city applications serve a broader, more heterogeneous user base composed of diverse citizens. These applications aim to benefit the entire population and are even more dependent on citizen acceptance, as citizens are both key stakeholders and end-users [10]. Despite the growing relevance of smart city applications, their potential societal and sustainability benefits, and the need for broad acceptance, existing technology acceptance models and their adaptations have largely measured only individual advantages. To our knowledge, they have not yet assessed the societal value of such applications. In smart cities, technology is not merely a personal tool that provides individual value but a communal resource that can enhance collective well-being and support sustainable development goals (SDGs) [11], [12]. This shortcoming highlights the necessity for an integrated framework that considers both individual and community-oriented motivations in technology acceptance.

Although not originally focused on technology, the concept of public value provides a relevant framework for evaluating the societal contributions of public services [13]. Public value can help understand the societal contributions of organizations or activities which primarily result from government performance. Given that smart city initiatives are often driven and funded by government, public value could offer a valuable perspective for identifying additional acceptance dimensions centered on societal benefit. Similar to previous research on service acceptance models that included sustainability and quality of life as important factors, user acceptance of smart city applications may extend beyond individual utility [14].

Drawing on public value theory and research on technology acceptance, this article thus answers the following research questions:

RQ 1: How can public value be conceptualized in the context of smart city applications?

RQ 2: To what extent do UTAUT variables reflect public value dimensions?

RQ 3: How could UTAUT be adjusted to reflect public value dimensions?

Although this article does not provide empirical evidence yet, we bridge public value with technology acceptance and provide a first conceptualization that paves the way for further research. Our findings contribute to research on technology acceptance and public value for smart cities by introducing an extension of UTAUT that reflects public value. For practice, we highlight the importance of citizens as central stakeholders of smart city solutions that are essential for the acceptance of smart cities.

To answer our research questions, this article is structured as follows. First, we review relevant literature on technology acceptance and public value, followed by a detailed description of our research process. Next, we propose a condensed conceptualization of public value and examine the extent to which UTAUT variables reflect the related dimensions. We then present an extension of UTAUT tailored to smart city applications, introducing the variable *perceived public value* (PPV) as a new dimension designed to capture the collective value smart city applications. Finally, we discuss our findings and outline directions for future research. With this study, we aim to support the integration of public value considerations into the development of smart city solutions, ultimately contributing to more sustainable smart cities that service people, planet, and prosperity.

II. Related Literature

A. Technology Acceptance in Sustainable Smart Cities

UTAUT and its predecessor TAM have been essential in predicting technology adoption behaviors [6], [8], [9]. While TAM focuses on perceived usefulness and ease of use as predictors of the attitude towards using a technology, UTAUT extends TAM by introducing constructs such as performance expectancy, effort expectancy, social influence, and facilitating conditions to forecast behavioral intentions and use [7], [8]. UTAUT has been extended to account for factors influencing use behavior for the consumer market by adding hedonic motivation, price value, and habit [15]. While these models have provided valuable insights into the factors influencing technology acceptance in private organizations, their use has been limited in the smart city context [16], [17], [18].

However, smart city applications differ from enterprise tools in both user base and purpose. Citizens represent a more heterogeneous user group compared to employees of one company, as they vary in terms of demographics (e.g., teenagers and seniors), socio-economic backgrounds (e.g., education levels, income, social status, and living conditions), cultural backgrounds (e.g., languages, values, and norms), as well as user capabilities and tech-savviness. Second, smart city application use is typically voluntary rather than mandated. Smart city solutions aim to contribute to benefits for citizens and thus to livability in the city, making cities inclusive, safe, resilient, and sustainable [12]. Despite these distinctions, prior acceptance studies have focused primarily on individual performance benefits [19], [20]. While UTAUT incorporates social influence, it largely addresses personal acceptance drivers rather than broader expectations of technology serving the public good, benefits for the community, or societal gain. Studies examining additional variables such as trust and government support have produced mixed results and did not assess broader societal value [21], [22], [23]. Similar to previous research on service acceptance models that included sustainability and quality of life as important factors, user acceptance in UTAUT might reach beyond individual benefits [14]. In sum, to our knowledge, no study has yet examined whether perceived community or societal value also has an influence on citizen's intention to use smart city applications.

B. Public Value

The concept of public value emerged in the 1990s in government research and provides a framework for evaluating the contributions of organizations or activities to society and, as such, to common good [13]. Since then, it has evolved in several directions that conceptualize public value from strategical-managerial, psychological, and normative perspectives. Further research also detailed public values, including human dignity, citizen involvement, or integrity [24].

Moore states that "the core idea is a simple one: public managers should be focused on 'creating public value' from the assets entrusted to them by the public." (Moore, 2021, p. 1). He conceptualizes public value from a managerial and strategic perspective as a strategic triangle encompassing legitimacy and support, operational capability, and public value [13]. Bozeman expands the idea from a normative perspective and defines public values as "those providing normative consensus about (a) the rights, benefits, and prerogatives to which citizens should (and should not) be entitled; (b) the obligations of citizens to society, the state, and one another; and (c) the principles on which governments and policies should be based" (Bozeman, 2007, p. 13). In this view, public values go beyond what the public wants, being collective and socially constructed and not reducible to individual preferences. The concept is further expanded with the introduction of the Public Value Scorecard, which draws on psychological needs theory to evaluate how individuals perceive public value across five organizational dimensions: task fulfillment, morality, quality of life, social cohesion, and profitability [27]. Faulkner and Kaufman describe public value as outcome-focused and group it in four dimensions, including outcome achievement, which assesses the social and economic impacts of an initiative; trust and legitimacy, which reflect the public's confidence in an organization and its fairness; service delivery quality, denoting client satisfaction and convenience; and efficiency, which considers whether the benefits of an activity outweigh its costs [28].

In sum, while definitions vary, public value aims to ensure that public organizations and managers deliver services and outcomes that are beneficial to the public, by considering efficiency, ethical factors, and social outcomes.

C. Research Gap

Considering the call for more sustainable smart city solutions that are accepted and used by the public, we see the potential of public value as a promising concept to explain technology acceptance beyond individual benefits since smart city applications can be a form of a public service. Despite its broad application in public organizations and first applications in e-Government [29], to our knowledge public value theory has not been incorporated in technology acceptance models yet.

Despite the advantages of TAM and UTAUT in assessing influencing factors of technology acceptance, we identified a gap in their ability to account for the collective notion of technology serving a greater good, or public value. These models, and their expansions, focus predominantly on individual acceptance factors and do not consider the broader societal influence that smart city technology should contribute to. To bridge these gaps, we suggest the incorporation of public value frameworks in existing technology acceptance theory in the context of smart cities. By incorporating public value perspectives, we can better assess the potential of smart city technologies to meet the collective needs of citizens and align with broader goals such as sustainability and livability. Ultimately, balancing individual and collective value while ensuring sustainable and effective implementation may enhance public acceptance of smart city applications. Considering the concept of public value in relation to the call for "IS for the better" [30], the expansion of existing technology models could thus challenge the notion that acceptance is solely based on individual advantages and fill the proposed research gap.

III. Research Process

To answer our three research questions, we structured our research process into three phases (Fig. 1). In the first phase, we ensured a theoretical foundation by identifying and analyzing relevant literature on public value. We selected four key contributions based on two criteria: 1) the number of citations, reflecting tehri relevance to the academic field, and 2) the requirement that they provide a clear conceptualization of public value. We selected the conceptualizations of public value by Moore [13], Bozeman [26], Faulkner and Kaufman [28], and Meynhardt [27]. We then conducted a comparative analysis of their conceptualizations of public value and identified five common dimensions among them, which we mapped in a synthesized public value concept. This synthesis aimed to answer how public value can be conceptualized in the context of smart city applications (RQ 1).

In the second phase, we synthesized the concepts of public value and technology acceptance. We selected UTAUT as technology acceptance model to evaluate public value, as it builds on TAM and captures additional dimensions beyond perceived usefulness and ease of use. We did not use UTAUT2 due to its tailoring to the consumer context, which includes dimensions such as price value and hedonic motivation. As smart city applications are typically offered free of charge and serve a public rather than a consumer-oriented purpose, these extended dimensions were deemed less relevant in our context. Next, we conducted a qualitative comparative analysis of the dimensions of the synthesized public value concept from phase 1 and the UTAUT dimensions. From this, we identified gaps in UTAUT that fail to reflect public value dimensions. The resulted findings addressed the extent to which UTAUT variables reflect public value dimensions (RQ 2).

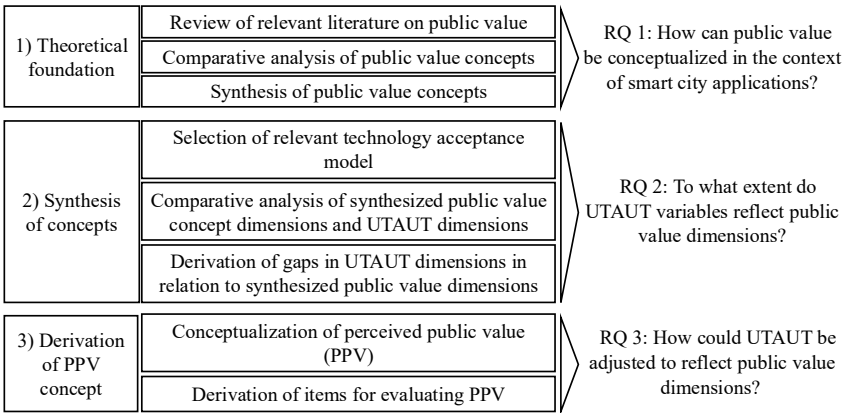

Fig 1. Research Process

In the third phase, we derived a new concept of *perceived public value* that could be added to UTAUT as an additional dimension to assess the influence of public value on the intention to use smart city applications. Furthermore, we derived initial measurement items that could be used in future evaluations of PPV. This phase aimed to answer how UTAUT could be adjusted to reflect public value dimensions (RQ 3). We present the results of this process in the following.

IV. Conceptualization of Perceived Public Value

The result from phase 1 was a synthesized conceptualization of public value. Table I summarizes the results from the comparative analysis of the selected public value concepts.

We first compared how each author defines public value to provide context for their conceptualizations. In the rows, we present the identified similarities between the concepts in five conceptual dimensions of public value:

- Legitimacy and trust,
- operational capacity,
- outcome orientation, efficiency, and profitability,
- citizen engagement and participation,
- and ethical/moral foundation.

In the columns, we assigned the related sources. The resulting table shows how each concept addresses the five conceptual dimensions. Some definitions and concepts might relate to more than one conceptual dimension, depending on the focus. For example, trust and legitimacy as defined by Faulkner & Kaufman (2018) can relate to a distinct dimension with emphasis on the trust in an organization but can also contribute in part to the dimension of ethical and moral foundation when focusing on the fairness of processes.

As a result of phase 2, Table II illustrates the conceptual overlap between the four UTAUT dimensions performance expectancy, effort expectancy, social influence, and facilitating conditions. We conducted a qualitative review of the UTAUT items and public value dimensions to assess overlap and distinction. We did not consider moderating variables of UTAUT. We used a plus sign (+) when UTAUT sufficiently reflects a public value dimension, a minus sign (-) when no overlap was found, and a combination of both (+/-) for partial overlap.

For *legitimacy and trust*, we observed partial overlap with social influence, which captures social or organizational pressure to adopt a system. This may relate to perceived legitimacy but does not reflect trust in institutions or government as a central theme. *Operational capacity* showed partial alignment with facilitating conditions, which refer to technical and organizational support for use. This partly reflects institutional readiness to deliver services. *Outcome orientation, efficiency, and profitability* aligned with performance expectancy, as both emphasize the belief that a system will improve performance. Effort expectancy also overlaps in terms of efficiency, assuming that ease of use contributes to effective service delivery. *Citizen engagement and participation* showed indirect overlap with social influence and effort expectancy. While UTAUT acknowledges social norms, it does not explicitly model participatory or co-creation processes. Effort expectancy also reflects ease of use which is somewhat reflected in service delivery quality as part of client satisfaction. Last, we did not find any overlapping dimension in UTAUT that reflects ethical or moral foundation, highlighting its value-neutral stance. Although several public value dimensions are only partially represented, the complete absence of a moral/ethical foundation stresses a significant conceptual gap between the two frameworks.

As results of phase 3, we developed a new dimension that could be added to UTAUT. While UTAUT captures drivers of individual technology acceptance, its constructs only partially address the broader dimensions of public value. This underscores the need for an expanded or integrated model when evaluating smart city application use. UTAUT assumes a rational individual actor motivated by personal benefit. However, in public administration, both managers and citizens may also be driven by collective, moral, and social values. The narrow individual focus of UTAUT thus overlooks the societal responsibilities and ethical expectations that may shape citizen attitudes towards smart city solutions.

TABLE I.
CONCEPTUALIZATION OF PUBLIC VALUE BASED ON [13], [26], [27], [28]

		Moore (1995)	**Bozeman (2007)**	**Faulkner & Kaufman (2018)**	**Meynhardt (2019)**
	Value definition	What the public values / benefits from	Rights, entitlements, and societal obligations	Achieving desirable outcomes (social, economic, etc.)	Subjective perception of value based on individual experience
Conceptual dimension	**Legitimacy and trust**	Legitimacy and support (political/legal)	Obligations of citizens to society, state, and one another; principles on which governments and policies should be based on	Trust and legitimacy (fair process, trust in organization)	Morality (is the organization decent) and social cohesion (is it acceptable)
	Operational capacity	Organizational ability to deliver	N/A	Efficiency	Implicit in task fulfillment
	Outcome orientation, efficiency, and profitability	Implicit in value creation	Implicit in value creation	Outcome achievement (strong emphasis on achieving social, economic, environmental and cultural outcomes)	Focus on individual (quality of life) and collective (morality, acceptance) well-being, but also on profitability
	Citizen engagement / participation	Implicit in focus on the mission of socially oriented public value	Obligations of citizens to society, the state, and one another	Service delivery quality (client satisfaction and suitable citizen engagement, accessibility, convenience)	Quality of life (positive experience) and social cohesion (satisfying needs for belonging)
	Ethical/moral foundation	Implicit in political and legal backing, benefits and useful outcomes for the public	Shared responsibility of citizens and government	Trust and legitimacy (transparent and fair process), service delivery quality (client satisfaction), Outcomes (social, economic, environmental, cultural)	Morality (satisfaction of moral-ethic needs)

We therefore propose a new dimension called *perceived public value* (PPV), defined as the extent to which an individual believes that a system will create value for the broader community. We chose PPV as a new term for two reasons. First, to distinguish it from prior definitions of public value. Second, to emphasize that public value may extend beyond the individual perspective, which cannot always be directly measured. While citizens likely value the personal benefits of smart city applications (performance expectancy), they may also be motivated by a sense of civic duty or community contributions. In such cases, adoption may stem as much from civic responsibility as from personal convenience.

To assess PPV, we developed six measurement items based on the public value dimensions that were not covered by UTUAT in phase 2 (Table III). We excluded the dimension *outcome orientation, efficiency, and profitability*, as it is sufficiently addressed by performance and effort expectancy. We developed the items based on the style of previous UTAUT questionnaires [6], [21], [23] and added the items according to the identified focus of each public value dimension. The proposed items are intentionally formulated broadly to allow adaptation to specific applications and use cases. We propose that incorporating PPV into UTAUT may improve understanding of citizen behavior in smart city contexts. Doing so acknowledges the civic motivations behind technology use, particularly in cases where collective adoption and use enhances overall system effectiveness.

TABLE II.
PUBLIC VALUE DIMENSIONS AND UTAUT MAPPING

Public Value Dimension (PPV)	**UTAUT Dimensions**	**Conceptual Overlap**
Legitimacy and Trust	Social Influence (some overlap)	+/-
Operational Capacity	Facilitating Conditions (some overlap)	+/-
Outcome Orientation, Efficiency, Profitability	Performance Expectancy, Effort Expectancy	+
Citizen Engagement and Participation	Social Influence (indirect), Effort Expectancy (indirect)	+/-
Ethical/Moral Foundation	Not Applicable	-

TABLE III.
MEASUREMENT ITEMS FOR PERCEIVED PUBLIC VALUE (PPV)

Measurement Item(s)	**Public Value Dimension**
PPV1: The application contributes to the city's objectives which are targeted with the application.	Legitimacy and Trust
PPV2: The application contributes to the main goal (for which it was developed).	Operational Capacity
PPV3: The application contributes to the feeling of community. PPV4: The application contributes to fulfilling citizen's needs beyond individual needs.	Citizen Engagement and Participation
PPV5: The application contributes to sustainability factors and the environment. PPV6: The application contributes to quality of life (in the city).	Ethical/Moral Foundation

V. DISCUSSION AND OUTLOOK

In this article, we introduced PPV as an additional dimension to be integrated into UTAUT to evaluate factors influencing citizens' intention to use smart city applications. Our research has both theoretical and practical implications. From a theoretical perspective, our study bridges a significant gap by proposing a novel way to account for community-centered benefits within technology acceptance models. Modifying UTAUT to incorporate public value may not only enhance its explanatory power in the context of smart cities but also align it more closely with broader sustainability goals. For practice, the inclusion of PPV emphasizes the importance of considering societal benefits in the design and evaluation of smart city applications. Our literature review demonstrated how public value represents a crucial foundation for smart city applications and how it may influence technology acceptance. We therefore encourage stakeholders to integrate assessments of public value early in the planning stages of smart cities to improve future acceptance of such solutions. This approach could promote the development of cities that are not only technologically advanced but also aligned with the SDGs.

Although we carefully conducted our research based on relevant literature and structured analyses, we acknowledge several limitations. First, our study is primarily conceptual and has not yet validated PPV as an extension of UTAUT. Future research should test this dimension and evaluate whether it improves the model's ability to explain citizens' intention to use smart city applications. This includes conceptualizing how PPV integrates into UTAUT and determining its appropriate placement within the model. In fact, we have already taken initial steps toward this goal and plan to report preliminary findings in the near future. Second, we based our comparative analysis in phase 2 on four conceptualizations of public value. While carefully selected, we recognize that our inclusion criteria may have excluded other relevant frameworks. A broader literature review may have yielded additional insights that could have extended the synthesized concept. Third, the perception of public value likely varies across demographic, cultural, and socio-economic contexts of the user base. Future research could explore how these contextual factors influence both the perception of public value and acceptance of smart city applications. Evaluating public value as a dimension of acceptance could help in developing smart city applications that include contributions to public value and thus correspond to citizens' needs, eventually improving future acceptance.

In conclusion, while empirical validation remains necessary, this research represents a foundational step in introducing public value into UTAUT. We contribute groundwork for future studies to empirically test the proposed dimension in real-world settings. We also emphasize the importance of recognizing the collective benefits of technology adoption, aligning with the broader objectives of sustainable development as key responsibility and goal of public organizations. Our work encourages further exploration of the intersection of public value and technology acceptance, urging researchers and

practitioners to consider the broader impacts of technology acceptance. The integration of public value considerations offers further opportunities for information systems research aimed at societal benefit. In this context, we expand upon our previous work on the relevance of citizen engagement for technology acceptance [31], [32].

We hope that our future empirical work on PPV will offer additional evidence for the importance of community-oriented perspectives. Through this lens, smart cities can evolve to become centers of technological advancement that while also serving citizen's needs and prioritizing sustainability, creating a more livable future for all.

***Abstract*—This paper tackles the challenge of adaptive level generation in video games, focusing on generating content that aligns with player skill. A key limitation of procedural content generation (PCG) is achieving semantic control. Specifically, generating levels of varying difficulty with limited training data. To address this problem, we propose a hybrid approach combining Large Language Models (LLMs) and Generative Adversarial Networks (GANs). An LLM is used to generate a diverse, difficulty-labeled dataset of Snake game levels, which are validated with A* pathfinding to ensure playability. These levels serve as training data for GANs that are able to efficiently generate new levels. The system is evaluated through user study and playability metrics. Results show that the LLM-assigned difficulty labels correlate strongly with human perception. The achieved playability is 87% for easy levels and 36% for hard levels. Our findings demonstrate that the hybrid LLM-GAN approach enables scalable and semantically controlled content generation, balancing quality, adaptability, and computational efficiency.**

***Index Terms*—procedural content generation, generative adversarial networks, large language models, video games, playability, adaptive systems.**

I. Introduction

THE greatest advances in the software industry today are due to the ability to adapt to the personal needs and preferences of individual users. Functionalities such as Netflix's recommendation system or Duolingo's customizable lessons have given companies an edge over the competition. In recent years, new large language models (LLMs) have also been developed to answer users' questions. Similar principles are being explored in the development of video games, particularly through the automatic generation of content based on players' skills and behavior [1].

A key challenge in adaptive content generation is semantic control, i.e. the ability to create content with specific, interpretable characteristics (such as difficulty level) that align with human perception and intent, rather than producing statistically similar outputs. Traditional procedural content generation methods face challenges. They either rely on manually created rules that limit creativity or require extensive datasets that may not exist for specific domains. And even when successful, they often lack the semantic understanding to produce content with certain meaningful characteristics.

This paper continues research into adaptive software systems [2,3], extending from dynamic software updating to adaptive content generation. Using the game Snake as a controlled environment, we investigated three approaches for AI-driven level generation: standalone GANs, standalone LLMs and a novel hybrid LLM-GAN approach.

Our research specifically examines whether modern AI approaches can provide reliable semantic control for difficulty adaptation. Initial experiments with GANs trained on limited data (15 levels) demonstrated severe overfitting and poor generalization. Pure LLM generation showed excellent quality control through semantic understanding but proved computationally expensive for real-time applications. This motivated our hybrid approach: using LLMs to bootstrap diverse training datasets for GAN training, combining the semantic precision of language models with the computational efficiency of adversarial networks. We validated the semantic control capabilities through user study, demonstrating a strong correlation between LLM-assigned difficulty labels and human perception. The focus is to determine whether the proposed hybrid pipeline can achieve the benefits of both approaches while mitigating their individual limitations.

II. Related Work

The field of procedural content generation (PCG) for video games [4] has made significant progress through the application of artificial intelligence techniques. This section presents the main approaches to game level generation: traditional PCG methods and their scalability limitations, generative model applications, and playability assurance techniques that ensure generated content meets functional requirements.

A. Procedural Content Generation

Togelius et al. [5] define procedural content generation (PCG) as the algorithmic creation of game content with limited or indirect user input. Some games such as Minecraft[1] use

This work was co-funded by the European Union through the National Recovery and Resilience Plan (NPOO), under the project *AutoEvolve – Automated Evolution of Software*, project code: NPOO.C3.2.R3-I1.05.0073.

PCG to create seemingly infinite worlds. Games in the roguelike and dungeon crawler genres, such as Spelunky[2], use it to create unpredictable levels that ensure each playthrough is unique. The challenge that arises from this approach is to manage the generation process to create meaningful and entertaining levels. This also requires substantial effort from the developer, who must set detailed restrictions to ensure playability.

B. Generative Models

Generative models are a class of machine learning algorithms designed to generate new data samples that resemble a given dataset. These models learn the underlying distribution of the data and can generate realistic outputs such as images, text, etc.

GANs [6] use the adversarial training process where the generator produces synthetic samples while the discriminator tries to distinguish real data from the generated ones. During the training process, the generator and discriminator play a mini-max game in which the goal for the generator is to produce realistic samples. Transformers [7], on the other hand, have introduced the mechanism of self-attention, which allows them to efficiently capture long-range dependencies. Although they are mainly used for text generation, they have also proven successful in image generation [8].

C. Generative Models for Level Creation

Recent research has investigated the use of machine learning (ML) for procedural content generation [9]. Generative Adversarial Networks (GANs) [6] have emerged as powerful tools for creating game levels that resemble human-designed content. As Volz et al. [10] have shown, GANs can capture the essence of existing Super Mario Bros levels while introducing new meaningful variations. Their approach uses a Covariance Matrix Adaptation Evolutionary Strategy (CMA-ES) [11] to optimize the latent space of the network, allowing the creation of levels with certain desired properties, such as the wall density or the number of enemies. However, this method relies heavily on large datasets of existing levels and is constrained by the design patterns present in the original corpus, potentially limiting novelty.

The CESAGAN (Conditionally Embedded Self-Attention GAN) framework [12] builds on basic GAN architectures and incorporates explicit constraints into the generation process. This model encodes specific requirements, such as the number of walls or enemies, into feature vectors that guide the generation process. Bootstrapping techniques were used to solve the problem of a lack of data in the game-level datasets. This involves iteratively adding newly generated levels that meet the playability criteria, such as the correct number of tile types and the existence of a path to all goals, to the training dataset. This approach has significantly increased the percentage of playable levels while reducing the number of duplicates.

D. Playability

One of the main problems encountered with PCG is ensuring that created levels can be completed by the players. There are several approaches to solving this problem from different perspectives. One innovative approach combines classification with explainability techniques [13]. After identifying unplayable levels, models such as SHAP (SHapley Additive exPlanations) [14] or Integrated Gradients [15] assign importance values to each coordinate in the level, highlighting areas that are responsible for the unplayability. These values lead to targeted changes to problematic areas, while the overall structure and aesthetics of the level are preserved.

Zhang et al. [16] used GAN to generate Zelda levels and then used Mixed Integer Linear Programming (MILP) to repair unplayable levels. MILP provides a mathematical approach to level repair by representing levels as graphs in which the nodes correspond to tiles (walls, empty spaces, players, keys, doors or enemies) and the edges represent the connections between tiles. The playability problem is formulated as a network flow problem with sources (e.g. players), targets (e.g. doors, keys) and obstacles (e.g. walls). The solution minimizes the number of changes required to make a level playable while satisfying constraints related to flow preservation and obstacle avoidance. While this approach guarantees playability, the complexity of implementation could increase significantly for games with dynamic elements such as moving opponents.

Cooper and Sarkar [17] have used specialized repair agents to identify and repair unplayable areas. These agents can perform otherwise forbidden actions (e.g., walking through walls), but at a high cost. By identifying expensive actions on an agent's path to the goal, the system can make targeted modifications to the level, such as converting walls into empty spaces.

Jain et al. [18] used autoencoders [19] to generate new levels based on an existing corpus of Super Mario Bros levels. Their model compresses the level designs into a lower-dimensional latent space and then reconstructs them, effectively learning the basic patterns and structures that compose valid

[2] https://www.spelunkyworld.com/

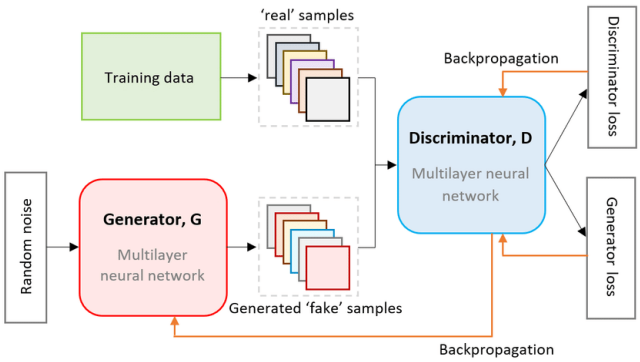

Fig. 2 Architecture of GAN [24]

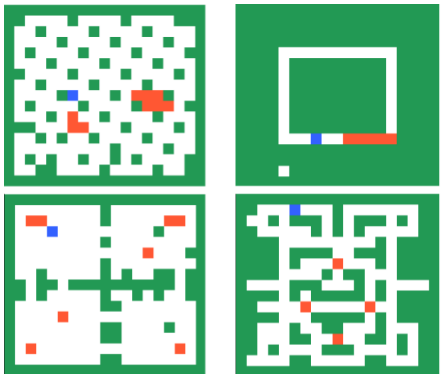

Fig. 3 Levels generated by GAN on initial dataset

levels. They have also used autoencoders to repair unplayable levels by running them through the model, which leverages its learned representations to reconstruct missing or problematic elements while maintaining overall coherence.

III. Hybrid Approach to Procedural Content Generation

This section describes our experimental framework for developing an adaptive Snake game that dynamically generates levels tailored to player skill. Our approach addresses a fundamental challenge in procedural content generation: balancing quality, controllability, and computational efficiency. While LLMs excel at generating semantically meaningful content with explicit difficulty control, they are computationally expensive for real-time applications. Conversely, once trained, GANs can efficiently generate content, but typically lack semantic understanding and require large datasets. Our hybrid pipeline combines these approaches by using LLMs to generate diverse, difficulty-labelled training data, then training specialized GAN models on this data for efficient generation at runtime. The system operates in two distinct phases. In the training phase, we use structured prompts to generate levels of controllable difficulty, validate their playability, and train separate GAN models for easy and hard difficulty levels.

A. Initial Dataset

One of the biggest challenges in training generative models is the lack of high-quality, diverse training data. The initial dataset was extracted from the 15 pre-made levels of the Google Snake Game Level Editor mod [20] (in Fig. 1).

However, this initial dataset of 15 levels presents a significant limitation for training GAN, which typically requires hundreds or thousands of training samples to learn meaningful data distributions and avoid overfitting. To address data scarcity, we used LLM to generate additional training data, as detailed in the section IV.A.

The pre-made levels consist of different types of tiles such as walls, crates, players and different types of food. To simplify the generation process, we have focused on 4 types of tiles that are essential for the game: walls, empty spaces, food and the player's starting position. All the different food types have been combined into one and all other tile types have been treated as empty spaces.

Individual pre-made level images are available on GitHub [21]. The images were processed by extracting tiles based on their colour. The levels can be displayed in different ways. Inspired by the game levels in The Video Game Levels Corpus (VGLC) [22], we opted for the 2D grid representation. A specific character symbol is used for each tile type. In our simplified levels, "W" stands for walls, "-" for empty areas, "F" for food and "S" for snake head, as shown in Fig. 4.

To encode the levels for training with GANs, each tile type is encoded in a separate channel, so that the levels were represented using four channels. Since the pre-made levels have different sizes, further preprocessing was required. In particular, all levels were padded with empty spaces up to a size of 32x32 tiles.

B. GAN Model

The architecture of the GAN model is based on the model from Arjovsky et al. [23]. In this design, the discriminator consists of blocks of strided convolutional layers followed by batch normalization layers and LeakyReLU activation layers. The generator uses transposed convolutional layers followed by batch normalization and ReLU layers. The last transposed convolutional layer is followed by the hyperbolic tangent function (*tanh*), which maps the outputs to the range [-1,1]. The architecture is adapted to 32x32 size images by removing the deepest layer of both the discriminator and the generator. The architecture of the entire system is shown in Fig. 2.

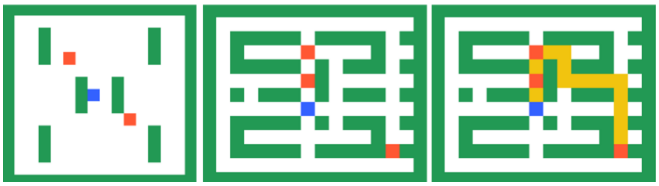

Fig. 5 a) Easy level generated by LLM, b) hard level generated by LLM and c) hard level generated by LLM with shortest path found with A* algorithm

After the training process, the generator can accurately replicate levels in the training dataset, as shown in Fig. 3. However, since only a limited amount of training data is available, the model tends to overfit. It replicates training samples instead of generating varied new levels. Furthermore, to generate levels with the desired difficulty, a larger, balanced dataset with difficulty labels is required.

C. LLM for Training Set

Instead of designing new levels manually, large language models (LLMs) can be used for this task. To generate new levels, the LLM must first be given clear instructions on how to generate them. It must also be given some levels as a reference. In most cases, text prompts are used as input to the model and the output is usually in the form of text. When generating levels with LLMs, we explored two primary output formats: 2D textual grids and structured representation. As level examples, we passed premade levels in 2D format, as shown in Fig. 4. The prompt to the model was as follows: "I have attached game levels for the game Snake. 'W' represents walls and '-' represents empty spaces. Generate more similar levels".

We found that the text outputs, especially for larger levels, often contained errors, such as an incorrect number of rows or an incorrect number of elements in a row. While most of these errors could be corrected manually, our goal is to automate the process. To generate high-quality, structured game layers, we combined GPT-4o and the OpenAI API Structured Outputs feature [25] that allowed us to capture the output in JSON format. To shape the whole process as a pipeline, we used the LangChain [26] framework in combination with a Pydantic-based output parser. Instead of generating free-form grids, we used pydantic.BaseModel to define a detailed schema to explicitly describe the components of a game level. The schema contains fields with the grid size (height and width of the level), a list of wall coordinates, the position of the snake head and a list of food coordinates. The output parser allowed us to validate each generated level and automatically discard levels that did not exactly match the schema. A typical prompt asked the model to generate a solvable Snake level of a given size with specific design constraints (the food must not be placed on the walls, the level must be solvable). The output was automatically parsed and validated. Inconsistencies or missing fields triggered errors, allowing us to discard or regenerate the sample in question. This approach provided a clean, normalized dataset suitable for conversion to structured tensors for GAN training. It also gave us the opportunity to generate new levels under certain conditions. The difficulty of the levels is particularly interesting. With carefully designed prompts, it is possible to generate easier or harder levels, as can be seen in Fig. 5. Easy levels have fewer walls, and food is generated closer to snake's head, while harder levels have more complex wall structures and food is harder to reach. In some cases, however, there is no clear difference in the difficulty of the generated levels.

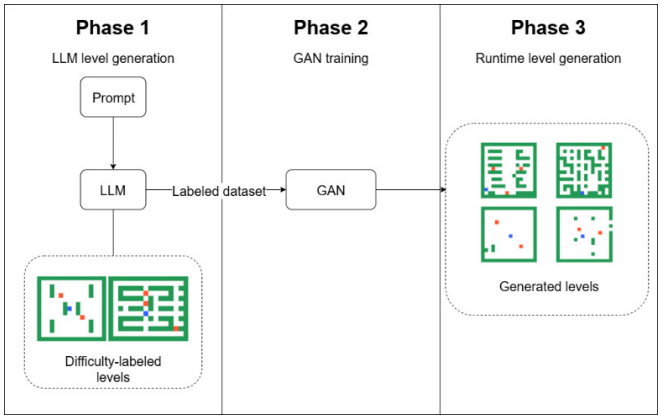

Fig. 6 System architecture of the hybrid LLM-GAN level generation pipeline

Even though there are multiple methods that can check the playability and even repair levels (section II.C), we only calculated the shortest path from the snake's head to all the food items. It can be calculated using the A* algorithm [27], adapted for multiple goals, where additional movement constraints apply: the snake cannot immediately turn back (return to the direction it just came from). The snake's ability to grow incrementally was not considered and it was treated as a single tile. The Manhattan distance was used as a heuristic function. Knowing the shortest path allows comparison of levels from the unbiased perspective of a "perfect player". We track metrics such as path length, the number of turns, the number of tight turns (around walls), and the longest straight path. We also track metrics related to the level itself, such as the percentage of walls, the number of dead ends, the number of "chokepoints" (narrow passages with walls on both sides). Regardless of these metrics, the difficulty depends significantly on the placement of the food.

IV. Experiment Setup

To create a substantially larger dataset for GAN training and validate our hybrid approach, we employed a comprehensive three-phase experimental framework. This methodology enables systematic comparison of the cost and quality of pure LLM generation, the effectiveness of hybrid GAN training, and the validation of semantic control through a user study, providing quantitative analysis of the trade-offs between the different approaches. The system architecture is shown in Fig. 6.

A. Generating Dataset for GAN Training

We used levels generated by an LLM in text format, as described in section III.A, and input them to LLM as examples. When selecting the examples, focus was to ensure that there

TABLE I

MODEL COMPARISON BETWEEN LEVEL DIFFICULTY

Model *Difficulty*	**Max (Avg) Playability Rate (PR)**	**Computational cost**	**Generation time**	**Semantic control**
GAN *Hard*	36 (24*) %	2h training duration	< 1s	Limited
GAN *Easy*	87 (74*) %	2h training duration	< 1s	Limited
LLM *Hard*	66 (100**) %	~705 tokens per level	~30s	Excellent
LLM *Easy*	100 %	~412 tokens per level	~30s	Excellent

*Average of top 5 hyperparameter configurations
**After validation and regeneration of failed levels

is a clear difference between hard and easy levels, like more open spaces and food closer to the player for easier levels, and more narrow passages and food placed in more difficult places for harder levels.

We then generated 50 easy and 50 difficult levels with structured few-shot prompts. Each generation started with a prompt with 3569 tokens for easy levels and 8495 tokens for difficult levels. The model's responses varied in complexity, averaging 412 tokens for easy levels and 705 tokens for difficult levels. Due to the nature of generative models that not all levels were viable. Some were unplayable or logically broken and had to be discarded, resulting in a higher number of tokens spent. As this process immediately generated 50 playable easy levels, there were 17 unplayable hard levels that we discarded. The total number of tokens used to generate all 100 levels was 617131. We can see that the generation process, while successful, consumes a lot of resources and is not practical when a big set of levels is needed.

B. GAN Training

With the generated dataset, we trained two separate GAN models: one for easy and one for difficult levels. Each model was trained[3] with a corresponding subset of 50 levels.

All levels were pre-processed as described in III.A. The training data was normalized to the range [-1,1] to align with the *tanh* activation in the generator's output layer, as mentioned in section III.B.

We explored different values for the learning rate, the stack size, the dimension of the latent vector, and the number of times the discriminator is trained before training the generator during each epoch. The playability rate (PR) was used as the optimization target. It is defined as number of solvable levels per 100 generated levels. The models were trained for 2000 epochs.

C. User Study for Semantic Control Validation

To evaluate the perceived difficulty of the LLM generated game levels, we conducted a user study involving seven participants. Each participant was asked to rate 100 level

[3]Training was conducted on NVIDIA GeForce GTX 1050 for approximately 4 hours. We used Optuna framework [28] for hyperparameters and monitored convergence through playability rate (PR) metric.

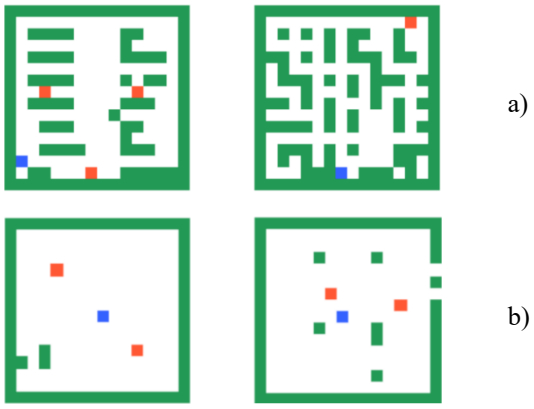

Fig. 7 Playable levels generated by GAN models trained on: a) "hard" dataset, b) "easy" dataset

images on a scale from 1 (very easy) to 5 (very difficult). The dataset consisted of 50 "easy" and 50 "hard" levels generated by a large language model in IV.A. However, users were not informed of these labels. The difficulty levels were randomly shuffled and presented to all users in the same order to ensure consistency. After collecting the individual ratings, we calculated the average rating for each level and analyzed its Pearson correlation with various structural features extracted from the levels described in III.C. This enabled us to identify which features most strongly influence the difficulty perceived by the users and the correspondence between the difficulty assigned as input to the LLM and the user ratings.

V. RESULTS

We present our findings in two main parts: first, validation of LLM semantic control through a user study, showing a strong correlation between assigned and perceived difficulty; second, the analysis of GAN performance when trained on LLM-generated datasets, revealing significant differences between easy and hard level generation complexity.

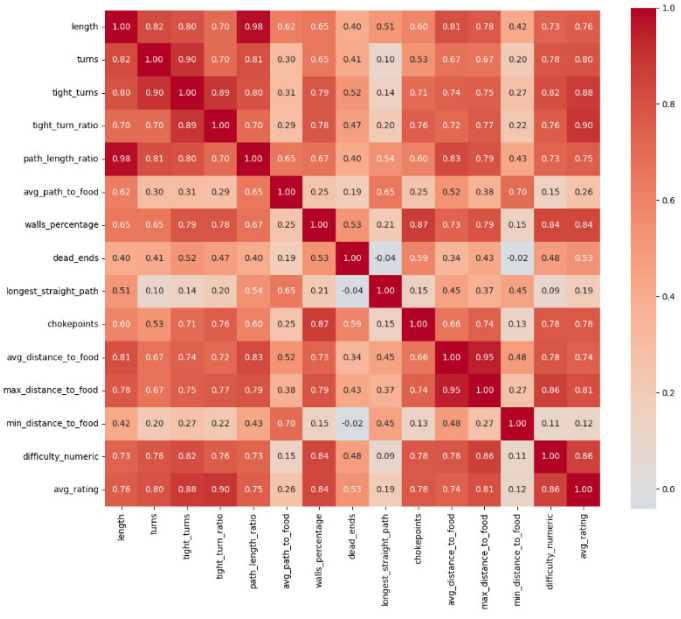

Fig. 8 Correlation matrix between structural level features and user difficulty ratings (n=7 participants, 100 levels)

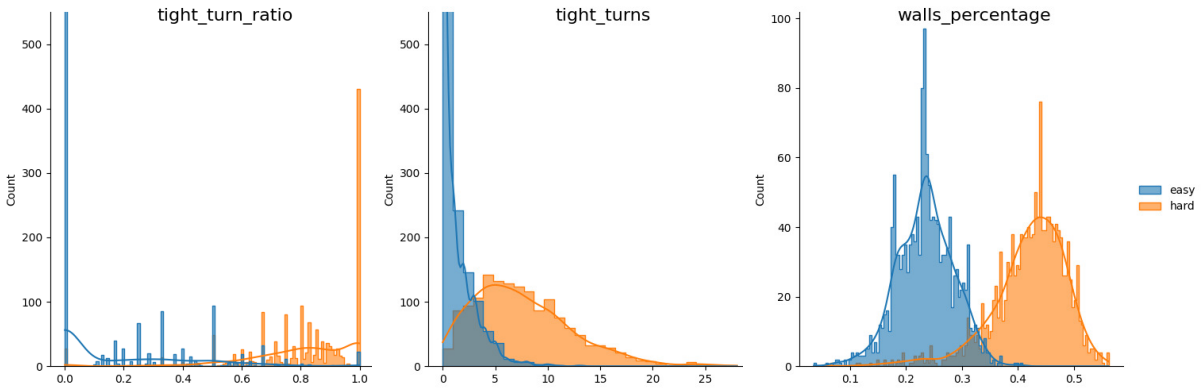

Fig. 9 Distribution comparison of key metrics between GAN-generated “easy” and “hard" levels

A. LLM Generated Levels

Based on the correlation (Fig. 8), we have identified several features that exhibit a strong relationship with user perceived difficulty. The most prominent is the *tight turn ratio*, which has the highest positive correlation with average user ratings, suggesting that levels requiring frequent sharp changes of direction are consistently rated as more difficult. Other features such as *total number of turns* and *percentage of walls* also correlate strongly with higher difficulty ratings, suggesting that spatial complexity and environmental constraints play a central role in perceived challenge. However, several features are highly intercorrelated, most notably *tight turns* and *turns*, as well as *average* and *maximum distance to food*, leading to redundancy and suggesting that a more compact feature set could be used without significant information loss. Interestingly, the binary *difficulty label* originally assigned to the level generation prompt ("easy" vs. "hard") shows a strong correlation with the actual user ratings.

Results show that the generated levels are highly consistent with players' perceptions, which strengthens confidence in the quality of the generated levels and can serve as a useful basis for further automation. However, a larger-scale study would be needed to confirm these findings across diverse player populations. It is important to note that our analysis is based on correlation rather than causation, further controlled experiments are needed to confirm which features directly influence perceived difficulty.

B. GAN Generated Levels

We have selected the five best performing hyperparameter configurations for each model (Easy GAN and Hard GAN) based on the playability rate (PR). For each of these configurations, we also identified the top three training checkpoints that produced the highest quality outputs. From each of these checkpoints, we generated 100 playable level samples, resulting in a diverse evaluation set. We then computed metrics described in IV.C for these generated levels. As shown in Table I, the model trained on the “hard” dataset generates much less playable levels than the one trained on the easy dataset. The significant difference in playability rates (87% vs 36%) suggests that difficult levels require more complex spatial reasoning that our current GAN architecture struggles to capture. This indicates that difficulty affects not only player perception but also computational generation complexity. Similar to the results in A, some features, such as number of *tight turns*, *tight turn ratio* and *percentage of walls*, show a clear difference between the generated easy and hard levels[4], as shown in Fig. 9. Models are able to generate completely new playable levels with distinct features as shown in Fig. 7.

VI. Conclusion

Our research explored different approaches to procedural content generation (PCG) of game level s. We found that, while efficient for generating a large number of levels, GANs require big and quality datasets. LLMs, on the other hand, produce high quality levels with very little input, but require a lot of resources to generate a larger amount of levels. We proposed a hybrid approach by combining the flexibility of large language models (LLMs) with the efficiency of generative adversarial networks (GANs). LLMs proved effective in generating structured and semantically rich level layouts, particularly when guided by schema-constrained prompting. However, due to high computational costs, LLMs are best suited for generating curated datasets. In contrast, GANs, once trained, can quickly generate large volumes of content but exhibit limited generalization when data is scarce. Our user study confirmed that LLM-labeled difficulty levels align well with player perceptions, and that certain structural features (e.g., tight turns, wall density) correlate strongly with perceived difficulty. These insights can guide future systems toward real-time, skill-adaptive content generation.

***Abstract*—This paper introduces the DivCrypt framework, a step-by-step guidance for validation of cryptographic implementations. The core idea is to decompose the evaluated implementation into components across complexity layers and validate each component through a structured five-step process. DivCrypt is not intended to replace existing standards, but rather to serve as a practical audit playbook. It can be easily adopted by evaluators in formal certification processes, researchers conducting security audits, and developers performing internal testing. The framework is also intended to encourage creators of novel, non-standardized cryptographic constructs to publish and maintain DivCrypt-aligned knowledge base. Such contributions, including test vectors and known implementation vulnerabilities, would support not only the application of DivCrypt, but also benefit the broader research and development community.**

I. Introduction

MODERN services increasingly depend on complex, multi-component IT/OT systems, highlighting the critical need to enhance their robustness. To establish trust, the security of these systems should be validated through external, independent security audits, typically performed in accordance with family of standards such as ISO/IEC 15408 [1] or ISA/IEC 62443 [2]. Compliance with such norms may be enforced by law or required in procurement for the defense sector. Given their fundamental role, cryptographic mechanisms are integral to these certification processes, serving as essential trust anchors. Even minor implementation flaws can significantly undermine security of the system, emphasizing the need for consistent and rigorous validation. Consequently, there are standards for both developing [3], [4] and testing [5], [6] of the cryptographic modules.

However, existing norms do not cover the validation of non-standardized cryptographic mechanisms. Notably, widely adopted community or industry tested cryptographic solutions sometimes enable advanced features in modern applications, yet the formal standardization processes can take years[1] resulting in significant gaps in official guidance. Security auditors evaluating novel cryptographic schemes currently rely on limited informal guidelines [9]. As a result, a comprehensive, high-level framework for the consistent validation of cutting-edge cryptography implementations is currently lacking.

[1]For example, the NIST Post Quantum Cryptography competition selected new standards: ML-KEM [7] and ML-DSA [8], after eight years of evaluation.

To address this gap, we introduce a methodology consisting of five sequential steps, grounded in a core principle: decomposing cryptographic solutions into smaller, manageable components. As illustrated in Figure 1, each component undergoes comprehensive security evaluation across four dimensions: *theoretical*, *functional*, *computational*, and *contextual*. The advantages of our framework include:

- **Efficiency.** Defines high-level procedural steps and methodologies without prescribing specific implementation details. The decomposition of the evaluated implementation and reuse of knowledge bases make the framework efficient by avoiding redundant efforts;
- **Inclusivity.** Accessible to a diverse range of users including developers, security auditors, and evaluators - thanks to its simplicity and flexibility in tool selection;
- **Universality.** Applicable to both standardized and emerging cryptographic protocols, including homomorphic encryption and non-interactive zero-knowledge proofs;
- **Estimability.** Once an implementation is decomposed, the total time required for evaluation becomes easy to estimate.

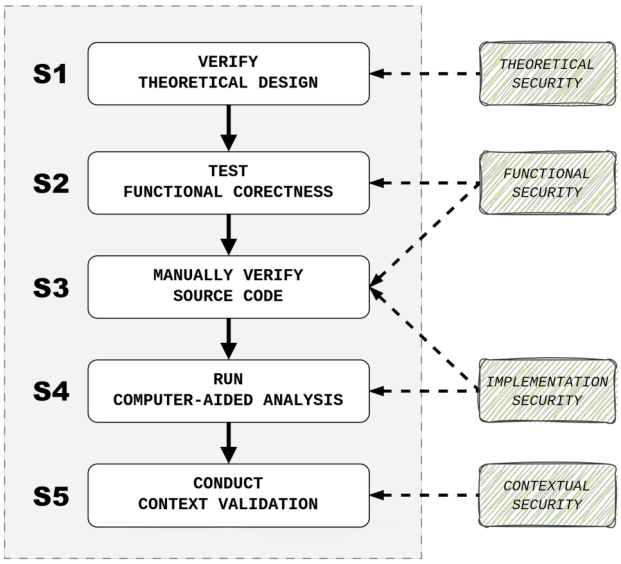

Fig. 1. The five sequential steps of DivCrypt comprehensively address four essential aspects of implementation security.

The absence of standards for novel cryptographic solutions poses significant challenges, especially under regulatory scrutiny of blockchain-based applications. In this domain, there is a growing adoption of zero-knowledge proofs, primarily to enhance privacy and scalability. Our framework is intended to bridge the gap between innovation and compliance, enabling consistent evaluation of cryptographic implementations across industry.

II. DivCrypt Framework

A. Terminology

The DivCrypt framework adopts a structured perspective on cryptographic implementations by organizing them into a hierarchy of four abstraction levels, referred to as *Cryptographic Layers* (CL):

CL1. cryptographic protocols;
CL2. cryptographic schemes;
CL3. cryptographic primitives;
CL4. underlying arithmetic.

We also introduce the notion of *Cryptographic Layer Object* (CLO) which denotes a specific instance at any given layer. For example, CLO can be: TLS v1.3 (CL1), Ed25519 (CL2), SHA-512 (CL3) or prime field (CL4). As a natural extension of CL and CLO, we define the notion of a *Cryptographic Layer Object Implementation* (CLOI), representing the actual implementation of a given CLO. The implementation under evaluation within the DivCrypt framework is referred to as the DivCrypt Target (DCT). DCT is subsequently decomposed into a directed acyclic graph, known as the DCT-graph, where the DCT itself serves as the root node with no parents. An illustrative example of such a decomposition is presented in Figure 2.

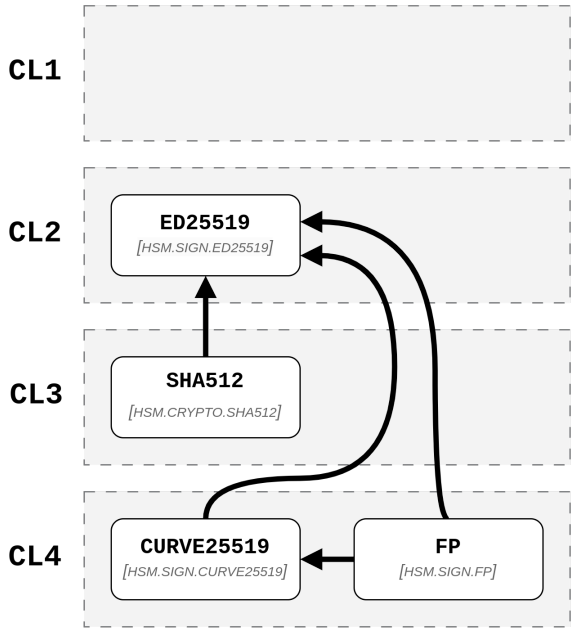

Fig. 2. The DCT-graph of the software implementation of Ed25519 digital signature scheme.

B. Testing procedure

The main idea behind DivCrypt is to conduct methodological analysis of cryptographic primitives, schemes, or protocols by applying divide-and-conquer-like approach, which materializes through the construction of the DCT-graph. The DivCrypt framework incorporates a range of validation techniques to comprehensively address all relevant security aspects of cryptographic algorithm implementations. It consists of three main parts:

1) ***Building the Knowledge Base****:* This is a continuous process of maintaining a database comprising two core elements described in the Section III: the *Cryptographic Validation Card* (CVC) and the *Cryptographic Vulnerability Reference* (CVR). This component is verification-independent and serves as a shared foundation for evaluations.

2) ***Decomposing into DCT-graph****:* By identifying each subcomponent according to its corresponding cryptographic layer, the DCT is decomposed into a directed acyclic graph with four levels of nodes, each visualizing a specific Cryptographic Layer (CL). The DCT-graph can be understood as a graph of dependencies, where edges represent implementation-level reliance. An example DCT-graph for Ed25519 [10] is shown in Figure 2. It is important to note that every node must be identified by its package name, as a DCT may contain multiple implementations of the same primitive (e.g., three different implementations of SHA-256). In Figure 2, package names are enclosed in square brackets. Each package name must be unique to ensure clarity and avoid ambiguity.

3) ***Validating DCT-graph****:* Validation is carried out through five sequential steps described in the Section IV, applied recursively from the leaf nodes to the root, ensuring that each node is verified before its parent. These steps, illustrated in Figure 1, define a strict sequence to follow, while allowing flexibility in how precisely each step is tailored to the context and assurance requirements of the evaluation.

III. Reusable Knowledge Base

During the decomposition of the DCT into the DCT-graph, it is necessary to ensure that every CLO is associated with a corresponding *Cryptographic Validation Card* (CVC) and *Cryptographic Vulnerability Reference* (CVR). The creation and maintenance of both artifacts are verification-independent tasks, performed prior to the validation phase. The purpose of this initial step is to establish and continuously update a knowledge base containing essential information about various CLOs. The CVC (Subsection III-A) captures the detailed specification and structure of CLO, incorporating both official and internally constructed test vectors. The CVR (Subsection III-B) enumerates known sources of security issues, including academic papers, vulnerability disclosures, and implementation-specific attack reports relevant to the examined CLO. The concept of utilizing a reusable knowledge

base to improve the efficiency and consistency of security evaluations has been applied in other contexts - for example, to streamline the complex documentation process for Common Criteria certification [11].

A. Cryptographic Validation Card

[CVC-1] Specifications. Reference to the official CLO specification, including relevant standards and technical documentation.

[CVC-2] Algorithms. A list of algorithms that collectively define the CLO.

[CVC-3] Dependencies. A list of other CLOs from lower cryptographic layers that are directly utilized by the CLO.

[CVC-4] Sources. Collection of useful materials, such as reference implementations and technical analyses.

[CVC-5] Official Test Procedures. References to official testing procedures developed by the authors of the cryptographic standard or proposal. Usually, this is a set of test vectors called Known Answer Tests (KATs).

[CVC-6] Other Test Procedures. Supplementary internal testing strategies aimed at verifying both correctness and robustness against failure scenarios. This can be achieved by designing test vectors that cover edge cases and applying them to both the reference and the evaluated implementation.

B. Cryptographic Vulnerability Reference

[CVR-1] Queries Table. A complete list of search queries used to collect entries for CVR-2, CVR-3, and CVR-4.

[CVR-2] CVE Entries. A list of relevant Common Vulnerabilities and Exposures (CVE) entries associated with the CLO.

[CVR-3] Academic Papers. A curated list of academic publications addressing implementation-specific aspects or vulnerabilities of the CLO.

[CVR-4] Media. A collection of publicly available sources, such as blog posts, technical write-ups, or incident reports, that refer to observed vulnerabilities or behaviors.

IV. DivCrypt's Evaluation Steps

S1. Verify theoretical design

Task. Evaluator shall verify that the DCT is listed in widely accepted standards.

Example. The evaluator confirmed that the Ed25519 signature scheme is included in NIST FIPS 186-5 [12].

Remarks. DivCrypt is not intended to analyze the security of the cryptographic protocols, schemes, or primitives, but only the implementation correctness of standardized ones.

S2. Test functional correctness

Task. Evaluator shall execute the test procedures specified in CVC-5 and CVC-6.

Example. The evaluator developed interfaces in Python for both the tested and reference implementations. A test script was run, invoking procedures described in CVC-5 and CVC-6. The results indicated all tests completed successfully.

Remarks. Testing with predefined or dynamically generated test vectors is the basic method of verifying implementation correctness. The reference implementation serves as a benchmark to validate the behavior of the evaluated cryptographic module.

S3. Source code verification

Task. Evaluator shall perform a comprehensive review of source files, focusing on critical functions and their usage, including input handling and side-channel resistance.

Example. The evaluator manually reviewed the codebase and, using all accessible CVC/CVR artifacts, concluded that the implementation conforms to current best practices and is appropriate for the intended application context.

Remarks. Although time-consuming, manual source code analysis provides deep insight and allows the evaluator to understand the implementation at a level comparable to its developers.

S4. Computer-aided analysis

Task. The evaluator shall apply static and/or dynamic analysis tools to identify implementation flaws.

Example. The evaluator used Wycheproof [13] and Cryptofuzz [14] to check the Ed25519 implementation. Then he applied a generic C++ static analyzer to detect unsafe coding practices.

Remarks. Static analysis does not require execution of the evaluated codebase and includes tools like Wycheproof [13]. Dynamic analysis is performed during execution and includes fuzzers and tools such as Valgrind [15] to detect runtime issues like memory leaks.

S5. Context validation

Task. The evaluator shall examine the interaction of the DCT with its external environment to identify context-related misuse or misconfiguration.

Example. The evaluator used the recursive `grep` command to list function calls and further analyzed the invoking context.

Remarks. Contextual validation ensures that even correctly implemented algorithms are not undermined by improper use. This step often goes beyond the scope of the DCT itself but is essential for assessing overall system security.

V. Case Study: ED25519 Implementation

To validate the implementation of the Ed25519 digital signature scheme [10], we constructed a knowledge base comprising a *Cryptographic Validation Card* and a *Cryptographic Vulnerability Reference* for each component shown in Figure 2. For brevity, Subsection V-A presents CVC of just one component - Ed25519 digital signature scheme. In the Subsection V-B we cover the concise record of the validation process. All future updates to the framework and its knowledge base will be made available in the project's GitHub repository at *https://github.com/arturmisztal/divcrypt*.

A. Cryptographic Validation Card for Ed25519

[CVC-1] Specifications.

- NIST FIPS 186-5 [12].
- RFC 8032 [16].
- EdDSA for more curves [17].
- High-speed high-security signatures [10].

[CVC-2] Algorithms.

- `ed25519-gen`
  - *description:* key generation
  - *input domain:* -
  - *output domain:* $\{0,1\}^{256} \times \{0,1\}^{256}$
- `ed25519-sig`
  - *description:* signature generation
  - *input domain:* message $\mathcal{M}$ of length less than 2^{128} bits
  - *output domain:* $\{0,1\}^{512}$
- `ed25519-ver`
  - *description:* signature verification
  - *input domain:* $\mathcal{M} \times \{0,1\}^{512} \times \{0,1\}^{256}$
  - *output domain:* $\{$`invalid, valid`$\}$

[CVC-3] Dependencies (Table I).

[CVC-4] Sources.

- NIST ACVP EdDSA [18].
- Ed25519 reference implementation [19].
- CRYPTREC Review of EdDSA [20].
- EdDSA signature verification edge cases [21].
- The Provable Security of Ed25519 [22].

[CVC-5] Official Test Procedures.[2]

- For the given set of messages and private keys, the signature is generated with `ed25519-sig` and the expected result is to be correctly verified by `ed25519-ver` [19].
- For the given set of messages and private keys, the signature is generated with `ed25519-sig`, incremented, and the expected result is that the forgery is detected by `ed25519-ver` [19].
- Ed25519 test vectors from RFC 8032 [16].
- EdDSA test procedures located in CCN-STIC 2100 [23].

[CVC-6] Other Test Procedures.[2]

- EdDSA-oriented adaptation of ECDSA test procedures located in SOG-IS Crypto Evaluation Scheme [6] and ISO/IEC 18367 [24].

[2]Although a standalone guide would describe the test procedures in details using pseudocode, this paper provides only a high-level overview due to space constraints.

TABLE I
LIST OF DIRECT `ED25519` DEPENDENCIES.

ALGORITHM	`ed25519-gen`	`ed25519-sig`	`ed25519-ver`
`curve25519-mul`	✓	✓	✓
`curve25519-add`	✗	✗	✓
`sha2-512`	✓	✓	✓
`fp-mul`	✗	✓	✗
`fp-add`	✗	✓	✗

B. Validation Process Record

1) The implementation under evaluation was identified as a portable C implementation of the Ed25519 digital signature scheme.
2) The DCT-graph for the Ed25519 implementation was constructed.
3) The implementation was investigated to ensure that each *Cryptographic Layer Object* (CLO) was uniquely represented. As the hash function was located in a separate file, two package families were created: [HSM.SIGN] and [HSM.CRYPTO] (see Figure 2).
4) The CVC and CVR artifacts were created for the following components:
   - prime field (`fp`),
   - elliptic curve Curve25519 (`curve25519`),
   - hash function SHA512 (`sha2-512`),
   - digital signature scheme Ed25519 (`ed25519`).

   In cases where CVC/CVR artifacts already existed, they only needed to be updated.
5) The five DIVCRYPT steps were performed sequentially for each *Cryptographic Layer Object Implementation* (CLOI). Test procedures (Step S2) were conducted using the Python programming language, while SageMath [25] was used to generate reference test vectors for `fp` and `curve25519`. Computer-aided analysis (Step S4) was performed using the general-purpose static code analysis tool CodeChecker [26].
6) As the evaluation of each CLOI was successful, the final verdict was PASS.

VI. COMPARISION WITH EXISTING STANDARDS

In the domain of systems security, standards can generally be classified into three categories: *theoretical components*, *evaluation criteria*, and *testing guidance*. When narrowing the focus specifically to cryptographic mechanisms, one can readily identify numerous specifications published by National Institute of Standards and Technology [27], whether these define a family of cryptographic solutions [12] or detail a single standardized scheme [7]. In addition, there exist global [3], regional [4] and national [28] standards that specify how and which schemes should be deployed. Unfortunately, when it comes to testing guidance, such documents are almost always tailored to specific schemes within particular application domains. Existing standards that describe testing methodologies for cryptographic implementations are summarized in Table II. According to our case study, we provide a brief overview of the procedures dedicated to the Ed25519 digital signature scheme recommended by each standard.

*a) **ISO/IEC 24759 [3]:*** This document defines the specific test procedures that a laboratory must use to check a module's conformance to the requirements in ISO/IEC 19790 [5]. For digital signatures, its procedures ensure a module can perform critical self-tests, such as the pair-wise consistency test upon key generation and various KATs.

TABLE II
A SELECTION OF ENGLISH-LANGUAGE STANDARDS FOR TESTING CRYPTOGRAPHIC IMPLEMENTATIONS.

YEAR	TITLE	SCOPE
2025	*ISO/IEC 24759: Test requirements for cryptographic modules* [5]	Global
2025	*CCN-STIC 2100: Cryptographic Mechanisms Evaluation Methodology* [23]	Spain
2023	*AEPD Guidelines for the validation of cryptographic systems in data protection processing* [29]	Spain
2022	*EN 17640: Fixed-time cybersecurity evaluation methodology for ICT products (Sections 6.11 and 6.12)* [30]	Europe
2020	*SOG-IS Crypto Evaluation Scheme: Harmonised Cryptographic Evaluation Procedures* [6]	Europe
2019	*FIPS 140-3: Security Requirements for Cryptographic Modules* [31]	USA
2016	*ISO/IEC 18367: Information technology - Security techniques - Cryptographic algorithms and security mechanisms conformance testing* [24]	Global
2015	*ANSSI-CC-CRY-P01: Methods For Carrying Out Cryptographic Analysis And Random Number Evaluations* [32]	France

b) ***CCN-STIC 2100 [23]****:* This document from Spain's National Cryptologic Center is a highly detailed and prescriptive methodology for evaluating specific, CCN-agreed cryptographic mechanisms against defined certification levels. It provides an exhaustive list of conformity tests for EdDSA (see Table 66 in [23]), including specific Validation Tests for signature generation and KATs for signature verification.

c) ***AEPD [29]****:* These guidelines from the Spanish Data Protection Agency provide a framework for assessing cryptographic systems, specifically to ensure they comply with GDPR [33] and effectively protect personal data. Its focus is on the governance and risk management surrounding the cryptosystem rather than detailing technical verification procedures for specific algorithms like EdDSA.

d) ***EN 17640 [30]****:* EN 17640 defines a modular evaluation methodology for ICT products designed to be performed within a fixed time budget, including tasks for basic and extended analysis of cryptographic mechanisms. Its recommendations cover conformance testing with KATs and source code analysis to check for implementation errors.

e) ***SOG-IS [6]****:* These harmonized procedures detail the evaluation tasks for cryptographic mechanisms within the formal SOG-IS scheme, which is used for Common Criteria evaluations in Europe. Crucially, this document defines a complete suite of evaluation tasks specifically for ECDSA-like digital signatures, including conformity testing and analysis of implementation pitfalls related to the underlying elliptic curve cryptography.

f) ***FIPS 140-3 [31]****:* This standard specifies the security requirements for a cryptographic module as a whole, covering areas from physical security to roles and services. It delegates the specific test procedures for approved algorithms like EdDSA to related standards.

g) ***ISO/IEC 18367 [24]****:* This standard provides guidelines for black-box and white-box conformance testing to ensure a cryptographic implementation correctly adheres to its specification. ISO/IEC 18367:2016 is based on conformance testing methods employed by the Japan Cryptographic Module Validation Program (JCMVP) and the NIST Cryptographic Algorithm Validation Program (CAVP).

h) ***ANSSI-CC-CRY-P01 [32]****:* This French procedure defines the formal roles and responsibilities for how approved evaluation labs must conduct cryptographic analyses for the national certification scheme, distinguishing between theoretical and implementation analysis. It specifies that an evaluator should perform analysis of conformity and vulnerability in cryptography implementation.

Many standards such as CCN-STIC 2100 [23], EN 17640 [30] or SOG-IS procedures [6] cover important topics related to cryptographic scheme sub-primitives, implementation pitfalls and usage context. However, a universal, formalized methodology that is equally applicable to both a simple stream cipher like ChaCha20 [34] and a complex non-interactive zero-knowledge protocol zk-STARK [35] is currently lacking, given their significant differences in cryptographic structure, complexity, and maturity. What these diverse cryptographic constructs do share is the need to address four fundamental aspects of implementation security, which DIVCRYPT covers through five dedicated actions (see Figure 1).

VII. CONCLUSION AND FUTURE WORK

This work introduced DIVCRYPT, a structured and layered framework for validating cryptographic implementations. By decomposing cryptographic solutions into layered components and evaluating each through structured steps, DIVCRYPT ensures that both standardized and emerging cryptographic mechanisms are subjected to thorough and context-aware analysis. The framework balances flexibility with rigor, offering evaluators a practical methodology that is both scalable and reusable across implementations. DIVCRYPT addresses a critical gap in current evaluation practices by introducing a reusable knowledge base (CVC and CVR), a clear abstraction hierarchy (CLO, CLOI and DCT-graph), and a comprehensive five-step validation process that covers theoretical design, functional correctness, code-level assurance, computer-aided analysis, and contextual robustness.

Future work should focus on several key directions. First, initiating a broader discussion with the community is essential to evaluate the advantages and limitations of the DIVCRYPT framework. Second, establishing a publicly accessible database of CVC and CVR entries would significantly support shared validation efforts and improve reproducibility. Finally, incorporating formal verification methods potentially as an optional step should be considered, as this would further strengthen the rigor and reliability of the validation process where applicable.

***Abstract*—In recent years, parallel architectures have become ubiquitous due to advancements in AI and cloud computing. However, parallel processing is not limited to x86 CISC CPUs and advanced graphics cards, GPUs; it also includes computations on ARM-based and RISC-V devices. In recent years, ARM processors have been adapted to incorporate an increasing number of cores. Today, mobile devices feature at least eight execution units, typically divided into energy-efficient and performance-oriented groups. RISC-based parallel processors are also integrated on development boards supported by the Linux kernel. In this article, we tested our NPDP Benchmark Suite for non-serial polyadic dynamic programming, primarily in the field of computer algorithms and bioinformatics, to evaluate the performance of the RISC processors under study, as well as code locality and cache efficiency. The benchmark consists of 10 kernels written in C++ and OpenMP. In the Android environment, we used the JAVA NDK (Native Development Kit) to port the application. For Apple machines, we used a port to OpenMP for parallelization. For the RISC-V native Linux environment, we applied the native Linux setup for efficient execution. Finally, we summarized the article and outlined future work.**

I. Introduction

RISC-based parallel processors, including ARM and RISC-V architectures, are becoming increasingly important in modern computing, particularly in mobile, embedded, and energy-efficient systems. Despite their growing adoption and multicore capabilities, their performance under complex, irregular workloads remains less explored compared to traditional x86-based platforms.

Nonserial Polyadic Dynamic Programming (NPDP) is an advanced class of dynamic programming techniques characterized by:

- Nonserial dependencies: subproblems do not follow a strict linear order;
- Polyadic recurrences: subproblems may depend on more than two others;
- Dynamic behavior: the dependency structure changes depending on input data or runtime conditions.

Such problems arise in domains like RNA folding, sequence alignment, and optimal polygon triangulation. Their nontrivial dependency patterns pose challenges for both parallel execution and efficient memory access.

Despite progress in compiler optimizations, limited attention has been paid to the performance of NPDP workloads on modern RISC-based architectures. In this work, we evaluate the execution-time performance of a 10-kernel NPDP benchmark suite compiled with OpenMP on several RISC platforms, including Apple ARM chips, Android smartphones, and a RISC-V development board. We apply three polyhedral compilers—Pluto, Traco, and Dapt—for automatic loop transformation and parallelization.

II. NPDP Benchmark Suite

The Non-serial Polyadic Dynamic Programming (NPDP) benchmark suite [1] consists of the following ten kernels:

1) Nussinov Algorithm - Predicts RNA secondary structures by identifying the optimal folding pattern.
2) Zuker Algorithm – An extension of RNA folding prediction that considers free energy minimization.
3) Smith–Waterman (SW) Algorithm – Performs local sequence alignment to identify similar regions between two nucleotide or protein sequences.
4) Needleman–Wunsch (NW) Algorithm – Conducts global sequence alignment for comparing entire sequences.
5) Smith–Waterman Algorithm for Three Sequences (SW3D) – Extends the original algorithm to align three sequences simultaneously.
6) Counting Algorithm – Used in RNA folding studies to count specific structural configurations.
7) McCaskill's Algorithm (Mcc) – Calculates the partition function and base-pairing probabilities in RNA secondary structures.
8) Maximum Expected Accuracy (MEA) Algorithm – Predicts RNA secondary structures based on maximizing expected accuracy.
9) Knuth's Algorithm – Determines the optimal binary search tree, minimizing the search time for a set of keys.
10) Optimal Polygon Triangulation – Divides a polygon into triangles to minimize the total edge length or another cost function.

III. Polyhedral optimization for NPDP loop nests

The polyhedral model represents loop nests as polyhedra with affine loop bounds and schedules. This model provides a foundation for advanced loop transformations and the analysis of data dependences. By harnessing the power of the polyhedral model, compilers can automatically optimize loops, enhance performance (especially in terms of locality with loop tiling), and exploit parallelism (particularly with loop skewing for NPDP codes) [2].

Nonserial Polyadic Dynamic Programming (NPDP) applications are generally easy to parallelize using a loop transformation technique known as skewing [3]. Skewing is a transformation applied to nested loops to restructure the iteration space,

ensuring that the dependent computations can be executed in parallel. It is particularly useful for NPDP problems where dependencies form a non-trivial pattern.

Consider a standard DP recurrence with dependencies on previous iterations:

$$DP(i,j) = f(DP(i-1,j), DP(i,j-1))$$

The corresponding loop structure might be:

```
for (i = 1; i <= N; i++) {
  for (j = 1; j <= N; j++) {
    DP[i][j] = f(DP[i-1][j], DP[i][j-1]);
  }
}
```

This loop cannot be directly parallelized because each iteration `(i, j)` depends on previous iterations. By applying the loop skewing transformation:

$$i' = i, \quad j' = i + j$$

we transform the loop structure into:

```
for(j' = 2; j' <= 2N; j'++) {
  lb = max(1, j'-N);
  ub = min(N, j'-1);
  for(i = lb; i <= ub; i++) {
    int j = j' - i;
    DP[i][j] = f(DP[i-1][j], DP[i][j-1]);
  }
}
```

Thus, NPDP problems, despite their complex dependencies, can be efficiently parallelized using loop skewing [3]. However, parallelization alone is not sufficient. Optimal cache utilization is also crucial, and scheduling blocks in NPDP remains challenging due to non-uniform dependencies [4], [5], [6].

NPDP problems, such as the Nussinov algorithm [7], can often be represented in the polyhedral model, enabling advanced loop transformations as performed by compilers like Pluto [8], Dapt [9], and Traco [5].

The polyhedral compilers Pluto [8], Dapt [9], and Traco [5] are based on affine transformation frameworks (ATF), space-time tiling, and tile correction, respectively. Pluto excels in generating well-balanced affine schedules, but for NPDP codes, the framework can address a set of affine equations to tile all loop nests [5]. ATF is unable to tile the Nussinov or SW kernels, and it cannot parallelize the tiled code of the Mcc kernel [1]. The Traco compiler generates 3D tiles using the transitive closure of the dependence graph of the union of loop dependences. For some tasks from the NPDP benchmark suite, it is not possible to compute the exact transitive closure of the dependency graph; in such cases, an over-approximation is applied [1]. Further transformations for 3D-tiling of NPDP codes were implemented in the Dapt compiler by dividing the iteration space into timed parallel spaces. Dapt addresses irregularities in code obtained in Traco, providing a comprehensive solution to optimize and refine the generated code [10].

Loop tiling, also referred to as loop blocking or loop partitioning, is a widely used optimization to improve cache efficiency [11]. It restructures loops into smaller blocks (tiles), reducing cache misses and improving memory access locality. In polyhedral compilation, tiling is often applied in combination with other transformations, such as skewing, to facilitate both locality and parallelism.

Ultimately, the compilers generate cache-efficient, parallelized code using the same underlying approaches—primarily the polyhedral model and its supporting library, ISL (Integer Set Library)—for both dependency analysis and code generation. This unified approach ensures that the code generation aligns with the dependency structure and optimizations applied.

Along with the original NPDP benchmark codes, the repository https://github.com/markpal/NPDP_Bench also includes OpenMP code generated by polyhedral compilers, which we adapted for execution on RISC-based devices.

IV. Experimental study

The experimental evaluation was conducted across three distinct RISC-based hardware platforms: Apple ARM-based laptops (M2 Pro, M3, and M4 Pro), a high performance RISC-V development board (Banana Pi BPI F3 SpacemiT K1), and an Android-based mobile device (Samsung Galaxy A55). All experiments focused on executing NPDP kernels compiled with OpenMP parallelisation support [12].

To ensure consistent and platform-specific testing, two separate benchmarking projects were developed. The first project, designed for macOS and the RISC-V platform, was responsible for executing the benchmarks and recording performance results to structured output files. The second project was implemented in Android Studio and dedicated to the Android operating system. It included a complete test execution scenario, with background task management and result storage integrated into the application logic.

Across all platforms, the NPDP computational kernels remained identical. Only the system-specific integration layer differed, adapting the same computational logic to the requirements of each operating system.

A. ARM-based Apple Platforms

The first experimental setup involved Apple machines equipped with ARM-based processors: M2 Pro, M3, and M4 Pro. These platforms feature heterogeneous multi-core architectures combining high-performance and energy-efficient cores. All experiments were conducted natively on macOS. Specifically, the M2 Pro system ran macOS Sequoia 15.1.1, the M3 system used macOS Sequoia 15.2, and the M4 Pro machine operated on macOS Sequoia 15.3. Since the default Apple Clang compiler does not provide support for OpenMP, the LLVM toolchain was installed via Homebrew, along with the necessary runtime library (libomp). The benchmarks were compiled using the following command:

```
/opt/homebrew/opt/llvm/bin/clang++
  -fopenmp \
  -I/opt/homebrew/opt/llvm/include \
  -L/opt/homebrew/opt/llvm/lib \
  -o test test.cpp
```

This configuration allowed for the successful compilation and execution of OpenMP-parallelized code on macOS. Tests were conducted in terminal shells with controlled background activity to minimize external interference. While we initially considered evaluating performance on iPhones, it was not possible to execute OpenMP code due to iOS restrictions. The operating system lacks support for dynamic linking against the OpenMP runtime, and instead promotes the use of proprietary concurrency models such as Grand Central Dispatch [13].

B. RISC-V Platform

The second experimental platform was based on the RISC-V architecture. We employed the Banana Pi BPI-F3 board [14], featuring an eight-core SpacemiT K1 [15], [16] processor with 16 GB LPDDR4 RAM and 128 GB of eMMC storage. The system ran Bianbu Linux 1.0rc1 (codename mantic) [17], a lightweight RISC-V–oriented distribution based on Ubuntu 23.10, designed for embedded and development use cases. The board was configured in a headless mode and accessed remotely via SSH over Ethernet.

Due to limited support for the RISC-V Vector Extension (RVV) in available prebuilt toolchains, we compiled a custom cross-compilation toolchain targeting rv64gcv on an external x86-64 machine. The NPDP benchmark suite was compiled with OpenMP and vectorization enabled, using the following command:

```
riscv64-unknown-linux-gnu-g++ \
  -march=rv64gcv -mabi=lp64d -O3 \
  -fopenmp -ftree-vectorize \
  -fopt-info-vec-optimized \
  -o test test.cpp
```

The compiled binaries were transferred to the Banana Pi board and executed under Bianbu Linux. This setup enabled the assessment of OpenMP-parallelized NPDP kernels on a native RISC-V platform with partial RVV support and a modern, minimal Linux runtime environment.

C. ARM-based Mobile Platform

The final test environment was a Samsung Galaxy A55 smartphone running Android 13. The device is powered by an ARM-based octa-core processor, comprising four Cortex-A78 cores (2.7 GHz) [18] and four Cortex-A55 cores (2.0 GHz) [19]. The NPDP benchmark suite was ported using the Android Native Development Kit (NDK) [20], allowing native C++ code to be executed within the Android runtime environment. The OpenMP-enabled kernels were compiled into shared libraries and invoked via a Java Native Interface (JNI) wrapper.

To minimize interference from the graphical interface and system events, the benchmarks were executed in the background using a dedicated background thread. This ensured isolated execution, independent of the UI thread. Results were written to files in the internal storage and subsequently retrieved for further analysis. This setup enabled reliable measurement of kernel performance under realistic conditions on mobile hardware, although variability due to thermal management and background activity could not be entirely eliminated. All measurements were repeated multiple times to ensure consistency.

D. Execution Time Constraints and Omitted Results

In all presented Tables 1-5, certain entries are marked with the symbol "–". These indicate cases in which a particular kernel execution was terminated or skipped due to exceeding predefined time limits. To maintain practical runtime and result comparability, thresholds were set at 20 minutes for input size 2200, and 40 minutes for larger sizes (5000 and 10000). If a kernel exceeded these limits, execution was interrupted and the result omitted from the final report.

This limitation was observed across all platforms and test configurations. Algorithms such as *Knuth*, *McCaskill*, *Triangulation*, and *Zuker* frequently exhibited prohibitive execution times, especially in the original and Traco-generated code variants. Additionally, computationally complex kernels such as *SW3D* and *MEA* consistently demonstrated exceedingly long runtimes and were therefore excluded from measurement.

As a result of preliminary testing, the input sizes used for RISC-V and Android platforms were deliberately limited to 500, 1000, and 2200. This decision was made to ensure feasibility on resource-constrained devices. Moreover, certain algorithms such as *Knuth* and *Zuker* were excluded entirely from tests on these two platforms due to previously observed stability and performance issues during execution, including excessive runtimes or failures. These exclusions were applied consistently across both platforms as a conservative measure to preserve experimental integrity.

The exclusion of the Knuth and Zuker algorithms was driven by consistent and reproducible performance issues. The Zuker kernel, which involves complex free-energy minimization and deeply nested loop structures, incurred high computational overhead. On several platforms, particularly those using Traco-generated variants, execution times exceeded predefined limits for larger input sizes. The Knuth algorithm, in turn, triggered instability on resource-constrained RISC-V systems, including segmentation faults and abnormal termination, likely due to its memory access patterns and recursive structure. These issues rendered reliable benchmarking infeasible and led to the omission of these kernels from the reported results.

It is important to note that all benchmarked algorithms were based on identical NPDP kernel implementations. The only platform-specific differences resided in the build system, integration method, and runtime environment.

E. Result Discussion

Tables I–V present execution times for all kernels across four code variants (Org, Traco, Pluto, Dapt) and five hardware platforms. Overall, the results confirm that polyhedral compilation significantly improves performance, and that Dapt frequently produces the fastest code across most tested configurations.

On Apple ARM platforms (M2–M4), the Dapt-generated code consistently outperforms both the original and other compiler variants. For example, on the M4 Pro (Table III), Dapt executes the Nussinov kernel in 17.85s for input size 10000, while the original version requires 244.97s. This trend is visible across most kernels and input sizes. However, it is worth noting that Apple systems are based on a heterogeneous architecture not explicitly designed for HPC-like parallel workloads. Their strong performance stems primarily from advanced chip design, high memory bandwidth, and aggressive power management at the cost of being proprietary and expensive.

Although Dapt yields strong results overall, certain kernels like Counting show comparable or even better performance with Traco on selected platforms. This may be due to Traco's tile correction approach occasionally producing layouts with better cache fit for specific iteration spaces [10]. While Dapt generally provides more consistent tiling across irregular kernels, localized cache effects may favor Traco in select scenarios.

The RISC-V platform, represented by the low-cost Banana Pi BPI-F3 board, completed all tests but with significantly

higher execution times. This reflects both early-stage toolchain maturity and the limited performance of the tested hardware. RISC-V remains promising due to its openness and Linux compatibility, and future work will explore more capable boards.

The Android platform (Samsung Galaxy A55) exhibits intermediate results. Despite using a modern ARM-based SoC, the performance is limited by the operating system, which does not prioritize background computation. For instance, thermal throttling and restricted OpenMP threading in the ART environment reduce the potential gains from polyhedral optimizations. Android also introduces unpredictable performance variability due to dynamic task scheduling and user-space constraints. As a result, OpenMP kernels run slower and less deterministically compared to Linux-based systems.

While the Dapt compiler provides robust performance across all platforms, the relative gains vary depending on the architecture. Moreover, some kernels (e.g., Knuth, Zuker, SW3D, MEA) were excluded due to excessive runtimes or instability, especially in Traco or original versions. This was consistent across all environments and input sizes.

In summary, the results highlight the benefits of polyhedral compilation techniques for NPDP workloads and expose the current disparity between platform classes. These results are in line with earlier work on multi-core systems, where OpenMP-based parallelization and loop restructuring also led to notable performance improvements in geospatial workloads [21]. Apple systems deliver the highest raw performance but are closed and costly. RISC-V is significantly slower on current boards but offers openness, modularity, and full Linux support — key advantages for long-term research. Android devices, while architecturally capable, suffer from system-level limitations that reduce usable compute throughput. These findings justify the need for continued testing on new RISC-V platforms and more refined kernel-level optimization.

V. Conclusion

When comparing research conducted on RISC processors, it is essential to consider factors such as cost, licensing model, and the intended application of the processing unit itself. In terms of raw performance, the fastest processors currently available are undoubtedly the high-end Apple M4 Pro units, although they also come at a significantly higher cost. However, Apple and Cortex processors are based on closed architectures, which limits their utility in development and research contexts. In contrast, RISC-V processors, due to their open-source architecture, offer far greater flexibility and potential for innovation.

Unfortunately, the studied Banana chip performance still lags behind ARM-based solutions. While Linux kernel support exists, substantial work remains to improve overall efficiency. Features such as vector processing are still in the developmental stage, and compilers require significant refinement to reach production-grade maturity. Nonetheless, the open-source nature of the platform and the dedicated efforts of volunteer contributors suggest a promising future—potentially more so than the long-standing but limited Android NDK.

In terms of performance at the same price point, it is currently easier to utilize older CISC CPUs or other types of RISC-based GPUs. While multi-board computers like Banana, Leeche, or other RISC-V developer boards are becoming more widespread, especially among emerging manufacturers from countries affected by U.S. sanctions, their performance capabilities are still maturing and not yet competitive with mainstream alternatives. However, the performance of RISC-V may improve in the future—the question is how rapidly this improvement will occur. We also plan to evaluate emerging high-performance RISC-V platforms, including 64-core development boards that are now becoming commercially available [22].

In future work, we will extend our research framework to include other polyhedral benchmark suites and a detailed analysis of the energy consumption on these devices.

***Abstract*—Classical life tables assume fully observed lifespans and ignore censoring, which can bias survival estimates. In this study, we compare the classical life table with two censoring-aware approaches: the Kaplan-Meier estimator applied to simulated censored lifetimes, and the actuarial estimator assuming uniform censoring within intervals.**

Using mortality data for the Czech Republic (from year 2021), we show that both the mentioned alternative methods yield systematically lower survival and life expectancy estimates, compared to life tables-based approach. The actuarial estimator is the most conservative, and we provide a formal proof that it underestimates survival relative to Kaplan-Meier.

These differences have practical implications for actuarial pricing and longevity risk. We advocate incorporating survival analysis techniques into actuarial workflows when dealing with incomplete or censored data.

***Index Terms*—life tables, survival analysis, censoring, Kaplan-Meier estimator, actuarial estimator, life expectancy overestimation, life expectancy underestimation, actuarial science**

I. Introduction

LIFE tables are a cornerstone of actuarial science and demographic research, offering standardized tools to assess mortality and survival in a given population. Based on aggregated counts of deaths and population exposures at each age, these tables enable the computation of key quantities such as age-specific death probabilities and life expectancy. In standard construction, however, life tables operate under the assumption of fully observed lifespans and do not incorporate censoring the fact that, in many contexts, we do not observe the complete lifespan for every individual.

Although this assumption holds in retrospective national mortality data, it becomes increasingly problematic in settings involving survey-based samples, incomplete registration systems, or real-time monitoring, where censoring is inherent in the data structure. Censoring occurs naturally when the full path of survival is not observed, either due to loss to follow-up, study end, or delayed entry. Right-censoring means that we do not know when an individual would experience the event of interest because the monitoring period ended before the event could occur.

The distinction could be nontrivial. As noted by Slud [1], the classical construction of life tables, based on central death rates and complete cohorts, fails to account for right-censoring, which can bias survival estimates if present but ignored. Missov and Vaupel [2] further explore the impact of censoring on mortality measures, showing that even small amounts of right-censoring can influence life expectancy and related metrics. Modern survival analysis, in contrast, is equipped to handle censored observations through estimators such as Kaplan-Meier, Nelson-Aalen, and parametric survival models.

In this study, we revisit classical life table methods using mortality data from the Human Mortality Database (HMD) [3] for the Czech Republic in 2021. We begin by constructing a traditional life table and estimating survival probabilities and life expectancy under the assumption of complete data.

This research was supported by the grant no. F4/36/2025 which has been provided by the Internal Grant Agency of the Prague University of Economics and Business.

We then introduce synthetic censoring at the aggregate level and evaluate its effect on survival metrics. Next, we simulate individual-level lifetimes with right-censoring and estimate the survival function [4] using the Kaplan-Meier estimator, a non-parametric method that accommodates incomplete observation [5], [6].

In addition, we implement the actuarial estimator of the survival function, which assumes uniformly distributed censoring within fixed intervals and is widely used when exact death times are not available [7]. We analytically demonstrate that this estimator yields lower survival estimates than Kaplan-Meier under the same data, and we confirm this property empirically.

By comparing all three approaches, i.e. the classical life table, Kaplan-Meier, and actuarial estimator, we quantify the extent of deviation in survival curves and life expectancy measures due to censoring and method choice. Finally, we discuss the implications of these differences and possible underestimation of the survivals for actuarial pricing, reserving, and longevity risk assessment.

II. Preliminaries

Life tables are traditionally constructed using a deterministic sequence of transformations, starting from observed age-specific death rates or death probabilities. The standard components of a complete life table include the probability of dying between ages x and $x+1$ (denoted as q_x), the number of survivors at age x (marked as l_x), the number of deaths at age x (d_x), the person-years lived between ages x and $x+1$ (here denoted as L_x), the total person-years remaining beyond a given age x (T_x), and the remaining life expectancy at age x (marked as e_x). These definitions are extensively documented in actuarial and demographic literature, for instance [8], [9], [10].

The death probability q_x is typically calculated from empirical data as

$$q_x = \frac{D_x}{N_x}, \tag{1}$$

where D_x is the number of deaths observed at age x, and N_x is the number of individuals exposed to risk at that age.

Starting from a radix $l_0 = 100,000$, the number of survivors at each age is recursively defined as

$$l_{x+1} = l_x(1 - q_x). \tag{2}$$

From this, the number of deaths is given by

$$d_x = l_x q_x, \tag{3}$$

and the number of person-years lived between ages x and $x+1$ is typically approximated by

$$L_x = l_x - \frac{1}{2}d_x, \tag{4}$$

assuming that deaths are uniformly distributed within each age interval. The cumulative future person-years T_x and the corresponding life expectancy e_x are then computed as

$$T_x = \sum_{k=x}^{\omega} L_k, \qquad e_x = \frac{T_x}{l_x}, \tag{5}$$

respectively, where ω denotes the maximum age in the life table.

III. Methods

In this section, we implement the above methodology using mortality and exposure data from the Human Mortality Database (HMD) for the Czech Republic in 2021. The resulting classical life table will serve as the benchmark for later comparison with methods that incorporate synthetic censoring.

All computations and visualizations were performed using the R language [11] with the packages `ggplot2` [12], `dplyr` [13], and `survival` [14], [15].

A. Classical Life Table Construction

Using mortality and exposure data from the Human Mortality Database for the Czech Republic in 2021, we constructed a complete life table following the standard actuarial approach. The key steps involved computing age-specific probabilities of death q_x, the number of survivors l_x, the number of deaths d_x, person-years lived L_x, cumulative person-years T_x, and remaining life expectancy e_x, always considering age x. The radix was set at $l_0 = 100{,}000$, and the last observed age $\omega = 109$ was treated as an absorbing state with $q_{109} = 1$, meaning that all remaining individuals are assumed to die within the interval $\langle 109, 110)$, as is standard in demographic practice, [8], [9], and is feasible even for research purposes, including this proceeding.

Part of the resulting table for ages 0–9 is shown in Tables I and II. It illustrates the decreasing pattern of life expectancy with age and the consistent structure of death probabilities and exposures.

Fig. 1 presents the curve of remaining life expectancy e_x as a function of age. The smooth and decreasing trajectory reflects the typical aging pattern in low-mortality populations.

B. Incorporating Synthetic Censoring

To assess how censoring could influence life table calculations even when working with aggregated population-level data, we construct a synthetic scenario in which a portion of the population at each age is assumed to be right-censored. This mimics conditions observed in longitudinal surveys, clinical studies, or incomplete registration systems, where not all individuals' times of death are observed. Since the dataset Human Mortality Database (HMD) does not include (or even

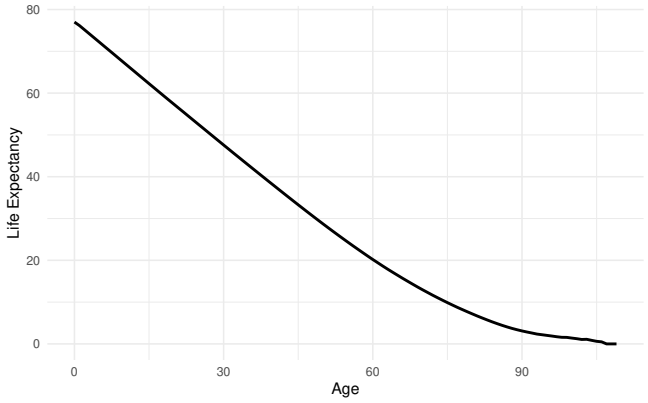

Fig. 1. Remaining life expectancy (in years) at age x based on classical life table construction.

consider) censoring, the synthetic, i.e. simulated censoring is the only way how to investigate its impact.

In our synthetic setup, we assume a fixed censoring probability c_x at each age. Specifically, we define $c_x = 0.10$, i.e., 10 % of the exposure at each age is assumed to be censored. This means that instead of observing N_x person-years fully at risk, we effectively observe only $(1 - c_x)N_x$ as uncensored exposure, while $c_x N_x$ is assumed to be censored.

Following the framework suggested by Slud [1] and the analytical concerns raised in Missov and Vaupel [2], we adjust the death probability coming from formula (1) calculation accordingly,

$$\tilde{q}_x = \frac{D_x}{(1 - c_x)N_x}, \tag{6}$$

where $\tilde{q}_x$ represents the adjusted probability of death under censoring. All subsequent life table quantities $\tilde{l}_x, \tilde{d}_x, \tilde{L}_x, \tilde{T}_x, \tilde{e}_x$ from formulae (2, 3, 4, 5) are computed using this modified death probability $\tilde{q}_x$, replicating the structure of the classical method.

We emphasize that this adjustment does not imply individual-level censoring but rather a proxy for its effect at the population level. The goal is to examine whether such synthetic censoring, even when introduced into aggregate mortality data, leads to meaningful differences in key survival metrics such as life expectancy.

In the next subsection, we present the life table results under the synthetic censoring assumption and compare them to the classical baseline.

C. Comparison of Results under Censoring

Fig. 2 shows the comparison between the classical and synthetically censored life tables in terms of remaining life expectancy. As expected, the life expectancy under synthetic censoring is systematically lower in all ages. This is a direct consequence of inflating the estimated mortality probabilities when only partial exposures are assumed to be observed. In other words, if classical life tables-based approach assumes non-censored framework when probability of death at given age x is, using formula (1), equal to $q_x = \frac{D_x}{N_x}$, while the death probability under censoring is (6), $\tilde{q}_x = \frac{D_x}{(1-c_x)N_x}$, obviously is $\tilde{q}_x > q_x$ for any $c_x > 0$, i.e., whenever there is nonzero censoring we are not aware of, the probability of death is in fact a bit higher and, consequently, the true remaining life expectancy is a bit lower.

When we assume that data are not censored we might get falsely optimistic classical estimate used in life tables. When incorporating censoring we can always see the downward shift in estimated life expectancy curve which might be closer to the reality.

In further sections we discuss methods for estimating survival function which is then used to model life expectnancy. We present the actuarial estimator and the Kaplan-Meier estimator.

IV. ACTUARIAL (LIFETABLE) ESTIMATOR

One of the approaches for estimating the survival function, i.e., a probability that an object will survive longer than a specified time point [4], is the actuarial or life table estimator [7]. This method is suitable for interval-censored or grouped data where exact times of death or censoring are not known. It is commonly used in demography and actuarial science when data are available in age or time intervals.

Let the time axis be partitioned into intervals $\langle t_{j-1}, t_j)$. For each interval, we define

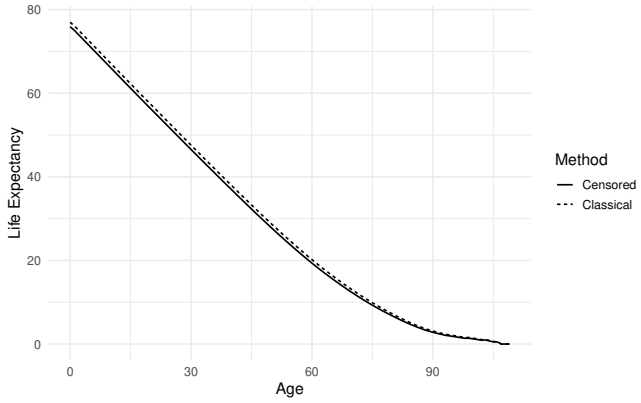

Fig. 2. Comparison of remaining life expectancy between classical life table and synthetic censoring scenario ($c_x = 10\,\%$).

- r_j as the number of individuals entering interval j,
- d_j as the number of deaths observed in interval j,
- c_j as the number of right-censored observations in interval j.

Assuming uniform censoring within the interval, the effective number at risk is approximated by

$$r'_j = r_j - \frac{c_j}{2}, \tag{7}$$

clearly saying that at a midpoint of the given interval (j), there is just half the censoring ($\frac{c_j}{2}$) of the entire interval (c_j). The conditional survival probability in interval j is then

$$p_j = \frac{r'_j - d_j}{r'_j} = 1 - \frac{d_j}{r'_j}. \tag{8}$$

The actuarial estimate of the survival function $\hat{S}(t)$ is obtained as the cumulative product,

$$\hat{S}_A(t) = \prod_{j:t_j \le t} p_j, \tag{9}$$

since, if an individial survived up to interval j, they had to survive also up to intervals $j-1, j-2, \ldots, 1$. Thus, we have to mutually multiply the interval-related probabilities p_j.

This estimator is generally more conservative in estimating survival than Kaplan-Meier, especially when censoring is heavy or uneven. The assumption of uniformly distributed censoring within intervals can lead to a downward bias in estimated survival compared to methods that use exact event times.

V. Kaplan-Meier Estimator

The Kaplan-Meier estimator is a non-parametric method for estimating the survival function $S(x)$, which represents the probability that a subject survives beyond age x [5], [6]. It is particularly well-suited for handling right-censored data, where the exact time of death is not observed for some individuals.

Let $t_1 < t_2 < \cdots < t_k$ denote the distinct observed failure times in the sample, d_j the number of events (deaths) between time points t_{j-i} and t_j, and r_j the number of individuals at risk just before t_j. Then the Kaplan-Meier estimator is given by

$$\hat{S}_{KM}(t) = \prod_{j:t_j \le t} \left(1 - \frac{d_j}{r_j}\right). \tag{10}$$

This step function decreases only at observed event times and remains constant in intervals where no events occur. Censored observations reduce the risk set r_j at subsequent time points but do not directly contribute to d_j.

Once the survival function is estimated, the life expectancy at birth e_0 can be computed as the area under the curve (which is not differentiable but is continuous, though),

$$e_0^{KM} = \int_0^\infty \hat{S}(x)\, dx, \tag{11}$$

which in practice is approximated as the sum over the discrete age grid,

$$e_0^{KM} \approx \sum_x \hat{S}(x), \tag{12}$$

where $\hat{S}(x)$ is an estimate of survival function, modeled using actuarial estimate $\hat{S}_A$ or Kaplan-Meier estimate $\hat{S}_{KM}$, as introduced before. This provides a consistent estimator of the mean remaining lifetime even in the presence of censoring, unlike classical life table methods that assume fully observed (non-censored) data.

We compare the actuarial estimator with the Kaplan-Meier estimator in the next section and quantify their divergence in terms of survival function and life expectancy.

VI. The Actuarial Estimator Underestimates Survival Compared to Kaplan-Meier Estimator

We now provide an analytical justification for why the actuarial estimator $\hat{S}_A(t)$ is systematically lower than the Kaplan-Meier estimator $\hat{S}_{KM}(t)$ under the same data.

Recall that in Kaplan-Meier from formula (10), the survival function decreases only at exact failure times,

$$\hat{S}_{KM}(t_j) = \hat{S}_{KM}(t_{j-1}) \cdot \left(1 - \frac{d_j}{r_j}\right), \tag{13}$$

where r_j is the number at risk just before time point t_j.

By contrast, the actuarial estimator assumes that censoring is uniformly distributed within interval $\langle t_{j-1}, t_j)$, so the effective number at risk is adjusted to

$$r'_j = r_j - \frac{c_j}{2}, \tag{14}$$

and the survival estimate is

$$\hat{S}_A(t_j) = \hat{S}_A(t_{j-1}) \cdot \left(1 - \frac{d_j}{r'_j}\right). \tag{15}$$

As comes from formulae (13, 15), terms $1 - \frac{d_j}{r_j}$ and $1 - \frac{d_j}{r'_j}$ are the key. Because $r'_j = r_j - \frac{c_j}{2} < r_j$ in most practical cases (i.e., if any censoring $c_j > 0$ occurs before the end of the interval), we have

$$\frac{d_j}{r'_j} > \frac{d_j}{r_j}, \tag{16}$$

which implies

$$1 - \frac{d_j}{r'_j} < 1 - \frac{d_j}{r_j}, \tag{17}$$

for every time point $t_j \le t$, and therefore, multiplying the terms from previous formula (17), we get

$$1 - \frac{d_j}{r'_j} < 1 - \frac{d_j}{r_j} \qquad \forall t_j \in \{t_1, t_2, \ldots, t\}$$

$$\prod_{j:t_j \le t} \left(1 - \frac{d_j}{r'_j}\right) < \prod_{j:t_j \le t} \left(1 - \frac{d_j}{r_j}\right)$$

$$\hat{S}_A(t) \overset{(8,9,10)}{<} \hat{S}_{KM}(t). \tag{18}$$

This inequality propagates multiplicatively, so the entire survival curve under the actuarial method lies below the Kaplan-Meier curve, if any censoring occurs. Hence, the actuarial estimator systematically underestimates survival compared to Kaplan-Meier, especially when censoring is substantial.

This property also directly impacts life expectancy estimates derived as area under the survival curve.

VII. Estimation with Simulated Censoring

To analyze the effect of censoring using a statistically rigorous survival model, we simulated individual-level lifetimes from the classical life table probabilities q_x and applied a 10 % right-censoring mechanism. We then estimated the survival function using the Kaplan-Meier estimator.

In parallel, we computed the actuarial survival function based on interval-level data and uniform censoring assumptions. The corresponding life expectancy was obtained as the discrete area under the actuarial survival curve,

$$e_0^A = \sum_x \hat{S}_A(x), \tag{19}$$

where $\hat{S}_A(x)$ denotes the actuarial survival estimate at the beginning of age x. This summation provides a consistent approximation of the expected remaining lifetime under the actuarial model.

Fig. 3 shows the comparison between the Kaplan-Meier estimate, actuarial estimate and the classical life table survival function $S(x) = l_x/l_0$, as the first two come from formulae (10, 9). The Kaplan-Meier curve lies systematically below the classical curve, indicating shorter estimated survival due to the presence of censoring. The curve estimated by the actuarial estimate lies below both curves. Fig. 4 shows estimated survival for ages above 75 years. The differences between the estimates, and, consequently, between the treatment of the censoring, are more clear in this figure.

In terms of overall life expectancy at birth[1], the classical method based on l_x gave $e_0^{LT} = 77.50$ (95% CI $[77.43, 77.57]$), while the Kaplan-Meier estimator yielded $e_0^{KM} = 76.54$ (95% CI $[76.46, 76.63]$) and the actuarial estimate gave $e_0^A = 75.97$ (95% CI $[75.90, 76.04]$), respectively. The differences here are quiet obvious. Between classical method and Kaplan-Meier estimate, the difference is approximately 0.96 years. Between classical estimate and actuarial estimate, the difference is 1.53 years and when comparing Kaplan-Meier and actuarial estimate the difference shows 0.57 years.

VIII. Discussion

The results of our study provide a comprehensive assessment of how censoring affects survival estimation using three different approaches: the classical life table, the Kaplan-Meier estimator, and the actuarial survival estimator. All methods were applied consistently to the same underlying mortality data for the Czech Republic in 2021, using synthetic (simulated) censoring.

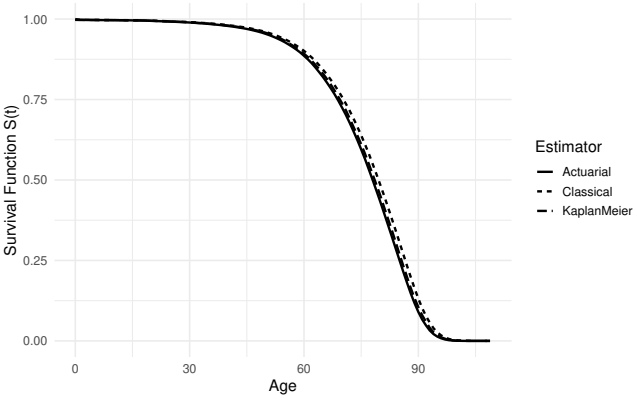

Fig. 3. Comparison of survival functions: Kaplan-Meier estimate, actuarial estimate and life table estimate.

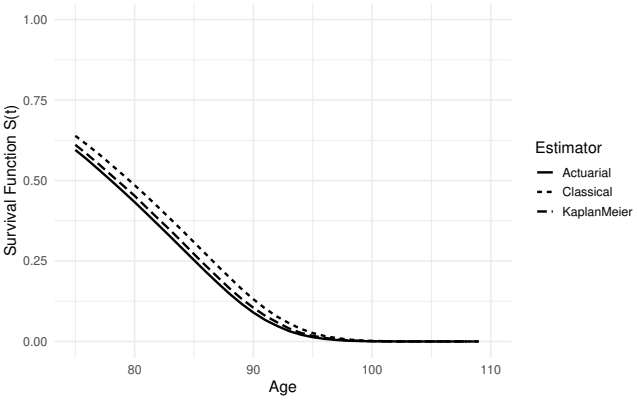

Fig. 4. Comparison of survival functions for ages 75+ years.

Our analyses revealed that the assumptions of no censoring in life table estimates might lead to falsely optimistic estimates. Incorporating censoring could bring the estimate closer to the reality. The classical life table estimate of life expectancy at birth was 77.50 years (95% CI $[77.43, 77.57]$), while the Kaplan-Meier estimator applied to simulated censored lifetimes yielded 76.54 years (95% CI $[76.46, 76.63]$), a nearly one-year difference. When the actuarial estimator was applied under uniform censoring assumptions (75.97 with 95% CI $[75.90, 76.04]$), life expectancy was lower still, confirming analytically and empirically that this method is the most conservative among the three.

From a demographic perspective, this highlights the critical importance of censoring-aware methodologies, especially in datasets where full lifespan observation is implausible. Ignoring censoring can lead to biased survival estimates and misleading conclusions about population longevity.

In an actuarial context, these differences carry tangible

[1]To report variability of the simulated estimates, 95% confidence intervals are constructed using the percentile bootstrap, i.e., using the 0.025-th and 0.975-th quantiles of the bootstrapped distribution of each estimator. Confidence intervals are reported in square brackets, preceded by the prefix "95% CI".

consequences. Life expectancy estimates directly influence pricing, reserving, and solvency calculations in life insurance and pension products. A lower estimated life expectancy typically leads to higher premiums for annuity products and lower reserves for life insurance, potentially introducing pricing inaccuracies if censoring is not handled correctly. Conversely, underestimating survival in products with longevity risk exposure may lead to systematic underreserving, e.g. two people with the same product but different life expectancy should lead to higher reserves for the person with higher probability of death. But when censoring is not accounted for these reserves could calculated to lower volume leading to underreserving. In other words when calculating death insurance under falsely optimistic estimates, lower probability of death (higher life expectancy) could lead to cheaper insurance policies and vice versa.

These findings reinforce the need to integrate non-parametric survival estimators such as Kaplan-Meier into actuarial workflows when individual-level or censored data are available. Even when working with grouped data, awareness of the limitations of life table and actuarial approximations is essential.

IX. Future Outlooks

This study opens several directions for further research. First, extending the analysis to various censoring levels (e.g., censoring of 5 %, 20 %, 30 % of available data) would reveal how estimator performance changes with increasing data incompleteness. Second, stratifying results by subgroups such as sex or region could uncover heterogeneity in censoring effects, which is relevant in pricing and reserving. Third, comparing classical and non-parametric estimators with parametric survival models, such as Weibull or Gompertz, may enhance accuracy where model assumptions are plausible. Finally, quantifying how survival differences (e.g., in life expectancy) translate into financial impacts, such as annuity prices or reserves, would strengthen the actuarial relevance of this work.

X. Conclusion

This study demonstrates that classical life tables, while effective under complete observation, can yield upwardly biased survival estimates in the presence of censoring. We showed that both synthetic censoring-like adjustments to exposure and non-parametric survival methods yield systematically lower survival curves and life expectancy values.

Among the three methods considered, the actuarial estimator produced the lowest survival estimates due to its structural assumption of uniform censoring. The Kaplan-Meier estimator, by leveraging precise event and censoring times, offered a more accurate and interpretable estimate under realistic data conditions.

Although the absolute difference in life expectancy across methods may seem modest, around one year at birth, such discrepancies can significantly impact actuarial outcomes. For annuity products, underestimating survival leads to financial strain due to underestimated liabilities, while for life insurance, overestimation may affect competitive pricing and risk pooling.

We conclude that integrating survival analysis techniques, particularly those accounting for censoring, is essential for reliable longevity modeling. These tools not only improve the statistical fidelity of survival estimates but also support more robust decision-making in insurance, demography, and public health.

***Abstract*—Understanding the mechanical behavior of cells is a complex challenge at the crossroads of physics, biology, and engineering. The cytoskeleton which is a dynamic network of filaments which helps cells maintain shape, move, and respond to their environment. Tensegrity structures, made of interconnected tensile and compressive elements, offer a compelling way to model these internal forces. In this work, we use Reinforcement Learning (RL) to simulate and optimize cellular mechanics. We propose an RL framework where an agent learns to minimize the total mechanical energy of tensegrity-based cell models by adjusting node positions. We consider diverse shapes from simple shapes like lines and triangles, to more complex shapes like cell-like geometries. Our approach shows that RL can effectively model mechanical adaptations in cells and opens the door to intelligent, bio-inspired simulations. This work bridges biophysics, AI, and structural mechanics, offering new ways to predict and understand how cells respond to mechanical stress.**

***Index Terms*—Reinforcement Learning, Tensegrity, Cell Mechanics, Structural Optimization, Deep Learning, PPO, Cytoskeleton**

I. Introduction

CELLS are not static entities; they are dynamic, mechanically active systems that continuously adapt their internal architecture in response to various environmental and biological cues [14]. One of the most compelling frameworks for modeling the mechanical integrity of cells is the tensegrity model, which represents the cytoskeletal network as a balance of tensile and compressive forces [1], [4]. Tensegrity—short for "tensional integrity"—describes a structural system composed of isolated struts (under compression) suspended within a web of tensile elements (like cables or filaments). This principle reflects the way real cells maintain their shape, transmit forces, and react to mechanical stress.

The tensegrity-based approach allows one to capture the interplay between cytoskeletal elements such as actin filaments, microtubules, and intermediate filaments, providing a robust platform to simulate how cells respond to external mechanical stimuli and internal biochemical signals [3]. Beyond biology, tensegrity models have also found significant applications in the design and development of soft robotic systems and bioinspired structural materials that mimic cellular mechanics and adaptability [15].

With the rapid advancement of artificial intelligence and machine learning, particularly in the realm of reinforcement learning (RL), new opportunities have emerged to understand and control dynamic systems in ways that were previously unfeasible [8]. RL algorithms allow agents to interact with complex environments and learn control strategies through trial and error [13].

In this work, we propose a novel integration of RL with tensegrity physics to simulate a biologically inspired cell model. An RL agent is tasked with iteratively adjusting the positions of the nodes within a tensegrity structure to achieve a configuration with minimal mechanical energy, a proxy of structural equilibrium. Previous work in robotics has demonstrated the efficacy of such approaches in enabling tensegrity-based systems to learn locomotion and adaptive behaviors [6], [17]. By extending these concepts to cellular modeling, we aim to bridge the gap between mechanobiology and intelligent control systems.

The rest of the paper is organised as follow: Section II presents related work where we review the exisitng work in cell mechanics as well as use of RL to solve various problems. The section III is about our system model and methodology were we present in details our approach and tensegrity structure visualizations using RL. We outlined the results of experiments in section IV, followed by a discussion in section V and conclusion in section VI.

II. Related Work

In this section, we report the relevant literature to highlight the limitation of existing work and contribution of our work.

The work in [18] proposes an interpretable machine learning framework of cell mechanics from protein images and neural

networks (NN) for prediction of traction forces from a single focal adhesion protein field. Agnostic and physics-constrained approaches learn interpretable rules for prediction. A DCell is proposed in [20] that is a visible NN embedded in the hierarchical structure of 2,526 subsystems and encompasses an eukaryotic cell. DCell is able to simulates cellular growth with reasonable accuracy after training on millions of genotypes. The proposed setup provides a foundation to decode the drug resistance, genetics of disease, and synthetic life.

An interesting work is done in [22] to develop the safe RL approaches specially for environments where non rewarded states are also important. Authors considered different scenario to validate their approaches and use of safe RL methods could have useful contribution in cell mechanics. RL methods are also used in important medical issues to provide assistance to patients with disabilities [19], [21]. These works demonstrate a useful application of RL algorithms but the such formulation of tensegrity representing a cell is work to be done.

Moreover, Deep RL (DRL) is utilized in [9] to infer collective cell behaviours and cell–cell interactions in tissue morphogenesis from 3D time-lapse images. Hierarchical DRL is applied to investiage cell migrations from the images with an ubiquitous nuclear label. The hierarchical DRL method HDRL reveals a modular, multiphase organization of cell movement to Caenorhabditis elegans embryogenesis. A hybrid RL model is proposed in [12] to manage process control efficiently. A probabilistic knowledge graph mdoel is developed characterizing the science and risk-based understanding of quantifying inherent stochasticity and biomanufacturing process mechanisms.

In our work, we investigate how reinforcement learning can be applied to better understand the ways in which biological cells adapt their shapes and internal structures in response to mechanical forces. The proposed work formulate a tensegrity model representing a cell into an RL setup and then design a RL agent using proximal policy optimization to find minimum energy in a tensegrity representing a cell.

III. Methodology

This section presents the methodology used in our work. The first step is to model the cell as a tensegrity structure—a network of compressive elements (rods) and tensile elements (cables)—to capture how real cells maintain mechanical balance through tension and compression [1].

To explore this model computationally, we employ a Reinforcement Learning (RL) agent that learns to adjust node positions in the tensegrity structure to reduce the total mechanical energy, guiding it toward a stable, low-energy configuration. We use the Proximal Policy Optimization (PPO) algorithm due to its robustness in continuous control tasks [2].

By integrating biophysics, artificial intelligence, and structural mechanics, this approach contributes to the understanding of how cellular behavior emerges from physical constraints. Such methods also support the design of soft robotic systems that mimic cellular mechanics [5].

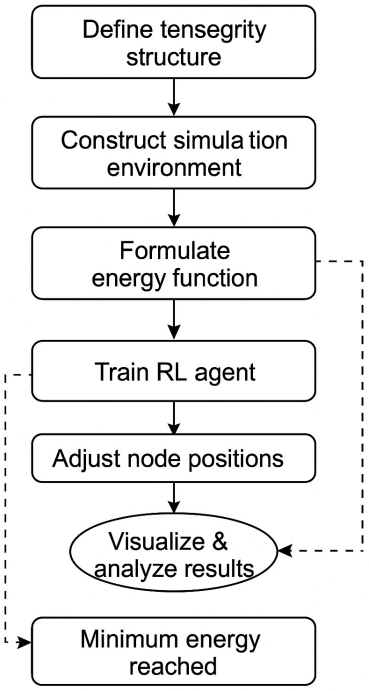

Fig. 1: Flowchart outlining the proposed approach.

The mechanical energy of the tensegrity structure is computed based on edge deformations relative to rest length:

$$E = \sum_{(i,j)\in \text{edges}} k_{ij} \cdot (||x_i - x_j|| - l_{ij}^0)^2$$

where x_i, x_j are 2D positions of nodes, l_{ij}^0 is the rest length, and k_{ij} is the stiffness constant (set to 1). This energy reflects internal stress.

1) Mechanical Energy Decomposition: To distinguish tension and compression, we decompose the total energy:

$$E_{\text{total}} = \sum_{(i,j)\in\mathcal{C}} k_{ij}^{(c)} \left(\|x_i - x_j\| - l_{ij}^0\right)^2 + \sum_{(i,j)\in\mathcal{T}} k_{ij}^{(t)} \left(\|x_i - x_j\| - l_{ij}^0\right)^2 \quad (1)$$

Here, $\mathcal{C}$ and $\mathcal{T}$ are sets of compressive and tensile elements, with different stiffness coefficients $k_{ij}^{(c)}$, $k_{ij}^{(t)}$, respectively.

2) Gradient of Energy with Respect to Node Position: Although PPO is model-free, internal forces can be approximated by the energy gradient:

$$\frac{\partial E}{\partial x_i} = \sum_{j\in\mathcal{N}(i)} 2k_{ij}(\|x_i - x_j\| - l_{ij}^0) \cdot \frac{(x_i - x_j)}{\|x_i - x_j\|} \quad (2)$$

This gradient represents the net force acting on node i, offering a physical interpretation of movement.

3) Proximal Policy Optimization (PPO) Loss: We use PPO's clipped surrogate loss [2]:

$$\mathcal{L}^{\text{PPO}}(\theta) = \mathbb{E}_t \left[\min \left(r_t(\theta)\hat{A}_t, \text{clip}\left(r_t(\theta), 1-\epsilon, 1+\epsilon\right)\hat{A}_t \right) \right] \tag{3}$$

with

$$r_t(\theta) = \frac{\pi_\theta(a_t|s_t)}{\pi_{\theta_{\text{old}}}(a_t|s_t)}$$

where $\hat{A}_t$ is the advantage estimate. This formulation ensures stable policy updates.

4) Energy Convergence Metric: To evaluate learning stability, we compute average energy change over the last N steps:

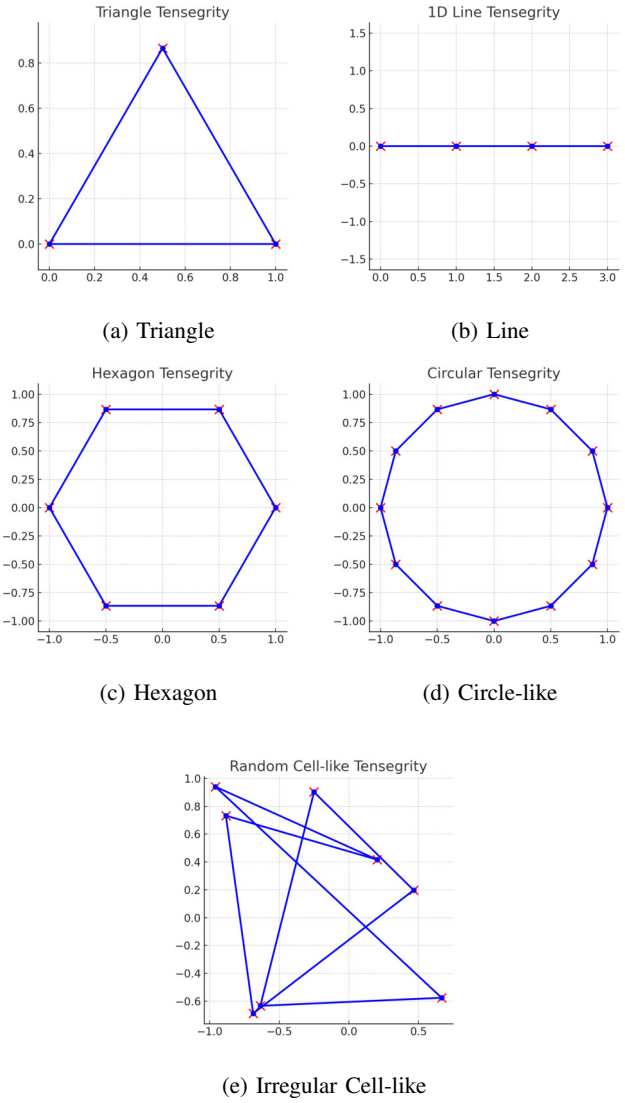
$$\Delta E = \frac{1}{N} \sum_{t=T-N+1}^{T} |E_t - E_{t-1}| \tag{4}$$

A small ΔE signals convergence to a stable, low-energy configuration.

5) RL Formulation:

- **State Space:** A flattened vector of 2D node coordinates representing the structure.
- **Action Space:** Small shifts $(\Delta x, \Delta y)$ applied to movable nodes.
- **Reward Function:** Negative of total mechanical energy.
- **Termination:** Fixed-length episodes without early stopping.

6) Implementation Steps:



- Model the cell as a tensegrity structure of nodes and rods/cables [3].
- Develop a Python simulation environment to update node positions.
- Define an energy function to evaluate mechanical stress.
- Use PPO (via Stable-Baselines3) to train the agent [2].
- Train the agent to iteratively reduce system energy.
- Visualize learning and adaptations of the structure.
- Analyze biological relevance of learned behaviors [5].
- Explore applications in mechanobiology and soft robotics [15].

A. Reproducibility and Future Extensions

Each structure is defined by nodes and edges (cables/rods). A custom Python environment updates positions using actions from the agent. The state is a flattened list of node coordinates, while actions apply perturbations. The reward is based on internal potential energy. All components are modular and can be adapted for future extensions, including 3D structures and additional biophysical constraints.

B. Tensegrity Structures Visualization

We consider diverse tensegrity structures, from simple to complex, in our work as shown in Figure 2. Each configuration is simulated and visualized using Python, enabling us to observe how reinforcement learning (RL) guides the system toward more stable, low-energy states. These structures ranging from basic geometries to biologically inspired shapes demonstrate the adaptability of RL in modeling cellular mechanics [6], [7].

(a) Triangle (b) Line

(c) Hexagon (d) Circle-like

(e) Irregular Cell-like

Fig. 2: Various tensegrity structures used in the study.

Each of the structures illustrated in Figure 2 represents a unique scenario in our simulations. Figure 2a shows a simple triangular tensegrity, serving as a basic case to validate the RL agent's energy minimization capability in a constrained geometry. Figure 2b presents a linear configuration, ideal for examining the agent's behavior in elongated systems. The symmetric hexagonal form in Figure 2c introduces more complexity, resembling biological structures. Figure 2d illustrates a radially balanced, circular tensegrity, while Figure 2e presents an irregular, cell-like morphology—a step toward realistic cellular modeling.

Across all cases, the RL agent effectively minimized system energy, reinforcing the concept that even simple tensegrity

models can provide meaningful insights into cellular biomechanics.

C. Towards Realistic Cell-like Tensegrity Structures

We demonstrate a biologically inspired tensegrity system that reflects the intricate architecture of real cells, in Figure 3. This advanced model incorporates elements resembling cytoskeletal components such as actin filaments and microtubules, which are critical for maintaining cell shape and enabling mechanical responsiveness. Such structures have been central to tensegrity-based modeling frameworks in cellular biomechanics [4], [5]. By simulating these complex geometries, we move closer to capturing the adaptive, dynamic nature of living cells.

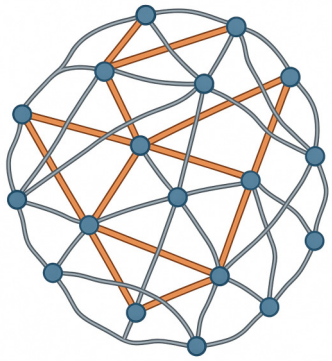


Fig. 3: A biologically inspired tensegrity model representing a complex cell.

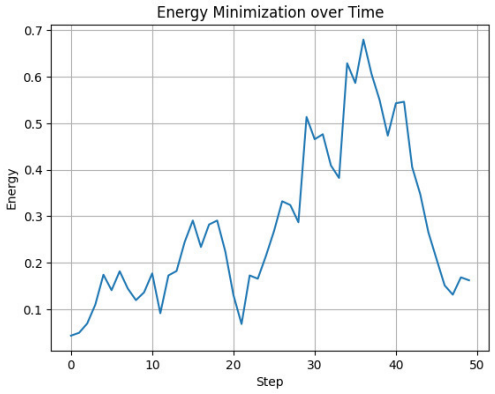
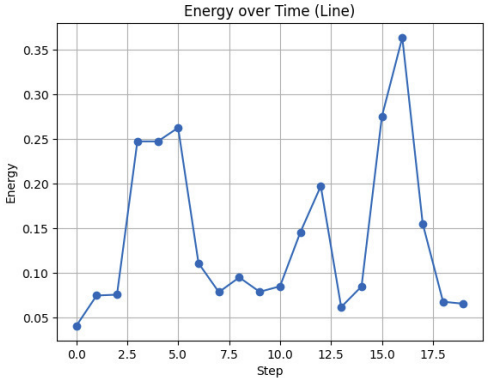


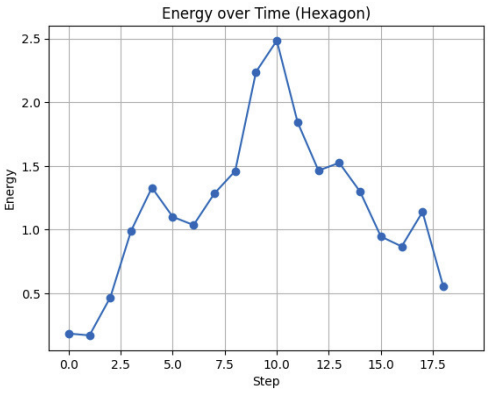
IV. Results

This section presents the experimental results that we performed while considering different structures.



Our experiments began with basic triangular tensegrity structures as shown in Figure 2a, where the RL agent consistently achieved noticeable reductions in total mechanical energy over training episodes. These early successes demonstrated the agent's capacity to learn stable configurations, even in minimal geometric setups.

As we progressed to more complex shapes such as hexagonal (Figure 2c) and circular configurations (Figure 2d), the RL agent adapted well, maintaining structural coherence while reducing energy levels. Notably, the hexagonal structures, which resemble symmetrical cell geometries, converged faster toward low-energy states. The circular models, simulating soft boundary conditions like those found in real cell membranes, further confirmed the agent's ability to generalize across geometries.



Visual analysis of the final tensegrity forms and energy plots validated the model's effectiveness. These findings are consistent with earlier research where RL-based policies achieved adaptive control and energy-efficient locomotion in soft tensegrity robots [7], [11].

(a) Triangle tensegrity

(b) Line tensegrity

(c) Hexagon tensegrity

Fig. 4: Energy of the tensegrity structures over training steps. (a) Triangle tensegrity (b) Line tensegrity (c) Hexagon tensegrity.

For tensegrity structures to train the RL agent, we employed the Proximal Policy Optimization (PPO) algorithm and used a reward function based on the system's mechanical energy. Specifically, the agent receives a negative reward equal to the sum of squared differences between the current and rest lengths of all links, effectively encouraging configurations that minimize internal tension and compression. The environment state is defined as a flat vector of 2D coordinates representing the positions of all nodes. This simple representation provides

the agent with sufficient spatial information to act. During early training, exploration is naturally handled through PPO's stochastic policy updates, allowing the agent to try unstable configurations and gradually converge toward energy-efficient ones.

Each experiment was trained over 100,000 timesteps, typically spanning 500 to 1,000 episodes depending on episode length. This duration provided the agent with enough interaction to consistently learn optimal or near-optimal configurations. For example, in the triangular and hexagonal tensegrities, the policy reliably minimized energy within the first 60,000 timesteps, while irregular cell-like shapes required more training to stabilize. We observed that once the energy starts decreasing steadily, subsequent steps fine-tune the positions rather than cause drastic shifts. Preliminary robustness checks indicate the learned policies remain effective when tested on slightly perturbed initial states.

While our current results are mostly qualitative, they offer clear and reproducible patterns of energy reduction across varied structures. In future work, we plan to include statistical metrics such as average final energy, convergence rate, and baseline comparisons with classical physics-based solvers. We are also extending our approach to 3D tensegrity models and exploring more expressive RL methods like Soft Actor-Critic (SAC) to improve learning in high-dimensional, nonlinear cellular geometries.

V. Discussion and Future Work

This study has demonstrated the feasibility of using reinforcement learning to manipulate tensegrity-based cell models toward stable and energy-efficient states. It provides a promising step in merging biophysical modeling with artificial intelligence, especially for systems that rely on structural tension and compression, like real cells. Despite its success in 2D structures, our framework opens the door to deeper biological relevance through future improvements as explained below:

- **Adding biological constraints**, such as anchor points representing extracellular matrix contacts or internal pressure mimicking cytoplasmic resistance [4].
- **Scaling to 3D tensegrity systems**, which can better replicate the spatial complexity of cytoskeletal networks found in living cells [10].
- **Incorporating viscoelasticity**, allowing simulation of how cells respond over time to mechanical stimuli and not just at equilibrium.
- **Integrating with real data**, such as microscopy-derived cell geometries, to improve biological validity and potentially guide experimental modeling [5].

Finally, we can summarize that as artificial intelligence continues to make significant contributions in the medical and healthcare domains, its integration into biological modeling is becoming increasingly relevant. Studies have shown how AI-driven approaches enhance diagnostic precision in areas such as skin cancer and COVID-19 detection [23], as well as in risk management [22]. In a similar spirit, our work demonstrates the potential of reinforcement learning for understanding complex biomechanical behavior at the cellular level. This further supports the growing trend of leveraging AI not only for diagnosis but also for predictive and mechanistic modeling of biological systems.

These enhancements would bring the relevant research community closer to a useful tool that can not only simulate the structure but also predict and interpret cellular mechanical behavior in health and disease.

In the future work, we will extend our work to more complex topologies and we will also consider including external constraints like cell-substrate interaction or intracellular pressure.

VI. Conclusion

In this work, we have presented a novel integration of tensegrity mechanics with reinforcement learning to explore how AI methods, specifically RL agent can autonomously discover stable, low-energy configurations of cell-like structures. By learning control strategies that minimize mechanical energy, the agent mimics cellular adaptation behaviors in silico. This framework lays the groundwork for more intelligent models of mechanobiology—capable of interpreting, simulating, and even designing cellular responses. With further development, it may contribute to advances in synthetic biology, bio-inspired robotics, and our theoretical understanding of cellular mechanics.

***Abstract*—The theory of smart environments assumes a diversity of human-supporting solutions that interact with each other and are oriented towards applying artificial intelligence. Concepts such as digital twin, software agent, and machine learning can aid the creation of smart environments by supporting the design and simulation of device behaviors. This article aimed to conduct research addressing the question how does multi-agent software impact smart grid security and show the practical exemplification of supporting smart grid security with multi-agents system. The paper's research findings discussed the AI-based knowledge management model in the context of the GRAI framework usage, which stands for Generative, Receptive Artificial Intelligence, and presents a proposal of an updated model that takes into account recent developments regarding GenAI and its consequences for KM. Based on the conducted research, an algorithm for collecting information from devices was proposed and used in a simulation based on the Isolation Forest algorithm.**

***Index Terms*—Digital Twin, Smart Grid, Internet of Things, Internet of Intelligence, Immersive Technology, Smart Environment**

I. Introduction

THE development of the Internet of Things (IoT) [5], and Internet of Intelligence (IoI) theory [26] points to a wide range of smart solutions in everyday life. Concepts such as smart city, smart home, smart grids, and others allow for the application of information solutions in user support and provide the capability to process large amounts of data. In the context of smart systems, perceiving them as distributed architecture systems requires appropriate management, monitoring, and security. Smart environments can encompass a variety of smart solutions, including smart grids, smart homes, and smart cities. The melding of these solutions is an important area of research. Exploring ways to integrate them represents a key direction in the development of smart-environment theory.

Smart environments refer to the multiple application domains where real-time Internet of Things (IoT) data processing allows for improved decision-making. These are ecosystems in which humans, conventional computer systems, and IoT devices are combined through cyber-physical services. Smart environments represent any physical environment augmented with a collection of embedded systems elaborating heterogeneous data and interacting with people.

Typically, smart cities aim at providing applications such as smart transportation, smart grids, smart surveillance, to enhance urban living standards by IoT, AI, digital twins, augmented reality, and the metaverse. A smart city typically comprises smart homes, smart health, smart roads, smart parking, and smart people. Similarly, smart health spaces like smart hospitals, smart gyms, or smart retirement homes are aimed at continuous patient monitoring and therapy provision. The term smart home is used to describe homes with home applications, illumination, heating, air conditioning, television, computers, audio and video entertainment systems, security systems, and camera schemes. Smart building is to monitor the energy and water utilization, as well as emissions and waste products. A smart environment can be made up of users' wearable and handheld devices, and several smart personal spaces. Smart agriculture assists farmers in minimizing wastage and improving productivity because the systems support irrigation and crop field monitoring. A smart traffic light

system can monitor green light times and automatically switch lights to avoid traffic jams. Smart environments encompass a large set of technologies, including computer networking, wireless communication, computational infrastructures, sensor networks, and algorithm design (Fig 1).

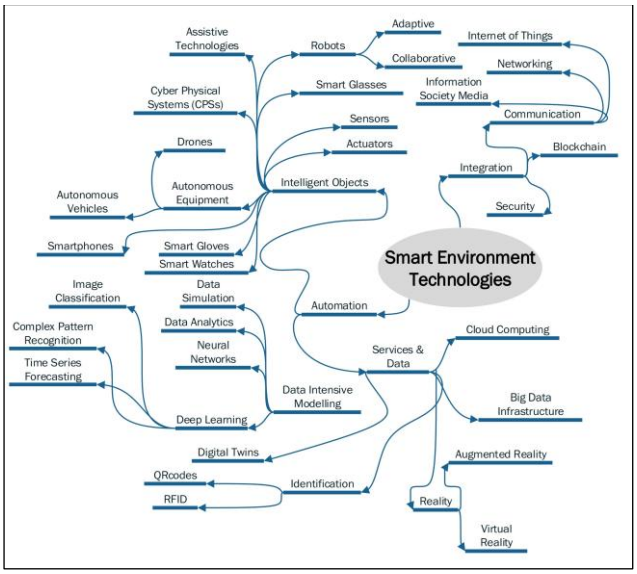

Fig 1. Smart environment technologies

The critical outcome of smart environment applications and execution is the generation of large-scale data sets. This large amount of data requires significant processing through artificial intelligence and machine learning algorithms. The term ‘smart’ was originally an acronym standing for “Self-Monitoring, Analysis and Reporting Technology”, but smart technology is now defined as much by its capacity to monitor and track its user activities, preferences, and regularities [29].

In this paper, the impact of multi-agents on the smart grid is detailed by the assumptions of smart grid security, adaptability, and user-friendliness factors. The following research questions were formulated:

- RQ1: How does multi-agent software impact smart grid security?
- RQ2: How to implement the multi-agent in a smart environment with current AI software?

The theoretical background was presented in Section 2. The research began with a preliminary study of the literature review, which is presented in Section 3. The empirical part of the study will demonstrate how a multi-agent system can be applied to enhance the security of a home grid network. The practical exemplification of the usage of multi-agent software was presented in Section 4.

The topic presented here is becoming increasingly actual and relevant in dynamically changing environments with its threats, which are related to, e.g., climate change, the energy crisis, or limited resources. The presented findings are an itemization of the factors that might be useful for further work, academic researchers, or business practitioners.

II. Theoretical Background

A. Multi-Agents software implementation

The areas of the Smart Environment theory, which include the smart grid theories discussed here, require the analysis of many aspects in the design and construction of modern computer systems. As the authors indicate [26], the Internet of Intelligence (IoI) requires defining the research area, the technologies in which the solution is being developed, its architecture, and identifying research gaps. Based on the research methodology, the studies undertaken in the article relate to Smart Grid/Energy in terms of application areas, Artificial Intelligence, Digital Twin, Immersive Technology in terms of considered technologies, and Modeling Intelligence and Security and Privacy in terms of the defined gaps in research discussed in the article.

From a technological perspective, the research considerations have been focused on multi-agent systems, which allow for the creation of intelligent and autonomous systems. These have the ability not only to automate processes but also to act on behalf of users within information systems in the context of Digital Twin (DT) theory. The use of multi-agent systems in the context of the Internet of Intelligence allows for a range of benefits such as the implementation of well-defined communication standards between agents and the creation of a system architecture within the framework of DT theory.

The features of multi-agent systems presented here suggest various possible scenarios for using these systems during the development of Internet of Intelligence systems.

B. Smart grid systems and security

One of the areas of implementing the IoI theory is smart grid systems. A smart grid (SG), also called smart electrical/power grid, intelligent grid, intelligrid, future grid, intergrid, or intragrid, is an enhancement of the 20th-century power grid. The traditional power grids are generally used to carry power from a few central generators to a large number of users or customers. In contrast, the SG uses two-way flows of electricity and information to create an automated and distributed advanced energy delivery network.

Due to the importance of the energy sector for the safety and uninterrupted operation of systems and devices, the search for solutions that safeguard such systems is a very important element in the development of IoI theory.

The Smart Grid term encapsulates the convergence of remote monitoring and control technologies with communication technologies, renewable generation, and analytics capabilities so that electric, natural gas, and water grid infrastructures can continuously provide information for operational and strategic management. The smart grids’ security challenges cover assurance of reliability and resilience of energy supply power, as well as safety, possible expansion and improvement plans, and efficiency of energy provision [2].

The ISO standards on smart grid security are as follows: ISO/IEC DIS 27019 Information technology Security techniques, Information security controls for the energy utility industry [38], ISO/IEC 30101:2014 Information technology,

Sensor networks: Sensor network and its interfaces for smart grid system [39].

C. Multi-Agent software in smart-grid system implementation

Within the framework of IoI theory, it becomes necessary to develop solutions that operate autonomously and are capable of collecting data, processing it, and making decisions regarding the behaviour of devices. One such solution is multi-agent systems.

Multi-agent systems (MASs) are particularly well suited for studying Smart Grid system implementation, such as a collection of at least two or more (artificial) agents, where the word agent can be succinctly described as an artificial entity that can act in its environment [1]. It is implicitly assumed that they are computational by design, that is, a decision about an action "can be broken down into primitive operations that can be implemented in a physical device" [7]. There exist several studies taking a MAS approach to studying community-based markets for electricity energy trading.

In the article [5], the authors presented a three-element architecture of the smart grid system, outlining elements such as Perception, Network, Service and Application Layer. In terms of possible applications of multi-agent systems, in addition to the levels presented, multi-agent systems allow for the division of the network layer into communication with IoT devices and communication between agents. The primary role of multi-agent systems is to provide control functions and assist communication in smart grid systems, particularly in microgrid systems [8]. Such a division of communication in smart grid systems relates to the security postulates of the systems, as discussed in the study [6]. Multi-agent systems, by their nature, resemble the concept of P2P systems used in smart grid theory [9], [11], but they have several additional features. These include the ability to define an agent's artificial intelligence mechanisms, dedicated communication standards that ensure the design patterns of the communication being conducted, agent mobility, and negotiation mechanisms. In the case of smart grids, the application of auction systems in the area of energy sharing [12], [13] can be facilitated by agents in the construction of auction systems, supported by agents. In the present article, the multi-agent system is examined within the context of a digital twin, wherein individual agent entities simulate the functioning of the network using real-world data. The simulation was developed based on the proposed algorithm and uses one of the machine learning models

III. Materials and Methods

This article used the literature analysis method. The literature review of the impact of multi-agents on the smart grid is detailed by the assumptions of smart grid security, adaptability, and user-friendliness factors. The data set of publications in the Web of Science was examined. The first query in the topic "Smart grid and security" referred to 5.888 publications discovered between 1900 and 2023. The topic was studied mostly by topics connected with the power grid, renewable energy resources, and the Internet of Things.

The previous studies and the state-of-the-art of smart grids concerning the surveys in different contexts. The most cited research about the security of smart grid by Fang et al. [3] showed the smart grid survey till 2011 as a new and improved power grid and showed the security features in IoT applications of smart grid, smart transportation, and smart cities, to demonstrate how fog/edge computing based IoT should be implemented in real world. Ellabban, Abu-Rub, and Blaabjerg showed the status, prospects, and enabling technology of renewable energy resources [4]. Lin et al. showed the architecture, enabling technologies, security and privacy, and applications of the Internet of Things [5]. Yan et al highlighted the major motivations, requirements, and challenges in smart grid communication infrastructures [6], as well as Mo et al. showed the vision of a secure smart grid infrastructure [33], and S. Sridhar et al. [34]. Deilami et al. presented the new real-time smart load management (RT-SLM) control strategy for coordinating the charging of multiple plug-in electric vehicles (PEVs) in a smart grid system performed by a utility energy distribution system [32]. The examples of the most cited studies were connected with smart-grid security issues, i.e., security technology for smart-grid networks, malicious data attacks on the smart grid with intrusion detection techniques for cyber-physical systems, and classifications and applications of physical layer security techniques for confidentiality.

A. The Literature Review Method

The research methodology was based on the literature review and research questions RQ1 and RQ2. The research questions were based on the research gap present in the previous research studies. The following query was formulated to verify the previous findings described as RQ1: Security aspects query: "Multi-Agents" AND "Smart Grid" AND "Security". Data collected from the Web of Science databases were used. The research findings were evaluated and discussed.

B. Research Results

The research results of RQ1 presented multidisciplinary publications in the field of security multi-agent systems for improving smart grid implementation. There are some features of multi-agent software usage and its role in smart grid systems that have been studied. Based on a review of the literature, the features are presented as research results based on literature review. Multi-agent software affects the security of smart grids, especially in relation to their expansion and modification. It cooperates with other solutions, which is necessary in the context of an intelligent network that is a system of systems with critical infrastructure. As the security solutions used in traditional IT networks are not sufficient for the system of systems [41], in the case of smart grids, such features of multi-agent systems as decentralized decision-making, adaptability, substitutability, communication, learning, mechanisms of trust, cooperation, resilience, and self-healing

gain in importance. As a result, multi-agent systems provide an adequate basis for the construction of security that is required in system of systems and critical infrastructure. Answering the RQ2 the example of studies influence of multi-agents software usage on a smart grid system was presented in Table I.

TABLE I.
INFLUENCE OF MULTI-AGENT SOFTWARE USAGE ON A SMART GRID SYSTEM

Smart Grid Feature	Multi-Agent Influence	Source
Adaptive robotics	Modular systems enable flexible adaptation in production. Human–robot interactions via mobile devices.	[15], [17]
Additive manufacturing	Possibility to individualize products in cost-effective, small batches.	[24]
Automated Home Energy Management	Secure Automated Home Energy Management in Multi-Agent Smart Grid Architecture	[19]
Cybersecurity	Methodologies allowing for automatic detection and response to cyberattacks; adaptive computational intelligent systems continuously evolving; a distributed multi-agent scheme to enhance the cybersecurity of smart power grids.	[28]
Decentralized Intrusion Prevention	Decentralized Intrusion Prevention (DIP) Against Coordinated Cyberattacks on Distribution Automation Systems	[30]
Demand forecasting	The MAS (Multi-Agent System) Model allows the VPP (Virtual Power Plant) to know in advance the amount of power and is based on artificial neural networks (ANNs)	[20]
Energy management	Smart grid management in prosumer communities, trading of energy	[13], [14], [16]
Demand response	Consumers can reduce their energy consumption through load curtailment, shift their energy consumption over time, or generate and store energy at certain times to provide the grid with more flexibility.	[21], [23]
User-Friendliness Environment	An effective modeling and simulation environment, in terms of generality, user-friendliness, modeling flexibility, interoperability with GIS datasets, and computational efficiency	[22]

The AI-Knowledge Management Process of implementing the agents in a smart environment could be discovered in future research. Nowadays, the RQ2 answer is based on the description of the AI-Knowledge Management model for agent tools implementation . The background is based on the revised SECI model, with the machine (AI agent) in the knowledge management process that can play an active or a passive role. The active role would generate an output or a response, while the passive role could be compared to listening and adapting/rebuilding the internal (knowledge) representation. Consequently, the four areas would each be split into a human perspective and a machine perspective, leading to eight fields of action in the new GRAI model [25]. More recent versions of LLM-based systems, such as OpenAI ChatGPT or Google Gemini, allow the human user to add additional relevant materials into the conversation, e.g., using the "memory function" of those systems. This context relates to the interaction field as it helps the machine to identify a more precise context with a domain-specific focus in the dialogue. This way, a general conversation can be leveraged toward a specific direction by the human user by providing externalized information to the machine. Another application use case that is emerging rather frequently here is the use of GenAI in retrieval-oriented task using Retrieval Augmented Generation (RAG), which combines an initial search query with specific document collections (externalized information) to derive a more specific search results when the original query is augmented by the generated content from the externalized information [26]. In contrast to the use case of information retrieval in enterprise-specific information sources (enterprise search), in the field of KM, the use of GenAI could introduce a bias in the results that originates from the foundation models used. However, these effects might be similar to the contextual integration of a human user and could be counteracted by carefully selecting and adopting the right foundation model [27]. In the case of a smart grid security project, the design of architecture, algorithms and simulation studies are becoming more important.

The example described in the paper illustrates RQ1 and RQ2 answers.

IV. PRACTICAL EXEMPLIFICATION

As detailed earlier, IoI and IoT underpin Smart Grid oversight and can be leveraged to strengthen the operation of these networks. Multi-agents could support Smart Grid Security, the robotisation of processes, and system adaptiveness. Authors' prior research into Smart Grid security devised a multi-agent system architecture to reinforce its security [18]. The resulting algorithm was calibrated to gauge the Grid's performance in terms of energy drawn by connected devices. In the example shown below, an algorithm for collecting information from IoT devices is described, the process in which it was used is presented, and a machine learning algorithm is employed to evaluate the collected data. The proposed algorithm was validated via a simulation conducted under the Digital Twin paradigm on the Jade platform. One possible application of IoT and Smart grid solutions is to support the monitoring of user and property security. The subsequent analysis concerns the Home Area Network (HAN) and Neighbourhood Area Network (NAN), where devices are examined locally, either within a single building or across multiple buildings in a given area. Home security systems, such as burglar alarms, sensors, can be supported by IoT devices and generate events related to the breach of defined rules. A problem encountered in IoT systems is the low performance of devices designed for minimal power consumption. In such solutions, it is crucial to use ML algorithms with low resource demands. For this experiment, we used the Isolation Forest algorithm. It is recognised for its low resource requirements.

The literature review [36], [37] allowed for an attempt at specifying an algorithm to support the operation of the network within the framework of IoI and IoT theory using a digital twin theory. To illustrate the conducted research experiment, elements of the architecture of a prototype using business process modelling and IoTDT-BPMN notation were developed. Fig. 2 presents the process of the system's operation

based on IoTDT-BPMN elements. Each pool constitutes a set of tasks executed by the individual devices used when experimenting.

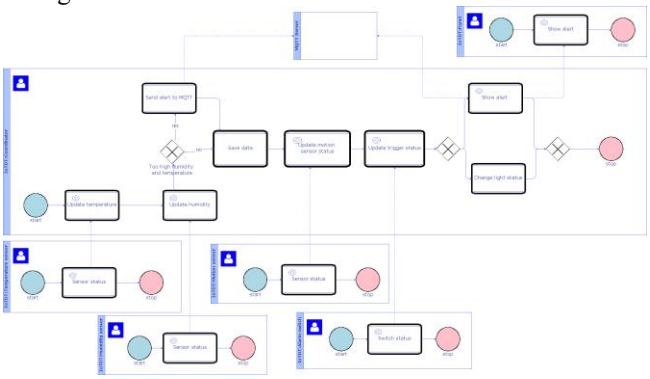

Fig 2. A process in the extended BPMN notation depicting the operation of the simulated system

The whole experiment was developed based on a JADE multi-agent system, which was used to perform the simulation. All the devices were registered in a multi-agent system, and agents' specific behaviours were defined. The implementation uses the IotDTBPMN2Jade algorithm available at GitHub [40]. Activation of the simulation led to the generation of communication between the agents, which resulted in the sending of a notification about a detected event and the development of a knowledge base of alert events. Data from the available sensors was gathered using the developed solution after the simulation phase. The data shown in the figure were collected from an IoT sensor connected to an MQTT server between 26 May 2025 and 8 May 2025. Two pronounced "spikes" in humidity levels can be observed, corresponding to emergency shutdowns of the ventilation system on 2 May 2025 and 4 May 2025. After this initial stage, the sensor readings were used to develop a model based on the Isolation Forest algorithm. One requirement of the algorithm is that the input data must be supplied at regular time intervals. In this project, the raw sensor readings were resampled into five-minute intervals. Since the sensor conserves power by reporting only when its state changes, any missing values were filled using linear interpolation. This ensured that every time slot was represented in the training set. The conducted experiments showed that, with the number of trees set to n_estimators=200 and a contamination level of 0.2 %, the model produced anomaly predictions that closely matched the real-world events illustrated in Fig. 3.

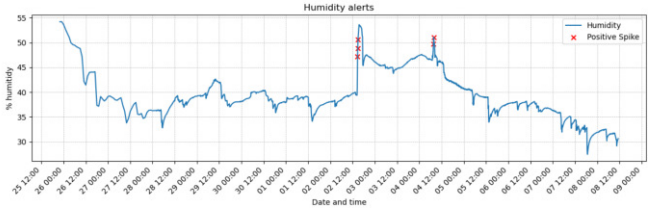

Fig 3. Outcomes of using the ML algorithm (humidity alerts)

The model flagged 5 points as anomalies from the initial 3,617 samples, which is about 0.14%. Increasing the contamination level to 0.5% raised the number of alerts to 12, while lowering it to 0.05% caused it to miss all anomalies. In the subsequent model test, a three-day dataset was prepared containing two events characterised by sudden spikes in humidity levels. The model's results on this simulated data are shown in Fig. 4. The model correctly detected the humidity spikes, indicating that the recommended 50% threshold was exceeded.

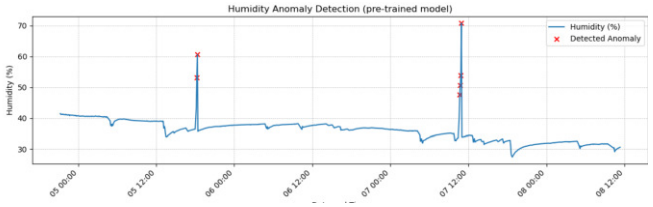

Fig. 4. Humidity anomaly detection

V. Conclusion

The paper showed the studies of theoretical and practical exemplification of multi-agents software security due to RQ1 and RQ2. The proposed research methodology was based on literature and focused on an IoT alarm-monitoring algorithm for smart homes and smart grids, which was described using an expanded BPMN notation and built on the idea of a digital twin. The algorithm specifies how agents evaluate the need to trigger alarms for particular model parameters and may serve to simulate the behaviour of IoT devices within Smart Grid networks. The algorithm's mechanism for gathering parameters from IoT devices offers further extension through the use of a SIEM-Connector concept. This idea involves a service provider continuously monitoring a large number of devices across several networks. Such integration allows real-time detection of threats reported by multiple domestic networks simultaneously. The use of the Isolation Forest algorithm facilitated the model's training and its effective identification of situations that could threaten the system's operational continuity. This was verified by the conducted simulation. The future research should be concerned with the implementation and usage of the AI-based Knowledge Management (AI-KM) models with GenAI and the internalization interaction between the machine agents. Internalization relates strongly to the creation of internal models (or representations) of the knowledge of the outer world of the agent, reflecting the views and beliefs of the agent. The assistance by GenAI might both help the internalization processes of the human agent, but might also be beneficial to proactively build or adapt (digital) representations for the machine agent.

***Abstract*—This paper presents an optimization method based on a particular polynomial lattice rule with interlaced factor two for estimating sensitivity indices in global sensitivity analysis, focusing on total, first-order and second-order Sobol indices. A comparison with one of the best available methods the Modified Sobol Sequence and component by component construction polynomial lattice rule have been done. Relative errors for key output quantities are analyzed and compared. Our results show that the proposed optimization method consistently outperforms other methods in accurately estimating both first-order and total-order sensitivity indices, especially for parameters with smaller effects. These findings highlight the strengths and limitations of each method, providing guidance for selecting appropriate stochastic sampling strategies in computational sensitivity analysis.**

I. Introduction

SENSITIVITY analysis (SA) [12], [14], [17], [21] is a fundamental technique in modeling and simulation that investigates how variations in input parameters influence the output of a given system. By identifying which inputs contribute most to uncertainty in the model results, SA provides valuable insights into the robustness and reliability of mathematical models. This approach is especially crucial in complex environmental, financial, and engineering systems, where numerous variables interact in nonlinear ways. SA not only enhances model transparency but also supports decision-making by highlighting the key drivers of system behavior. Quasi Monte Carlo methods (QMC) methods are powerful technique for performing SA [14], [21].

Venelin Todorov was partially supported by the Centre of Excellence in Informatics and ICT under the Grant No BG16RFPR002-1.014-0018, financed by the Research, Innovation and Digitalization for Smart Transformation Programme 2021-2027 and co-financed by the European Union and by BNSF under Projects KP-06-N62/6 "Machine learning through physics-informed neural networks".

The input data for SA has been obtained during runs of a large-scale mathematical model for remote transport of air pollutants - **Uni**fied **D**anish **E**ulerian **M**odel (UNI-DEM) [11], [16], [26]. UNI-DEM is described mathematically [23], [24], [25]) by the following system of PDEs:

$$\frac{\partial c_s}{\partial t} = -\frac{\partial (uc_s)}{\partial x} - \frac{\partial (vc_s)}{\partial y} - \frac{\partial (wc_s)}{\partial z} + \\ + \frac{\partial}{\partial x}\left(K_x \frac{\partial c_s}{\partial x}\right) + \frac{\partial}{\partial y}\left(K_y \frac{\partial c_s}{\partial y}\right) + \frac{\partial}{\partial z}\left(K_z \frac{\partial c_s}{\partial z}\right) + \\ + E_s + Q_s(c_1, c_2, \ldots, c_q) - (k_{1s} + k_{2s})c_s, \quad s = 1, 2, \ldots, q.$$

The number of studied pollutants by UNI-DEM determines the number q of equations in the system. It follows the other dimensions of the model:

- c_s - pollutant concentrations,
- u, v, w - wind components along the coordinate axes,
- K_x, K_y, K_z - diffusion coefficients,
- E_s - space emissions,
- k_{1s}, k_{2s} - dry and wet deposit coefficients, respectively ($s = 1, \ldots, q$),
- $Q_s(c_1, c_2, \ldots, c_q)$ - nonlinear functions describing chemical reactions between pollutants.

It is assumed that the mathematical model can be presented by a model function

$$\mathrm{u} = f(\mathrm{x}), \quad \text{where} \quad \mathrm{x} = (x_1, x_2, \ldots, x_s) \in U^s \equiv [0;1]^s \tag{1}$$

is a vector of input parameters with a joint **p**robability **d**ensity **f**unction (p.d.f.) $p(\mathrm{x}) = p(x_1, \ldots, x_s)$.

The concept of Sobol approach is based on a decomposition of an integrable model function f [20]:

$$f(\mathrm{x}) = f_0 + \sum_{\nu=1}^{s} \sum_{l_1<\ldots<l_\nu} f_{l_1\ldots l_\nu}(x_{l_1}, x_{l_2}, \ldots, x_{l_\nu}), \qquad (2)$$

where f_0 is a constant. The representation (2) is referred to as the ANOVA-representation of the model function $f(\mathrm{x})$ if each term satisfy [20]:

$$\int_0^1 f_{l_1\ldots l_\nu}(x_{l_1}, x_{l_2}, \ldots, x_{l_\nu})\mathrm{d}x_{l_k} = 0,\ 1 \le k \le \nu, \nu = 1, \ldots, s.$$

The quantities

$$\mathbf{D} = \int_{U^s} f^2(\mathrm{x})\mathrm{d}\mathrm{x} - f_0^2,\ \mathbf{D}_{l_1\ \ldots\ l_\nu} = \int f^2_{l_1\ \ldots\ l_\nu}\mathrm{d}x_{l_1}\ldots\mathrm{d}x_{l_\nu} \qquad (3)$$

are the so-called total and partial variances, respectively. A similar decomposition holds for the total variance that is represented by the corresponding partial variances: $\mathbf{D} = \sum_{\nu=1}^{s}\sum_{l_1<\ldots<l_\nu}\mathbf{D}_{l_1\ldots l_\nu}$. The main sensitivity measures following the Sobol approach are the so-called Sobol global sensitivity indices [20], [17] defined by

$$S_{l_1\ \ldots\ l_\nu} = \frac{\mathbf{D}_{l_1\ \ldots\ l_\nu}}{\mathbf{D}}, \quad \nu \in \{1, \ldots, s\}. \qquad (4)$$

and the **t**otal **s**ensitivity **i**ndex (TSI) of an input parameter $x_i, i \in \{1, \ldots, s\}$ defined by [20], [17]:

$$S_i^{tot} = S_i + \sum_{l_1 \ne i} S_{il_1} + \sum_{l_1, l_2 \ne i, l_1<l_2} S_{il_1l_2} + \ldots + S_{il_1\ldots l_{s-1}}, \qquad (5)$$

where S_i is called *the main effect (first-order sensitivity index)* of x_i and $S_{il_1\ldots l_{j-1}}$ is the j-th order sensitivity index. The higher-order terms describe the interaction effects between the unknown input parameters $x_{i_1}, \ldots, x_{i_\nu}, \nu \in \{2, \ldots, s\}$ on the output variance. This implies that performing global sensitivity analysis from a mathematical standpoint involves calculating total sensitivity indices (see Equation 5), which—according to the formulations in Equations 3–4—reduces to the evaluation of multidimensional integrals.

II. The Stochastic Approaches

Let us consider the following task for multidimensional integration:

$$S(f) := I = \int_{U^s} f(x)dx.$$

The first algorithm that we are going to use is the modified Sobol sequence based on procedure of shaking.

We will use a method that looks like the stratified symmetrized Monte Carlo [19]. For our Monte Carlo algorithm based on modified Sobol sequence (MCA-MSS-2-S), the original domain of integration is divided into m^s disjoint subdomains with equal volumes $\mathbf{K}_i^s, i = 1, \ldots, m^s$, where m is the number of subintervals used for the partition in each dimension. Here two pseudorandom points are generated. The first ξ_i is generated uniformly distributed inside the subdomain $\mathbf{K}_i^s$ and second $\xi_i^{'}$ is computed to be symmetric to ξ_i according to the central point s_i in $\mathbf{K}_i^s$. The concept in two-dimensional case for MCA-MSS-2-S is illustrated on Figure 1.

The value of the integral can be approximated [6]:

$$I(f) \approx \frac{1}{2m^s}\sum_{i=1}^{m^s}\left[f(\xi_i) + f(\xi_i^{'})\right].$$

It is proved that the algorithm MCA-MSS-2-S has an optimal rate of convergence $(n^{-\frac{1}{2}-\frac{2}{s}})$ for the class of continuous functions with continuous first derivatives and bounded second derivatives [7]. Up to now this method gives one of the best results for estimating sensitivity indices [6].

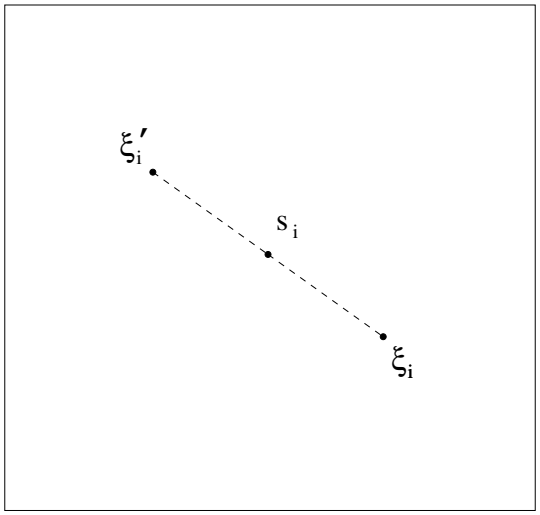

Fig. 1. Generation of a pseudorandom point $\xi_i(\xi_i') \in \mathbf{E}_i^2$.

Now we will use the so-called lattice rules. To introduce rank-1 lattice rule we will use the following formula [22]:

$$\mathbf{x}_k = \left\{\frac{k}{N}\mathbf{z}\right\},\ k = 1, \ldots, N, \qquad (6)$$

where N is an integer, $N \ge 2$, $\mathbf{z} = (z_1, z_2, \ldots z_s)$ is the generating vector and $\{z\}$ denotes the fractional part of z. For the definition of the $E_s^\alpha(c)$ and $P_\alpha(z, N)$ see [22].

In 1959 Bahvalov [1] proved that there exists an optimal choice of the generating vector $\mathbf{z}$:

$$\left|\frac{1}{N}\sum_{k=1}^{N} f\left(\left\{\frac{k}{N}\mathbf{z}\right\}\right) - \int\limits_{[0,1)^s} f(u)du\right| \le cu(s,\alpha)\frac{(\log N)^{\beta(s,\alpha)}}{N^\alpha}, \qquad (7)$$

for the function $f \in E_s^\alpha(c)$, $\alpha > 1$ and $u(s,\alpha), \beta(s,\alpha)$ do not depend on N.

The first generating vector in construction of our lattice rule is the generalized Fibonacci numbers of the corresponding dimension and the method will be called FIBO. FIBO will use the following generating vector [22]:

$$\mathbf{z} = (1, F_n^{(s)}(2), \ldots, F_n^{(s)}(s)), \qquad (8)$$

where we use that $F_n^{(s)}(j) := F_{n+j-1}^{(s)} - \sum_{i=0}^{j-2} F_{n+i}^{(s)}$ and $F_{n+l}^{(s)}$ ($l = 0, \ldots, j-1, j$ is an integer, $2 \leq j \leq s$) is the term of the s-dimensional Fibonacci sequence [22].

Now we will consider a special lattice rule based on the component by component construction method [2], [3], [18]. An optimal generating vector based on the rank-1 lattice rules with prime number of points is obtained using the component by component construction method. More specifically, let us initially set $z_1 := 1$. Then, assuming z_1 remains fixed, and $z_2 \in U^N := z \in \mathbb{N} : 1 \leq z \leq N-1,\ \gcd(z, N) = 1$ is chosen in such a way that a predefined error criterion [5], [15] is minimized in two dimensions. Then, iteratively for $i = 3, \ldots, s$, z_i is selected from U^N in such a manner that it minimizes the predefined error criterion in i dimensions. At the first step of the algorithm s dimensional optimal generating vector $\mathbf{z} = (z_1, z_2, \ldots z_s)$ is generated by the fast component by component construction method described above. On the second step of the algorithm we generate the points of lattice rule by formula $\mathbf{x}_k = \left\{ \frac{k}{N}\mathbf{z} \right\},\ k = 1, \ldots, N$. And at the third and last step of the algorithm an approximate value I_N of the multidimensional integral is evaluated by the formula:

$$I_N = \frac{1}{N} \sum_{k=1}^{N} f\left(\left\{ \frac{k}{N}\mathbf{z} \right\} \right).$$

The steps of working for the method are given on the flowchart on Fig. 2.

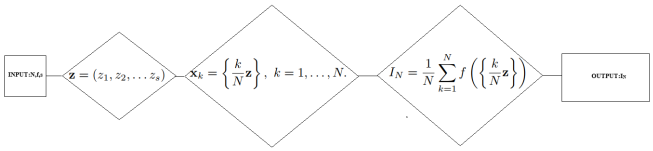

Fig. 2. The flowchart of the algorithm

Now we will continue with our optimization method based on polynomial lattice rule with special generating matrices never used for this computational task before. Let b be prime, let p be a polynomial and $deg\ p = m$ with coefficients in Z_b, and let $q_1, \ldots q_s$ be polynomials and $deg(q_1, \ldots, q_s) \leq m-1$ with coefficients in Z_b. Then we will choose C_j, the j^{th} generating matrix.

Let for $u_1, u_2, \cdots \in Z_b$:

$$\frac{q_j(x)}{p(x)} = \frac{u_1}{x} + \frac{u_2}{x^2} + \ldots.$$

Then set

$$\mathbf{C_j} = \begin{pmatrix} u_1 & u_2 & u_3 & \ldots & u_m \\ u_2 & u_3 & \ldots & \ldots & u_{m+1} \\ u_3 & \ldots & \ldots & \ldots & u_{m+2} \\ \ldots & \ldots & \ldots & \ldots & \ldots \\ u_m & u_{m+1} & u_{m+2} & \ldots & u_{2m-1} \end{pmatrix} \in Z_b^{m \times m}. \tag{9}$$

The digital net [4] with $C_1, \ldots, C_s$ is named a polynomial lattice point set (PLPS), and a QMC rule using a polynomial lattice point set is named a polynomial lattice rule, where p is the modulus, and $(q_1, \ldots, q_s)$ is the generating vector of polynomials [13].

Let $m, s, d \in \mathbb{N}$ be defined with $d > 1$. Let $p \in Z_b$ be defined as $\deg(p) = m$ and let $q = (q_1, \ldots, q_{ds}) \in (Z_b)^{ds}$. An interlaced polynomial lattice rule of order d is actually a point set composed by b_m points $x_0, \ldots, x_b^{m-1}$ which are defined as [4]

$$x_n := D_d(z_n),$$

the n^{th} point z_n of a PLPS $P_{b^m,ds}(q, p)$ is presented by

$$z_n := \left(v_m\left(\frac{n(x)q_1(x)}{p(x)} \right), v_m\left(\frac{n(x)q_2(x)}{p(x)} \right), \ldots, v_m\left(\frac{n(x)q_{ds}(x)}{p(x)} \right) \right) \in [0,1)^{ds}$$

for $0 \leq n < b^m$. For explanation of $n(x)$ see [13]. A QMC rule, that uses this point set is called an interlaced polynomial lattice rule (of order d). Generating matrices used for the construction of interlaced polynomial lattice point sets were based on the implementation of the Sobol sequence with interlacing factor $d = 2$, as described in [15].

III. Case study - UNI-DEM model

The efficient MC algorithms for multidimensional numerical integration described above have been applied to sensitivity studies of concentration variations of air pollutants with respect to emission levels and some chemical reactions rates. More information can be found in [8], [9], [10].

A. Sensitivity Studies with Respect to Emission Levels

TABLE I
COMPARISON OF RELATIVE ERRORS FOR SENSITIVITY INDICES ESTIMATION USING VARIOUS STOCHASTIC APPROACHES ($n \approx 65536$).

EQ	RV	MSS-2S	IPLR2	CBCCM	FIBO
f_0	0.048	**2e-08**	7e-06	8e-06	9e-06
$\mathbf{D}$	0.0002	**2e-06**	8e-05	6e-04	3e-04
S_1	9e-01	5e-04	**2e-05**	**2e-05**	4e-04
S_2	2e-04	7e-02	**3e-03**	4e-01	2e-01
S_3	1e-01	1e-02	**9e-05**	3e-03	3e-03
S_4	4e-05	6e-01	**1e-02**	1e+00	5e-01
S_1^{tot}	9e-01	1e-03	**1e-05**	3e-04	5e-04
S_2^{tot}	2e-04	3e-03	**2e-03**	1e-01	3e-01
S_3^{tot}	1e-01	4e-03	**8e-05**	9e-04	2e-03
S_4^{tot}	5e-05	1e-01	**2e-02**	4e-01	5e-01

Firstly we will study the sensitivity of the model output (in terms of mean monthly concentrations of several important pollutants) with respect to variation of input emissions of the anthropogenic pollutants. The anthropogenic emissions input consist of 4 different components $\mathbf{E} = (\mathbf{E^A}, \mathbf{E^N}, \mathbf{E^S}, \mathbf{E^C})$ as follows:

$\mathbf{E^A}$ – ammonia (NH_3);
$\mathbf{E^S}$ – sulphur dioxide (SO_2);
$\mathbf{E^N}$ – nitrogen oxides $(NO + NO_2)$;
$\mathbf{E^C}$ – anthropogenic hydrocarbons.

The output of the model is mean monthly concentration of the following 3 pollutants:

- s_1 – ozone (O_3);
- s_2 – ammonia (NH_3);
- s_3 – ammonium sulphate and ammonium nitrate ($NH_4SO_4 + NH_4NO_3$).

In our particular case we are interested in sensitivity studies of the mean monthly concentrations of ammonia in Milan. The domain under consideration is the 4-dimensional hypercubic domain $[0.5, 1]^4$).

This table I compares the relative errors (RE) for estimating sensitivity indices of various input parameters using four stochastic approaches, with a sample size of approximately 65536. The Reference Values (RV) are included for context. for the model function MSS-2S stands out with the smallest relative error (2e-08), indicating exceptional accuracy in estimating the mean output. IPLR2, CBCCM, and FIBO are all orders of magnitude less precise here (errors in the range of 7e-06 to 9e-06). This suggests MSS-2S is highly efficient for estimating basic function averages. For the total variance ($\mathbf{D}$) MSS-2S again shows the lowest RE (2e-06), confirming its strength in capturing overall variance. IPLR2 (8e-05) and FIBO (3e-04) are better than CBCCM (6e-04) but lag behind MSS-2S.

For S_1 (most influential parameter), both IPLR2 and CBCCM achieve the best RE (2e-05), outperforming MSS-2S and FIBO. This suggests these two methods are more precise in estimating dominant first-order effects. For S_2, IPLR2 performs best (3e-03), significantly better than MSS-2S (7e-02), CBCCM (4e-01), and FIBO (2e-01). For S_3 and S_4, IPLR2 consistently has the smallest errors (9e-05 and 1e-02 respectively), with MSS-2S and FIBO trailing and CBCCM performing worst. This indicates IPLR2 is very efficient at estimating sensitivity for less dominant variables. For S_1^{tot} IPLR2 outperforms others with 1e-05 error, better than CBCCM (3e-04), MSS-2S (1e-03), and FIBO (5e-04). For S_2^{tot} IPLR2 again leads with 2e-03, while MSS-2S (3e-03) performs well but CBCCM and FIBO lag behind (0.1 and 0.3). For S_3^{tot} and S_4^{tot}, IPLR2 maintains the best accuracy with relative errors of 8e-05 and 2e-02, respectively, indicating strong performance on total effect indices across less influential parameters.

To summarize, in this case, if the goal is to accurately estimate the mean and total variance, MSS-2S is the method of choice. For detailed sensitivity analysis—precisely estimating both first-order and total-order indices, especially those with smaller magnitude—IPLR2 offers superior accuracy. CBCCM and FIBO show relatively larger errors, suggesting they may be less suitable for high-precision sensitivity studies with this sample size.

B. Sensitivity Studies with Respect to Chemical Reactions Rates

In this part we will study the sensitivity of the ozone concentration in Genova according to the rate variation of some chemical reactions: ## $1, 3, 7, 22$ (time-dependent) and $27, 28$ (time independent) reactions of the condensed CBM-IV scheme ([23]). The simplified chemical equations of these reactions are as follows:

$$
\begin{aligned}
&[\#\mathbf{1}] \quad NO_2 + h\nu \Longrightarrow NO + O;\\
&[\#\mathbf{3}] \quad O_3 + NO \Longrightarrow NO_2;\\
&[\#\mathbf{7}] \quad NO_2 + O_3 \Longrightarrow NO_3;\\
&[\#\mathbf{22}] \quad HO_2 + NO \Longrightarrow OH + NO_2;\\
&[\#\mathbf{27}] \quad HO_2 + HO_2 \Longrightarrow H_2O_2;\\
&[\#\mathbf{28}] \quad OH + CO \Longrightarrow HO_2.
\end{aligned}
$$

The domain under consideration is the 6-dimensional hypercubic domain $[0.6, 1.4]^6$).

TABLE II
COMPARISON OF RELATIVE ERRORS (RE) FOR AE OF SIS ACROSS SELECTED METHODS ($n \approx 2^{16}$).

EQ	RV	MSS-2S	D-α2-Cs-1	CBCCM	FIBO

S_{12}	6e-03	7e-01	**2.8e-03**	3e-01	3e+00
S_{14}	5e-03	1e+00	**6.5e-03**	3e-02	8e+00
S_{24}	3e-03	1e+00	**4.5e-03**	5e-02	1e+01
S_{45}	1e-05	4e+00	**3.3e-02**	1e+00	4e+01

This table II compares the relative errors (RE) for estimating sensitivity indices of various input parameters using four stochastic approaches, with a sample size of approximately 65536.

FIBO performs poorly overall, especially in detecting higher-order and small-effect indices. It delivers acceptable errors only for dominant first-order indices, such as S_1 and S_2, but is far less accurate for total-effect and interaction indices. Also, it is characterized with substantial divergence in weak-effect indices like S_5, S_5^{tot}, and interaction terms—REs are several orders of magnitude larger than other methods. FIBO is inadequate for high-precision sensitivity analysis, particularly in higher-dimensional or low-sensitivity contexts.

CBCCM offers moderately good performance, better than FIBO but generally not better than MSS-2S or IPLR2 It excels in select indices like S_1^{tot} and S_2^{tot} but is not the best in any single row of the table. It tends to perform worse than IPLR2 in detecting fine-grained or subtle effects, although it outperforms MSS-2S and FIBO in some higher-order interactions. CBCCM is reliable but not exceptional. It represents a solid compromise between computational cost and accuracy.

MSS-2S delivers excellent accuracy for f_0 and $\mathbf{D}$, both with errors as low as 10^{-7} to 10^{-4}. It performs well for low-to-moderate variance indices (e.g., S_1, S_2, S_3), but poorly on

higher-order or subtle interactions like S_{24} and S_{45}. It notably fails in estimating some higher-order interactions and weak effects (e.g., very high RE in the smallest in value S_5 and S_5^{tot} which are very important for the reliability of the results). MSS-2S is accurate and efficient for dominant effects, but may be unstable for weak sensitivities or higher-order interactions.

Among all methods, IPLR2 provides the lowest RE for the majority of first-order and total-effect indices, including: S_1, S_2, S_3, S_4, S_1^{tot} through S_6^{tot} and many second-order terms like S_{12}, S_{14}, S_{24}, and S_{45}. It is exceptionally robust across both low and high sensitivity parameters, and particularly effective in capturing small effect sizes (e.g., S_5). It is very competitive even for interaction terms, where other methods tend to diverge. IPLR2 stands out as the most consistently accurate and robust method, particularly effective for precise SI estimation across the full spectrum of effects.

IV. Conclusion

The computational experiments reveal that the optimization method IPLR2 developed are amongst the most effective stochastic strategies currently available for determining sensitivity indices, particularly for the most challenging task – assessing the least value sensitivity indices, which are crucial for the dependability of the model's outcomes. These findings are of considerable significance for environmental conservation and the credibility of future predictions.

The results underscore the trade-off between method complexity and accuracy: MSS-2S excels in some global measures, while IPLR2 is more balanced for all sensitivity indices. Among the evaluated methods for estimating sensitivity indices, our optimization method IPLR2 consistently delivers the most accurate and robust results, especially across both dominant and subtle effects, including higher-order interactions. MSS-2S performs well for main effects but lacks stability in weak or complex interactions. CBCCM offers balanced performance but is never the top performer. In contrast, FIBO and RV show significant limitations in accuracy and should be avoided in precision-critical sensitivity analyses. Overall, the proposed optimization method is the recommended method for comprehensive and reliable global sensitivity estimation.

***Abstract*—This paper addresses the challenge of data augmentation for monochrome images, which are still highly relevant in machine vision. Current augmentation methods designed for natural scenes focus on geometric transformation and often fall short in simulating real-world illumination variations. We propose a novel approach that leverages a two-step monochrome image processing technique consisting of image pseudo-colorization followed be a specific decolorization scheme. Our method generates diverse and unpredictable intensity variations, effectively emulating illumination changes and, if only a specific category of color maps are used, preserving the naturalness of the resulting images. To exclude the results which closely replicate images already in the dataset, we rank these maps, identifying a subset that significantly alters illumination characteristics of the originals. A popular SSIM measure is used for that purpose. The proposed technique enhances the illumination diversity of datasets, offering a valuable tool for improving the robustness of AI/ML models in monochrome imagery.**

NOTE: ***All figures are best viewed in high resolution*.**

I. Motivation and Introduction

DATA augmentation is a crucial AI/ML technique that artificially expands training datasets by generating modified samples, [1]. This process enhances robustness of machine vision models to unseen data, reduces overfitting, and improves performance, particularly in scenarios with data scarcity or imbalance, [2]. By leveraging existing data, the need for expensive and time-consuming data collection efforts is minimized.

The data augmentation problem for a specific category of visual data, i.e., monochrome images, is the subject of this paper. These images continue to be a popular and informative source, comparable in relevance to color images.

Commonly, the augmentation of monochrome visual data (e.g., [3], [4]) relies on geometric transformations, encompassing rotation, scaling, cropping, shearing, homography, and random occlusions. Illumination and intensity transformations are less frequently employed, largely due to their limited options, which primarily include adjustments to contrast and brightness, alongside standard image processing techniques like blurring or sharpening. Significantly, current augmentation methods often fall short in their ability to simulate the unpredictable intensity variations caused by real-world illumination changes, such as those arising from diverse weather or visibility conditions.

Consequently, this paper focuses on augmenting visual data by addressing this specific limitation. Directly visualizing the effects of real-world illumination or visibility changes is generally infeasible due to the extremely complex computational demands of 3D scene reconstruction and illumination modeling based on identified or artificially embedded light sources. Instead, we propose utilizing an image processing technique capable of producing varying and unpredictable outcomes that can effectively emulate diverse illumination changes, even though the underlying physical characteristics of these changes remain unspecified and undetermined.

The proposed approach leverages a recently developed image decolorization algorithm [5], which has been subsequently adapted to enhance the quality of grayscale images in [6], [7]. The algorithm is a specific grayscaling scheme which effectively enhances the visual prominence of original color images by incrementally determining pixel intensities based on the colors and intensities of their already processed neighbors (details in [5]). Example results are shown in Fig. 1.

.

Fig. 1. Example images from COLOR250 dataset [8] decolorized using the method described in [5].

Subsequently, any monochrome image can be transformed into a color variant using pseudo-colorization, a common technique for visualizing grayscale data from diverse, primarily non-visual domains, e.g., [9], [10], and then decolorized using the aforementioned approach. We have observed that this two-step process can significantly enhance image perceptibility compared to the original grayscale image, given the application of a suitable *color map* in the initial step. Optimal color maps for this purpose are identified in [6], [7], both for general monochrome images (targeting primarily those from non-visual domains) [7]), and for images depicting natural

scenes, [6]. However, we also observed that for images of natural scenes, many color maps produce monochrome results that, regardless of improved perceptibility, can resemble the same scenes under different illumination conditions, as shown in Fig. 2.

Fig. 2. The original image (left) and its variants, generated using diversified color maps in the first step of our method.

This finding forms the core principle of this paper, as such images are incorporated into the augmented dataset.

First, Section II categorizes color maps employed in pseudo-colorization and identifies the sub-category suitable for the proposed data augmentation scheme. Within this context, the key features of the adopted decolorization scheme are also briefly highlighted. In Section III, those color maps are ranked so that only maps which statistically generate the most diverse (and different from the dataset originals) images are retained. In this way, we exclude the augmented images that basically replicate visual information already provided in the training dataset.

Finally, Section IV presents examples of this augmentation and discusses further aspects of the method, including its limitations.

II. Principles of the Method

A. Remarks on Image Decolorization (more in [5])

The decolorization scheme presented in [5] assumes, but does not directly apply, linear *rgb-to-gray* mappings defined by:

$$I = k_R R + k_G G + k_B B, \tag{1}$$

where the coefficients $[k_R, k_G, k_B]$ are optimized either globally (e.g., [11], [12]) or locally (e.g., [13], [14]) to enhance the visual expressiveness of the resulting monochrome images.

Instead, we observe that a pixel with $[R, G, B]$ values can only be assigned an intensity I within the constrained range:

$$min(R, G, B) \leq I \leq max(R, G, B), \tag{2}$$

regardless of the specific values of $[k_R, k_G, k_B]$ in Eq.1.

Eq. 2 allows us to identify pixels with the narrowest range of feasible grayscale intensities. For these pixels, their grayscale values are either randomly selected from this restricted range or assigned deterministically when when $min(R, G, B) = max(R, G, B)$.

These pixels serve as the starting points (the *initial list*) for the decolorization process, which employs a randomized variant of a *flood-fill* algorithm. Subsequently, pixels with already decolorized neighbors are assigned grayscale intensities (constrained by Eq. 2) in proportion to their color differences from those neighbors. This iterative process continues until all pixels are processed, completing the decolorization step.

Furthermore, as discussed below, Eq. 2 indirectly determines the color maps that can be effectively used in the first step (image pseudo-colorization) of the proposed image augmentation.

B. Color Maps

Various color maps are designed for diverse purposes (e.g., [15], [16]); however, we specifically focus on *sequential color maps*, where the luminance Y of assigned colors changes monotonically with intensity. That is, *if* $I_1 < I_2$ *then* $Y(RGB(I_1)) < Y(RGB(I_2))$. This constraint ensures that the pseudo-colorized image preserves the perceptual order of luminance, which is important for maintaining the natural appearance of the augmented images.

To further preserve perceptual naturalness, we impose another constraint on the color maps, derived from Eq. 2. Specifically, we only use those sequential color maps that satisfy the condition:

$$max[R(0), G(0), B(0)] < 0.5 < min[R(255), G(255), B(255)]. \tag{3}$$

This condition implies that after pseudo-coloring and subsequent decolorization, the darkest pixels in the original image always remain darker than the brightest pixels. Combined with the fact that the average intensity in Eq. 2 generally increases for sequential color maps, the original hierarchy of intensities is statistically maintained. We will jointly refer to sequential maps satisfying Eg. 3 as SEQ3 maps.

At least 42 SEQ3 maps exist, as identified from the publicly available map catalog [17] and other sources.

Figure 3 provides examples of those categories of color maps.

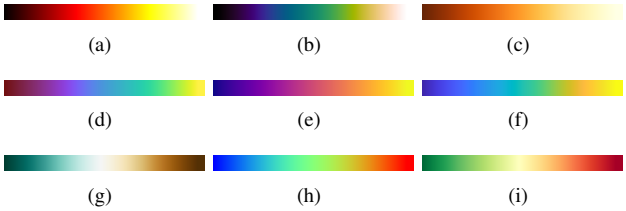

Fig. 3. Examples of: (a,b,c) sequential color maps satisfying Eq. 3 (SEQ3 maps); (d,e,f) non-SEQ3 sequential color maps; and (g,h,i) non-sequential color maps.

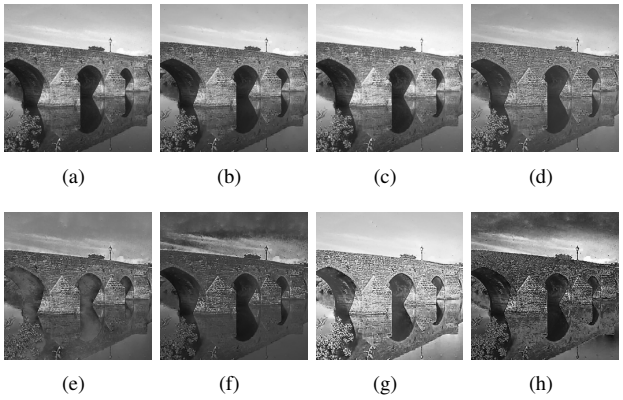
To further illustrate the significance of using only SEQ3 color maps, examples are provided in Fig. 4. The results obtained with SEQ3 maps effectively emulate alternative illumination conditions, whereas the image generated using a non-sequential map appears too unrealistic (despite its high visual clarity) to be considered an augmented variant of the original.

III. Restricting the Number of Color Maps



Although our proposed method allows any SEQ3 map to generate realistically-looking alternatives of monochrome images, some maps yield outputs nearly indistinguishable from the originals. Such near-identical images are unsuitable for data augmentation as they essentially replicate existing

(a) (b) (c) (d)

Fig. 4. Original image (a) compared with two variants using SEQ3 maps SEQ3 maps (b,c) and a variant using a non-sequential color map (d), which shows an unacceptable loss of naturalness.

dataset items in terms of overall visual impression. Instead, we should prioritize maps that introduce substantial variations in illumination characteristics. Illustrative examples of both scenarios are provided in Fig. 5.

(a) (b) (c) (d)

(e) (f) (g) (h)

Fig. 5. (a) Original image; (b-d) variants closely resembling the original (*bone*, *greys*, *ice* SEQ3 maps); and (e-h) variants with significantly different illumination characteristics (*haline*, *inferno*, *OrRd*, *rainforest* SEQ3 maps).

To assess the statistical suitability of various SEQ3 maps for illumination-targeting data augmentation in monochrome imagery, we utilized a large number (N) of grayscale images randomly extracted from the widely used SUN dataset [18]. This dataset was selected to facilitate future research comparing the classification performance of diverse DL architectures trained on either color images or their grayscale versions.

Each test image was processed by our method using all (SEQ3(1) through SEQ3(42)) maps. Subsequently, we evaluated the illumination disparity between each generated image and its original. The most dissimilar results would be potential candidates for inclusion in the augmented dataset.

While visual inspection could assess this dissimilarity, its burden on human evaluators quickly becomes impractical even with a small number of test images. Therefore, after considering several common image similarity metrics, we opted for the structural similarity index measure (SSIM) for automatic evaluation.

The SSIM is defined by a weighted combination of three measures that broadly represent statistical similarities between the intensity, contrast, and structure of two images, X and Y:

$$SSIM(X,Y) = i(X,Y)^{\alpha} \times c(X,Y)^{\beta} \times s(X,Y)^{\gamma} \quad (4)$$

where $i(X,Y) = \frac{2\mu_X\mu_Y+c_1}{\mu_X^2+\mu_Y^2+c_1}$, $c(X,Y) = \frac{2\sigma_X\sigma_Y+c_2}{\sigma_X^2+\sigma_Y^2+c_2}$ and $s(X,Y) = \frac{\sigma_{XY}+c_3}{\sigma_X\sigma_Y+c_3}$, see [19].

The structural similarity index measure (SSIM) ranges from -1 to 1, with a maximum value of 1 indicating identical images.

While lower SSIM values suggest various distortions between an original image and its processed version, in our specific scenario, the image structure is perfectly preserved. Therefore, intensity variations are the primary factor contributing to the SSIM-measured dissimilarity, making it a suitable metric for our focus on illumination changes.

Consequently, for each test images $X(n)$ (where n = 1,...,N), we calculate 42 SSIM values, denoted as their 42 $SSIM(X(n), X_i(n))$ (where i=1,...,42). These values represent the similarity between the original image and its variants $X_i(n)$ generated using each of the 42 SEQ3 maps.

Subsequently, we estimate the norms of the SSIM value vectors across all test images.

$$norm\left\{[SSIM(X(1), X_i(1)), ..., SSIM(X(N), X_i(N))]\right\} \quad (5)$$

The SEQ3 maps are ranked based on the increasing values of the metric defined in Eq. 5. Consequently, maps exhibiting the lowest vector norms are considered strong candidates for data augmentation, as they statistically produce images with significant dissimilarity from the originals. Conversely, maps with the highest vector norms tend to generate near-identical images, rendering them unsuitable for this purpose.

We explored various vector norms, primarily L^k norms with different values of k, both with and without outlier removal. Remarkably, the resulting rankings of SEQ3 maps remained nearly identical across these different norms, especially within the top (recommended maps) and bottom (least recommended maps) tiers. Specifically, the **top** 5 and **bottom** 5 map sets consistently contained the same members, with only minor variations in their internal order, as detailed in Table I, irrespective of the chosen norm.

TABLE I
RANKING OF SEQ3 MAPS, INDICATING THE TOP AND BOTTOM TIERS.

rank	1	2	3	4	5	...	38	39	40	41	42
map	*rainforest*	*hotM*	*hot*	*YlOrBr(OrRd)*	*OrRd(YlOrBr)*	.....	*ocean(ice)*	*ice(ocean)*	*copper*	*greys*	*bone*

Additionally, we have found that the maximum subset of color maps which are always on top of this ranking (although sometimes in a slightly varying order) irrespective of the norm applied in Eq. 5, contains 14 SEQ3 maps.

We further assessed, using SSIM, the cross-dissimilarity of the outputs generated by these color maps. Generally, the results exhibited substantial differences, with the notable exception of *hotM* and *hot*. These two maps, being nearly identical, understandably produced very similar images, suggesting that one should be excluded.

Consequently, for illumination-targeting data augmentation in monochrome natural scene imagery, we recommend employing the following color maps in the first step of our proposed monochrome-to-monochrome (via pseudo-coloring) image alternations:
(1) *rainforest*, (2) *hot*, (3) *YlOrBr*, (4) *OrRd*, (5) *YlOrRd*, (6) *oranges*, (7) *nuclear*, (8) *RdPu*, (9) *reds*, (10) *PuRd,* (11) *speed*, (12) *warm* and (13) *inferno*.

Detailed information on these maps can be found in [17] and other resources.

Specifically, Figures 3(a) 3(b) and 3(c) illustrate the *hot*, *rainforest* and *YlOrBr*, respectively.

Our limited-scale visual validation strongly supports the suitability of these automatically identified color maps.

IV. Summary

A. Examples

Figures 6 to 9 illustrate the augmentation results achieved with the recommended color maps. These figures display original monochrome images of natural scenes and the corresponding outputs produced by a random selection of seven out of the thirteen recommended maps. While some image fragments may show resemblance, their illumination characteristics diverge significantly in other parts.

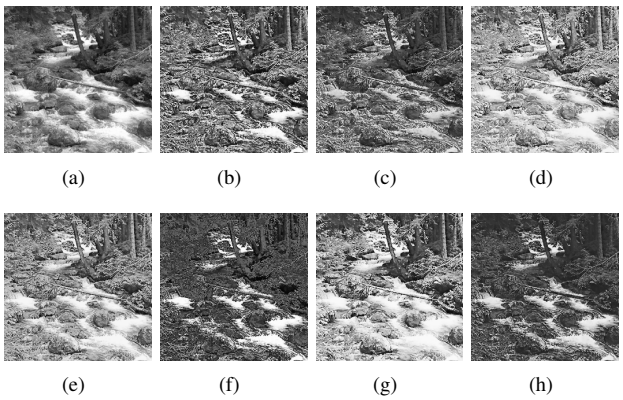


Fig. 6. (a) Original image; augmented variants obtained by using: (b) *hot*, (c) *inferno*, (d) *OrRd*, (e) *PuRd*, (f) *rainforest*, (g) *RdPu* and (h) *speed* SEQ3 maps.

B. Concluding Remarks

Overall, the SEQ3 color maps generate randomized and often unpredictable intensity changes while preserving the natural appearance of the original images. This means our proposed augmentation method effectively produces scene variations that could occur under various unspecified illumination conditions, an effect not achievable with traditional image processing techniques.

Nevertheless, it's important to highlight that our approach addresses only a limited range of potential illumination variations. Specifically, within the proposed model, we cannot simulate the effects of relocating light sources or changing their numbers. Despite this limitation, we believe our method offers a valuable tool for augmenting training data in monochrome imagery, introducing items with unseen and diversified illumination characteristics. Notably, when combined with geometry-based augmentation, this method can yield sufficiently large and diverse training datasets, even when the availability of images from a particular domain is limited.

Finally, it should be noted that restricting the augmenta-

tion to only SEQ3 color maps is not a strict requirement. Generally, non-SEQ3 sequential color maps or non-sequential maps produce unacceptably unnatural outputs, as illustrated in Fig. 3(d). However, if extremely unusual and unpredictable visibility conditions are anticipated in a specific scenario, one might consider incorporating non-SEQ3 or even non-sequential maps into the data augmentation process. Fig. 10 provides an illustrative example of such a case.

Additionally, we have experimentally verified that our approach offers a superior level of intensity diversification compared to standard image processing techniques. We evaluated over ten common, *non-task-specific* image enhancement algorithms. Of these, only two - *image sharpening* and the *LoG* filter - produced statistically comparable SSIM dissimilarity results. However, even these methods were noticeably inferior to ours. It is important to note that image sharpening and the LoG filter primarily enhance edges. This means the visual differences observed with these techniques largely stem from structural modifications, not from the genuine intensity diversification our proposed method achieves.

In the future, we plan to extend our proposed data augmentation scheme to natural color images. Preliminary experimental results for this extension are shown in Figure 11.

***Abstract*—This paper investigates upper bounds on the length of the shortest watchman route in simple polygons using minimal structural information – specifically, the number and placement of reflex vertices – rather than full geometric detail. We show that the set of reflex vertices alone suffices to guarantee full visibility of the polygon: every interior or boundary point is visible from at least one reflex vertex. Moreover, these vertices can always be connected by a polyline within the polygon, enabling a constructive approach to route design. While it is known that the shortest watchman route is bounded above by the perimeter of the polygon, we prove that this bound is tight and cannot be improved in general. However, we identify several important classes of polygons where significantly better bounds are achievable. In particular, for polygons with exactly two reflex vertices, we establish that the shortest watchman route is strictly shorter than half the perimeter. We also introduce a novel triangulation method – *successive dual-edge triangulation* – in which each triangle is constructed by attaching to existing polygon edges. When such a triangulation is possible, the resulting watchman route has length strictly less than half the perimeter, regardless of the number of sides or reflex vertices. These results are not only theoretical but also constructive, offering efficient route designs when geometric data is available. The approach is particularly well suited to real-world environments such as industrial halls or private courtyards, where structural simplicity often permits route planning without requiring full geometric reconstruction. In such cases, our methods provide a significant and elegant reduction in route length compared to perimeter-based patrolling, making them applicable to scenarios such as autonomous drone navigation and indoor surveillance.**

I. Introduction

THE watchman route problem is a fundamental question in computational geometry and visibility theory. It seeks the shortest path within a polygonal domain from which every point is visible, with applications in robotic surveillance, patrolling, and security optimization.

For simple polygons (without holes), several polynomial-time algorithms exist. The first general solution, by Carlsson et al. [1], had worst-case complexity $\mathcal{O}(n^6)$, later improved to $\mathcal{O}(n^5)$ by Tan [2], and to $\mathcal{O}(n^4 \log\log n)$ in special cases by Chin and Ntafos [3], where n is the number of vertices. These methods assume full geometric detail, making them less practical when only structural features are known.

In polygons with holes, Mitchell showed the problem is NP-hard and proposed the first polynomial-time approximation algorithm with an $\mathcal{O}(\log^2 n)$ factor and showed strong inapproximability results [4]. Dumitrescu and Tóth [5] provided asymptotic upper bounds on the watchman route length in polygons with holes, expressed as $\mathcal{O}\left(\mathrm{perim}(\mathcal{P}) + \sqrt{k} \cdot \mathrm{diam}(\mathcal{P})\right)$ for a polygon $\mathcal{P}$ with k holes, perimeter $\mathrm{perim}(\mathcal{P})$, and diameter $\mathrm{diam}(\mathcal{P})$. However, they did not derive explicit route lengths or provide exact constants in the upper bounds. In contrast, this paper provides exact and constructive bounds for specific polygon classes.

Extensions of the problem include limited-visibility models [6], [7], multi-watchman strategies [8], and static coverage ratios from art gallery results [9], [10]. Similar geometric reasoning appears in other domains such as bioinformatics. For example, Lavor et al. [11] solve the discretizable molecular distance geometry problem using partial distance constraints and structural sparsity to infer configurations.

Most existing approaches to the watchman route problem focus on minimizing algorithmic complexity or improving approximation ratios, typically assuming full geometric data.

In practice, however, environments such as industrial halls or courtyards often have simple layouts, where detailed mapping is unnecessary and only coarse information – such as the number of vertices or reflex angles – is available.

This paper studies the watchman route problem in simple polygons under such limited assumptions. We show that the set of reflex vertices alone suffices to ensure full visibility, and that these vertices can always be connected by a polyline. The shortest watchman route is thus bounded above by the polygon's perimeter, and we prove that this bound is tight in general.

We then identify special structural cases that allow for strictly better bounds. For example, if the polygon has exactly two reflex vertices, the length of the shortest route is strictly less than half the perimeter. We also introduce a geometric method – *successive dual-edge triangulation* – in which the polygon is incrementally triangulated by attaching new triangles to existing edges. When such a triangulation is possible, the route length is guaranteed to be strictly less than half the perimeter, regardless of the polygon's size or complexity.

While our results are derived from general structural principles, they also yield constructive algorithms. These are well suited to practical scenarios where detailed geometry is unavailable, and even when such data is present, our method offers an elegant and analytically grounded alternative to exhaustive geometric search.

II. Preliminaries

This section introduces the geometric foundations, mostly elementary but essential, that underlie our results. We define point visibility and show that every point in a simple polygon is visible from some boundary point. In convex polygons, all pairs of points are mutually visible. For polygons with reflex vertices, each point is visible from at least one reflex vertex. Finally, we show that all reflex vertices can be connected by a polyline within the polygon, a key step in the proposed constructing watchman routes.

Definition 1 (Visibility of a point by another)**.** *Let $\mathcal{P}$ be a simple polygon and let $A \in \mathcal{P}$, $B \in \mathcal{P}$ be two points (either in the interior or on the boundary of $\mathcal{P}$). We say that* point A is visible by point B *(or equivalently,* B is visible from A*) if the closed line segment $\overline{AB}$ lies entirely within $\mathcal{P}$, that is, $\overline{AB} \subset \mathcal{P}$. Equivalently, we may say that* point A sees point B*, or vice versa.*

Lemma 1 (Visibility from the boundary of polygon)**.** *Let $\mathcal{P}$ be a simple polygon (of a finite size). Then every point $A \in P$ (including points in the interior and on the boundary) is visible by at least one point $B \in \partial\mathcal{P}$, where $\partial\mathcal{P}$ denotes the boundary of the polygon.*

Proof. Obviously $\partial\mathcal{P} \subset \mathcal{P}$ (†). Let $A \in P$ be an arbitrary point.

If A lies on the boundary $\partial\mathcal{P}$, i.e. $A \in \partial\mathcal{P}$, then it is trivially visible by itself, so $B = A$, because

$$\overline{AB} = B = A \in \partial\mathcal{P} \overset{(\dagger)}{\subset} \mathcal{P}.$$

Suppose A lies in the interior of $\mathcal{P}$. Since $\mathcal{P}$ is a simple polygon of a finite size, the line segment from A to any direction will eventually intersect the boundary of $\mathcal{P}$. Let us select an arbitrary direction and consider the ray starting at A in that direction. Let C be the first point where this ray intersects the boundary $\partial\mathcal{P}$, so $C \in \partial P$. Since $\mathcal{P}$ is simple and of a finite size (i.e., it has no self-intersections and encloses a connected finite region), the point C exists, segment $\overline{AC}$ has $|\overline{AC}| < \infty$ and lies entirely within $\mathcal{P}$, i.e., $\overline{AC} \subset \mathcal{P}$ (‡). Hence, $B = C$ and A is visible by B because

$$\overline{AB} = \overline{AC} \overset{(\ddagger)}{\subset} \mathcal{P}.$$

Thus, in all cases, there exists a boundary point $B \in \partial\mathcal{P}$ such that A is visible by B. □

Lemma 2 (Mutual visibility in convex polygons)**.** *Let $\mathcal{P}$ be a simple and convex polygon. Then every pair of distinct points $A \in \mathcal{P}$, $B \in \mathcal{P}$ (including interior and boundary points) are mutually visible; that is, the segment $\overline{AB}$ lies entirely within $\mathcal{P}$.*

Proof. Let $A, B \in \mathcal{P}$ be two distinct points, each either in the interior or on the boundary of the convex polygon $\mathcal{P}$. Consider the line $\overleftrightarrow{AB}$ passing through points A and B. Since $\mathcal{P}$ is convex and of finite size, the intersection of this line with the polygon $\mathcal{P}$ is a single line segment $\overline{CD}$, where $C, D \in \partial\mathcal{P}$ are the boundary points where the line enters and exits the polygon. Because $\mathcal{P}$ is convex, the entire segment $\overline{CD}$ lies within $\mathcal{P}$. Since both A and B lie on the segment $\overline{CD}$, so $\overline{AB} \subseteq \overline{CD}$, it follows that $\overline{AB} \subseteq \mathcal{P}$. Therefore, $\overline{AB} \subseteq \mathcal{P}$, which implies that A is visible by B and vice versa. □

Theorem 1 (Visibility from reflex vertices)**.** *Let $\mathcal{P}$ be a simple polygon with boundary $\partial\mathcal{P}$, and suppose that $\mathcal{P}$ contains at least one vertex $V \in \partial\mathcal{P}$ with a reflex angle. Then every point $A \in \mathcal{P}$ (including interior and boundary points) is visible by at least one reflex vertex of $\mathcal{P}$.*

Proof. Let $A \in \mathcal{P}$ be an arbitrary point. Let $\mathcal{W}_A$ denote the set of all boundary points visible from A, that is,

$$\mathcal{W}_A = \left\{\forall B \in \partial\mathcal{P} : \overline{AB} \subset \mathcal{P}\right\}.$$

Case 1: Suppose A sees the entire boundary, i.e., $\mathcal{W}_A = \partial\mathcal{P}$. Since $\mathcal{P}$ contains at least one reflex vertex V, it follows that $V \in \mathcal{W}_A$, and therefore $\overline{AV} \subset \mathcal{P}$. Hence, A is visible by a reflex vertex V.

Case 2: Suppose A does not see the entire boundary, i.e., $\mathcal{W}_A \subset \partial\mathcal{P}$. Let $C \in \partial\mathcal{P} \setminus \mathcal{W}_A$ be a boundary point not visible from A.

Subcase 2a: If $\mathcal{W}_A$ contains at least one reflex vertex V, then A is visible by V, and the statement holds.

Subcase 2b: Suppose $\mathcal{W}_A$ contains no reflex vertices; that is, every boundary point visible from A is either a convex vertex or a point on an edge between convex vertices. Since C is not visible from A and $\mathcal{P}$ is a simple polygon (i.e., it has no self-intersections or holes), the obstruction to visibility must be caused by some part of the boundary of $\mathcal{P}$. Consider the

collection of points $D \in \partial\mathcal{P}$ that obstruct the visibility from A to C; thus, $\overline{AC} \not\subset \mathcal{P}$. Among these, let $D^* \in \partial\mathcal{P}$ be a point such that the angle $\angle AD^*C$ is maximized. Since $\overline{AC} \not\subset \mathcal{P}$, this angle must be reflex, i.e., $|\angle AD^*C| > 180°$. This implies that D^* is a vertex of $\mathcal{P}$ with a reflex angle. Let $\overleftrightarrow{AD^*}$ denote the line passing through points A and D^*. Furthermore, since $C^* \in \overleftrightarrow{AD^*} \cap \partial\mathcal{P}$ is visible from A (if not, angle $\angle AD^*C$ cannot be maximized), so $\overline{AC^*} \subset \mathcal{P}$ and because $\overline{AD^*} \subset \overline{CD^*}$, the segment $\overline{AD^*}$ lies within $\mathcal{P}$, confirming that A is visible by D^*.

In both cases, we have shown that point A is visible by at least one reflex vertex of $\mathcal{P}$. Since $A \in \mathcal{P}$ was arbitrary, the result holds for all interior and boundary points of $\mathcal{P}$. □

Theorem 2 (Connectivity of reflex vertices)**.** *Let $\mathcal{P}$ be a simple polygon with a finite number of vertices, and suppose that $\mathcal{P}$ contains at least one reflex vertex. Then all reflex vertices of $\mathcal{P}$ can be connected by a polyline lying entirely within $\mathcal{P}$.*

Proof. Let $\mathcal{R} = \{R_1, R_2, \ldots, R_k\}$ denote the set of all reflex vertices of $\mathcal{P}$, where $k \geq 1$ and each $R_i \in \partial\mathcal{P}$ is a vertex, i.e. a point of polygon boundary $\partial\mathcal{P}$, at which the internal angle exceeds $180°$.

Case 1: If $k = 1$, there is only one reflex vertex. It is trivially connected to itself, so the statement holds.

Case 2: Let $k \geq 2$. We aim to construct a polyline connecting all reflex vertices using segments that lie entirely within $\mathcal{P}$. Select any two distinct reflex vertices, say A and B, where $A \in \mathcal{R}$, $B \in \mathcal{R}$.

Subcase 2a: If the segment $\overline{AB} \subset \mathcal{P}$, then A and B are directly connected.

Subcase 2b: If $\overline{AB} \not\subset \mathcal{P}$, the segment is obstructed by the boundary of $\mathcal{P}$. Since $\mathcal{P}$ is a simple polygon, the obstruction must be due to other parts of the boundary, not self-intersections or holes. Following a similar argument as used in reflex vertex visibility, we consider points along the boundary that block the visibility from A to B. Among those, there exists a vertex $D \in \partial\mathcal{P}$ such that the angle $\angle ADB$ is maximized. Because the segment $\overline{AB}$ is not entirely in $\mathcal{P}$, this angle must be greater than $180°$, implying that D is a reflex vertex. Clearly, the segment $\overline{AD} \subset \mathcal{P}$, so A and D are connected. If $\overline{DB} \subset \mathcal{P}$, then D and B are connected as well, and hence A, D, and B are connected via a polyline. If $\overline{DB} \not\subset \mathcal{P}$, we repeat the same argument: select a reflex vertex $D' \in \partial\mathcal{P}$ such that $\angle DD'B$ is maximized. Again, D' is a reflex vertex, and we connect D to D' via a segment in $\mathcal{P}$. If needed, this process is repeated. Since $\mathcal{P}$ has a finite number of vertices, and each iteration introduces a new reflex vertex not previously used, this process must terminate after a finite number of steps. Eventually, a polyline connecting A to B through intermediate reflex vertices is constructed.

By repeating this process for all pairs of reflex vertices, a single polyline connecting the entire set $\mathcal{R}$ within $\mathcal{P}$ can be constructed.

Hence, all reflex vertices in $\mathcal{P}$ can be connected by a polyline lying entirely within the polygon. □

III. Upper bounds on the shortest watchman route length based on the number of reflex vertices

In this section, we study upper bounds on the length of the shortest watchman route within a simple polygon, based on the number of reflex vertices it contains. We begin by formally defining a watchman route as a path within the polygon from which every point is visible from at least one position along the path.

We then analyze several cases: polygons with no reflex vertices, one reflex vertex, and two reflex vertices, showing how these configurations lead to increasingly tighter bounds on the route length. For polygons with three or more reflex vertices, we demonstrate that the general upper bound – equal to the perimeter of the polygon – cannot be improved in all cases. This is supported by a specific construction in which the shortest watchman route is (almost) necessarily equal to the perimeter. However, we also introduce a geometric technique we call *successive dual-edge triangulation*, and show that if such a triangulation is possible for the given polygon, the upper bound on the route length can be improved significantly – specifically, to below half the perimeter.

Definition 2 (Watchman route)**.** *Let $\mathcal{P}$ be a simple polygon. A* watchman route *is a continuous path $\Gamma \subseteq \mathcal{P}$ such that for every point $A \in \mathcal{P}$, there exists a point $B \in \Gamma$ for which $\overline{AB} \subseteq \mathcal{P}$. In other words, every point of the polygon is visible from at least one point along the route.*

For a polygon with no reflex vertices or with only a single reflex vertex, the shortest watchman route is straightforward to determine, and its length admits a tight and easily computable upper bound.

Theorem 3 (Upper bound on watchman route length in polygon with no reflex vertex)**.** *Let $\mathcal{P}$ be a simple polygon with no reflex vertices. Then the shortest watchman route in $\mathcal{P}$ has length zero, and any single point within $\mathcal{P}$ (including boundary points) serves as a valid watchman route.*

Proof. Since $\mathcal{P}$ has no reflex vertices, it is convex by definition. By Lemma 2, every point in $\mathcal{P}$ is visible from every other point. Therefore, any single point $A \in \mathcal{P}$ satisfies the condition that every point in the polygon is visible from A. Hence, the constant path $\Gamma = \{A\}$ is a valid watchman route. Because this path consists of a single stationary point, its length is zero, $|\Gamma| = |\{A\}| = 0$. Thus, the upper bound on the shortest watchman route length is exactly zero, and any point in $\mathcal{P}$ realizes this bound. □

Theorem 4 (Upper bound on watchman route length in polygon with one reflex vertex)**.** *Let $\mathcal{P}$ be a simple polygon with exactly one reflex vertex R. Then the shortest watchman route in $\mathcal{P}$ has length zero, and the reflex vertex R itself serves as a valid watchman route, so $\Gamma = \{R\}$.*

Proof. By Theorem 1, every point in $\mathcal{P}$ (interior or boundary) is visible from at least one reflex vertex. Since $\mathcal{P}$ contains exactly one reflex vertex R, it follows that every point in $\mathcal{P}$

is visible from R. Thus, the constant path $\Gamma = \{R\}$ is a valid watchman route. Since it consists of a single stationary point, its length is zero, $|\Gamma| = |\{R\}| = 0$. Therefore, the upper bound on the shortest watchman route length is zero, and R realizes this bound. □

Remark 1. *While the reflex vertex R is guaranteed to serve as a valid watchman route, other points in $\mathcal{P}$ may also provide full visibility. However, R is a point that ensures this property without requiring further geometric analysis.*

We now consider the case of a simple polygon containing exactly two reflex vertices. In this setting, we show that a valid watchman route not only exists but can also be constructed with a length strictly less than half the perimeter of the polygon.

Theorem 5 (Upper bound on watchman route length in polygon with two reflex vertices)**.** *Let $\mathcal{P}$ be a simple polygon with exactly two reflex vertices, denoted R_1 and R_2. Then the shortest watchman route in $\mathcal{P}$ has length strictly less than half the perimeter of $\mathcal{P}$.*

Proof. By Theorem 1, every point in $\mathcal{P}$ is visible from at least one of the two reflex vertices R_1 or R_2. By Theorem 2, the two reflex vertices can be connected by a polyline lying entirely within $\mathcal{P}$. Since there are only two reflex vertices, the polyline reduces to the segment $\overline{R_1R_2}$. Therefore, any point visible from R_1 or R_2 is also visible from any point on the segment $\overline{R_1R_2}$, as visibility is preserved along the connecting segment. We now prove that the length of this segment is strictly less than half the perimeter of $\mathcal{P}$. Let the perimeter of $\mathcal{P}$ be denoted by $p = \text{perim}(\mathcal{P})$. Traversing from R_1 to R_2 along the boundary of $\mathcal{P}$, there are two distinct polygonal paths: one in the clockwise direction, denoted Π_1, and one in the counter-clockwise direction, denoted Π_2. Let ℓ_1 and ℓ_2 be the respective lengths of these two paths. Then,

$$|\Pi_1| + |\Pi_2| = \ell_1 + \ell_2 = p = \text{perim}(\mathcal{P}). \tag{1}$$

Since $\mathcal{P}$ is simple and R_1, R_2 lie on its boundary, the segment $\overline{R_1R_2}$ is a chord that spans across the interior of the polygon and lies entirely within $\mathcal{P}$. At least one of the polygonal (perimeter) paths Π_1 or Π_2 must contain at least one additional vertex, as a polygon $\mathcal{P}$ cannot consist of only two vertices. Without loss of generality, assume that the path Π_1 contains additional (distinct) vertices $A_1, A_2, \ldots, A_m$ for $m \geq 1$. By the triangle inequality, we have

$$\begin{array}{rcccl} |\overline{R_1R_2}| & < & |\overline{R_1A_1}| & + & |\overline{R_2A_1}|, \\ |\overline{R_2A_1}| & < & |\overline{A_1A_2}| & + & |\overline{R_2A_2}|, \\ \cdots & < & \cdots & + & \cdots, \\ |\overline{R_2A_{m-1}}| & < & |\overline{A_{m-1}A_m}| & + & |\overline{R_2A_m}|. \end{array}$$

Repeatedly substituting $|\overline{R_2A_i}|$ for $i \in \{1, 2, \ldots, m-1\}$ in each inequality with the corresponding bound from the next inequality yields

$$|\overline{R_1R_2}| < |\overline{R_1A_1}| + \sum_{i=1}^{m-1} |\overline{A_iA_{i+1}}| + |\overline{R_2A_m}| = |\Pi_1| = \ell_1.$$

The path Π_2 may contain no additional vertices, so it follows directly that $|\overline{R_1R_2}| \leq |\Pi_2| = \ell_2$. Hence, we have

$$|\overline{R_1R_2}| < \ell_1 \qquad \text{and} \qquad |\overline{R_1R_2}| \leq \ell_2,$$

and thus, $|\overline{R_1R_2}| + |\overline{R_1R_2}| = 2 \cdot |\overline{R_1R_2}| < \ell_1 + \ell_2$, so

$$|\overline{R_1R_2}| < \frac{\ell_1 + \ell_2}{2} \overset{(1)}{=} \frac{p}{2}.$$

So, the segment $\overline{R_1R_2}$ has length strictly less than half the perimeter, and it serves as a valid watchman route since every point in $\mathcal{P}$ is visible from R_1 or R_2 and thus from a point on $\overline{R_1R_2}$.

This establishes that the shortest watchman route in a polygon with two reflex vertices has length strictly less than half the polygon perimeter. □

Remark 2. *The following examples illustrate the variability in shortest watchman routes for polygons with two reflex vertices:*

(a) In a butterfly-shaped polygon, the reflex vertices form symmetrical "wings", and a centrally placed point can see the entire region. Here, the shortest watchman route Γ has length zero, consistent with Theorem 5. See Fig. 1, part (a).

(b) In contrast, a polygon with a long rectangular base and two small inward-curved reflex "horns" may require a segment connecting the reflex vertices for full visibility. In this case, Γ approaches half the perimeter, showing that the bound in Theorem 5 is tight. See Fig. 1, part (b).

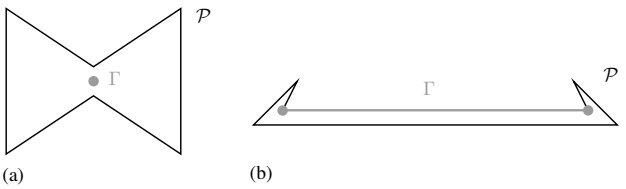

Fig. 1. Examples of polygons with two reflex vertices: (a) a butterfly-shaped polygon $\mathcal{P}$, where a single-point watchman route Γ (in grey) suffices; (b) a skinny polygon $\mathcal{P}$ with inward reflex "horns", where the shortest route Γ (in grey) approaches half the perimeter.

We now turn to the case of polygons with three or more reflex vertices. In general, the shortest watchman route in such polygons can approach the full perimeter, and we show that this upper bound cannot be improved in all cases. However, for certain polygonal structures, the application of a *successive dual-edge triangulation* – when possible – enables a significant improvement, reducing the upper bound on the route length to below half the perimeter.

Theorem 6 (Upper bound on watchman route length in polygon with three or more reflex vertices)**.** *Let $\mathcal{P}$ be a simple polygon with at least three reflex vertices. Then the length of the shortest watchman route in $\mathcal{P}$ is at most equal to*

the perimeter of $\mathcal{P}$. Moreover, this upper bound cannot be generally improved.

Proof. By Lemma 1, every point in $\mathcal{P}$ is visible from at least one point on the boundary $\partial\mathcal{P}$, so a route along the boundary guarantees full visibility. Thus, the perimeter is a valid upper bound for the shortest watchman route. To potentially improve this bound, one might consider a polyline connecting all reflex vertices, since Theorem 1 ensures that every point in $\mathcal{P}$ is visible from at least one of them. However, this polyline may still approach the perimeter length. To show this, we construct a family of polygons, see Fig. 2, with alternating convex and reflex vertices arranged as repeated triples (A_i, B_i, R_i), where R_i is reflex. Each "tooth" – a subregion formed near vertex B_i, which lies behind a reflex corner – necessitates that the watchman visit the corresponding reflex vertex R_i to maintain visibility, particularly of the B_i vertices. Connecting the reflex vertices yields a route Γ whose length closely matches the perimeter, as the segments $\overline{R_iR_{i+1}}$ are only slightly shorter than the corresponding polygonal arcs $\overline{R_iA_{i+1}B_{i+1}R_{i+1}}$. Therefore, while the perimeter is always a valid upper bound, it is asymptotically tight in general and cannot be improved without additional structural assumptions. □

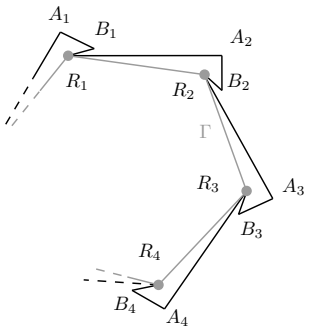

Fig. 2. A polygon constructed from repeated vertex triples (A_i, B_i, R_i), where A_i and B_i are convex and R_i is reflex. The visibility constraints force the watchman to visit each reflex vertex, resulting in a route Γ (in grey) whose length approaches the full perimeter. This demonstrates that the general upper bound cannot be improved for polygons with three or more reflex vertices.

Definition 3 (Successive dual-edge triangulation)**.** *Let $\mathcal{P}$ be a simple n-sided polygon with vertices $A_1, A_2, \ldots, A_n$. A triangulation $\mathcal{T} = \{T_1, T_2, \ldots, T_m\}$ is called a* successive dual-edge triangulation *of polygon $\mathcal{P}$ if the following conditions are satisfied,*

- *each triangle $\tau_j \in \mathcal{T}$ is formed by three vertices of $\mathcal{P}$ and lies entirely within $\mathcal{P}$;*
- *the union of all triangles in $\mathcal{T}$ exactly covers the interior of $\mathcal{P}$ without overlaps or gaps;*
- *the first triangle $\tau_1 = \triangle A_{i_1}A_{i_2}A_{i_3}$ shares at least two of its edges with the boundary $\partial\mathcal{P}$ of polygon $\mathcal{P}$;*
- *Every subsequent triangle τ_j for $j > 1$ shares one edge with the previously constructed triangle τ_{j-1}, and one or two of its edges must coincide with edges of $\partial\mathcal{P}$. Consequently, triangle τ_j has two edges not shared with $\partial\mathcal{P}$ for $j < m$, and one such edge if $j = m$.*

Fig. 3 illustrates an example of a polygon with a successive dual-edge triangulation. The triangulation proceeds from triangle $\tau_1 = \triangle A_1A_2A_3$ and continues through adjacent triangles such as $\tau_2 = \triangle A_1A_3A_{24}$ and $\tau_3 = \triangle A_3A_{23}A_{24}$, ultimately reaching $\tau_{21} = \triangle A_{12}A_{13}A_{14}$. The dotted lines indicate the internal diagonals added during the successive construction.

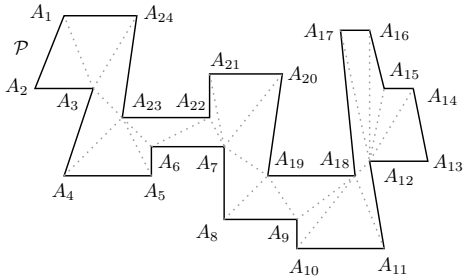

Fig. 3. An example of a polygon $\mathcal{P}$ with 24 vertices, demonstrating a successive dual-edge triangulation. Dotted lines represent internal diagonals added in a step-by-step manner. The triangulation includes, among others, the triangles $\tau_1 = \triangle A_1A_2A_3$, $\tau_2 = \triangle A_1A_3A_{24}$, $\tau_3 = \triangle A_3A_{23}A_{24}$, and continues up to $\tau_{21} = \triangle A_{12}A_{13}A_{14}$.

Theorem 7 (Upper bound improvement via successive dual-edge triangulation)**.** *Let $\mathcal{P}$ be a simple polygon with perimeter p, and suppose that $\mathcal{P}$ admits a successive dual-edge triangulation as defined in Definition 3. Then the length of the shortest watchman route in $\mathcal{P}$ is strictly less than $\frac{p}{2}$.*

Proof. Let $\mathcal{T} = \{\tau_1, \tau_2, \ldots, \tau_m\}$ be a successive dual-edge triangulation of $\mathcal{P}$, as defined in Definition 3. We construct a watchman route Γ by connecting the midpoints of edges not shared with the polygon boundary $\partial\mathcal{P}$ that appear in the triangles of $\mathcal{T}$.

For the initial triangle τ_1, we add a segment connecting the midpoint of one boundary edge to the midpoint of the edge not shared with $\partial\mathcal{P}$. For each subsequent triangle τ_j with $1 < j < m$, we add a segment connecting the midpoints of its two edges that are not shared with the boundary. For the final triangle τ_m, we again add a segment connecting the midpoint of the edge not shared with $\partial\mathcal{P}$ to the midpoint of one boundary edge. By the construction of the triangulation, these segments are connected consecutively and lie entirely within the interiors of the corresponding triangles. Since the union of all triangles in $\mathcal{T}$ covers the entire polygon $\mathcal{P}$, the resulting path Γ guarantees visibility of the entire region.

Each segment in the route corresponds to half the length of a polygon boundary edge (or two such edges in the case of τ_1 and τ_m). Since no boundary edge is used in more than one triangle, the total contribution to the route is at most the sum of half-lengths of all boundary edges. Moreover, the first and last triangles each involve two boundary edges but contribute only one midline segment, meaning that two boundary edges are not halved and do not contribute to the route.

Therefore, the total length of the constructed watchman route Γ is strictly less than half the perimeter, $|\Gamma| < \frac{p}{2}$. □

Figure 4 illustrates the construction of a watchman route

based on a successive dual-edge triangulation of a 24-vertex polygon, using midlines of interior triangles to ensure visibility.

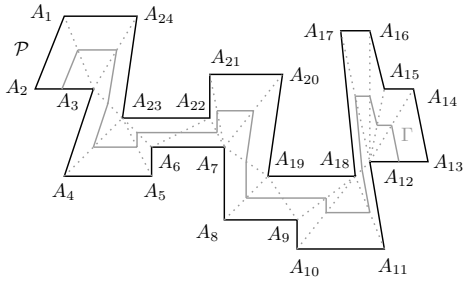

Fig. 4. A simple polygon $\mathcal{P}$ with 24 vertices, along with its successive dual-edge triangulation (indicated by dotted lines) and a watchman route Γ (shown as a bold grey polyline) constructed by connecting midpoints of selected triangle edges. The route lies entirely within the polygon and ensures full visibility while having total length strictly less than half the perimeter.

The example in Fig. 4 also illustrates the practical applicability of our approach. Although the polygon has a complex structure with 24 vertices and numerous reflex angles – resembling environments such as industrial halls or an irregular courtyard of a large private property – it admits a successive dual-edge triangulation. By connecting midpoints of interior triangle edges, we construct a watchman route that ensures full visibility and is provably shorter than half the perimeter. This method serves not only as a theoretical upper bound but also as a constructive algorithm for efficient route planning in scenarios where full geometric detail is available. Compared to strategies that rely on exhaustive perimeter traversal, our approach can substantially reduce route length. However, as visible in the figure, further local improvements may be possible in subregions without reflex vertices, suggesting opportunities for route refinement beyond the triangulation-based construction.

IV. Conclusion

We have analyzed upper bounds on the length of the shortest watchman route in simple polygons under varying structural conditions. For polygons with no reflex vertex, the upper bound is trivial: any point within the polygon suffices, and the shortest watchman route has length zero. Similarly, in polygons with a single reflex vertex, the upper bound remains zero, with the reflex vertex itself serving as a valid watchman position. In polygons with exactly two reflex vertices, we showed that the shortest watchman route can be constructed to have a length strictly less than half the polygon's perimeter, and we further demonstrated that this bound cannot be improved in general. For polygons with three or more reflex vertices, the general upper bound equals the full perimeter, and we likewise showed that this bound is tight in the worst case. However, if the polygon admits a successive dual-edge triangulation, the upper bound can be reduced to less than half the perimeter.

This triangulation not only offers a sharper theoretical bound but also enables a constructive algorithm when the full geometric structure of the polygon is known. It provides a systematic way to plan efficient watchman routes in practical scenarios. Nonetheless, we note that the triangulation-based route may not always be optimal, and local refinements – particularly in convex or reflex-free subregions – could lead to even shorter paths.

***Abstract*—We propose a statistical hypothesis test for determining whether a given integer $n \geq 2$ is prime. Under the null hypothesis H_0, we assume that n is not a prime (i.e., composite). The test operates by randomly sampling integers from the candidate divisor set $\mathcal{D} = \{2, 3, \ldots, \lfloor\sqrt{n}\rfloor\}$ and checking whether any of them divide n. If a proper divisor is found, H_0 is not rejected and n is declared composite. If no divisor is found among an initial set of k_0 samples, additional k samples are drawn, and a p-value is computed based on the probability of missing all actual divisors under H_0. This probability is calculated exactly via a hypergeometric distribution and approximated using an exponential bound. We derive a closed-form upper bound for the minimal number of trials k required to reject H_0 at a given significance level α under the conservative assumption of only one true divisor ($m = 1$). The algorithm has worst-case time complexity $\mathcal{O}(\sqrt{n})$, matching that of classical trial division, but its expected runtime is substantially lower when n has multiple divisors. The proposed test is simple, statistically interpretable, and well-suited both as an educational tool and as a lightweight probabilistic pre-check in layered primality testing pipelines.**

I. Introduction

THE problem of determining whether a given integer n is a prime number is a fundamental question in number theory and theoretical computer science. Primality testing has widespread applications in modern cryptography (such as RSA encryption [1]), secure key generation, error-correcting codes, hashing schemes, and symbolic computation. In many such contexts, fast and reliable primality tests are crucial for both correctness and efficiency [2].

A straightforward approach to primality testing is to check whether any integer in the range $\{2, 3, \ldots, n-1\}$ divides n, or, more effectively, the range of possible divisors is firstly reduced to $\{2, 3, \ldots, \lfloor\sqrt{n}\rfloor\}$ and each one is tested whether divides n. If no such divisor is found, then n is declared prime. While conceptually simple, this method becomes computationally expensive for large n, as it requires up to $\mathcal{O}(\sqrt{n})$ divisibility tests in the worst case. This naive method does not scale well for applications involving large integers or repeated primality checks.

Several more advanced primality tests have been developed, many of which rely on algebraic or number-theoretic properties. Notable examples include the following.

- The *Fermat primality test*, based on Fermat's little theorem, assumes $H_0 : n$ is prime, and checks whether $a^{n-1} \equiv 1 \pmod{n}$ for a random base a [3]. Failure to satisfy this congruence implies n is composite, but passing it does not guarantee primality due to pseudoprimes and Carmichael numbers [4].
- The *Miller–Rabin test*, a widely used probabilistic test, strengthens the Fermat test by testing additional congruences derived from factorization of $n - 1$. It is efficient and has a controllable error probability [5].
- The *AKS primality test*, a deterministic polynomial-time algorithm, decides primality unconditionally. However, it is relatively complex and not competitive in practice for large inputs [6].

While these methods are powerful, most of them assume the null hypothesis that n is prime and look for algebraic contradictions [7]. In this paper, we propose a novel *statistical hypothesis test* for primality that takes a fundamentally different approach: we assume the null hypothesis H_0 that n is

not prime, and assess how "surprising" the observed outcomes of random divisor tests are under this assumption.

Specifically, we randomly sample integers from the set $\{2, 3, \ldots, \lfloor\sqrt{n}\rfloor\}$ and test whether they divide n. If a proper divisor is found, we do not reject H_0 and declare that n is composite. If no divisor is found, we compute a p-value based on the probability of missing all actual divisors under H_0, using both exact combinatorial formulas and exponential approximations. We also derive closed-form bounds for the minimum number of integers that must be tested as potential divisors to achieve a given significance level α, and we analyze the algorithmic complexity of this test in comparison to the classical exhaustive approach.

The proposed test is simple to implement, statistically interpretable, and often requires significantly fewer checks than exhaustive search – especially when n has many proper divisors. It can serve as a practical and educational tool, or as a component in probabilistic or layered primality testing frameworks.

II. Preliminaries

This section establishes basic mathematical facts used in the formulation and justification of the proposed test.

We begin by showing that it is sufficient to restrict our attention to potential divisors of n that are less than or equal to $\lfloor\sqrt{n}\rfloor$.

Lemma 1 (Sufficiency of checking divisors up to $\sqrt{n}$)**.** *Let $n \geq 2$ be an integer. Then n is composite if and only if there exists a proper divisor d such that $2 \leq d \leq \lfloor\sqrt{n}\rfloor$.*

Proof. Let $n \geq 2$ be arbitrary. Suppose first that n is composite. Then there exist integers d, q such that $n = d \cdot q$ with $2 \leq d < n$ and $2 \leq q < n$. Without loss of generality, assume $d \leq q$. Then it is $d \cdot d \leq d \cdot q$, but $d \cdot q = n$, so $d^2 \leq d \cdot q = n$, or simply $d^2 \leq n$. Consequently, it is $d \leq \sqrt{n}$, and since $d \in \mathbb{N}$, it is also $d \leq \lfloor\sqrt{n}\rfloor$. So, d is a proper divisor of n and satisfies $2 \leq d \leq \lfloor\sqrt{n}\rfloor$, the claim follows.

Conversely, suppose there exists a proper divisor d of n such that $2 \leq d \leq \lfloor\sqrt{n}\rfloor$. Then $d \mid n$, so n is not a prime. Hence, n must be composite. □

The following lemma formalizes the intuitive fact that, when sampling from a finite population with few successes, drawing without replacement decreases the chance of obtaining no successes at all compared to drawing with replacement.

Lemma 2 (Probability of no success is lower or equal without replacement)**.** *Let $N \geq 1$ and $1 \leq M < N$ be integers representing a population of N items, M of which are marked as successes. Consider drawing k items from this population with $1 \leq k \leq N - M$. Then the probability of drawing zero successes without replacement is less than or equal to the probability of drawing zero successes with replacement.*

Proof. The probability of no success in k draws *with replacement* is given by

$$P_{\text{with}}(0) = \left(1 - \frac{M}{N}\right)^k. \tag{1}$$

The probability of no success in k draws *without replacement* is

$$P_{\text{without}}(0) = \frac{\binom{N-M}{k}}{\binom{N}{k}} = \prod_{i=0}^{k-1} \left(1 - \frac{M}{N-i}\right). \tag{2}$$

Since for each i in $0 \leq i \leq k-1$ we have $N - i \leq N$, it follows that $\frac{M}{N-i} \geq \frac{M}{N}$, and thus

$$\left(1 - \frac{M}{N-i}\right) \leq \left(1 - \frac{M}{N}\right).$$

Consequently, the product of k such terms satisfies

$$\prod_{i=0}^{k-1} \left(1 - \frac{M}{N-i}\right) \leq \prod_{i=0}^{k-1} \left(1 - \frac{M}{N}\right)$$

$$\prod_{i=0}^{k-1} \left(1 - \frac{M}{N-i}\right) \leq \left(1 - \frac{M}{N}\right)^k$$

$$P_{\text{without}}(0) \overset{(1,2)}{\leq} P_{\text{with}}(0).$$

Hence, the probability of no success is lower than or equal to when drawing without replacement. □

III. Proposed methodology

We now introduce a statistical hypothesis testing procedure for primality, based on the idea of randomly sampling potential divisors of a given integer n. The method is built upon a probabilistic interpretation of missing actual divisors under the assumption that n is composite. In addition to defining the logic, hypotheses, and operational steps of the proposed test, we derive exact and approximate expressions for the resulting p-value and analyze the algorithm's time complexity in comparison to classical exhaustive methods.

A. Test logic and procedure

Let $\mathcal{D} = \{2, 3, \ldots, \lfloor\sqrt{n}\rfloor\}$ be the set of candidate proper divisors of $n \in \mathbb{N}$ with $n \geq 2$ large. Using Lemma 1, we know that investigating potential divisors not lower than or equal to $\lfloor\sqrt{n}\rfloor$ is sufficient to determine primality. Denote its cardinality by $|\mathcal{D}|$, where obviously

$$|\mathcal{D}| = |\{2, 3, \ldots, \lfloor\sqrt{n}\rfloor\}| = \lfloor\sqrt{n}\rfloor - 1. \tag{3}$$

If n is composite, then it must have at least one divisor in $\mathcal{D}$. This observation motivates a statistical hypothesis test based on sampling elements from $\mathcal{D}$ and checking whether they divide n.

We define the null and alternative hypotheses as follows.

H_0 : n is not a prime, i.e., there exists at least one $d \in \mathcal{D}$ such that $d \mid n$.

H_1 : n is a prime, i.e., no element of $\mathcal{D}$ divides n, or also $\forall d \in \mathcal{D} : d \nmid n$.

The test consists of the following steps.

(i) We randomly select $k_0 \geq 0$ integers from the set $\mathcal{D}$ without replacement, and test each to see whether it divides n.
- If any sampled value divides n, we do not reject H_0 and declare that n is composite.
- If no divisor is found, we proceed to the next step.

(ii) We randomly select an additional $k \geq 1$ integers from the remaining elements of $\mathcal{D}$, again without replacement, and test them for divisibility.
- If any sampled value divides n, we do not reject H_0 and declare that n is composite.
- If no divisor is found, we compute the p-value under H_0.

(iii) We define the p-value as the probability that none of the k additional randomly selected integers divide n, under the assumption that n is composite and has $m \geq 1$ actual divisors in $\mathcal{D}$. Although the exact value of m is unknown in practice – if it were known, we could straightforwardly decide whether n is prime – we can still compute valid upper bounds on this probability. The smaller the p-value, the more extreme the observed outcome (i.e., absence of divisors) appears under H_0, and the stronger the evidence against the assumption that n is composite. If the p-value is less than or equal to a given significance level α, we reject H_0 and declare that n is likely a prime.

This method enables a sequential, interpretable, and probabilistically grounded test for primality. The exact and approximate computation of the p-value, as well as guidance for selecting k given a desired confidence level, are discussed in the following subsections.

B. Exact derivation of the p-value

We now derive the exact p-value used in the proposed hypothesis test. This value represents the probability of observing no divisors among a randomly selected subset of potential divisors, under the assumption that n is composite.

Let $\mathcal{D} = \{2, 3, \ldots, \lfloor\sqrt{n}\rfloor\}$ be the set of candidate proper divisors of n. Suppose – under H_0 – that n is composite and has exactly $m \geq 1$ proper divisors in $\mathcal{D}$. We assume m is fixed but unknown.

After testing an initial set of $k_0 \ll |\mathcal{D}|$ integers from $\mathcal{D}$ with no observed divisor, we draw an additional k values uniformly at random without replacement from the remaining $|\mathcal{D}| - k_0$ elements. We are interested in the probability that none of these k values divide n, conditioned on the assumption that n is composite and has m proper divisors in $\mathcal{D}$.

Let X denote the number of divisors observed in the additional k draws. Under H_0 and fixed m, the distribution of X follows the hypergeometric distribution,

$$X \sim \text{Hypergeometric}(|\mathcal{D}| - k_0, m, k).$$

Then, the p-value is defined as the probability of observing $X = 0$ under H_0,

$$p\text{-value} = \mathbb{P}(X = 0 \mid H_0) = \frac{\binom{|\mathcal{D}|-m-k_0}{k}}{\binom{|\mathcal{D}|-k_0}{k}}, \tag{4}$$

or also

$$p\text{-value} = \frac{\binom{|\mathcal{D}|-m-k_0}{k}}{\binom{|\mathcal{D}|-k_0}{k}} = \prod_{i=0}^{m-1} \frac{|\mathcal{D}| - k_0 - k - i}{|\mathcal{D}| - k_0 - i}. \tag{5}$$

This expression quantifies the likelihood of missing all true divisors in the k additional samples, under the null hypothesis that n is not a prime. Inspecting formulas (4) and particularly (5), we can see that as k increases or m increases, the p-value decreases, providing stronger evidence against H_0. Thus, the exact p-value decreases as the number of actual divisors m increases. That is, the more true divisors exist in the candidate set $\mathcal{D}$, the less likely it is that a random sample of size k misses all of them. Formally,

$$p\text{-value} = \frac{\binom{|\mathcal{D}|-m-k_0}{k}}{\binom{|\mathcal{D}|-k_0}{k}} \leq \frac{\binom{|\mathcal{D}|-1-k_0}{k}}{\binom{|\mathcal{D}|-k_0}{k}},$$

or also

$$p\text{-value} \leq \frac{\binom{|\mathcal{D}|-1-k_0}{k}}{\binom{|\mathcal{D}|-k_0}{k}} \overset{(5)}{=} 1 - \frac{k}{|\mathcal{D}| - k_0} \overset{(3)}{=} 1 - \frac{k}{\lfloor\sqrt{n}\rfloor - 1 - k_0}, \tag{6}$$

for all $m \geq 1$, where $m \leq \lfloor\sqrt{n}\rfloor - 1 - k_0 - k$. Thus, the case $m = 1$ corresponds to the worst-case scenario (i.e., highest possible p-value under H_0), and can be used as a conservative upper bound. This allows the test to remain valid even when the number of actual divisors is unknown. Also, controlling the p-value under $m = 1$ yields a conservative test.

C. Exponential approximation and upper bound of the p-value

While the exact p-value expression in (4) is combinatorially precise, it can be computationally demanding to evaluate, especially when one wishes to determine the minimal value of k for which the p-value falls below a given significance level α, particularly under the worst-case assumption $m = 1$.

To enable more practical reasoning and simplify the estimation of the required sample size k, we now derive an upper bound on the p-value using an exponential approximation.

Let's assume $k \ll |\mathcal{D}| - m - k_0$, which is natural since k is typically chosen much smaller than $|\mathcal{D}| = |\{2, 3, \ldots, \lfloor\sqrt{n}\rfloor\}| = \lfloor\sqrt{n}\rfloor - 1$. Under this assumption, sampling without replacement is numerically close to sampling with replacement. In particular, using Lemma 2, the probability of missing all m true divisors when drawing without replacement is slightly lower than when sampling with replacement, and hence,

$$p\text{-value} = \frac{\binom{|\mathcal{D}|-m-k_0}{k}}{\binom{|\mathcal{D}|-k_0}{k}} \leq \left(1 - \frac{m}{|\mathcal{D}| - k_0}\right)^k. \tag{7}$$

This bound follows from the fact that each draw without replacement strictly reduces the remaining pool size, increasing the probability of hitting a true divisor. On the other hand, when drawing with replacement, the chance of selecting a true divisor remains constant across draws. As a result, sampling with replacement underestimates the chance of detection, making the bound conservative.

D. Minimum number k of potential divisors to satisfy a given significance level

Having derived an exponential upper bound on the p-value in (7), we now invert this inequality to estimate the minimum number k of integers that need to be checked as potential divisors of n to ensure that the p-value falls below a desired significance level α, where $0 < \alpha < 1$.

Combining formulas (4) and (7) and comparing the result to the significance level α, we obtain

$$p\text{-value} = \frac{\binom{|\mathcal{D}|-m-k_0}{k}}{\binom{|\mathcal{D}|-k_0}{k}} \leq \left(1 - \frac{m}{|\mathcal{D}| - k_0}\right)^k \leq \alpha,$$

and focus on the rightmost inequality to solve for k. Taking logarithms on both sides yields

$$k \cdot \log\left(1 - \frac{m}{|\mathcal{D}| - k_0}\right) \leq \log(\alpha). \tag{8}$$

Since $\log(1-x) < 0$ for $x \in (0,1)$, inequality (8) leads to the following lower bound

$$k \geq \frac{\log(\alpha)}{\log\left(1 - \frac{m}{|\mathcal{D}|-k_0}\right)},$$

or also

$$k \overset{(3)}{\geq} \frac{\log(\alpha)}{\log\left(1 - \frac{m}{\lfloor\sqrt{n}\rfloor-1-k_0}\right)}. \tag{9}$$

This expression provides a closed-form estimate of the number of random checks needed after the initial k_0 samples in order to reject H_0 at significance level α. The most conservative bound arises under the worst-case scenario $m = 1$ (i.e., n has exactly one proper divisor in $\mathcal{D}$). Substituting $m = 1$ into (9) gives

$$k \geq \frac{\log(\alpha)}{\log\left(1 - \frac{1}{|\mathcal{D}|-k_0}\right)},$$

or also

$$k \overset{(3)}{\geq} \frac{\log(\alpha)}{\log\left(1 - \frac{1}{\lfloor\sqrt{n}\rfloor-1-k_0}\right)}. \tag{10}$$

This value of k guarantees that the p-value under H_0 does not exceed α for any possible number of actual divisors $m \geq 1$, thus ensuring a valid and conservative decision threshold even when m is unknown.

IV. Practical usage of the proposed test

The proposed statistical hypothesis test for primality can be applied in two main modes: a classical version with a precomputed sample size k, and an adaptive version that incrementally samples potential divisors until a statistically justified conclusion can be reached. We describe both approaches in this section.

A. Fixed-sample usage with conservative decision threshold

A straightforward way to use the test is to choose a fixed sample size k of candidate divisors in advance, based on a desired significance level α. This guarantees that the computed p-value will fall below α unless a divisor is found, as long as k satisfies the inequality derived in formula (10) under the worst-case assumption that n has only one proper divisor in $\mathcal{D}$ (i.e., when $m = 1$). The steps for such usage are as follows.

(i) The user first selects $k_0 \geq 0$ initial values to test.
(ii) Then, they choose k based on the exponential bound from formula (10) to ensure that the p-value will be sufficiently low if no proper divisor of n is found.
(iii) If any of the tested values divide n, the number is declared composite, since H_0 cannot be rejected.
(iv) If no divisor is found and the computed p-value is below α, then H_0 is rejected, and n is declared probably prime (at the given statistical significance level α).
(v) Otherwise (i.e., if k was chosen too small), the test may be inconclusive: no divisors of n are found in $\mathcal{D}$ (so n may be a prime), but p-value $> \alpha$, and thus H_0 (claiming that n is composite) cannot be rejected.

This fixed-sample approach is simple and deterministic, but may be inefficient if k is much larger than necessary, or inconclusive if k is too small.

B. Adaptive usage with incremental k sampling

An alternative approach is to use the test adaptively: incrementally draw one candidate divisor at a time, and terminate as soon as either a divisor is found (in which case H_0 cannot be rejected), or the p-value's upper bound, calculated using formula (6), drops below α (in which case H_0 is rejected). This version avoids the need to specify k in advance and can potentially stop earlier, depending on the observed evidence.

We present this version formally in Algorithm 1, which assumes a conservative worst-case bound with $m = 1$ and computes the p-value after each additional draw.

This variant can be seen as a probabilistic filter with automatic stopping conditions and is particularly useful when computational efficiency is critical or when n is large and sparsely divisible.

V. Algorithmic Complexity Analysis

We now analyze the computational complexity of the proposed statistical primality test. The analysis is based on the number of basic divisibility checks required to reach a statistically justified conclusion, assuming that a single test of the form $d \mid n$ takes constant time.

Algorithm 1: Adaptive statistical primality test via incremental k sampling

Input : Integer $n \geq 2$; significance level α; initial batch size $k_0 \geq 0$
Output: Decision: "n is `composite`" or "n is `probably prime` (at statistical significance α)"

Let $\mathcal{D} \leftarrow \{2, 3, \ldots, \lfloor\sqrt{n}\rfloor\}$
Randomly sample k_0 integers from $\mathcal{D}$ without replacement
foreach d *in the* k_0*-sample* **do**
  if $d \mid n$ **then**
    return do not reject $H_0 \implies n$ is `composite`
Let $\mathcal{D}' \leftarrow \mathcal{D} \setminus \{\text{already tested values}\}$
Set $k \leftarrow 0$ `// counter of post-initial checks`
while $\mathcal{D}'$ *is not empty* **do**
  Randomly select one $d \in \mathcal{D}'$ and remove it from $\mathcal{D}'$
  if $d \mid n$ **then**
    return do not reject $H_0 \implies n$ is `composite`
  $k \leftarrow k + 1$
  Compute p-value's upper bound:
  $$p\text{-value}_{\text{upper}} \overset{(6)}{\leftarrow} 1 - \frac{k}{\lfloor\sqrt{n}\rfloor - 1 - k_0}$$
  if $p\text{-value}_{upper} \leq \alpha$ **then**
    return reject $H_0 \implies n$ is `probably prime` (at statistical significance α)

A. Search space size

Let $\mathcal{D} = \{2, 3, \ldots, \lfloor\sqrt{n}\rfloor\}$ be the set of candidate proper divisors. Its cardinality satisfies

$$|\mathcal{D}| = \lfloor\sqrt{n}\rfloor - 1 = \Theta(\sqrt{n}). \tag{11}$$

A classical exhaustive trial division test checks all values in $\mathcal{D}$, resulting in a worst-case complexity of $\mathcal{O}(\sqrt{n})$.

B. Worst-case bound for the proposed test

Unlike exhaustive search, the proposed statistical test samples values randomly from $\mathcal{D}$ and stops either when a divisor is found or when the computed p-value drops below the significance threshold α.

From formula (9), the minimum number of values k to sample (after initial k_0 values) that guarantees p-value $\leq \alpha$ is

$$k_{\min} = \left\lceil \frac{\log(\alpha)}{\log\left(1 - \frac{m}{|\mathcal{D}|-k_0}\right)} \right\rceil, \tag{12}$$

where m is the number of proper divisors in $\mathcal{D}$. In the worst-case, $m = 1$, yielding

$$k_{\min} = \left\lceil \frac{\log(\alpha)}{\log\left(1 - \frac{1}{|\mathcal{D}|-k_0}\right)} \right\rceil. \tag{13}$$

Using the standard approximation $\log(1-x) \approx -x$ for small $x > 0$ coming from Taylor series, we derive the asymptotic behavior as

$$\begin{aligned}
\Theta(k_{\min}) &= \Theta\left(\left\lceil \frac{\log(\alpha)}{\log\left(1 - \frac{1}{|\mathcal{D}|-k_0}\right)} \right\rceil\right) \overset{(\dagger)}{\approx} \\
&\overset{(\dagger)}{\approx} \Theta\left(\left\lceil \frac{\log(\alpha)}{-\frac{1}{|\mathcal{D}|-k_0}} \right\rceil\right) \approx \\
&\approx \Theta\left(\lceil -\log(\alpha)(|\mathcal{D}| - k_0)\rceil\right) \approx \\
&\approx \Theta\left(\left\lceil \log\left(\frac{1}{\alpha}\right)(|\mathcal{D}| - k_0) \right\rceil\right) \overset{(11)}{\approx} \\
&\overset{(11)}{\approx} \Theta\left(\left\lceil \log\left(\frac{1}{\alpha}\right)\sqrt{n} \right\rceil\right) \approx \\
&\approx \Theta\left(\log\left(\frac{1}{\alpha}\right)\sqrt{n}\right) \approx \\
&\approx \Theta\left(\sqrt{n}\right).
\end{aligned} \tag{14}$$

Thus, the number of divisor checks required to make a valid decision at level α is bounded by $\mathcal{O}\left(\sqrt{n}\right)$.

C. Expected number of checks

In practice, the number of checks is usually smaller due to the following two stopping mechanisms,

(i) a divisor is found early, particularly when m is large;
(ii) no divisor is found, but the p-value falls below α.

Assuming uniform sampling without replacement from $\mathcal{D}$ and a uniform distribution of the m divisors within $\mathcal{D}$, there is, on average, one divisor in every $\frac{1}{m}$-fraction of the set. Therefore, we expect to check approximately $\frac{|\mathcal{D}|}{m} = \frac{\sqrt{n}-1}{m}$ potential divisors. Thus, the expected number of trials until the first divisor is observed is approximately

$$\mathbb{E}[T_{\text{hit}}] = \frac{|\mathcal{D}|}{m} = \frac{\sqrt{n}-1}{m} \approx \frac{\sqrt{n}}{m}. \tag{15}$$

Alternatively, if no divisor is found, the test terminates when $k = k_{\min}$ as given in (12). Therefore, the number of checks is bounded by

$$T(n, m) \overset{(11,12,15)}{\approx} \mathcal{O}\left(\min\left(\frac{\sqrt{n}}{m}, \frac{\log(\alpha)}{\log\left(1 - \frac{m}{\sqrt{n}}\right)}\right)\right).$$

D. Summary

The test adapts to the actual number of divisors: it runs faster when n has many proper divisors. In the extreme case $m = \Theta(\sqrt{n})$, the expected number of checks becomes constant. The worst-case complexity of $\mathcal{O}(\log(1/\alpha) \cdot \sqrt{n})$ arises only when $m = 1$. This adaptivity makes the proposed method significantly more efficient in practice compared to exhaustive search, which always requires $\Theta(\sqrt{n})$ steps.

VI. Illustration of p-value behavior for varying number of divisors

To better understand the behavior of the p-value in the proposed test, we analyze how it changes as a function of the number of random trials k for different values of m, the number of actual proper divisors in the candidate set $\mathcal{D} = 2, 3, \ldots, \lfloor\sqrt{n}\rfloor$. Fig. 1 illustrates this relationship for $n = 10007$, where $|\mathcal{D}| = \lfloor\sqrt{10007}\rfloor - 1 = 99$.

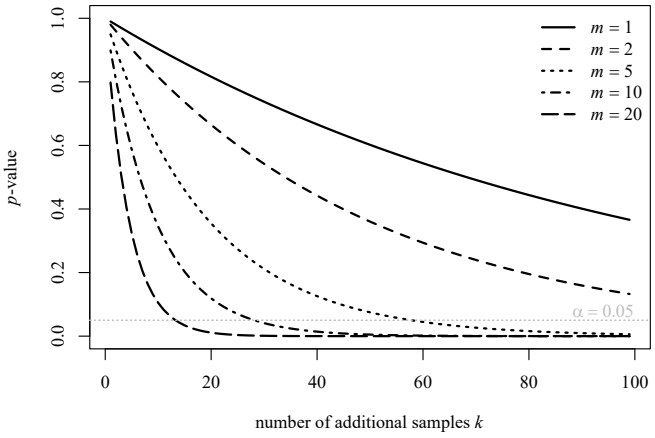

Fig. 1. Decay of the p-value with increasing number k of additionally sampled candidate divisors from $\mathcal{D}$ for various numbers m of true divisors under H_0. The horizontal dotted line marks the significance level $\alpha = 0.05$. Each curve shows the upper bound $\left(1 - \frac{m}{|\mathcal{D}|-k_0}\right)^k$ on the p-value, highlighting how the test becomes more decisive as either m or k increases.

Table I shows corresponding values of the minimum number $k_{\min}$ of samples required to reduce the p-value below the significance threshold $\alpha = 0.05$, based on the exponential bound $\left(1 - \frac{m}{|\mathcal{D}|-k_0}\right)^k$ from formula (7). This bound is conservative, especially for small values of m, and in some cases leads to estimates $k_{\min}$ exceeding the size of the candidate set, i.e., $k_{\min} > \lfloor\sqrt{n}\rfloor - 1$. This inefficiency illustrates that the bound is useful for providing safe, but not necessarily tight, thresholds.

TABLE I
Minimum number of random divisor checks $k_{\min}$ to reject H_0 at significance level $\alpha = 0.05$, for various numbers of actual divisors m, using the exponential bound with $n = 10007$, where $|\mathcal{D}| = \lfloor\sqrt{10007}\rfloor - 1 = 99$.

m	$k_{\min}$ such that p-value ≤ 0.05	is $k_{\min} \leq \lfloor\sqrt{n}\rfloor - 1$?
1	297	no
2	148	no
5	59	yes
10	30	yes
20	15	yes
40	8	yes
75	4	yes

Obviously, the p-value decreases exponentially with k, and this decay is faster when the number of divisors m increases. This demonstrates the adaptivity of the proposed method: when a composite number has more divisors, fewer random checks are typically needed to either discover one or to obtain a statistically significant p-value.

VII. Conclusion

We have proposed and rigorously analyzed a statistical hypothesis test for assessing the primality of a given integer n. The test is based on randomly sampling potential divisors from the set $\mathcal{D} = \{2, 3, \ldots, \lfloor\sqrt{n}\rfloor\}$ and computing a p-value under the null hypothesis H_0 that n is composite. If no divisor is found and the p-value falls below a given significance level α, the test rejects H_0, suggesting that n is likely a prime.

We derived both exact and exponential approximations of the p-value and provided a closed-form expression for the minimum number of additional checks k needed to guarantee a statistically valid conclusion. The exponential upper bound for the p-value decreases as either the number of actual divisors m or the number of random trials k increases. The test allows for an optional initial sample of $k_0 \geq 0$ values, which can be used for early termination or warming up the process, and is fully accounted for in the p-value computations and bounds. Moreover, we analyzed the worst-case and expected algorithmic complexity of the test, showing that the method is adaptive: it performs significantly better when the tested number has more divisors.

Compared to classical exhaustive methods, the proposed approach offers some practical advantages: it is statistically interpretable, simple to implement, and can terminate early in favorable cases. While the worst-case complexity remains $\mathcal{O}(\sqrt{n})$, the average-case performance is often much better, especially for composite numbers.

This paper provides a theoretical introduction to the proposed statistical primality test. Practical evaluations, methodological improvements, simulations, and comparisons with existing methods are part of ongoing work and will be addressed in future research.

***Abstract*—A common way for chess players to practice tactical awareness is to solve chess puzzles, consisting of an initial position and a sequence of moves to achieve a winning position. This practice is more effective when puzzles are matched to the player's skill level. In this work, we present an approach for estimating the difficulty of a chess puzzle using only the initial position and the sequence of correct moves. Our approach uses a fine-tuned modification of the Maia-2 model combined with a set of hand-crafted features and features extracted from chess engines such as Leela Chess Zero and Stockfish. All of these features are then used as input to a gradient boosted decision tree model that predicts the final rating of the puzzle. We applied our approach to the *FedCSIS 2025 Challenge on Predicting Chess Puzzle Difficulty Part 2*, where it achieved first place.**

***Index Terms*—chess, chess puzzle, machine learning, transformer, neural network, gradient boosted decision tree**

I. Introduction

SOLVING chess puzzles, where a player is presented a specific chess position and needs to find a sequence of moves leading to a winning advantage, is an important part of any chess player's training routine. Solving puzzles allows the player to learn important tactical patterns much more quickly compared to just playing chess games, since a puzzle always contains a critical position, and similar patterns can thus be practiced far more frequently than they would appear in actual games.

Chess puzzles are widely available on online platforms [1], [2], [3] and may be automatically created by analyzing online games and finding critical positions where a specific sequence of moves leads to a winning position for one side [4]. While the creation of puzzles can be automated, the process of determining the difficulty remains mostly dependent on human input. The puzzle difficulty is usually estimated by having a number of different people attempt the puzzle and measuring the success rate. This information can then be used to calculate the puzzle rating, using for instance the Elo [5] or Glicko-2 [6] algorithm. The drawback of this process is that determining the puzzle rating accurately is quite time-consuming, requiring the input of multiple human solvers. Automating the process of determining the difficulty would allow newly included puzzles to be immediately shown to players of suitable strength, which would improve the puzzle solving experience.

Fig. 1. An example of a chess puzzle. The opponent (black pieces), just made the move `Qd8xd4`, capturing a pawn (red circle), leaving the black queen undefended. Thus the puzzle solver (white pieces) can make the move `Bd3xb5`, capturing the black pawn (green arrow) and checking the black king (green circle). After the opponent captures the bishop (red arrow) to escape check, the white queen captures the black queen with the move `Qd1xd4` (blue arrow). In the final position black is without a queen while white has only lost a bishop, leaving white with a decisive material advantage.

The FedCSIS 2025 Challenge on Predicting Chess Puzzle Difficulty Part 2 [7] is centered around automating the task of predicting the difficulty of chess puzzles using only the initial position and the sequence of moves, without the need for repeated human solving. The competition is a follow-up to the IEEE Big Data Cup 2024 Challenge on Predicting Chess Puzzle Difficulty [8]. The second edition of the competition introduces more chess puzzles in the training dataset. Additionally, the training data features also include success probabilities computed using the Maia-2 [9] model.

In this work, we introduce an approach for estimating the

difficulty of chess puzzles which adapts and fine-tunes Maia-2, originally trained to predict the probability of humans making certain moves in a specific position. We also utilize ideas from the approaches of the first [10] and second place [11] teams from the first edition of the competition, as well as extend our own previous method [12] which placed third. Our new approach was applied to the second edition of the challenge, achieving first place.

II. Related work

While the estimation of chess puzzle difficulty had been analyzed on a small scale previously [13], [14], the main body of work related to the problem of predicting the difficulty of chess puzzles is due to the IEEE Big Data Cup 2024 Challenge on Predicting Chess Puzzle Difficulty [8], which we later refer to as the *first edition* of the competition. The top performing teams of the first edition used the following methods:

1) The winning team [10] used multiple Maia-1 [15] and Leela Chess Zero [16] models to encode the chess positions in a puzzle into vectors and then used an RNN to combine these position embeddings into one puzzle embedding, which was used to predict the puzzle rating.
2) The second place team [11] used a CNN architecture similar to Leela Chess Zero to encode each position in the puzzle and trained the model from scratch to predict the rating. The model also predicted the next move in the position and used the loss of that prediction as an additional feature when predicting the rating.
3) The third place team [12] (our submission to the first edition) used hand-crafted features and features extracted from chess engines, as well as a rating predicted by a residual neural network as input to a LightGBM [17] model to predict the puzzle rating.

Other approaches used in the first edition of the competition include a RankNet-based deep neural network model [18], a Transformer-based approach using a modified version of ChessFormer [19] and other CNN-based solutions [20], [21].

III. Chess Puzzle Challenge Dataset

The dataset of chess puzzles available for training provided by the FedCSIS 2025 Challenge on Predicting Chess Puzzle Difficulty Part 2 [7] consists of approximately 4.55 million chess puzzles obtained from the Lichess open database [22]. An example puzzle can be seen in Figure 1. Each puzzle in the training dataset contains an initial position given in FEN notation [23] and the sequence of the correct moves of the puzzle in long algebraic notation [24]. Additionally, the training dataset contains metadata such as rating deviation, attempt count, popularity, tactical themes, and opening info. A new addition to the second edition of the competition is the inclusion of 22 success probability predictions, describing how likely humans of varying playing strength are to correctly solve the puzzle. The target variable is the rating of the puzzle, determined by repeated solving of the puzzle in the Lichess trainer [1]. The distribution of ratings is shown in Figure 2.

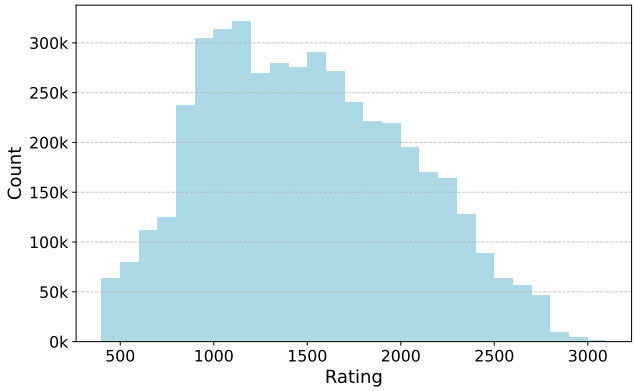

Fig. 2. The distribution of the puzzle ratings in the training set. A large number of puzzles have a rating near the initial puzzle rating of 1500, with another visible concentration of puzzles around 1000.

The competition also provides a public test set containing 2,235 puzzles. The public test set does not contain any of the metadata that is available for the training set — it only has the initial position, the solution moves as well as the predicted human success probabilities. The goal of the competition is to predict accurate ratings for the public test set. The public test set is further split into a holdout set used to compute the preliminary score, and a final test set, used for the final competition ranking.

IV. Approach

Our approach is based mainly on the following observation: The first place solution [10] in the first edition used pre-trained chess engine models to extract position embeddings but did not fine-tune the engine model weights. The second place solution [11], on the other hand, used the model architecture of a chess engine model and trained it end-to-end, but did not initialize the model weights with any pre-trained model. Thus, we wanted to analyze whether these two methods could be combined by both training a model end-to-end and initializing the model with pre-trained weights. The reason why no team did this in the first edition of the competition is likely related to the difficulty of extracting the trained weights from Maia-1 and Leela Chess Zero models for use in a commonly used deep learning library like PyTorch.

Shortly after the first edition of the competition finished, the Maia-2 [9] model was released. This model turned out to be a great candidate to both initialize a model with and to fine-tune, since the model code and weights are freely available, and the model is written in PyTorch, making it easy to modify and extend. Thus, we decided to use the Maia-2 model as the backbone of our approach.

We also wanted to verify whether the use of hand-crafted features and features extracted from other chess engines is still useful even when fine-tuning a deep learning model to predict the ratings, so we decided also to include and extend the features used in our third place solution for the first edition [12].

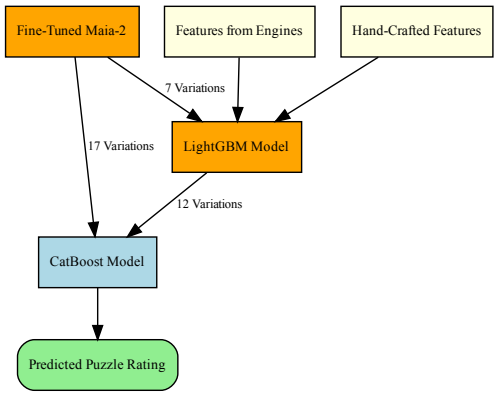

Fig. 3. Flowchart showing the basic structure of the method to predict the Glicko-2 rating for chess puzzles. Ratings are first predicted by a fine-tuned Maia-2 model as well as a LightGBM model. Multiple variations of both models are trained, and the predicted ratings are given as input to a final CatBoost model that ensembles the ratings into a final prediction. The different models and features are described in detail in Section IV.

An overview of our approach is shown in Figure 3. We first train a fine-tuned Maia-2 model to predict the rating of puzzles, and use this rating as well as hand-crafted and chess engine features as input to a LightGBM model to predict the puzzle rating. Finally, we use ratings predicted by multiple variants of the fine-tuned Maia-2 and the LightGBM model as input to a final CatBoost ensemble, which then predicts the final puzzle rating. For the predictions submitted to the competition, we additionally perform a linear scaling to account for the differences in the rating distribution between the training set and the public test set.

A. Fine-Tuned Maia-2

1) Architecture: Maia-2 [9] is a model trained to predict the probability of a human making a specific move in a certain chess position. Maia-2 consists of a ResNet backbone that embeds a position to a set of patch embeddings, and of a Transformer model that takes the patch embeddings as input and outputs a *position embedding* encoding relevant information about the board state. The Transformer layers incorporate skill-aware attention which allows the model to see information about the skill level of the players when predicting the next move. The position embedding is used as input to three different heads: The *move head* predicting the probability of each possible next move, the *auxiliary head* predicting, among others, the legal moves and move-specific information such as whether the move is a check or capture, and the *value head* predicting the result of the game.

An overview of how we use the Maia-2 model is shown in Figure 4. We utilize the model for predicting the puzzle rating as follows: First, for each position in the puzzle (up to and including the fifth move), we compute the position embedding using the ResNet backbone and the Transformer model. We inject a constant skill value to the Transformer model since puzzle solvers are unknown.

Additionally, for each position in the puzzle, we compute the move and auxiliary predictions by passing the position embedding to the heads. Then, we compute the cross-entropy loss of these using the ground truth (which is known because all the puzzle moves are available), following how move predictions were used in [11]. Finally, we embed the correct move in the position using a two-layer MLP. The final embedding of the position is a concatenation of the Maia-2 position embedding and the move and auxiliary prediction losses, as well as the correct move embedding. We also experimented with using the Maia-2 value head here, but it did not improve the rating predictions, so we ultimately left it out.

To obtain a single embedding for an entire puzzle, we pass the final position embedding sequence into a bi-directional GRU model (with two layers and a hidden size of 512) to obtain a single 1024-dimensional embedding for the entire puzzle, similarly as in [10]. The main difference from their solution is that we use the Maia-2 model instead of Maia-1 and Leela, and we also fine-tune the entire model instead of keeping the position embedder frozen.

The final predicted rating is obtained by passing the puzzle embedding given by the GRU to a final linear layer. This layer predicts the rating of the puzzle, normalized to zero mean and unit variance.

As an additional variant, we also include a set of other features as input to the final linear layer. These features are a subset of the ones used as input to the LightGBM model (described in section IV-B). These features are embedded using a residual neural network, and the output embedding is concatenated with the puzzle embedding and given as input to the final linear layer.

2) Training: The Maia-2 model is implemented using *PyTorch* [25], so we also implement our additional layers using PyTorch and use it to train the model. We initialize the Maia-2 model with the pre-trained rapid or blitz weights. The entire model is trained end-to-end, meaning that also the pre-trained Maia-2 layers change during training. We use mean squared error (MSE) loss for the predicted rating, and we additionally also compute the cross-entropy loss for the move and auxiliary predictions from Maia-2 to keep them from diverging, with the cross-entropy losses having significantly lower weight than the rating MSE loss. We also weigh the loss of each puzzle by the inverse of its rating deviation to prevent the model from paying too much attention to puzzles that have a very uncertain rating.

We use the Schedule-Free AdamW optimizer [26] to train our model, which allows us to use a fixed learning rate for the entire training. The model is trained using approximately 4.1 million puzzles. We use a batch size of 128 puzzles and evaluate the model every 5,000 iterations. The training is stopped when the validation loss hasn't improved for three consecutive evaluations.

A single NVIDIA RTX 4070 GPU is used to train the model, and we run the training using bfloat16 automatic mixed

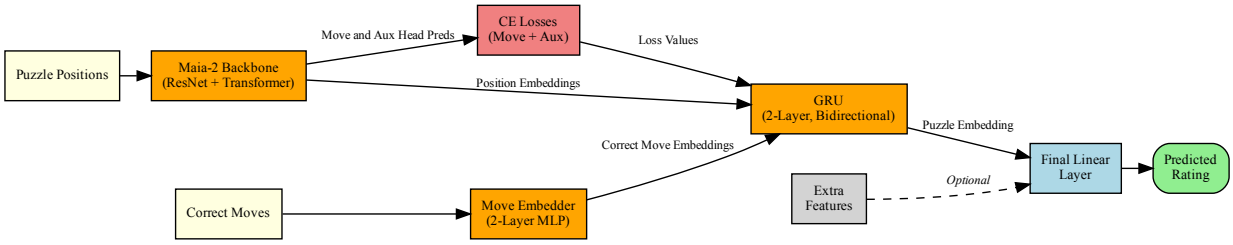

Fig. 4. Diagram describing how the fine-tuned and customized Maia-2 model for predicting puzzle ratings. First, each position in the puzzle is encoded using the Maia-2 backbone. Then, the predictions of the move and auxiliary heads are used to compute a loss using the ground-truth values. Additionally the correct move in the position is embedded using an MLP. The position embeddings, loss values and move embeddings of a puzzle are then combined into a single puzzle embedding using a GRU model. The predicted rating is then computed using a final linear layer, which also may obtain as input additional hand-crafted or engine features. The model is trained end-to-end with all layers being trained or fine-tuned simultaneously. For more details, see Section IV-A.

precision to speed up the training and reduce memory usage. A single training run takes about two hours. Multiple variants of the model are trained with different hyperparameters (dropout, weight decay, learning rate, loss weights) and slightly different model configurations and weights (Maia-2 rapid or blitz).

B. LightGBM model

The next step in our rating prediction pipeline is training a gradient boosted decision tree model using *LightGBM* [17] that receives as inputs three different types of features:

1) Ratings predicted by the fine-tuned Maia-2 model, as described above in section IV-A
2) Features extracted from various chess engines such as Leela, Maia-1 and Stockfish
3) Hand-crafted features created from the initial position and the solution moves

The LightGBM model is trained with approximately 4.4 million puzzles using MSE loss. The training is stopped if the validation loss doesn't improve in 50 iterations. Multiple different versions of the model are trained using slightly different feature sets and hyperparameters (like different dropout and bagging factor). We chose to use LightGBM due to its fast training speed when using a large number of features and puzzles. In the final ensemble we instead used CatBoost [27], which is slower but results in a slightly more accurate model.

1) Ratings predicted by fine-tuned Maia-2: The LightGBM model uses as input the rating predicted by seven different versions of the fine-tuned Maia-2 model. For six of these versions we trained the Maia-2 model multiple times using different folds, and then predicted the rating for the training set with the model where the fold was not used for training, following our previous approach [12]. We also included the rating of one fine-tuned Maia-2 model that was trained only once due to time constraints, meaning the LightGBM model retrieved ratings predicted on the train set of the Maia-2 model. We added Gaussian noise to these ratings to make sure the model didn't overfit to this specific feature.

2) Features extracted from chess engines: The main feature extracted from chess engines is the probability that the correct puzzle move is made in different positions during the puzzle, as in [12]. The probability is computed for the first five player and opponent moves, with a default value of 1.0 being used if the puzzle is shorter than five moves. We compute the probability using the engine evaluation function only, without any search being performed. This feature is obtained using the following models:

- All Maia-1 models (1100, 1200, ..., 1900) [15]
- Leela "best nets" T1-256x10 and T1-512x15x8h [28]
- BadGyal-8, GoodGyal-5, GoodGyal-7 and TinyGyal-8 [29]
- Additional Leela networks LD2, J104.1-30, T73_RL.2-10000 and J64-180 [30]

We also use Stockfish 17 [31] to extract the material, positional, and total evaluations according to its evaluation function. Stockfish is also used to compute the final centipawn value after the last move of the puzzle, as well as to compute whether the correct move is found on a certain depth. For this purpose we used depths 1 through 100,000 in powers of ten.

Additionally we use the success probabilities provided by the competition organizers in the original dataset.

3) Hand-crafted features: We extract three feature families using *python-chess* [32] and *pandas* [33]: puzzle-level basic features, move/position features, and tactical features.

a) Puzzle-level basic features: These features are computed once per puzzle: solution length; is the player white?; Lichess themes from the puzzle tagger [4]; initial piece placement (board array) before the first player move.

b) Move/position features: These features are computed for the first five moves by each side, and are listed in Table I.

c) Tactical features: Features indicating tactical motifs, described in Table II. Unless noted, computed for the first five moves by each side.

C. Final CatBoost ensemble

To obtain the final predicted rating, we train a gradient boosted tree model using *CatBoost* [27] that receives as input

TABLE I
MOVE- AND POSITION-SPECIFIC FEATURES

Category	Features
Position state	# legal moves; in-check flag
Forcing moves	# checking moves / pieces; # capturing moves / pieces; captures winning material; materially safe captures
Correct move	Check flag; moving piece mobility; captures undefended piece; material gain; piece type; from/to column and row
Material and structure	Side material and material diff.; mobility by piece type; undefended pieces (# and value); attackers/defenders near each king
Pawn structure	Pawn islands; doubled / isolated / passed pawns
Other	Over-/under-defended pieces; castling status (both sides); castling/en passant flags

TABLE II
TACTICAL FEATURES

Feature	Notes
Accepted sacrifice	Correct move accepts a sacrifice
Interposition defence	Correct move blocks a check
Mate threat	First five *player* moves only; correct move poses a mate threat, detected using Stockfish assuming opponent skips a turn
Recapture	First five *player* moves only; correct move recaptures previously lost piece

the predictions of 17 different versions of the fine-tuned Maia-2 model, as well as 12 different versions of the LightGBM model. Additionally, the model uses as input the number of moves in the puzzle solution and the probability of making the correct puzzle move according to the following Leela nets: T3-512x15x16h [30], T82-768x15x24h and BT3-768x15x24h [28]. We include these probabilities in this late stage instead of in the larger LightGBM model due to the computation of the probabilities with these models being quite slow.

The CatBoost model is trained using 100,000 puzzles, with MSE loss. We note that using a gradient boosted tree model for ensembling gives slightly better results compared to using just a simple average or learned weighted average.

D. Scaling of predicted ratings

Since the public test set puzzles have on average fewer attempts than the ones in the training set [8], they are also likely to have fewer extremely high and low ratings, due to puzzles with such extreme true ratings requiring many solving attempts to converge. To account for this difference, we follow the method used in [11] and apply linear scaling to align the predicted ratings more closely with the estimated mean $c = 1600$ of the test set distribution using the formula

$$\hat{y}_{scaled} = c + g * (\hat{y} - c),$$

where g is the scaling factor. The mean value was found by weighing our own test set (extracted from the training data) to better match the distribution of the public test set (similarly to how we weighed our own validation set in the first edition [12]). The raw predicted ratings we used for the final submissions in the FedCSIS 2025 competition all came from the same final CatBoost ensemble. We then applied the scaling using factors g of 0.7, 0.8 and 0.9 to obtain three different variations of the ratings.

V. RESULTS

TABLE III
FINAL FEDCSIS 2025 COMPETITION RESULTS (TOP 5 TEAMS OUT OF 31)

Rank	Prelim. MSE	*Final MSE*	Rel. diff.
1	55,382	*52,311*	-
2	58,186	*54,377*	+3.9%
3	58,892	*55,938*	+6.9%
4	61,524	*57,492*	+9.9%
5	67,062	*61,045*	+17%

In the FedCSIS 2025 Challenge, the predicted puzzle ratings are evaluated on the public test set by comparing the predicted puzzle ratings to the ground truth ratings and computing the MSE loss. Our method achieved a preliminary score of 55,382, and a final score of 52,311, resulting in first place in the final results (as well as on the preliminary leaderboard). The scores of the top five teams (out of a total of 31 teams with a final score) are shown in Table III. The final score of the second place team is 3.9% higher than our score, and all of the top four teams are within 10% of our score. This indicates that the second edition of the competition was much closer than the first edition, where the difference between the first and second place teams was around 15% [8].

TABLE IV
RESULTS OF DIFFERENT VARIATIONS OF OUR MODEL

Model	Test set MSE	Rel. diff.
Final CatBoost ensemble	35,400	-
LightGBM (all feats)	36,400	+2.9%
LightGBM w/o hand-crafted feats	36,800	+4.1%
LightGBM w/o engine feats	37,300	+5.4%
Fine-tuned Maia-2 (with extra feats)	38,900	+10%
Fine-tuned Maia-2 (w/o extra feats)	40,800	+15%
LightGBM w/o fine-tuned Maia-2	52,600	+49%

We also performed an ablation study to verify the impact of different parts of our solution, using a test set of 50,000 puzzles extracted randomly from competition training set. The results of the ablation study are shown in Table IV. From the results we can see that the fine-tuned Maia-2 model is critical to our solution, since the LightGBM model without these ratings has an MSE that is 49% higher than our final solution. We also see that the final CatBoost ensemble is useful, since without it the loss is 2.9% higher.

The ablation study also confirms that both the chess engine features and hand-crafted features are still useful. Additionally we see that even though the fine-tuned Maia-2 model is critical for our model, by itself it performs around 15% worse than

our final ensemble, which would place it close to the fifth place finisher, assuming the results transfer to the competition public test set.

VI. Conclusion

In this work, we described an approach for predicting the difficulty of a chess puzzle based on fine-tuning the Maia-2 model and combining the predicted rating from this model with hand-crafted features as well as features extracted from chess engines. We showed that fine-tuning the pre-trained Maia-2 model achieved strong performance for the puzzle rating prediction by itself, and that hand-crafted and chess engine features are still a useful addition to this deep learning-based method. We demonstrated the effectiveness of the method, achieving first place in the FedCSIS 2025 Challenge on Predicting Chess Puzzle Difficulty.

***Abstract*—Accurately estimating the difficulty of the chess puzzle is important for adaptive training systems, personalized recommendations, and large-scale content curation. Unlike engine evaluations optimized for perfect play, this task involves modeling human-perceived solving difficulty, typically expressed by Glicko-2 ratings. We present a multi-stage framework developed for the FedCSIS 2025 Challenge. The method trains four rating-banded neural regression models in different Elo ranges to capture localized difficulty patterns and reduce bias from unbalanced data. Their predictions are combined with statistical attributes, including success probabilities, failure distributions, and solution length, through a feature-based regression stage to improve cross-range generalization. A final calibration step adjusts the output to statistically plausible rating levels, mitigating systematic prediction biases without adding computational complexity. An additional mask selection procedure was explored as part of the competition extension to identify 10% of the puzzles that are most likely to benefit from the refined evaluation. The proposed solution ranked 5th on the public leaderboard and 6th in the final standings. These results demonstrate that a lightweight and interpretable regression pipeline can achieve competitive precision in modeling human-perceived chess puzzle difficulty.**

***Index Terms*—Chess puzzle difficulty prediction, Multi-stage framework, Regression, Calibration, Mask selection**

I. Introduction

PREDICTING the difficulty of chess puzzles is a challenging but important problem that integrates machine learning, human cognition, and game theory. The difficulty of the puzzle on platforms such as Lichess[1] is expressed as a Glicko-2 rating[2] that dynamically updates based on the success or failure of the players. Automating this rating prediction accelerates puzzle curation, enables personalized recommendations for players of varying skill levels, and provides insight into which tactical or strategic motifs challenge human solvers the most. This is also the goal of the FedCSIS 2025 Challenge [1] organized on the KnowledgePit platform[3].

A. Related Work

Research on puzzle difficulty prediction has advanced considerably in recent years. Early approaches used handcrafted features with classical machine learning: Björkqvist [2] modeled puzzle "puzzlingness" via positional and tactical indicators, and Rafaralahy [3] applied pairwise learning-to-rank to capture ordinal relations between puzzles. With the rise of deep learning, sequence-based and representation-learning methods became prominent. Ruta et al. [4] applied convolutional neural networks (CNNs) to predict puzzle ratings directly from move sequences, Miłosz and Kapusta [5] proposed Transformer-based models treating puzzles as sequences, and Omori and Tadepalli [6] developed a CNN-LSTM model incorporating moves and timing to jointly estimate puzzle and player ratings.

The IEEE BigData Cup 2024 [7] demonstrated the success of hybrid pipelines that integrate statistical features and learned representations. Woodruff et al. [8] trained neural models with rating-based features, while Schütt et al. [9] introduced a human-problem-solving-inspired architecture combining move distribution analysis and cognitive heuristics.

B. Motivation and Contributions

Despite these advances, two key challenges remain. First, models trained across broad rating ranges often exhibit systematic biases, overestimating simple puzzles and underestimating long tactical sequences due to global error optimization. Second, while models trained on different rating distributions provide complementary perspectives, effectively integrating them to improve generalization is non-trivial.

To address these challenges, we propose a multi-stage framework that first trains four independent neural models on separate rating ranges to capture localized difficulty patterns and reduce bias caused by imbalanced data. Their predictions are then combined with statistical attributes, including success probabilities, failure distributions, and solution length, in a feature-based regression stage to improve cross-range generalization. A final calibration step adjusts the outputs toward statistically plausible rating levels, reducing systematic prediction biases without increasing computational complexity. Additionally, the framework was extended with a mask selection procedure to identify the 10% of puzzles most likely to benefit from refined evaluation, as required in the competition extension.

Our method ranked 5th on the public leaderboard and 6th in the final standings of the FedCSIS 2025 Challenge, demonstrating that a lightweight, interpretable pipeline can achieve competitive accuracy in modeling human-perceived chess puzzle difficulty.

The remainder of this paper is organized as follows. Section II briefly describes the challenge, dataset, and evaluation metric. Section III presents the methodology. Section IV discusses the mask selection task. Section V shows xperimental results. Finally, Section VI concludes the paper and outlines future directions.

II. FEDCSIS 2025 CHALLENGE

This competition continues the established task from IEEE Big Data 2024 [7], asking participants to predict the perceived difficulty of chess puzzles based on puzzle configurations and human solving statistics. The objective remains to estimate the Glicko-2 rating assigned to each puzzle, which reflects the likelihood that players of various skill levels can solve it, using only board position and solution moves.

A. Dataset

The official dataset consists of a large annotated training set and a separate unlabeled test set. The training set contains approximately 4.56 million puzzles, each labeled with a human-derived difficulty rating, while the test set includes 2,235 puzzles sharing the same feature structure but without ratings.

Each puzzle is described by multiple feature groups derived from both game records and engine analysis:

- Core identifiers: a unique puzzle ID, board state in Forsyth–Edwards Notation (FEN)[4], and the solution sequence in Portable Game Notation (PGN)[5].
- Human performance indicators (training only): Glicko-2 rating, rating deviation, popularity, and the number of attempts.
- Contextual metadata (training only): puzzle themes, associated game URLs, and opening tags.
- Engine-based success statistics: estimated success probabilities for players at different Elo levels, provided separately for rapid and blitz time controls (10 columns each), approximating human solving likelihood across skill tiers.

Puzzle ratings range from about 400 (trivial tactics) to over 3000 Elo (complex master-level combinations). The distribution is heavily imbalanced, with most puzzles clustered around intermediate difficulty. No official validation set is provided; participants typically constructed small internal validation splits for hyperparameter tuning and model selection.

A training sample (puzzle) of the initial state of the chessboard decoded by FEN and the rating is illustrated in Figure 1.

B. Evaluation Protocol

Predictions are evaluated using the mean squared error (MSE) between the predicted and actual ratings:

$$\text{MSE} = \frac{1}{N}\sum_{i=1}^{N}(\hat{y}_i - y_i)^2,$$

[4]https://en.wikipedia.org/wiki/ForsythEdwards_Notation
[5]https://en.wikipedia.org/wiki/Portable_Game_Notation

Figure 1. Example of the chess puzzle Rating 1902: initial state of the chessboard decoded by FEN: "r6k/pp2r2p/4Rp1Q/3p4/8/1N1P2R1/PqP2bPP/7K b - - 0 24".

where N is the number of puzzles in the test set. The test set is partitioned internally, with 10% used for provisional public leaderboard updates and the remaining 90% for final ranking. Only the public subset is visible during the competition.

C. Optional Mask Extension

An additional post-evaluation extension allows participants to submit a binary mask marking 10% of test puzzles predicted to have the highest potential benefit from re-evaluation. For these selected puzzles, predictions are replaced by ground-truth ratings, and MSE is recalculated. While this mask-based scoring does not affect the main leaderboard, it serves as an auxiliary measure of a model's ability to recognize cases where its predictions are less reliable.

III. METHODS

Our approach employs a multi-stage pipeline that integrates localized learning of puzzle difficulty with statistical adjustment to correct systematic biases. The design philosophy stems from two key observations. First, the relationship between puzzle features—such as tactical motifs, material configurations, and success probabilities—and human-perceived difficulty is not uniform across the rating spectrum; a single global model tends to bias its predictions toward the overrepresented mid-range puzzles. Second, models trained purely to minimize global mean squared error often fail to respect structural regularities observed in human solving behavior, particularly for very easy or very hard puzzles. We therefore decompose the task into specialized components: localized rating-band models to better learn within-range patterns, a meta-learning step to integrate complementary predictions and additional structural attributes, a calibration step to align outputs with statistical difficulty indicators, and a final averaging procedure to stabilize predictions.

Figure 2 outlines this four-stage pipeline. The first stage trains multiple models specialized for different rating bands to disentangle the heterogeneous difficulty distribution. In the second stage, their predictions are combined with auxiliary

features using tree-based meta-regressors trained on a fixed validation subset. The third stage applies a statistical calibration that shifts the predictions toward historically plausible difficulty levels by exploiting failure distributions and their higher-order characteristics. Finally, the calibrated regressors are averaged to reduce variance and further improve generalization.

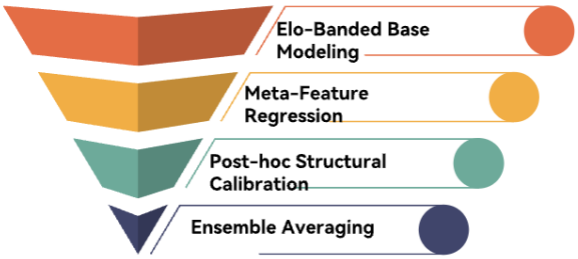

Figure 2. Overview of the proposed prediction pipeline.

A. Rating-Banded Base Models

The first stage employs a rating-banded learning strategy to address heterogeneous solving patterns across Elo levels. Lower-rated puzzles, often simple mate-in-one or basic forks, exhibit solving distributions heavily concentrated in low-skill buckets, whereas higher-rated puzzles show sparse but sharper failure transitions at advanced skill levels. A single global regressor tends to minimize global loss by fitting the over-represented mid-range, which leads to biased underestimation for high-rated puzzles. Inspired by the band-wise modeling idea explored in prior work [8], we explicitly partition the data into four difficulty bands and train separate regressors for each band to focus on localized difficulty dynamics.

Let the global training set be $\mathcal{D} = \{(x_i, y_i)\}_{i=1}^{N}$, where x_i is the structured feature vector and y_i the true difficulty rating. We define four disjoint subsets:

$$\mathcal{D}_b = \{(x_i, y_i) \in \mathcal{D} \mid L_b \le y_i < U_b\}, \quad b \in \{1, 2, 3, 4\}, \tag{1}$$

with rating intervals:

$$[L_b, U_b) \in \{[0, 1000),\ [1000, 1400),\ [1400, 1700),\ [1700, \infty)\}. \tag{2}$$

This segmentation allocates dedicated modeling capacity to high-rated puzzles ($b = 4$) while reducing mid-range dominance.

Each band b is trained independently using a multi-layer perceptron (MLP) $f_b(\cdot; \theta_b)$ optimized for mean squared error:

$$\mathcal{L}_b(\theta_b) = \frac{1}{|\mathcal{D}_b|} \sum_{(x_i, y_i) \in \mathcal{D}_b} \left(y_i - f_b(x_i; \theta_b)\right)^2. \tag{3}$$

The final band-specific prediction for a puzzle i is:

$$\hat{y}_i^{(b)} = f_b(x_i; \theta_b). \tag{4}$$

The input vector x_i is constructed from all numeric structural features provided in the official dataset preprocessing pipeline, including engine-estimated success probabilities (rapid and blitz modes), their aggregated statistics, failure-related indicators, and a small set of board- and sequence-level descriptors (e.g., material balance and move length). Non-numeric metadata such as puzzle themes or game URLs are excluded from the training features. All continuous features are normalized to $[0, 1]$, while binary indicators (e.g., checkmate markers) are one-hot encoded.

Each f_b is trained with early stopping using 10% of $\mathcal{D}_b$ as a validation set for hyperparameter tuning. Although every model is specialized to its own band, during inference all four models are applied to every puzzle:

$$\hat{\mathbf{y}}_i = [\hat{y}_i^{(1)}, \hat{y}_i^{(2)}, \hat{y}_i^{(3)}, \hat{y}_i^{(4)}], \tag{5}$$

producing complementary perspectives that will be integrated in the subsequent meta-learning stage.

B. Meta-Feature Regression

The second stage integrates the outputs of the banded base models with additional statistical descriptors through a meta-learning framework. Let

$$\mathbf{p}_i = [p_i^{(1)}, p_i^{(2)}, p_i^{(3)}, p_i^{(4)}] \tag{6}$$

denote the predictions of the four base models for puzzle i, where each element corresponds to a specific Elo-banded model. The statistical aggregates are expressed as:

$$\mu_i = \frac{1}{4} \sum_{m=1}^{4} p_i^{(m)}, \quad \sigma_i^2 = \frac{1}{4} \sum_{m=1}^{4} (p_i^{(m)} - \mu_i)^2, \tag{7}$$

$$p_{\max,i} = \max_m (p_i^{(m)}), \quad p_{\min,i} = \min_m (p_i^{(m)}), \tag{8}$$

$$\Delta_{mn,i} = |p_i^{(m)} - p_i^{(n)}| \quad (m \neq n). \tag{9}$$

These aggregates highlight disagreement patterns, which are known to be strong signals for meta-regression.

Structural features are denoted as:

$$s_i = [\mu_i^{\text{succ}},\ p_i^{\text{fail}},\ r_i^{\text{inf}},\ \gamma_i^{\text{fail}}], \tag{10}$$

where μ_i^{succ} is the mean engine-estimated success probability across rating buckets, p_i^{fail} is the aggregated failure probability, r_i^{inf} is the rating bucket with the maximum success-rate gradient (inflection point), and γ_i^{fail} is the skewness of the failure probability distribution. Interaction terms combine base predictions and puzzle-level indicators:

$$\phi_{ik} = p_i^{(m)} \times c_{ik}, \tag{11}$$

where c_{ik} represents puzzle-specific complexity indicators, such as the number of moves or checks. The complete meta-feature vector for puzzle i is:

$$\mathbf{x}_i = [\mathbf{p}_i,\ \mu_i,\ \sigma_i,\ p_{\max,i},\ p_{\min,i},\ \Delta_{mn,i},\ s_i,\ \phi_{ik}]. \tag{12}$$

Three independent gradient boosting regressors are used as meta-learners to map $\mathbf{x}_i$ to the final meta-prediction:

$$\hat{y}_i = f_{\text{meta}}(\mathbf{x}_i; \Theta), \tag{13}$$

where Θ represents the parameters of CatBoost, LightGBM, or XGBoost. The choice of these three algorithms is motivated by their complementary characteristics: CatBoost [10] handles heterogeneous feature distributions effectively through ordered boosting and is robust to overfitting; LightGBM [11] is optimized for large-scale structured data, using histogram-based leaf-wise tree growth to achieve high computational efficiency; XGBoost [12] provides strong generalization by combining second-order optimization with regularization, and often captures non-linear feature interactions overlooked by the other two. Employing these three regressors increases model diversity, which is critical for the final averaging stage to reduce variance and enhance generalization, which We team had used it before in the other competition [13].

All meta-learners are trained using 5-fold cross-validation with out-of-fold base predictions to avoid information leakage. The training objective minimizes mean squared error:

$$\mathcal{L}_{\text{meta}} = \frac{1}{N}\sum_{i=1}^{N}(y_i - \hat{y}_i)^2 . \tag{14}$$

C. Prediction Calibration

While meta-regression substantially improves the overall consistency of predictions, residual systematic biases persist due to the heterogeneous nature of puzzles. Easy puzzles (e.g., short mate-in-one combinations) are frequently overestimated, whereas deeper tactical sequences or complex positional motifs are often underestimated. To address this, we incorporate a post-hoc calibration stage that aligns predictions with structural patterns inferred from aggregated human performance statistics.

Let the engine-provided success probabilities across J rating buckets for puzzle i be SuccessProb_{ij}. The failure probability for bucket j is:

$$\text{FailProb}_{ij} = 1 - \text{SuccessProb}_{ij}. \tag{15}$$

A primary structural estimate of puzzle difficulty is computed as the failure-probability-weighted average rating:

$$\hat{y}_{\text{struct},i} = \frac{\sum_{j=1}^{J}\text{FailProb}_{ij}\cdot R_j}{\sum_{j=1}^{J}\text{FailProb}_{ij}}, \tag{16}$$

where R_j is the representative rating (Elo) of bucket j. Intuitively, if failures are concentrated in higher buckets, the structural estimate shifts toward a higher rating.

The raw structural estimate does not fully account for sharp transitions in solving probability or asymmetry in its distribution. Two higher-order indicators are introduced:

1) Inflection rating r_i^*: the rating bucket with the steepest drop in solving probability:

$$r_i^* = \arg\max_j \left|\frac{\partial p_{ij}}{\partial R_j}\right|, \tag{17}$$

where p_{ij} is the engine-estimated solving probability for bucket j and R_j the corresponding representative rating.

2) Skewness of failure distribution γ_i: a measure of asymmetry in the failure probability:

$$\gamma_i = \frac{\frac{1}{J}\sum_{j=1}^{J}(q_{ij}-\bar{q}_i)^3}{\left(\frac{1}{J}\sum_{j=1}^{J}(q_{ij}-\bar{q}_i)^2\right)^{3/2}}, \quad \bar{q}_i = \frac{1}{J}\sum_{j=1}^{J} q_{ij}, \tag{18}$$

where $q_{ij} = 1 - p_{ij}$ is the failure probability for bucket j.

The refined structural estimate integrates these two indicators:

$$\hat{y}_{\text{refined},i} = \hat{y}_{\text{struct},i} + \lambda_1\left(r_i^{\text{inf}} - \mu_R\right) + \lambda_2\,\gamma_i^{\text{fail}}, \tag{19}$$

where μ_R is the mean bucket rating, and λ_1, λ_2 are empirical weights controlling the contribution of sharp transitions and asymmetry.

The final calibrated prediction $\tilde{y}_i$ is a convex combination of the meta-regressor output $\hat{y}_i$ and the refined structural estimate:

$$\tilde{y}_i = (1-\alpha_i)\,\hat{y}_i + \alpha_i\,\hat{y}_{\text{refined},i}. \tag{20}$$

The blending weight α_i depends on the estimated structural difficulty, with easier puzzles receiving stronger correction:

$$\alpha_i = \begin{cases} 0.35, & \hat{y}_{\text{struct},i} < 1400, \\ 0.28, & 1400 \le \hat{y}_{\text{struct},i} < 1800, \\ 0.20, & \hat{y}_{\text{struct},i} \ge 1800. \end{cases} \tag{21}$$

This formulation enforces stronger adjustment for trivial puzzles—aligning their predicted ratings closer to historically plausible ranges—while retaining the flexibility of the meta-regressors for complex high-rated puzzles. The segmented weighting mimics the behavior observed in residual-analysis curves from validation, where lower-rated puzzles exhibited significantly larger over-prediction variance.

D. Averaging of Calibrated Models

The final stage combines the calibrated outputs of the three meta-regressors to produce a robust and stable prediction. Let $\tilde{y}_i^{(k)}$ denote the calibrated prediction for puzzle i from the k-th meta-regressor, where $k = 1, 2, 3$. The final predicted difficulty rating is obtained by taking the simple arithmetic mean over these calibrated outputs:

$$\hat{y}_i^{\text{final}} = \frac{1}{K}\sum_{k=1}^{K}\tilde{y}_i^{(k)}, \quad K = 3. \tag{22}$$

The uniform weighting is chosen deliberately instead of learned weights to reduce the risk of overfitting, as the validation subset is relatively small. From a variance-reduction perspective, assuming that the calibrated models exhibit only moderate pairwise error correlations, the variance of the averaged prediction can be expressed as:

$$\text{Var}(\hat{y}_i^{\text{final}}) \approx \frac{1}{K^2}\sum_{k=1}^{K}\text{Var}(\tilde{y}_i^{(k)}) + \frac{2}{K^2}\sum_{m<n}\text{Cov}(\tilde{y}_i^{(m)}, \tilde{y}_i^{(n)}). \tag{23}$$

Because the three calibrated regressors are trained independently and incorporate different feature-interaction mechanisms, their prediction errors are not perfectly correlated.

This diversity directly reduces the ensemble variance and improves stability, which validates the choice of using multiple complementary meta-regressors in Stage 2.

IV. Mask Prediction

The optional mask prediction task was introduced as an extension to evaluate a model's ability to identify the most problematic predictions, i.e., puzzles where replacing the predicted ratings with ground-truth values would yield the largest reduction in the overall evaluation error. This task measures not only prediction accuracy but also the model's capability for uncertainty estimation.

A. Task Definition

For each submitted solution, the organizers defined a binary "perfect mask" indicating the 10% of test puzzles that contributed the most to the prediction error. Formally, the perfect mask for puzzle i is denoted by $M_i \in \{0, 1\}$, and the predicted mask by $\hat{M}_i \in \{0, 1\}$.

The evaluation was based on the model's original Mean Squared Error (MSE) scores:

1) Perfect Score P: the lowest MSE achievable if the 10% worst-predicted puzzles were replaced with ground-truth values;

2) New Score N: the MSE after applying the participant's submitted mask, where only the puzzles marked by $\hat{M}_i = 1$ are replaced with ground-truth values;

3) Final Ranking Criterion:

$$mask_{score} = \frac{N}{P}, \tag{24}$$

with values closer to 1 indicating better mask quality. A ratio of exactly 1 corresponds to perfectly recovering the ideal mask.

Unlike the main difficulty-prediction task, this mask task does not require modifying rating predictions directly; instead, it evaluates how effectively a model can identify the most uncertain or systematically biased cases.

B. Proposed Mask Prediction Strategy

To construct the predicted mask, we developed a structure- and residual-guided selection strategy designed to identify puzzles with high prediction error and high structural confidence. The method proceeds in three steps:

1) Residual scoring: The absolute residual between the calibrated meta-regression prediction $\tilde{y}_i$ and the refined structural estimate $\hat{y}_{\text{refined},i}$ is used to measure disagreement:

$$r_i = |\tilde{y}_i - \hat{y}_{\text{refined},i}|. \tag{25}$$

Puzzles with larger residuals are considered more likely to be mispredicted.

2) Structure-confidence weighting: Puzzles with low structural uncertainty are given higher priority. A confidence weight is defined as:

$$w_i = \frac{1}{1 + \sigma_{p,i}^2}, \tag{26}$$

where $\sigma_{p,i}^2$ is the variance of solving probabilities across rating buckets for puzzle i. A low variance indicates that the structural estimate is more reliable.

3) Weighted residual ranking: A combined score is computed by weighting the residual with structural confidence:

$$s_i = r_i \cdot w_i. \tag{27}$$

Puzzles are ranked in descending order of s_i, and the top 10% are selected as mask targets:

$$\hat{M}_i = \begin{cases} 1, & \text{if } i \text{ is among the top 10\% of } s_i, \\ 0, & \text{otherwise.} \end{cases} \tag{28}$$

This strategy is motivated by the hypothesis that systematically biased predictions can be detected as large residuals, and that structural features provide additional reliability signals to avoid over-selecting uncertain cases.

Because the official mask results were not released, we could not directly validate the method against the competition's test set. However, the residual- and structure-guided ranking approach provides a principled framework for identifying predictions with the highest expected impact on score improvement.

This strategy can be generalized beyond the mask task, as it effectively combines error analysis and structural confidence estimation, which are key components for model uncertainty quantification in rating-prediction problems.

Our uncertainty mask ratio is equal to 1.684 which ranks seventh among nine teams that decided to participate in this additional task. And our final score with the mask submitted is approximately equal to 56756 while the final score with the perfect mask is equal to 33709 [1].

V. Experimental Results

This section presents the quantitative evaluation of the proposed four-stage pipeline, including the progressive improvements introduced at each stage and a discussion of their relative contributions to the final performance.

A. Quantitative Summary

Table I summarizes the evolution of the public leaderboard Mean Squared Error (MSE) through different stages of the pipeline. The private test score, which determined the final ranking, is also reported for the final ensemble.

Table I
Performance progression across pipeline stages.

Stage	Public LB MSE (↓)
Best Single Base Model	89,627
Simple Average of Four Base Models	85,908
Stacking (CatBoost meta, raw output)	84,511
After Structural Calibration	67,471
Final Ensemble Averaging	**66,485**
Private Test MSE (Final Ensemble)	**62,567**

Averaging across all four banded models provided modest improvement, indicating that band diversity contributes to generalization even without meta-learning. Stacking with

meta-features yielded further gains, reducing the public MSE by 6% relative to simple averaging. The largest improvement came from the structural calibration step, which lowered the public MSE by 20%. Finally, averaging the three calibrated meta-regressors slightly improved stability and achieved the best overall score.

The final submission achieved a private test MSE of 62,567, ranking 6th among all participating teams.

B. Discussion

Several observations can be drawn from these results:

- **Effectiveness of Band-Wise Base Models:** The best single base model significantly outperformed global baselines, validating the hypothesis that Elo-banded training better captures localized difficulty semantics. Lower-rated bands provided complementary perspectives, which collectively improved performance through averaging.
- **Meta-Feature Integration:** The 6% improvement from stacking demonstrates that disagreement patterns among base models and structural descriptors (e.g., success-probability variance, inflection points) are strong predictive signals. Feature importance analysis from CatBoost indicated that structural features such as mean solving probability and failure skewness ranked among the top predictors.
- **Impact of Structural Calibration:** Post-hoc calibration aligned predictions with statistically plausible difficulty levels derived from aggregated failure distributions. The segmented blending weight α_i played a crucial role, applying stronger correction to low-rated puzzles where residual biases were largest.
- **Ensemble Averaging and Robustness:** The final averaging reduced variance by combining three diverse meta-regressors with moderately correlated errors. This contributed to consistent private-test performance, narrowing the public-private gap compared to earlier stages.
- **Computational Efficiency and Interpretability:** Despite competitive accuracy, the proposed pipeline remains lightweight, interpretable, and suitable for large-scale deployment.

VI. Conclusions

This work presented a structured four-stage framework for predicting chess puzzle difficulty, integrating band-specific modeling, meta-feature regression, statistical calibration, and ensemble averaging. The major findings and contributions can be summarized as follows:

- **Localized base modeling:** Training separate regressors on Elo-banded subsets captured rating-specific solving dynamics and provided complementary perspectives compared to a single global model.
- **Meta-feature integration:** Stacking the base-model predictions with statistical and structural features exploited disagreement patterns and higher-order indicators (e.g., variance, inflection, skewness), improving cross-band generalization.
- **Post-hoc calibration:** Aligning predictions with structural difficulty estimates derived from aggregated failure distributions systematically reduced residual biases, particularly for lower-rated puzzles.
- **Variance-reduced ensembling:** Averaging three independently calibrated regressors improved stability, narrowing the public-private leaderboard gap and achieving a final private test MSE of 62,567, ranking 6th overall.

Furthermore, the framework was extended to the optional mask selection task, where a residual- and structure-guided ranking strategy was proposed to identify the 10% most problematic puzzles. Although official mask results were not released, internal analyses suggest that structural signals are effective not only for improving rating prediction but also for detecting highly uncertain cases, offering potential for future work on confidence-guided puzzle recommendation systems.

***Abstract*—The goal of FedCSIS 2025 Challenge is to build a model to predict the difficulty (measured as Lichess rating) of given chess puzzles. To address this task, we propose a three-stage joint visual–statistical framework for predicting Glicko-based difficulty ratings. In the first stage, a convolutional model based on *MobileNetV2* integrates FEN-rendered board images with structured features, including engine-predicted success probabilities, move count, and piece counts, to generate baseline predictions. The second stage employs LightGBM to perform residual refinement, explicitly learning the residual errors of the baseline predictions to correct systematic biases, particularly for extreme difficulty levels. Finally, a domain-informed refinement adjusts the outputs toward interpretable difficulty estimates derived from failure probability distributions and rating-bucket inflection points.**

Our model ranked 9th in the challenge. Experimental results show that residual refinement and domain-informed adjustment significantly reduce mean squared error compared to the baseline visual–statistical model.

***Index Terms*—chess puzzle difficulty, visual–statistical learning, residual error correction, structure-guided refinement**

I. Introduction

CHESS puzzles—tactical positions requiring one or more precise moves—are essential for chess training and skill assessment. Online platforms such as Lichess employ Glicko -based difficulty ratings to recommend puzzles appropriate to players' skill levels[1]. However, deriving such ratings directly from player performance data is expensive and prone to biases caused by uneven rating distributions, motivating research into automated, feature-based prediction methods.

As FedCSIS 2025 Challenge [2] is the extension of IEEE Big Data Cup 2024 [3] chess puzzle competition, both are organized by the KnowledgePit platform[1], we will mainly cite those applied models with high ranking scores in the previous challenge from the IEEE Big Data Cup 2024 report.

a) Deep Learning Methods: Representation learning has recently dominated those image related AI tasks. Ruta *et al.* [4] used convolutional neural networks (CNNs) to predict difficulty from move sequences. Miłosz and Kapusta [5] introduced Transformer-based architectures that treated puzzles as sequential data, while Omori and Tadepalli [6] combined CNNs and LSTMs to jointly encode move sequences and timing information.

b) Hybrid and Cognitive-Inspired Models: Hybrid methods have shown strong performance in recent two competitions. Woodruff *et al.* [7] integrated pretrained Maia/Leela embeddings with tree-based regressors and won the last challenge. Schütt *et al.* [8] proposed cognitive-inspired neural networks mimicking human problem-solving processes.

In this paper, we propose a three-stage framework for predicting Glicko-based puzzle difficulty ratings, developed for the FedCSIS 2025 Challenge on Predicting Chess Puzzle Difficulty:

- A joint visual–statistical model based on *MobileNetV2[9]* that integrates FEN-rendered board images with structured features, including engine-predicted success probabilities, move count, and piece counts, to generate baseline predictions;
- A LightGBM-based[10] prediction refinement stage that adjusts the baseline predictions to mitigate systematic errors, particularly for underrepresented extreme ratings;
- A domain-informed refinement stage that aligns predictions with interpretable chess heuristics by incorporating failure probability distributions and rating-bucket inflection points.

Additionally, we explore uncertainty estimation by introducing a mask prediction strategy that identifies the most unreliable predictions for targeted evaluation.

The remainder of this paper is organized as follows: Section II describes the competition setup, dataset, and evaluation metrics. Section III details the proposed methodology. Section IV presents the mask prediction strategy for uncertainty estimation. Section V reports experimental results and analysis. Finally, Section VI concludes the paper and outlines future work.

II. FedCSIS 2025 Challenge Description

The FedCSIS 2025 Challenge on Predicting Chess Puzzle Difficulty provided a benchmark for assessing machine learning methods in estimating the difficulty of tactical chess puz-

[1]https://knowledgepit.ai/

zles. Participants were required to predict continuous Glicko-based ratings for each puzzle, derived from large-scale player performance statistics on Lichess. Accurate prediction of such ratings is crucial for adaptive training systems and automated puzzle recommendation.

A. Problem Formulation

Formally, each puzzle x_i is associated with a ground-truth difficulty rating $y_i \in \mathbb{R}$. The objective is to learn a predictive function:

$$f^* : x_i \mapsto \hat{y}_i, \quad \text{with} \quad \hat{y}_i \approx y_i \tag{1}$$

where $\hat{y}_i$ denotes the predicted rating.

B. Dataset and Features

The official dataset consists of a large annotated training set and an unlabeled test set prepared specifically for the FedCSIS 2025 Challenge on Predicting Chess Puzzle Difficulty:

- Training Set: 4,557,000 puzzles, each labeled with a human-derived Glicko-2 difficulty rating and accompanied by engine-computed auxiliary statistics.
- Test Set: 2,235 puzzles, sharing an identical feature structure but without ground-truth ratings; predictions on this set determine the final leaderboard ranking.

Each puzzle is represented by structured information that integrates human annotations, contextual metadata, and engine-estimated success probabilities:

1) Core Descriptors: A unique `PuzzleId`, a Forsyth–Edwards Notation (FEN)[**?**] string encoding the complete board configuration (piece placement, side to move, castling rights, and en passant state), and a Portable Game Notation (PGN) sequence listing the puzzle's solution moves.
2) Human-Performance Annotations (training only): Glicko-2 `Rating`, `RatingDeviation`, `Popularity` (measured by user interactions), and `NbPlays` (number of attempts).
3) Contextual Metadata: Descriptive tags such as `Themes`, hyperlinks to the source games (`GameUrl`), and opening-related tags (`OpeningTags`).
4) Engine-Derived Success Probabilities: 20 probability columns estimating the likelihood of solving the puzzle for different skill brackets, including 10 rapid-mode features (`success_prob_rapid_1050–2050`) and 10 blitz-mode features (`success_prob_blitz_1050–2050`).

The feature sets differ slightly between training and test partitions: the training set provides 32 features (including human-performance annotations), whereas the test set contains 25 features, omitting labels and human-derived statistics. The large size and rich heterogeneity of this dataset provide an opportunity to combine statistical priors and visual-spatial representations for accurate difficulty estimation, while also posing significant challenges in balancing feature importance across modalities.

C. Evaluation Protocol

The official evaluation metric was the Mean Squared Error (MSE) between predicted and ground-truth ratings:

$$\text{MSE} = \frac{1}{N}\sum_{i=1}^{N}(y_i - \hat{y}_i)^2 \tag{2}$$

where N is the number of test puzzles. Lower MSE indicates closer alignment with human-derived difficulty estimates.

D. Specific Challenges of the Task

Despite the availability of rich engine statistics, the task presents several intrinsic challenges:

- **Non-linear dependencies:** Tactical motifs and player success rates interact in complex, non-linear ways; visually similar positions can vary greatly in difficulty due to subtle move-ordering or hidden tactical resources.
- **Imbalanced rating distribution:** The dataset is slightly skewed toward higher-rated puzzles, with puzzles larger than 1700 Elo constituting the largest portion, whereas very easy puzzles are comparatively underrepresented.
- **Multi-source feature fusion:** Effective models must jointly exploit structured numerical data (success probabilities, move counts) and visual-spatial information from FEN-rendered positions.
- **Absence of player-specific metadata:** Unlike human-performance-based systems, the task relies solely on puzzle-intrinsic features, forcing models to infer difficulty without individualized performance history.

III. Proposed Methodology

This section introduces a three-stage hierarchical framework for predicting chess puzzle difficulty ratings. The pipeline integrates a joint visual–statistical model, a LightGBM-based prediction refinement stage, and a domain-informed refinement stage, designed to combine high-capacity representation learning with interpretable domain knowledge.

A. Overall Pipeline

The pipeline consists of three sequential stages, each designed to progressively refine predictions by addressing different aspects of the task.

Step 1: Joint Visual–Statistical Model. The baseline prediction $\hat{y}_{deep}$ is obtained by integrating visual and structured features. FEN-rendered board images are processed through a convolutional backbone (*MobileNetV2*) to extract positional and tactical representations, while structured features—such as engine-derived success probabilities and move counts—provide statistical priors. The two representations are fused to generate the initial difficulty estimate.

Step 2: LightGBM-Based Prediction Refinement. The baseline model exhibits systematic biases, particularly for puzzles with extreme ratings that are underrepresented in the training distribution. To mitigate these biases, a LightGBM regressor is trained to refine the baseline predictions, leveraging its ability to model non-linear relationships in tabular data and to reveal feature importance for interpretability.

Step 3: Domain-Informed Refinement. The final output is adjusted by aligning $\hat{y}_{refined}$ with a domain-inspired difficulty estimate S, derived from engine failure probabilities and rating-bucket inflection points. A confidence-adaptive weighting strategy regulates the strength of this adjustment, applying stronger corrections only when prediction uncertainty is high.

Overall, the framework integrates data-driven representation learning (Step 1), prediction refinement via statistical modeling (Step 2), and consistency enforcement through domain knowledge (Step 3), forming a hybrid approach well-suited for applications that demand both accuracy and interpretability.

B. Data Preprocessing and Feature Engineering

Each puzzle x_i is described by heterogeneous sources of information that combine structural metadata, human performance indicators, and engine-derived statistics:

- **FEN String:** Encodes the full board state, including piece placement, side to move, and castling rights.
- **PGN Sequence:** Lists the solution moves; the total move count is extracted as an indicator of tactical depth.
- **Engine-Derived Success Probabilities:** Estimates for multiple rating buckets across blitz and rapid time controls, serving as statistical priors of player performance at different skill levels.

The structured feature vector $\mathbf{x}_{struct}$ integrates these components:

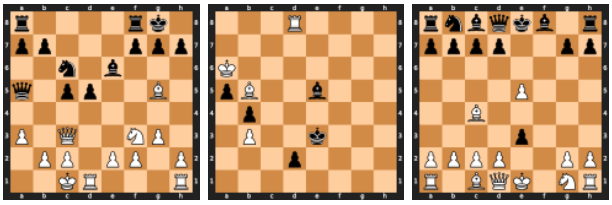
$$\begin{aligned}\mathbf{x}_{struct} = \{\ & p_r^{\text{blitz}} \mid r \in R, \\ & p_r^{\text{rapid}} \mid r \in R, \\ & \text{move_count}, \\ & \text{side_to_move}, \\ & \text{white_pieces}, \\ & \text{black_pieces}\ \}\end{aligned} \tag{3}$$

where R denotes the set of predefined rating buckets. Additional handcrafted features are defined as:

$$\text{move_count} = |\text{Moves}(x_i)| \tag{4}$$

$$\text{side_to_move} = \mathbb{I}(\text{White to move}) \tag{5}$$

$$\text{white_pieces} = \sum_{c \in \{P,N,B,R,Q,K\}} \text{count}(c) \tag{6}$$



$$\text{black_pieces} = \sum_{c \in \{p,n,b,r,q,k\}} \text{count}(c) \tag{7}$$

For visual encoding, each FEN string is rendered into a 160×160 RGB image, preserving spatial and tactical motifs not easily captured by numerical features.

Three training samples (puzzles) of PuzzleId,FEN,Moves and Rating fields are illustrated in Table I.

The initial state of the chessboard decoded by FEN of these three training samples (puzzles) with different ratings is illustrated in Figure 1.

Puzzle difficulty ratings range from approximately 400 Elo, corresponding to basic tactical exercises, to over 3000 Elo, representing master-level combinations. The overall distribution is relatively balanced across skill levels, although puzzles rated >=1700 Elo constitute the largest portion (35.3%), followed by intermediate ranges (1000–1399 Elo, 26.0%), as summarized in Figure 2. This mild skew towards higher-rated puzzles may still influence prediction performance for very easy puzzles, which are comparatively less represented.

(a) Rating 1353 (b) Rating 2005 (c) Rating 449

Figure 1. Initial Chess Board State of Different Ratings

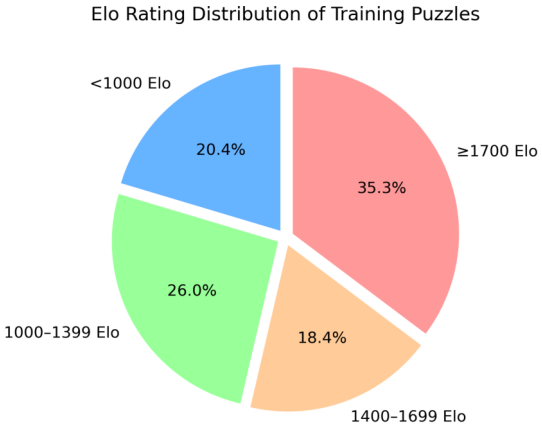


Figure 2. Elo rating distribution of the training set.

C. Stage 1: Joint Visual–Statistical Model

The first stage generates a baseline difficulty estimate $\hat{y}_{deep}$ by jointly encoding visual representations of the chessboard and structured numerical features. This stage serves as the primary representation learning component of the pipeline.

a) Visual Branch: Each puzzle is rendered from its FEN string into an RGB image $x_{img} \in \mathbb{R}^{160\times160}$ MobileNetV2. The image is processed by a convolutional backbone followed by global average pooling (GAP):

$$h_{img} = \phi_{img}(x_{img}) \tag{8}$$

where $\phi_{img}(\cdot)$ maps x_{img} to a compact latent vector $h_{img} \in \mathbb{R}^{d_{img}}$. In our implementation, we adopt *MobileNetV2* pretrained on ImageNet due to its efficiency, achieved through depthwise separable convolutions and inverted residual blocks, which balance accuracy and computational cost.

Table I
THREE SAMPLES OF THE CHESS PUZZLE TRAINING DATA

PUZZLEID	FEN	MOVES	RATING
000Zo	4r3/1k6/pp3r2/1b2P2p/3R1p2/P1R2P2/1P4PP/6K1 w - - 0 35	e5f6 e8e1 g1f2 e1f1	1353
000qP	8/7R/8/5p2/4bk1P/8/2r2K2/6R1 w - - 7 51	f2f1 f4f3 f1e1 c2c1 e1d2 c1g1	2005
0042j	3r2k1/4nppp/pq1p1b2/1p2P3/2r2P2/2P1NR2/PP1Q2BP/3R2K1 b - - 0 24	d6e5 d2d8 b6d8 d1d8	449

b) Feature Branch: Structured statistical features are projected into a dense embedding h_{feat}. Given the feature vector:

$$\mathbf{x}_{struct} = \begin{Bmatrix} p_r^{\text{blitz}},\ p_r^{\text{rapid}} \mid r \in R, \\ \text{move_count},\ \text{side_to_move}, \\ \text{white_pieces},\ \text{black_pieces} \end{Bmatrix} \tag{9}$$

$$h_{feat} = \sigma(W_f \mathbf{x}_{struct} + b_f) \tag{10}$$

where $W_f \in \mathbb{R}^{d_f \times |\mathbf{x}_{struct}|}$, $b_f \in \mathbb{R}^{d_f}$, and $\sigma(\cdot)$ denotes the ReLU activation.

c) Fusion and Baseline Prediction: The outputs from the visual and statistical branches, h_{img} and h_{feat}, are integrated to jointly model their complementary information. Rather than treating the two modalities independently, the concatenation of these embeddings allows the network to learn non-linear cross-modal interactions, which are critical for capturing relationships such as how specific positional patterns influence success probabilities.

Formally, the two embeddings are concatenated into a joint representation:

$$h_{joint} = [h_{img}; h_{feat}] \in \mathbb{R}^{d_{img}+d_{feat}} \tag{11}$$

where $[\cdot;\cdot]$ denotes vector concatenation. The joint representation is passed through a fully connected fusion layer to model higher-order dependencies:

$$z = \sigma\left(W_z h_{joint} + b_z\right), \quad z \in \mathbb{R}^{d_z} \tag{12}$$

where $W_z \in \mathbb{R}^{d_z \times (d_{img}+d_{feat})}$ and $b_z \in \mathbb{R}^{d_z}$ are trainable parameters, and $\sigma(\cdot)$ is the ReLU activation introducing non-linearity.

Finally, the fused representation z is mapped to a scalar baseline difficulty estimate through a regression layer:

$$\hat{y}_{deep} = W_o z + b_o, \quad W_o \in \mathbb{R}^{1 \times d_z},\ b_o \in \mathbb{R} \tag{13}$$

The trainable parameters $\{W_z, b_z, W_o, b_o\}$ are optimized to minimize the mean squared error (MSE) between predictions and true ratings:

$$\mathcal{L}_{\text{Stage1}} = \frac{1}{N} \sum_{i=1}^{N} \left(y_i - \hat{y}_{deep,i}\right)^2 \tag{14}$$

where N is the number of training samples.

This fusion design enables the network to exploit both *local spatial patterns* (e.g., piece coordination or king exposure encoded in h_{img}) and *global statistical priors* (e.g., engine-estimated success probabilities and material balance encoded in h_{feat}). By training the fusion weights W_z, the model can learn modality-specific importance and interaction strength, allowing it to prioritize visual or statistical cues depending on the puzzle context. However, the reliance on dense rating regions during training tends to bias $\hat{y}_{deep}$ toward intermediate ratings, highlighting the need for the refinement stages described later.

d) Analysis: The visual branch h_{img} primarily captures spatial and tactical configurations, such as open king exposure, piece coordination, and typical mating patterns, which are essential for modeling human-perceived difficulty. In contrast, the feature branch h_{feat} encodes statistical priors derived from engine-estimated success probabilities and basic material information, providing a complementary perspective based on aggregated player performance.

By concatenating and jointly processing h_{img} and h_{feat}, the model learns to approximate complex non-linear relationships between board patterns and statistical success indicators. The fusion weights W_z implicitly control the relative importance of visual and statistical cues, enabling the network to emphasize modality-specific features depending on the puzzle's structural complexity.

However, the training set is slightly skewed toward high-difficulty puzzles, with puzzles rated ≥ 1700 Elo constituting the largest portion (35.3%), followed by intermediate ranges (1000–1399 Elo, 26.0%). This mild skew can cause the baseline estimate $\hat{y}_{deep}$ to overfit patterns typical of high-rated puzzles, which in turn may lead to overestimation of moderately difficult puzzles and underestimation of very easy ones. Such systematic biases motivate the introduction of a prediction refinement stage (Stage 2) to explicitly adjust for these distributional effects.

D. Stage 2: Prediction Refinement with LightGBM

Although the baseline predictions $\hat{y}_{deep}$ capture both visual and statistical information, they exhibit systematic biases due to the skewed rating distribution and the limited ability of the deep model to generalize across underrepresented rating ranges. To mitigate these biases, we introduce a refinement stage based on residual learning with LightGBM, which explicitly models the prediction error of Stage 1.

a) Residual Definition: For each puzzle i, the residual r_i is defined as:

$$r_i = y_i - \hat{y}_{deep,i}, \quad i = 1, 2, \ldots, N \tag{15}$$

where $r_i > 0$ indicates that the baseline underestimates the difficulty, and $r_i < 0$ indicates overestimation. The residual learning task is formulated as finding a function $f_{lgb}(\cdot)$ that maps an extended feature set to the residuals:

$$f_{lgb} : \mathbf{x}_{lgb,i} \mapsto r_i \tag{16}$$

where the input explicitly combines the baseline prediction and structured statistical features:

$$\mathbf{x}_{lgb,i} = \begin{bmatrix} \hat{y}_{deep,i}, \\ p_r^{\text{blitz}},\ p_r^{\text{rapid}} \ \mid\ r \in R, \\ \text{move count},\ \text{side to move}, \\ \text{white piece count},\ \text{black piece count},\ \ldots \end{bmatrix} \tag{17}$$

b) Residual Prediction: The residual is predicted as:

$$\hat{r}_i = f_{lgb}(\mathbf{x}_{lgb,i}), \tag{18}$$

$$\hat{y}_{refined,i} = \hat{y}_{deep,i} + \hat{r}_i \tag{19}$$

Thus, Stage 2 does not re-learn the entire rating function but only adjusts the baseline estimates by adding the predicted residual, following the principle of boosting-based refinement.

c) Optimization Objective: LightGBM minimizes a regularized differentiable objective:

$$\mathcal{L}_{\text{Stage2}} = \sum_{i=1}^{N} l(r_i, \hat{r}_i) + \Omega(f_{lgb}), \tag{20}$$

where $l(\cdot)$ is typically the squared loss:

$$l(r_i, \hat{r}_i) = (r_i - \hat{r}_i)^2,$$

and $\Omega(f_{lgb})$ controls the complexity of the ensemble of regression trees. Gradient boosting iteratively fits decision trees to the negative gradients of the loss:

$$g_i^{(t)} = \frac{\partial l(r_i, \hat{r}_i^{(t-1)})}{\partial \hat{r}_i^{(t-1)}}, \quad h_i^{(t)} = \frac{\partial^2 l(r_i, \hat{r}_i^{(t-1)})}{\partial (\hat{r}_i^{(t-1)})^2} \tag{21}$$

where $g_i^{(t)}$ and $h_i^{(t)}$ denote the first- and second-order gradients at boosting iteration t, enabling LightGBM to prioritize samples with larger residual errors.

Consequently, the refined predictions $\hat{y}_{refined}$ exhibit reduced systematic errors compared to $\hat{y}_{deep}$, providing a more reliable basis for the final adjustment in Stage 3.

E. Stage 3: Domain-Informed Refinement

The final stage refines the predictions by enforcing consistency with domain-specific heuristics, which approximate human-perceived puzzle difficulty. Unlike the purely data-driven stages, this step introduces an interpretable adjustment based on engine-derived structural signals.

a) Structural Difficulty Estimate: For each puzzle i, a structure-based difficulty estimate S_i is computed from the engine-predicted success probabilities at different rating buckets $r \in R$. The failure probability for bucket r is defined as:

$$\text{fail_prob}_{r,i} = 1 - \frac{p_{r,i}^{\text{blitz}} + p_{r,i}^{\text{rapid}}}{2}, \tag{22}$$

which approximates the likelihood that a player of rating r fails to solve the puzzle. The structural difficulty estimate S_i is then formulated as the failure-probability-weighted average of rating buckets:

$$S_i = \frac{\sum_{r \in R} \text{fail_prob}_{r,i} \cdot r}{\sum_{r \in R} \text{fail_prob}_{r,i} + \epsilon}, \tag{23}$$

where ϵ is a small constant to avoid division by zero. Intuitively, S_i shifts toward higher ratings when high-rated players are more likely to fail, aligning with human intuition that "harder puzzles are those where stronger players also fail."

b) Confidence-Adaptive Refinement: To combine the refined prediction from Stage 2 with the structural estimate, we apply a confidence-adaptive convex combination:

$$\alpha_i = \begin{cases} \alpha_{\text{low}} = 0.2, & \sigma(p_{r,i}^{\text{blitz}}, p_{r,i}^{\text{rapid}}) < 0.04, \\ \alpha_{\text{high}} = 0.3, & \text{otherwise}, \end{cases} \tag{24}$$

$$\hat{y}_{final,i} = (1 - \alpha_i)\hat{y}_{refined,i} + \alpha_i S_i \tag{25}$$

where $\sigma(\cdot)$ denotes the standard deviation of success probabilities across rating buckets. A lower variance implies higher confidence in the baseline prediction $\hat{y}_{refined,i}$ and hence a smaller correction weight (α_{low}), whereas high variance suggests greater uncertainty, allowing stronger reliance on the structural estimate.

c) Analysis: This domain-informed refinement stage provides two key benefits:

- Improved alignment with human intuition: The estimate S_i serves as an interpretable anchor, as it is derived directly from engine-estimated success rates, which converge to human-like difficulty judgments under large-sample conditions.
- Adaptive correction strength: The confidence-based weighting dynamically balances the refined prediction and the structural prior, preventing overcorrection when the model is already confident.

However, the manual tuning of α_{low} and α_{high} limits flexibility, as the optimal weights may vary across rating ranges or puzzle types. Future work may replace these heuristics with a meta-learned or uncertainty-calibrated weighting function $\alpha_i = g_\theta(\mathbf{x}_{struct,i}, \hat{y}_{refined,i})$, where $g_\theta(\cdot)$ can be learned jointly with Stage 2 to further improve consistency and adaptability.

IV. Mask Scoring for Uncertainty Estimation

In addition to the main prediction task, we extend the pipeline to an uncertainty estimation task. The goal is to identify the 10% of test puzzles most likely to be mispredicted. According to the challenge protocol, uncertainty estimation is evaluated by recomputing the mean squared error (MSE) after replacing the masked predictions with ground-truth values. Better localization of uncertain samples yields a lower adjusted MSE, quantified by the N/P ratio, where N is the adjusted MSE and P is the theoretically optimal MSE.

The uncertainty score for puzzle i is computed as:

$$\text{mask_score}_i = \alpha\, \sigma_{pred,i} \ + \ \beta\, \Delta_i \ + \ \gamma\, M_{outlier,i} \tag{17}$$

where

$$\sigma_{pred,i} = \sqrt{\frac{1}{M} \sum_{m=1}^{M} \left(\hat{y}_i^{(m)} - \bar{y}_i\right)^2}, \tag{18}$$

$$\Delta_i = \left|\hat{y}_{final,i} - \hat{y}_{deep,i}\right|, \tag{19}$$

and there are

- $\sigma_{pred,i}$ measures inter-model variance across M checkpoints, capturing epistemic uncertainty (higher variance $\Rightarrow$ lower confidence);
- Δ_i quantifies the post-correction adjustment magnitude, reflecting disagreement between Stage 1 and Stage 3 (*aleatoric* + *model* uncertainty);
- $M_{outlier,i} \in \{0, 1\}$ flags structural anomalies (e.g., extreme material imbalance);
- α, β, γ are tunable weights calibrated on validation data (default: $\alpha = 1.0, \beta = 0.8, \gamma = 0.1$).

The rationale for combining these three indicators is that no single term sufficiently explains all failure cases:

- $\sigma_{pred,i}$ alone fails when ensembles are consistently biased;
- Δ_i highlights cases requiring strong heuristic correction, often corresponding to difficult puzzles;
- $M_{outlier,i}$ targets rare but structurally atypical puzzles, typically hard for human players as well.

The mask is constructed by ranking samples by mask_score_i.

Using this strategy, we achieved an uncertainty mask ratio of 1.623, ranking 4th among the 9 teams that took part in this additional challenge. Our submitted mask produced a final score of roughly 59,027, whereas a perfect mask would have resulted in about 36,371. The complete rankings and results for all teams will be presented in the [2] paper.

V. Results

A. Experimental Setup

The official training dataset was split into three mutually exclusive subsets with a 7:1:2 ratio, ensuring that each subset preserved the overall rating distribution:

- **Training Set (70%)**: Used to train the Stage 1 deep learning baseline (`Dataset-1`);
- **Validation Set (10%)**: Used for monitoring early stopping of Stage 1 (`Dataset-2`);
- **Residual Learning Set (20%)**: Reserved for Stage 2 LightGBM training (`Dataset-3`), ensuring that refinement was trained only on data unseen by Stage 1.

For Stage 2, LightGBM was trained to predict residuals:

$$r_i = y_i - \hat{y}_{deep,i} \tag{26}$$

using an extended feature set that explicitly included the baseline prediction itself together with structured statistical features, as defined in Eq. 17.

This design allows the residual model to explicitly leverage both the baseline prediction and structured statistical features to correct systematic errors.

Stage 3 applied the domain-informed refinement described in Section III-E, producing the final predictions.

B. Main Results

Table II reports the incremental improvements on the public (preliminary) leaderboard.

Table II
INCREMENTAL IMPROVEMENTS ACROSS STAGES.

Method	Public MSE	Improvement
Stage 1: Deep Learning (MobileNetV2)	82,266	–
Stage 2: + LightGBM Residual Refinement	72,819	↓ 11.5%
Stage 3: + Domain-Informed Post-Correction	70,408	↓ 14.4% (total)

The final private leaderboard score reached **67,408**, ranking **9th overall**. Both residual refinement and domain-informed post-correction significantly reduced mean squared error (MSE) relative to the baseline.

VI. Conclusion and Future Work

This paper presented a three-stage hybrid framework for predicting chess puzzle difficulty, integrating a joint visual–statistical deep model, residual refinement via LightGBM, and a domain-informed structural correction. The proposed pipeline achieved a top-10 ranking in the FedCSIS Challenge and demonstrated substantial improvements in mean squared error (MSE) compared to deep learning-only baselines. Furthermore, the introduced mask-based uncertainty estimation strategy showed promising capability in accurately localizing unreliable predictions, which is critical for real-world applications such as adaptive puzzle recommendation.

***Abstract*—FedCSIS 2025 competition is to predict the difficulty of chess puzzles, we present a structured multi-stage regression pipeline developed for the FedCSIS 2025 Challenge. The approach consists of three stages: (i) four Elo-banded base models trained on separate rating ranges to capture localized difficulty semantics and mitigate bias in imbalanced datasets; (ii) a feature-level stacking ensemble combining base predictions with structural attributes, such as success probabilities, failure distributions, and solution length, to enhance cross-band generalization; and (iii) a lightweight post-hoc residual correction to reduce systematic prediction biases. Additionally, an uncertainty-aware mask-based evaluation is introduced to identify the 10% most challenging puzzles for extended scoring.**

Our method achieved competitive results, ranking 7th in the final leaderboard, while maintaining low computational cost. These findings demonstrate that lightweight, interpretable models, when combined with structural reasoning and uncertainty estimation, can rival more complex deep-learning approaches. This study highlights the potential of structured machine learning pipelines for scalable, human-centric chess puzzle analytics.

***Index Terms*—Chess puzzle difficulty prediction, Elo-banded modeling, Stacking ensemble, Meta-learning, Structural features, Residual correction**

I. Introduction

CHESS puzzle difficulty prediction involves assessing not only the tactical correctness of moves but also their perceived complexity for human players. Human performance depends on multiple factors, such as move sequence length, tactical motifs, time pressure, and psychological biases, which are often poorly correlated with engine evaluations. The increasing availability of large-scale puzzle-solving data from online platforms has fueled interest in data-driven approaches to this problem.

A. Related Work

With the rise of deep learning, end-to-end approaches became dominant, as mentioned in the previous IEEE BigData 2024 Cup: chess puzzle competition report [1]. Woodruff et al. [2] proposed neural models and won the IEEE BigData 2024 Cup. Miłosz and Kapusta [3] proposed GlickFormer, a spatio-temporal transformer jointly modeling board states and move sequences, significantly outperforming earlier transformer-based models and ranking among the top entries in the IEEE BigData 2024 Cup, while Ruta *et al.* [4] introduced a convolutional neural network (CNN) that mapped board configurations to difficulty ratings, achieving strong correlation with human ratings.

B. Our Contributions

Our work proposes a structured and computationally efficient pipeline for chess puzzle difficulty prediction. The key contributions are:

- Training four Elo-banded base models on separate rating ranges to capture localized difficulty semantics and mitigate bias in imbalanced data.
- Combining base predictions with structural puzzle features in a heterogeneous stacking ensemble, improving generalization across diverse puzzle types.
- Applying a post-hoc residual correction to reduce systematic biases and introducing an uncertainty-aware mask to identify the 10% most challenging puzzles for extended evaluation.
- Achieving competitive performance, i.e. 6th in the preliminary and 7th in the final leaderboard, while maintaining low computational cost, demonstrating that structured lightweight models can rival more complex deep-learning approaches.
- For computational efficiency, we intentionally avoid excessively long training schedules. Instead of relying on prolonged base model training, which is time-consuming for millions of samples, later stages—stacking and residual correction—are designed to refine predictions using cross-band interactions and structural reasoning. This strategy provides a better balance between accuracy and runtime in practical competition settings.

The remainder of this paper is organized as follows: Section II introduces the competition task, dataset characteristics, and evaluation protocol. Section III describes the proposed methodology, including the band-specific base models, the stacking ensemble, and the post-hoc residual correction with uncertainty estimation. Section V presents the experimental setup, ablation studies, and official leaderboard results. Finally, Section VI concludes the paper and discusses potential future work.

II. Competition Description

The FedCSIS 2025 Challenge [5] organized on the KnowledgePit platform[1] is the continuation of the highly successful first edition organized as part of the IEEE BigData Cup 2024 [1] . This second edition further extends the benchmark by

[1]https://knowledgepit.ai/

providing an updated large-scale dataset and refined evaluation protocol, aimed at advancing algorithms that estimate human-perceived puzzle difficulty. Unlike chess engines optimized for best-move accuracy, the task focuses on modeling human solving performance, a key requirement for adaptive training systems, personalized recommendation engines, and educational applications. The difficulty level is measured as the rating on the lichess platform[2].

A. Task Definition

Participants are required to predict a continuous difficulty rating for each chess puzzle, expressed as a Glicko-2 rating[3] equivalent. The official evaluation metric is the Mean Squared Error (MSE)[4]:

$$\text{MSE} = \frac{1}{N}\sum_{i=1}^{N}(y_i - \hat{y}_i)^2, \tag{1}$$

where y_i is the ground-truth human-derived rating and $\hat{y}_i$ is the predicted rating. The competition adopts a two-stage leaderboard system:

- Preliminary Stage: A public leaderboard based on a subset of the test set for iterative submissions.
- Final Stage: A private leaderboard evaluated on the full hidden test set, determining the official ranking.

B. Dataset and Features

The official dataset comprises a large labeled training set and an unlabeled test set:

- Training Set: 4,557,000 puzzles annotated with human-derived Glicko-2 ratings and engine-computed statistics.
- Test Set: 2,235 puzzles sharing the same feature structure but without difficulty ratings. Predictions for this set are used for final evaluation.

Each puzzle is described by 32 structured features in the training set and 25 features in the test set:

1) Core Information: PuzzleId, Forsyth–Edwards Notation (FEN)[5] for board state, and Portable Game Notation (PGN)[6] for solution moves.
2) Human-Performance Annotations (training only): Rating (Glicko-2 difficulty), RatingDeviation, Popularity, and NbPlays.
3) Contextual Metadata: Themes, GameUrl, and OpeningTags.
4) Engine-Derived Success Probabilities: 10 rapid-mode columns (success_prob_rapid_1050–2050) and 10 blitz-mode columns (success_prob_blitz_1050–2050), representing estimated human success rates at different skill levels.

By decoding the FEN, the chessboard can be illustrated into image. For example, the below Figure 1 shows the chessboard initial state decoded by FEN and the rating is 1300.

Figure 1. FEN: "8/4R3/1p2P3/p4r2/P6p/1P3Pk1/4K3/8 w - - 1 64".

C. Key Challenges

The challenge introduces several unique difficulties:

- Human-Centric Bias: Ratings are derived from solver statistics rather than engine evaluations, so engine-trivial tactics may still be difficult for humans.
- Imbalanced Difficulty Distribution: Sparse high-Elo samples are prone to underestimation by global models trained on mid-range-dominated data.
- High-Dimensional Structured Features: Success probabilities across multiple skill bands must be effectively combined without overfitting.
- Scalability and Interpretability: Models must efficiently process millions of samples while maintaining transparency for educational use cases.

D. Extended Mask-Based Evaluation

An additional subtask evaluates uncertainty estimation. Participants submit a binary mask identifying the 10% most error-prone test puzzles. Scores are recomputed by replacing masked predictions with ground-truth ratings, and rankings are determined by the ratio between the adjusted score and the theoretical "perfect mask." This extension highlights the importance of reliable uncertainty estimation.

III. Methodology

This section presents the detailed methodology of our solution for the FedCSIS 2025 Challenge main task. The proposed approach follows a structured multi-stage pipeline designed to balance accuracy, interpretability, and computational efficiency. We first provide an overview of the entire pipeline, then highlight its key methodological contributions, followed by a detailed description of each stage.

A. Overall Pipeline

The pipeline consists of three major stages:

1) Elo-Banded Base Models: Four band-specific models are trained on separate Elo ranges using structured puzzle features (engine-derived statistics and positional indicators) to capture localized difficulty semantics and

reduce prediction bias caused by highly imbalanced rating distributions.

2) Feature-Level Stacking Ensemble: Outputs from base models are combined with structural puzzle features in a heterogeneous meta-learning framework, improving cross-band generalization.
3) Post-Processing Rating Prediction: A lightweight residual correction adjusts systematic biases, producing the final predicted ratings submitted to the competition.

This design allows predictions to be progressively refined: base models specialize in local rating regions, stacking integrates global patterns, and post-processing corrects residual systematic errors.

B. Major Contributions in Method Design

The key methodological contributions include:

- Band-Specific Specialization: Instead of a single global model, band-wise training explicitly targets the diverse difficulty distributions across Elo ranges.
- Structured Feature Utilization: Engine-derived success probabilities and handcrafted positional indicators are explicitly exploited both in base and stacking models, improving interpretability and generalization.
- Hybrid Meta-Learning: By combining a linear model (Ridge), a tree-based model (XGBoost), and a neural network (MLP), the stacking ensemble exploits complementary strengths.
- Lightweight but Scalable: All components are computationally efficient and scalable to millions of samples, unlike many deep-learning-based solutions.
- Bias Mitigation via Post-Processing: A simple, interpretable residual correction effectively addresses underestimation in high-Elo regions.

C. Step 1: Elo-Banded Base Models

Puzzle ratings span from approximately 400 Elo (basic tactics) to over 3000 Elo (master-level combinations), leading to a potential imbalanced difficulty distribution, as summarized in Fig. 2. Although high-Elo puzzles (≥ 1700) constitute over one-third of the data, their solving patterns differ substantially from lower bands, and a single global model trained on such mixed distributions often overfits mid-range samples while underestimating high-Elo puzzle difficulty.

To address this, we adopt a band-wise modeling strategy, training four independent models, each specialized for a designated Elo range [2]. This specialization allows each model to focus on localized difficulty patterns, improving prediction accuracy across heterogeneous rating bands.

1) Training Data Selection: All training samples are assigned to exactly one band-specific model according to their difficulty ratings. Unlike the default global-training setup of the baseline regression code, we manually configured the training pipeline to filter puzzles into four disjoint Elo bands:

- **Small model:** Rating $<$ 1000 (beginner-level puzzles with simple tactical motifs),

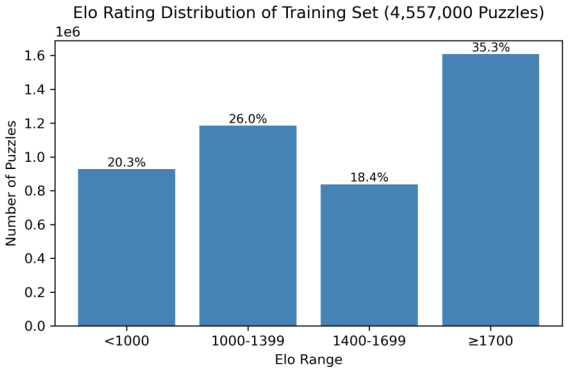

Figure 2. Elo rating distribution of the training set (4,557,000 puzzles), showing heterogeneous distributions across rating bands.

- **1300 model:** 1000 $\leq$ Rating $<$ 1400 (intermediate-level puzzles),
- **1500 model:** 1400 $\leq$ Rating $<$ 1700 (club-level puzzles with mixed tactical and strategic depth),
- **1700+ model:** Rating $\geq$ 1700 (advanced puzzles requiring deeper tactical reasoning).

This standardized partitioning ensures full data utilization and enables each model to learn the statistical patterns and solving dynamics specific to its designated Elo range, which is particularly beneficial for the sparse high-Elo band.

2) Model Architecture: All four band-specific models are trained as Multi-Layer Perceptron regressors (MLP), following a standard supervised learning framework:

- Input Representation: Each puzzle is represented entirely by structured features extracted from the official dataset:
  - Engine-derived statistics such as per-move success probabilities, mean, standard deviation, max, and min probabilities,
  - failure probability and distribution skewness,
  - material balance,
  - solution length and other positional descriptors.

  All continuous features are normalized to the range [0,1].
- Network Structure: Each model consists of several fully connected layers with ReLU activations, followed by a single linear regression head that outputs a scalar difficulty rating. This MLP architecture is well-suited to tabular structured data and provides efficient training on millions of samples.
- Training Objective: All models are optimized with the standard Mean Squared Error (MSE):

$$\mathcal{L}_{\text{base}} = \frac{1}{N}\sum_{i=1}^{N}(y_i - f_\theta(x_i))^2, \tag{2}$$

  where f_θ is the band-specific MLP and y_i the ground-truth difficulty rating.
- Epochs and Fine-Tuning: The number of training epochs is determined empirically based on validation performance, typically ranging from 10 to 20 epochs depending

on band size, model convergence speed, and computational budget. This relatively small epoch range reflects a trade-off between convergence and time efficiency, as prolonged training provides diminishing returns and is computationally expensive for large-scale data.
An internal validation set, sampled as 10% of the band-specific training data, is used exclusively for hyperparameter tuning and to save the best-performing checkpoints based on validation MSE.

3) Inference and Outputs: After training, each model is applied independently to the official test set using a standardized inference pipeline. The four models generate separate predictions corresponding to the small, 1300, 1500, and 1700 Elo bands. These predictions form the base inputs for the stacking ensemble in Step 2.

D. Step 2: Stacking Ensemble

1) Motivation: While band-specific models effectively capture localized difficulty patterns, they lack global consistency and fail to fully exploit cross-band correlations. A meta-learning strategy can integrate predictions from multiple bands and leverage structural attributes to correct residual inconsistencies. In particular, features such as failure probability and move counts provide complementary information about puzzle-solving dynamics that is not fully encoded in the band-wise models.

2) Meta-Feature Construction: A comprehensive meta-feature vector is constructed by combining base-model predictions and structural puzzle attributes:

$$\begin{aligned}\mathbf{z} = [&p_1,\ p_2,\ p_3,\ p_4,\ \tilde{p},\ \sigma_p,\\ &\text{avg_success},\ \text{fail_prob},\ \text{inflection_rating},\\ &\text{fail_skew},\ \text{num_move}]\end{aligned} \tag{3}$$

where:

$$\tilde{p} = \text{median}(p_i), \qquad \sigma_p = \sqrt{\frac{1}{4}\sum_{i=1}^{4}(p_i - \tilde{p})^2}. \tag{4}$$

Here, $\tilde{p}$ represents the robust central tendency of the base predictions, while σ_p serves as an implicit confidence measure, indicating inter-model disagreement.

3) Meta-Learners and Complementarity: The stacking ensemble integrates three heterogeneous meta-learners chosen for their complementary modeling capacities:

- Ridge Regression: A linear regression model with L_2 regularization, which stabilizes coefficient estimation by penalizing large weights. Ridge captures global linear trends between structural attributes (e.g., average success probability, number of moves) and target ratings. Its interpretability provides valuable insight into the relative importance of meta-features.
- XGBoost: An ensemble of gradient-boosted regression trees that sequentially fits residual errors. XGBoost is well-suited for modeling nonlinear feature interactions and conditional relationships, such as detecting puzzles that are deceptively difficult despite short move sequences.
- MLP Regressor: A lightweight feedforward neural network configured with two hidden layers (128 and 64 neurons, ReLU activation). This configuration provides a balance between model capacity and overfitting risk for the low-dimensional meta-feature vector, while effectively capturing high-order nonlinear dependencies not easily approximated by tree-based methods.

4) Prediction Aggregation: The outputs of the three meta-learners are aggregated via an adaptive weighted average:

$$\hat{y}_{stack} = w_{\text{ridge}}\hat{y}_{\text{ridge}} \ + \ w_{\text{xgb}}\hat{y}_{\text{xgb}} \ + \ w_{\text{mlp}}\hat{y}_{\text{mlp}}, \tag{5}$$

where the weights are inversely proportional to the validation residual variance:

$$w_j = \frac{1/\sigma_j^2}{\sum_k (1/\sigma_k^2)}, \qquad j \in \{\text{ridge}, \text{xgb}, \text{mlp}\}. \tag{6}$$

This dynamic weighting emphasizes models with more stable validation performance. Ridge contributes stability and interpretability, XGBoost captures local conditional interactions, and the MLP learns complex nonlinear relationships, resulting in improved generalization across heterogeneous puzzle types.

E. Step 3: Post-Processing Rating Prediction

1) Motivation: Although the stacking ensemble improves overall prediction accuracy, residual analysis reveals systematic biases: high-Elo puzzles tend to be underestimated, while some low-Elo puzzles are slightly overestimated. These biases arise because the meta-learners only indirectly exploit engine-derived structural signals, which often contain strong priors about puzzle difficulty.

2) Structure-Aware Residual Correction: To explicitly incorporate these priors, we introduce a lightweight residual correction that adjusts the stacking predictions toward a refined structural difficulty estimate.

First, a baseline structural estimate s is computed as a failure-probability-weighted average of rating buckets:

$$s = \frac{\sum_j (1 - \bar{p}_j)\, r_j}{\sum_j (1 - \bar{p}_j)}, \tag{7}$$

where $(1 - \bar{p}_j)$ represents the failure probability in bucket r_j. This estimate is then refined by incorporating two additional structural signals:

- The inflection point r_{inf}, indicating the rating at which the success probability changes most sharply.
- The failure-probability skewness γ, which captures asymmetric difficulty distributions where certain skill groups systematically misjudge a puzzle. highlighting difficulty transitions perceived by human solvers;

The final refined structural estimate is defined as:

$$s^* = 0.6\, s \ + \ 0.2\, r_{\text{inf}} \ + \ 0.2\,(1700 + 300\,\gamma) \tag{8}$$

Finally, the corrected rating prediction is obtained through a residual fusion with the stacking output:

$$\hat{y}_{\text{final}} = \hat{y}_{\text{stack}} \; + \; \lambda \left(s^* - \hat{y}_{\text{stack}} \right), \qquad \lambda = 0.3. \tag{9}$$

This correction introduces no additional learnable parameters and is computationally efficient. By explicitly leveraging interpretable structural priors, it consistently improves accuracy, particularly in high-Elo regions where data sparsity makes residual biases more severe.

IV. Mask-Based Uncertainty Evaluation

In addition to the main rating prediction task, the FedCSIS 2025 Challenge introduced an extended evaluation explicitly designed to assess uncertainty estimation. Participants were required to submit a binary mask marking the 10% of test puzzles most likely to be mispredicted by their models. The final score was recalculated by replacing predictions for these masked samples with ground-truth ratings, and the ratio between the adjusted score and the theoretically optimal score determined the subtask ranking.

We designed a structure-aware uncertainty estimation method that integrates model disagreement, prediction instability, and structural difficulty indicators into a unified scoring framework. This approach balances model-based and feature-based uncertainty cues, improving the alignment of selected samples with actual model errors.

A. Scoring Function Design

The composite uncertainty score for each puzzle is defined as:

$$u_i = \alpha \cdot \sigma_{p,i} \; + \; \beta \cdot \delta_i \; + \; \gamma \cdot \psi_i \tag{10}$$

where:

- $\bar{p}_i$: average success probability across rating buckets for puzzle i,
- z_i: Z-score of the material balance in the training data; for the test set, this term defaults to zero as no material information is provided,
- $\mathbb{I}(|z_i| > \tau)$: indicator of extreme material imbalance, with $\tau = 3.0$ as the outlier threshold.

The weighting coefficients were empirically set to $\alpha = 1.0$, $\beta = 1.0$, and $\gamma = 0.4$ to optimize the uncertainty ranking quality.

B. Mask Generation

Puzzles are ranked according to u_i, and the top 10% are assigned a mask value of 1:

$$\text{mask}_i = \begin{cases} 1, & i \text{ in top } 10\% \text{ highest scores}, \\ 0, & \text{otherwise}. \end{cases} \tag{11}$$

This binary mask was submitted separately from the rating predictions, providing an explicit measure of the model's uncertainty estimation capability.

C. Discussion

The proposed uncertainty estimation method combines model-driven and feature-driven indicators in a single interpretable framework. Its main advantages include:

- improved consistency between selected samples and actual prediction errors compared to variance-only methods;
- and explicit consideration of structural puzzle difficulty, beyond pure statistical disagreement.

However, the method still relies on the alignment of raw and post-processed predictions and may overlook systematic biases shared across all models. Despite these limitations, the approach provides a strong baseline for uncertainty-aware chess puzzle difficulty estimation.

Our uncertainty mask ratio is 1.696, placing us 8th out of the 9 teams that chose to participate in this additional task. Using our submitted mask, our final score is approximately 57,931, while using a "perfect mask" would yield a score of about 34,162. The full results for all teams will be published in the competition report [5].

V. Experimental Setup

A. Dataset and Preprocessing

The dataset provided by the organizers consists of two disjoint parts:

- Training set: Approximately 4,557,000 puzzles, each labeled with a human-perceived difficulty rating derived from aggregated player performance in Lichess (Glicko-2 system). This set is fully annotated and serves as the only source of labeled data for model development.
- Test set: An unlabeled set of 2,235 puzzles used exclusively for the final evaluation. Participants are required to submit predicted ratings for this set, while the ground-truth ratings remain hidden.

To ensure balanced representation across different rating bands, the official training set is split using stratified sampling within each Elo band:

- Base-model training subset: 90% of puzzles per Elo band, used for training the four band-specific base models.
- Validation subset: 10% of puzzles per Elo band, reserved exclusively for generating unbiased out-of-sample predictions for stacking and for residual bias calibration.

The stacking meta-learners are trained solely on this held-out validation subset to prevent data leakage. To improve generalization within the stacking stage, a 10-fold cross-validation is performed on the validation subset: in each fold, the meta-learners are trained on 90% of the fold and validated on the remaining 10%, and the out-of-fold predictions are averaged for final submission.

All continuous features, including success probabilities, failure distributions, and structural statistics, are normalized to the [0,1] range. PGN sequences are parsed to compute derived attributes such as the number of solution moves (*num_move*), and FEN strings are used to extract positional features such as castling rights and piece material balance.

B. Training Details

Each Elo-banded base model is implemented as a lightweight multi-layer perceptron (MLP) following the official baseline recommendations. The models are trained for 20–30 epochs with early stopping based on validation loss. The best-performing checkpoints are selected, and no cross-validation is applied at the base-model stage to keep training computationally efficient.

The meta-learner integrates Ridge regression (L2 regularization), XGBoost (max depth = 8, learning rate = 0.01-0.05, 1000-2000 boosting rounds) and a lightweight MLP (two hidden layers: 128 and 64 neurons, ReLU activation, dropout = 0.1). The meta-features are constructed exclusively from base model predictions on the validation subset (out-of-sample), and a 10-fold cross-validation within this subset is used to improve the robustness of the meta-learners.

A structure-aware residual correction is fitted to the validation residuals, explicitly adjusting the stacking predictions toward structural difficulty estimates, especially mitigating underestimation in sparse high-Elo regions.

C. Overall Performance

Table I shows the progressive improvements across pipeline stages.

Table I
PROGRESSIVE IMPROVEMENTS ACROSS PIPELINE STAGES (INTERNAL HOLD-OUT TEST SET).

Pipeline Stage	MSE	Relative Gain
Base Models (avg/median)	78,000–80,000	–
Stacking Ensemble (10-Fold)	71,000–73,000	+9–11%
Post-Processing + Best Avg	66,600–68,000	+6–8%

The pipeline shows clear incremental gains: stacking substantially improves cross-band consistency, while residual correction yields additional improvements in high-Elo regions.

D. Ablation Study

Table II highlights the contribution of each major component.

Table II
ABLATION STUDY: CONTRIBUTION OF EACH COMPONENT (VALIDATION SET).

Configuration	MSE	Change vs. Full
Full Pipeline	66,600–68,000	Baseline
w/o Structural Features	∼72,000	+6–8%
w/o Stacking Ensemble	∼78,000	+15–18%
Single Global Model	>85,000	+25%

Removing structural features increases variance, confirming their role as complementary difficulty indicators. Stacking yields the largest single improvement by integrating base-model predictions with structural cues, while replacing band-wise models with a single global model leads to severe bias, particularly for high-Elo puzzles.

E. Discussion

These results confirm the effectiveness of a structured and interpretable pipeline:

- Elo-banded modeling alleviates data imbalance and reduces extreme rating bias;
- Stacking with structural reasoning provides the largest performance gain by capturing cross-band interactions;
- Residual calibration yields additional improvements in sparse high-Elo regions with negligible computational cost.

The final MSE of 62,685 ranks among the top solutions, demonstrating that a lightweight and transparent ensemble can rival more computationally expensive deep-learning models, making it suitable for educational or large-scale online puzzle recommendation systems.

VI. CONCLUSION

This study presented a structured and interpretable pipeline for chess puzzle difficulty prediction in the FedCSIS 2025 Challenge. The approach combines three complementary stages: (1) Elo-banded base models specialized for different rating ranges to reduce distributional bias, (2) a feature-level stacking ensemble that integrates base predictions with structural puzzle attributes to improve cross-band generalization, and (3) a lightweight structure-aware residual correction to mitigate systematic errors, particularly in sparse high-Elo regions.

Extensive experiments demonstrated clear incremental improvements at each stage, achieving a final MSE of 62,685 and ranking 7$^{\text{th}}$ in the final leaderboard among resource-intensive deep-learning solutions. The results confirm that carefully designed ensembles, when combined with domain-specific structural reasoning, can achieve competitive accuracy with far lower computational cost and higher interpretability.

***Abstract*—The FedCSIS 2025 Challenge on Predicting Chess Puzzle Difficulty tasked participants with estimating puzzle ratings directly from board states and solution sequences, without relying on human solver statistics.**

We propose a three-stage hybrid framework integrating gradient-boosting regressors, a multi-modal neural network, and an XGBoost stacking ensemble. The boosting stage modeled handcrafted structural features derived from FEN and engine metadata, while the multi-modal network jointly learned from structured features and image-rendered chessboards to capture positional and tactical patterns. The residual-based stacking stage explicitly modeled prediction errors to correct systematic biases and enhance performance, particularly for high-difficulty puzzles.

Our method achieved a competitive performance, ranking 7th in the preliminary stage and 8th in the final leaderboard. These results demonstrate that combining interpretable boosting models with visual-tactical deep representations and meta-learning provides a robust and computationally efficient alternative to large-scale transformer-based approaches.

I. Introduction

THE prediction of chess movements has evolved dramatically since the landmark achievement of IBM's Deep Blue in 1997[1], when it famously defeated world champion Garry Kasparov. Automated prediction of chess puzzle difficulty plays an increasingly important role in online training platforms, enabling adaptive puzzle recommendation and accurate tracking of player progression.

Early research focused on handcrafted features, employing gradient-boosting or support vector regressors trained on material balance, king safety, and piece mobility [2], [3]. Although these models lacked scalability, they demonstrated the importance of domain knowledge and interpretability in difficulty estimation. With the advent of deep learning, convolutional neural networks (CNNs) [4] were introduced to treat the chessboard as an image, successfully capturing spatial and tactical patterns such as attacking piece clusters and exposed kings. Later, hybrid CNN-LSTM [5] architectures integrated sequential move information, showing that temporal reasoning improves alignment with human-rated difficulty. Transfer learning approaches, such as DeepChess [6], adapted game prediction networks for puzzle rating, implicitly learning tactical patterns from large-scale game data.

More recently in the IEEE Big Data Cup 2024 [7], transformer-based architectures, such as GlickFormer [8], achieved state-of-the-art results by modeling spatio-temporal dependencies in move sequences. However, these models are computationally expensive and thus less practical for real-time puzzle rating systems. Competition-oriented solutions, such as the Bread Emoji team's hybrid ensemble combining engine-derived success probabilities with neural embeddings [9], have demonstrated that combining interpretable features with lightweight neural models can remain competitive while being computationally efficient.

Our team has an extensive history of successful participation in data science competitions hosted on the KnowledgePit platform[1]. We have consistently leveraged Gradient Boosting Decision Tree (GBDT) algorithms to tackle a wide range of predictive tasks—including classification, regression, forecasting, and image recognition—achieving top-ranked results and earning multiple awards[10] - [20]. Motivated by this strong background, we approach the present challenge with the same commitment to excellence.

Our work proposes a hybrid three-stage framework designed to achieve high predictive accuracy while maintaining interpretability and efficiency. We integrate 3 parts, which are

- three gradient-boosting models for robust tabular predictions,
- a multi-modal neural network to extract visual-tactical cues from rendered chessboard images,
- and an XGBoost stacking ensemble to fuse predictions into a single optimized output.

Additionally, we extend the method with a mask-based uncertainty estimation task, where the goal is to identify the most error-prone puzzles.

The remainder of this paper is organized as follows. Section II describes the challenge setup, dataset, and evaluation metric. Section III details the proposed methodology. Section IV presents the mask extension for uncertainty estimation. Section V reports experimental results and ablation studies. Finally, Section VI concludes the paper and discusses future research directions.

II. Challenge Description

The FedCSIS 2025 Challenge [21] is the second edition of IEEE BigData Cup 2024 chess puzzle competition [7] on Predicting Chess Puzzle Difficulty addressed the problem of estimating puzzle difficulty ratings directly from board configurations and solution sequences. The task was formulated as a regression problem, where each puzzle was assigned a continuous difficulty rating analogous to Lichess[2] puzzle ratings, typically ranging between 800 and 2800. These ratings approximate the skill level of players expected to solve the puzzle with a 50% success probability, making the task closer to modeling human cognitive difficulty than engine evaluation.

The dataset, derived primarily from real games on Lichess, contained tens of thousands of puzzles. Each puzzle was described by:

- FEN (Forsyth–Edwards Notation)[3]: Encodes the board state at the start of the puzzle, including piece placement, side to move, castling rights, and en passant possibilities.
- PGN[4] moves: The sequence of solution moves forming the intended tactical line.
- Puzzle rating: The target variable representing human-perceived puzzle difficulty.
- Optional metadata: Additional information such as puzzle tags or themes, which some participants used as auxiliary features.

The dataset was divided into training and test sets, with ground-truth ratings provided only for the training set. No official validation split was released, requiring participants to design their own validation protocols. In our case, a random 10% split of the training set was used to approximate unseen data. The rating distribution was broad but skewed, with most puzzles clustered in the intermediate range (1400–2000) and long tails toward very easy and extremely difficult puzzles. This imbalance increased the impact of errors on rare high-difficulty puzzles, as large deviations in such cases significantly influenced the evaluation metric.

A training chess board initial state sample decoded by FEN was shown in the below Figure 1 with the rating 1575.

Submissions were scored using the Mean Squared Error(MSE)[5] between predicted ratings $\hat{y}_i$ and ground-truth ratings y_i:

$$\text{MSE} = \frac{1}{N}\sum_{i=1}^{N}(y_i - \hat{y}_i)^2, \tag{1}$$

where N denotes the number of test samples. Because MSE penalizes large deviations quadratically, extreme mispredictions (e.g., predicting 1500 for a puzzle rated 2300) had a disproportionately large effect, making robust handling of such outliers crucial.

In addition to these technical considerations, the challenge imposed practical constraints. The test set was unlabeled,

[4]https://en.wikipedia.org/wiki/Portable_Game_Notation
[5]https://en.wikipedia.org/wiki/Mean_squared_error

Figure 1. A training chess board state sample of rating 1575 and FEN "8/8/4k1p1/2KpP2p/5PP1/8/8/8 w - - 0 53".

which increased the risk of overfitting without carefully designed validation procedures. The diversity of puzzle types, i.e. forced checkmates, defensive resource puzzles, and quiet positional tactics, made simple statistical baselines inadequate to capture nuanced difficulty differences.

Finally, there was a trade-off between accuracy and interpretability. Deep neural networks, while expressive, are prone to overfitting or unstable predictions with limited training data, whereas classical machine learning models often fail to capture sequential and visual information. Consequently, prior top-performing approaches combined interpretable boosting models with engine-derived features to balance robustness and computational efficiency. Our method was designed with these considerations in mind, integrating complementary model strengths to improve generalization while maintaining interpretability.

III. Methodology

Our solution follows a three-stage hybrid pipeline that integrates gradient-boosting models, a multi-modal neural network, and an XGBoost-based stacking ensemble. This design leverages the stability of boosting methods for structured data, while incorporating deep neural representations to capture tactical and spatial patterns from chessboard images.

A. Gradient-Boosting Base Models

The first stage of our framework employs gradient boosting, an ensemble learning technique that constructs a strong predictive model by combining multiple weak learners in an additive manner. Given a differentiable loss function $\mathcal{L}(y, F(x))$, gradient boosting iteratively fits a new base learner to the negative gradient of the loss with respect to the current prediction. At the m-th iteration, the ensemble is updated as:

$$F_m(x) = F_{m-1}(x) + \eta \cdot h_m(x), \tag{2}$$

where $F_m(x)$ is the updated ensemble prediction, and $h_m(x)$ is the weak learner trained on the residuals:

$$r_{i,m} = -\frac{\partial \mathcal{L}(y_i, F_{m-1}(x_i))}{\partial F_{m-1}(x_i)}, \tag{3}$$

and $\eta \in (0, 1]$ is the learning rate controlling the contribution of each learner. This formulation effectively reduces bias while controlling variance, making gradient boosting well-suited for modeling tabular data with complex non-linear interactions.

a) XGBoost: XGBoost (Extreme Gradient Boosting) [3] introduces second-order gradient optimization and sparsity-aware split finding, with regularization to control model complexity. The overall objective function is:

$$\mathcal{L}_{\text{XGB}} = \sum_{i=1}^{N} \ell(y_i, \hat{y}_i) + \sum_{k=1}^{K} \left(\gamma T_k + \frac{1}{2} \lambda \sum_j w_{kj}^2 \right), \quad (4)$$

where:

- T_k is the number of leaves in the k-th decision tree,
- w_{kj} is the weight of leaf j in tree k,
- γ and λ are regularization coefficients controlling tree complexity and weight shrinkage.

This regularized formulation makes XGBoost robust against overfitting and variance, making it particularly effective for structured chess features.

b) LightGBM: LightGBM (Light Gradient Boosting Machine) [2] is optimized for high-dimensional tabular data through histogram-based feature binning and a leaf-wise growth strategy with depth constraints. Its split gain is computed as:

$$\text{Gain} = \frac{1}{2} \left(\frac{G_L^2}{H_L + \lambda} + \frac{G_R^2}{H_R + \lambda} - \frac{(G_L + G_R)^2}{H_L + H_R + \lambda} \right) - \gamma, \quad (5)$$

where G_L, H_L and G_R, H_R are the accumulated gradients and Hessians of the left and right nodes. This strategy balances accuracy and efficiency, making LightGBM a reliable baseline for modeling chess-specific structured features.

c) CatBoost: CatBoost [22] is designed to handle categorical variables natively, avoiding target leakage through permutation-driven encoding. Its ordered target encoding for a categorical feature is:

$$\hat{y}_{cat} = \frac{\sum_{i<j} y_i + p}{n + q}, \quad (6)$$

where p and q are prior parameters for Bayesian smoothing, and n is the number of preceding samples. This makes CatBoost particularly effective for categorical chess features, such as castling rights and the side-to-move indicator.

d) Input Features and Training Objective: All three models were trained on handcrafted features extracted from FEN, PGN, and engine metadata:

- **Structural features:** Material balance, piece counts for both sides, castling rights, and check status—key indicators of positional complexity.
- **Move count:** Total number of moves in the puzzle's solution sequence, often correlated with tactical depth.
- **Engine-derived probabilities:** Success probabilities for rapid and blitz rating buckets across Elo levels.
- **Average success rate:**

$$s_{\text{avg}} = 0.5 \times (s_{\text{rapid}} + s_{\text{blitz}}), \quad (7)$$

providing a balanced indicator of expected human solvability.

- **Aggregated statistics:** Maximum and standard deviation of success probabilities ($s_{\max}, s_{\text{std}}$) to capture tactical ambiguity—high variance typically indicates multiple equally strong candidate moves, increasing cognitive complexity.

All boosting models were optimized with the Mean Squared Error (MSE):

$$\mathcal{L}_{\text{MSE}} = \frac{1}{N} \sum_{i=1}^{N} (y_i - \hat{y}_i)^2, \quad (8)$$

where y_i and $\hat{y}_i$ denote the ground-truth and predicted ratings.

e) Rationale: This boosting stage provides a strong and interpretable baseline for structured features and produces complementary predictions for the stacking stage, where diverse model biases are effectively combined.

B. Multi-Modal Neural Network

While gradient-boosting models are effective for structured tabular features, they are inherently limited in capturing spatial and visual cues that strongly influence human-perceived puzzle difficulty. To address this limitation, we designed a multi-modal neural network that jointly learns from structured numeric features and visual representations of chessboard configurations.

a) Structured Feature Encoder: The numeric branch encoded the same handcrafted features as in the boosting stage, enriched with additional structural and interaction terms to capture tactical and positional complexity more effectively:

- **New structural features:** Piece density, defined as:

$$d_p = \frac{n_w + n_b}{64}, \quad (9)$$

where n_w and n_b denote the counts of white and black pieces, respectively, serves as a compact measure of board congestion. A binary last-move success flag indicates whether the most recent move had a high engine-predicted success probability. Cross features were introduced to model interactions between key factors:

$$f_1 = s_m \cdot m_b, \quad (10)$$

$$f_2 = n_m \cdot s_{\text{avg}}, \quad (11)$$

where s_m is the side-to-move indicator (1 for White, 0 for Black), m_b is the material balance, n_m is the total move count, and s_{avg} is the average engine-predicted success probability.

- **Engine statistics:** Aggregated success probabilities, including mean (s_{mean}), maximum ($s_{\max}$), and standard deviation (s_{std}), were used to capture tactical ambiguity. High variance (s_{std}) typically indicates multiple equally strong candidate moves, increasing cognitive difficulty for human players.

The numeric features were standardized and passed through two fully connected layers (64 and 32 neurons, ReLU activation). Formally:

$$\mathbf{h}_1 = \sigma(\mathbf{W}_1\mathbf{x} + \mathbf{b}_1), \tag{12}$$

$$\mathbf{z}_{\text{num}} = \sigma(\mathbf{W}_2\mathbf{h}_1 + \mathbf{b}_2), \tag{13}$$

where $\mathbf{x}$ is the standardized feature vector, $\mathbf{W}_1, \mathbf{W}_2$ and $\mathbf{b}_1, \mathbf{b}_2$ are trainable parameters, and $\sigma(\cdot)$ denotes the ReLU activation.

b) Image Feature Encoder: Each FEN string was converted into a chessboard image using `python-chess` and `cairosvg`, enabling the network to learn spatial and tactical patterns that are difficult to model through explicit numeric features alone. Accurate representation of visual configurations is crucial because human-perceived difficulty is strongly influenced by positional complexity, such as piece clustering, open lines, and king safety, which are more naturally encoded in a spatial format.

A single high-capacity convolutional backbone was adopted. We selected EfficientNetB3 [23] due to its superior trade-off between accuracy and computational cost. Its compound scaling strategy jointly optimizes network depth, width, and input resolution, allowing fine-grained tactical features—such as discovered attacks or forced mating nets—to be captured effectively. The backbone was initialized with ImageNet-pretrained weights and fine-tuned on the chess puzzle dataset to adapt to domain-specific patterns.

Let $\phi_{\text{E3}}(\cdot)$ denote the EfficientNetB3 backbone and $GAP(\cdot)$ the Global Average Pooling operation. The encoded visual representation is given by:

$$\mathbf{z}_{\text{img}} = GAP\left(\phi_{\text{E3}}(I_{\text{fen}})\right), \tag{14}$$

where I_{fen} is the rendered chessboard image.

c) Fusion and Output Layer: The visual embedding $\mathbf{z}_{\text{img}}$ was concatenated with the numeric branch embedding $\mathbf{z}_{\text{num}}$ to form a joint latent representation:

$$\mathbf{z}_{\text{fusion}} = \begin{bmatrix} \mathbf{z}_{\text{num}} \\ \mathbf{z}_{\text{img}} \end{bmatrix}, \tag{15}$$

which was passed through a fully connected fusion head:

$$\hat{y} = W_3\,\sigma(W_2\,\sigma(W_1\,\mathbf{z}_{\text{fusion}} + b_1) + b_2) + b_3, \tag{16}$$

where $\sigma(\cdot)$ is the ReLU activation. A dropout layer ($p = 0.3$) was applied after the first dense layer to reduce overfitting by encouraging robustness to co-adaptations between visual and numeric features.

d) Training Procedure: The network was trained end-to-end using the Adam optimizer (learning rate $= 10^{-4}$) and the Mean Squared Error (MSE) loss:

$$\mathcal{L}_{\text{MSE}} = \frac{1}{N}\sum_{i=1}^{N}(y_i - \hat{y}_i)^2, \tag{17}$$

where y_i and $\hat{y}_i$ denote the ground-truth and predicted difficulty ratings for sample i. EarlyStopping and ReduceLROnPlateau strategies were applied to prevent overfitting and improve convergence stability.

Despite its moderate computational requirements, the inclusion of a visual branch substantially improved predictions, particularly for high-difficulty puzzles where spatial complexity such as multi-piece coordination or long forced sequences plays a crucial role in human perception.

C. Residual-Based XGBoost Stacking Fusion

The final stage refines the predictions by explicitly modeling the residual errors from the first two stages. Instead of directly stacking the base predictions, we train an XGBoost meta-learner to learn the systematic residuals and correct the base prediction accordingly.

a) Base Prediction and Residual Definition: Let $\mathbf{p}_{\text{boost}} \in \mathbb{R}^3$ denote the three boosting model predictions from Step 1, and $p_{\text{nn}} \in \mathbb{R}$ denote the multi-modal neural network prediction from Step 2. The base prediction $\bar{p}_i$ for sample i is defined as the simple average of all four models:

$$\bar{p}_i = \frac{1}{4}\left(p^{(1)}_{\text{boost},i} + p^{(2)}_{\text{boost},i} + p^{(3)}_{\text{boost},i} + p_{\text{nn},i}\right), \tag{18}$$

although in practice, weighted averages were also evaluated during validation.

The residual for each sample is computed as:

$$r_i = y_i - \bar{p}_i, \tag{19}$$

where y_i is the ground-truth puzzle rating.

b) Stacking Input Construction: The XGBoost meta-learner is trained to predict the residuals r_i rather than the final ratings directly. Its input vector is constructed from:

- The individual residual components of each base learner:
$$r_i^{(k)} = y_i - p_i^{(k)}, \quad k = 1, 2, 3, \text{nn}, \tag{20}$$
where $p_i^{(k)}$ is the prediction of the k-th base learner.
- Key structural features correlated with human difficulty:
$$\mathbf{f}_{\text{key},i} = \begin{bmatrix} s_{\text{avg},i} \\ n_{m,i} \\ m_{b,i} \end{bmatrix}, \tag{21}$$
where $s_{\text{avg},i}$ is the average success rate (Eq. 7), $n_{m,i}$ the move count, and $m_{b,i}$ the material balance.

The complete stacking input is:

$$\mathbf{x}_{\text{stack},i} = \begin{bmatrix} r_i^{(1)} \\ r_i^{(2)} \\ r_i^{(3)} \\ r_i^{(\text{nn})} \\ \mathbf{f}_{\text{key},i} \end{bmatrix} \in \mathbb{R}^7. \tag{22}$$

c) Meta-Learner Training and Final Prediction: The XGBoost meta-learner $\mathcal{F}_{\text{XGB}}$ minimizes the Mean Squared Error (MSE) of the residuals:

$$\mathcal{L}_{\text{stack}} = \frac{1}{N}\sum_{i=1}^{N}\left(r_i - \hat{r}_i\right)^2, \tag{23}$$

where $\hat{r}_i = \mathcal{F}_{\text{XGB}}(\mathbf{x}_{\text{stack},i})$ is the predicted residual.

Finally, the corrected prediction for sample i is obtained by adding the predicted residual to the base prediction:

$$\hat{y}_{\text{final},i} = \bar{p}_i + \hat{r}_i. \tag{24}$$

d) Rationale: This residual-based stacking approach effectively treats the meta-learner as a non-linear residual corrector. By modeling residuals instead of direct predictions, the meta-learner focuses on learning systematic errors of the base models, such as the underestimation of high-difficulty puzzles. Incorporating structural features (Eq. 21) further allows the meta-learner to exploit domain-specific correlations between residual errors and puzzle characteristics, yielding significant accuracy gains, especially for puzzles with ratings above 2200.

IV. Mask Prediction – Competition Extension

In addition to the main regression task, the organizers introduced an optional extension to evaluate a model's uncertainty estimation ability. Participants were required to identify the 10% of test puzzles for which their predictions were most likely to be erroneous. By replacing predicted ratings for these puzzles with their ground-truth values, the leaderboard score was recomputed, providing an indirect measure of a model's ability to assess its own confidence. Formally, each submission consisted of a binary mask $M \in \{0,1\}^N$ satisfying

$$M_i = \begin{cases} 1, & \text{if puzzle } i \text{ is highly uncertain (masked)}, \\ 0, & \text{otherwise}, \end{cases}$$
$$\text{s.t.} \quad \sum_{i=1}^{N} M_i = N \times 10\% \tag{25}$$

where N is the total number of test samples. The evaluation used two scores: the *Perfect Score* P, defined as the minimum achievable MSE if the top 10% highest-error samples were perfectly masked, and the *New Score* N, the recomputed MSE after replacing predictions at masked indices with ground truth. The optimization objective was to minimize the ratio

$$\text{score} = \frac{N}{P}, \tag{26}$$

with the optimal value approaching 1.

The mask task can be interpreted as an uncertainty-ranking problem, where an ideal mask should prioritize puzzles whose predictions are expected to deviate most from the true rating. Our heuristic design followed two intuitive assumptions:

- samples whose predicted ratings deviate strongly from the overall rating distribution are more likely to be erroneous,
- and puzzles with longer solution sequences tend to involve deeper tactical reasoning and are thus harder for both humans and models.

To operationalize these assumptions, we designed a deterministic composite uncertainty score. For each puzzle i, the score is defined as

$$\text{mask_score}_i = 0.6\, u_i + 0.4\, c_i, \tag{27}$$

where u_i measures normalized prediction deviation and c_i quantifies move-based complexity:

$$u_i = \frac{|\hat{y}_i - \mu_y|}{\sigma_y}, \tag{28}$$
$$c_i = \frac{n_{m,i} - \mu_{n_m}}{\sigma_{n_m}}, \tag{29}$$

with $\hat{y}_i$ denoting the predicted rating, μ_y and σ_y the mean and standard deviation of predicted ratings, $n_{m,i}$ the move count of puzzle i, and μ_{n_m}, σ_{n_m} its distribution statistics. The top 10% samples with the highest mask_score_i were selected as

$$M_i = \begin{cases} 1, & \text{if } \operatorname{rank}(\text{mask_score}_i) \le 0.1N, \\ 0, & \text{otherwise.} \end{cases} \tag{30}$$

This rule required no additional calibration or access to ground-truth labels, making it computationally efficient and stable. Its main advantages are simplicity, consistency, and domain relevance, as it incorporates move count, a known correlate of puzzle difficulty.

Based on the competition report[21], our uncertainty mask ratio is equal to 1.648. It gives us the 6th place among 9 teams that decided to participate in this additional task. Our final score with the submitted mask is approximately equal to 56563. And our final score with the perfect mask would be equal to 34312.

V. Experimental Results

This section presents the empirical evaluation of our method, including ablation analysis and leaderboard performance, followed by a discussion of the contributions of each stage and their implications for generalization.

All experiments were conducted on the official training dataset. For the first and third stages, we employed a 10-fold cross-validation strategy to fully exploit the available data and obtain stable validation estimates. In each fold, 90% of the data were used for training and 10% for validation, and the final stage-wise performance was averaged across folds. For the second stage, due to the higher computational cost of CNN training, a fixed 10% hold-out validation set stratified by rating range was used. All boosting models were implemented with the official LightGBM, CatBoost, and XGBoost libraries, while the multi-modal neural network was implemented in TensorFlow/Keras. Early stopping based on validation MSE was applied for all models.

Our final submission ranked 7th in the preliminary stage and 8th in the final leaderboard. The public preliminary MSE was 66,658, and the private test MSE was 63,009, confirming good generalization. Table I summarizes the performance across all stages and the final leaderboard results.

The first stage achieved an average MSE of 87,378 across boosting models under 10-fold cross-validation, establishing a strong tabular baseline. The second stage reduced the MSE to 78,379 (+10.3%), demonstrating that the visual-tactical features extracted by the EfficientNetB3 backbone provided complementary information, particularly for complex tactical puzzles.

The residual-based XGBoost stacking in the third stage brought the most significant improvement, reducing the error to 68,029 (+22.1%). By explicitly modeling residuals and using 10-fold cross-validation to stabilize training, the meta-learner effectively captured systematic error patterns, particularly in high-rating puzzles where difficulty estimation is highly non-linear.

Table I
OVERALL RESULTS: ABLATION STUDY AND LEADERBOARD PERFORMANCE

Stage	Public LB MSE	Improvement (%)	Remarks
Best Average of Boosting Models (10-fold)	87,378	–	Average predictions from LightGBM, CatBoost, and XGBoost
Multi-Modal CNN (EfficientNetB3, hold-out)	78,379	10.3	Visual-tactical features complement structured predictions
Residual XGBoost Stacking (10-fold)	68,029	22.1	Explicit residual modeling, effective in high-rating puzzles
Final Ensemble Averaging (Public LB)	66,658	23.7	Combines top models for stable leaderboard score (7th place)
Private Test MSE (Final Ensemble)	*63,009*	*27.9*	*Generalizes well to unseen data (8th place)*

Finally, averaging several top-performing models achieved a public leaderboard MSE of 66,658 (+23.7%) and a private test MSE of 63,009 (+27.9%), confirming strong generalization. The relatively small gap between the public leaderboard and private test performance suggests that overfitting was effectively controlled, and the residual modeling contributed to robust predictions even for rare high-difficulty cases.

VI. CONCLUSION AND FUTURE WORK

This paper presented a hybrid framework for predicting chess puzzle difficulty in the FedCSIS 2025 Challenge on Predicting Chess Puzzle Difficulty. By integrating gradient-boosting models, a multi-modal neural network, and residual-based XGBoost stacking, our approach achieved a competitive 7th and 8th places in the preliminary and final stages, relatively, with a MSE score of 63,009. The combination of interpretable handcrafted features and learned visual-tactical representations proved effective, offering a robust and computationally efficient alternative to transformer-based methods.

VII. ACKNOWLEDGMENT

***Abstract*—This paper presents our third-place solution for the FedCSIS 2025 Challenge: Predicting Chess Puzzle Difficulty — Second Edition. Building on our prior GlickFormer architecture, we develop a transformer-based approach featuring a novel multitask pretraining strategy that combines masked-square reconstruction with solution policy prediction. Our spatial-only architecture directly embeds solution moves, eliminating temporal modules, while integrating human-centric priors through Maia-2 engine solve-rate predictions. Evaluated on the Lichess puzzle corpus, our approach reduces validation MSE by 30.4% compared to from-scratch training and achieves competitive results (test MSE: 55.9k) despite distribution shifts in the competition environment. In an auxiliary uncertainty-masking side competition organized post hoc, our simple calibration-sensitivity mask achieved the best score and won the side competition. Details are provided in the Appendix.**

***Index Terms*—Chess AI, Transformer Pretraining, Puzzle Difficulty, Self-Supervised Learning, Glicko-2**

I. Introduction

CHESS puzzles challenge players to identify tactical sequences that yield decisive gains. On platforms like Lichess, puzzle difficulty is quantified via Glicko-2 ratings derived from human solve rates. The requirement for thousands of human attempts makes rapid rating of new puzzles impractical, motivating automated difficulty prediction methods that model human problem-solving rather than engine-optimal play.

Building on our prior GlickFormer (11th place in 2024) [1], we introduce GlickFormer v2, which placed third in the FedCSIS 2025 Challenge: Predicting Chess Puzzle Difficulty — Second Edition. [2] While retaining a transformer backbone, this new version simplifies computation by eliminating explicit temporal modules in favor of embedding future solution moves directly in the input representation. Additionally, we incorporate human-centric priors through solve-rate predictions from Maia chess engines [3] across various Elo bands.

Our core contribution is a novel multitask pretraining strategy inspired by large language models (LLMs), which simultaneously trains the model to reconstruct randomly masked board squares while predicting the puzzle's correct solution move. When fine-tuned on the 4.7 million-position training set, this pretraining significantly outperforms both from-scratch training and masked-only pretraining baselines. To address the distribution shift between validation and test ratings, we implement post-hoc distribution scaling technique used by Woodruff et al. [4].

The resulting model achieves competitive performance despite its simplified architecture, demonstrating that the combination of efficient spatial processing, human-aligned inputs, and targeted pretraining can effectively capture human puzzle-solving complexity without expensive temporal modeling.

II. Related Work

Early approaches to chess puzzle difficulty estimation relied primarily on human-derived ratings, but recent competitions have established new state-of-the-art benchmarks. The 2024 IEEE BigData Cup [5] saw significant advances: Björkqvist et al. [6] combined handcrafted features with engine-extracted signals from Maia, Leela, and Stockfish using a residual neural network and LightGBM to place third. Schütt et al. [7] developed a human problem-solving inspired CNN with auxiliary theme and move-prediction tasks, securing second place. Rafaralahy [8] applied a pairwise learning-to-rank framework using RankNet to simulate puzzle "matches" for Glicko-2 rating inference, achieving fourth place.

The current state-of-the-art was established by the bread emoji team [4], winners of the 2024 competition. Their solution employed an ensemble of pretrained Maia and Leela embedders with distribution rescaling postprocessing, achieving over 13% reduction in MSE compared to runner-up solutions. Our original GlickFormer [1] leveraged a factorized spatio-temporal transformer to model board states and move sequences, placing 11th in 2024 while demonstrating attention mechanisms' potential for capturing human-like puzzle difficulty, though its computational costs were substantial.

Our multitask pretraining approach draws inspiration from LLM strategies. The masked reconstruction component adapts BERT's masked language modeling objective [9] to chess by predicting masked board squares based on spatial context. This technique shares strong parallels with Vision Transformers (ViT) [10], which successfully adapted BERT-style pretraining to image recognition tasks by treating image patches as tokens. The policy prediction task shares similarities with next-token prediction in autoregressive models like GPT [11], but focuses

specifically on identifying optimal tactical moves. This dual-objective approach mirrors multi-task pretraining in models like T5 [12], creating robust representations through diverse objectives. Recent chess-specific transformers like the Chess Transformer [13] have demonstrated the value of language-modeling-inspired approaches for move generation, though not specifically for difficulty prediction.

Building on these foundations, GlickFormer v2 integrates efficient spatial-only transformers with LLM-inspired multitask pretraining and competition-proven calibration techniques. Our approach adapts established language modeling paradigms to structured prediction tasks in chess while building upon the state-of-the-art results from the 2024 competition.

III. Methodology

Building upon our previous GlickFormer architecture, we maintain the core data pipeline and noise-aware target sampling strategy while introducing three key enhancements: improved input representations, a leaner spatial-only transformer backbone, a novel multitask pretraining schedule, and the integration of post-hoc distribution calibration.

A. Data and Stochastic Target Sampling

The training corpus comprises 4.7 million puzzles with Glicko-2 ratings r_i, rating deviations RD_i, complete solution move sequences, and solve-rate predictions from the Maia-2 chess engine [3]. These predictions are provided for multiple Elo bands (approximately 1000-2100, though exact ranges were unspecified by competition organizers), including both rapid and blitz time control configurations. The solution moves represent the optimal tactical sequence required to solve each puzzle, typically ranging from 1-5 moves in length.

To evaluate model performance during development, we reserve 1% of puzzles (approximately 47,000) for validation, selected via stratified sampling across puzzle themes to ensure representativeness.

For pretraining, we construct a 14-channel input representation where 13 binary planes indicate piece occupancies: each plane corresponds to a specific piece type-color combination or empty square, with values set to 1 where present and 0 otherwise. This is supplemented with a binary mask-indicator plane that marks randomly selected squares for masking (1 = masked, 0 = visible), with all other channels zeroed out at masked positions.

During fine-tuning, we use a richer 55-channel input with three components: the same 13 binary board-state planes; 20 binary planes encoding the complete solution line (truncated or zero-padded to exactly 5 moves, each move represented as side $\times$ {from,to} pairs); and 22 continuous-valued Maia-2 solve-rate priors broadcast as constant spatial planes. All channels are linearly projected to form 64 tokens (one per board square) for transformer processing.

For stochastic target sampling, we normalize ratings using dataset statistics:

$$\mu_i = \frac{r_i - \mu_{\text{dataset}}}{\sigma_{\text{dataset}}} \tag{1}$$

$$\sigma_i = \frac{\mathrm{RD}_i}{\sigma_{\text{dataset}}} \tag{2}$$

where μ_{dataset} and σ_{dataset} represent the mean and standard deviation of all puzzle ratings in the training set. We model each rating as a normal distribution $\mathcal{N}(\mu_i, \sigma_i^2)$ and generate noisy targets during mini-batch sampling:

$$y_i \sim \mathrm{clip}\left(\mathcal{N}(\mu_i, \sigma_i^2), \mu_i - 3\sigma_i, \mu_i + 3\sigma_i\right) \tag{3}$$

This injects label noise that regularizes the regression objective while respecting rating deviation bounds.

B. Model Architecture

GlickFormer v2 employs 12 encoder-only transformer blocks with 768-dimensional embeddings and 24 attention heads with Smolgen positional encoding, using Mish activation functions. [14] The model processes different inputs during pretraining and fine-tuning phases: pretraining uses only the 14-channel tensor, while fine-tuning incorporates the extended 55-channel tensor where both the solution-move projector W_{sol} and Maia-prior projector W_{maia} are randomly initialized and trained alongside the backbone.

Each input stack undergoes projection via linear embedding into 64 tokens (one per chess square), which are then processed by the transformer backbone. During pretraining, two specialized heads operate simultaneously: a masked-square classifier implemented as an MLP applied independently to each token predicts piece types at masked positions, while a policy head employs two parallel MLPs to project each token to "from" (query) and "to" (key) vectors. Move logits are computed as dot products between all query-key pairs ($\mathbf{q}_a^\top \mathbf{k}_b$ for move $a \to b$), implementing the Leela Chess Zero policy formulation [15]. This formulation considers only square-to-square transitions without special move types, inherently omitting promotion moves since puzzles rarely involve pawn underpromotions in their solution lines.

For policy prediction during pretraining, we consider only the first move of each puzzle's solution sequence. This design choice reflects that the initial move typically represents the most significant tactical insight distinguishing puzzle difficulty, while subsequent moves are often forced responses or technical conversions contributing less to human solve-rate variance. This simplification maintains predictive power while reducing computational complexity.

For fine-tuning, both pretraining heads are discarded and replaced with the value head architecture from the original GlickFormer. This consists of a linear layer that projects the entire sequence of 64 token embeddings to a hidden dimension, followed by Mish activation and a final linear layer that outputs a scalar difficulty prediction. The entire model - including the transformer backbone, input projectors, and regression head - is trained end-to-end during this phase,

allowing the pretrained representations to adapt while specializing for rating prediction.

C. Multitask Pretraining

Our pretraining approach masks k random squares per puzzle, where $\mathcal{M}$ denotes the set of masked squares. We define two complementary loss functions:

The masked reconstruction loss predicts missing piece types:

$$\mathcal{L}_{\text{msk}} = -\frac{1}{|\mathcal{M}|} \sum_{i \in \mathcal{M}} \log p_{\text{msk}}(c_i) \tag{4}$$

where c_i is the true piece class at square i.

The policy loss identifies the correct solution move:

$$\mathcal{L}_{\text{pol}} = -\log p_{\text{pol}}(a^\star) \tag{5}$$

where $a^\star$ is the ground-truth solution move.

The combined pretraining objective balances these losses:

$$\mathcal{L}_{\text{pre}} = \lambda_{\text{msk}} \mathcal{L}_{\text{msk}} + \lambda_{\text{pol}} \mathcal{L}_{\text{pol}} \tag{6}$$

Figure 1 illustrates our dual pretraining objectives. The model receives boards with randomly masked squares (Fig. 1a), then must both reconstruct the original pieces at masked positions (Fig. 1b) and predict the optimal solution move indicated by the arrow (Fig. 1c).

Following the Chinchilla scaling rule [16], we train with $20\times$ more tokens than parameters using AdamW optimization with batch size 256, dropout rate 0.1, weight decay 0.1, initial learning rate 5×10^{-4}, 10% linear warmup, and cosine decay to final learning rate 5×10^{-5}. We empirically set $k = 8$ and weighting coefficients $\lambda_{\text{msk}} = 1$, $\lambda_{\text{pol}} = 0.1$ based on validation performance.

D. Fine-Tuning Procedure

During supervised fine-tuning, we employ the 55-channel input tensor with newly initialized projectors for solution-move and Maia-prior planes. The entire model trains end-to-end without freezing components. We discard pretraining heads and replace them with the regression head described in Model Architecture section, minimizing the mean squared error:

$$\mathcal{L}_{\text{ft}} = \frac{1}{N} \sum_{i=1}^{N} (\hat{r}_i - r_i)^2 \tag{7}$$

using AdamW optimization [17] with dropout rate 0.1, weight decay 0.1, batch size 256, and initial learning rate 5×10^{-5}. We reduce the learning rate by a factor of 0.1 after each epoch without validation improvement, with a maximum of two reductions. This configuration maintains consistency with our original GlickFormer implementation while leveraging the enhanced pretrained representations.

E. Post-Hoc Distribution Calibration

To address distribution shifts between validation and test environments, we implement the distribution rescaling technique introduced by Woodruff et al. This calibration corrects systematic biases in predicted ratings caused by the key difference in data collection: limited solving attempts (25-50 per puzzle) compared to the training data, which shifts the rating distribution toward the mean μ by preventing full convergence.

The calibration function is defined as:

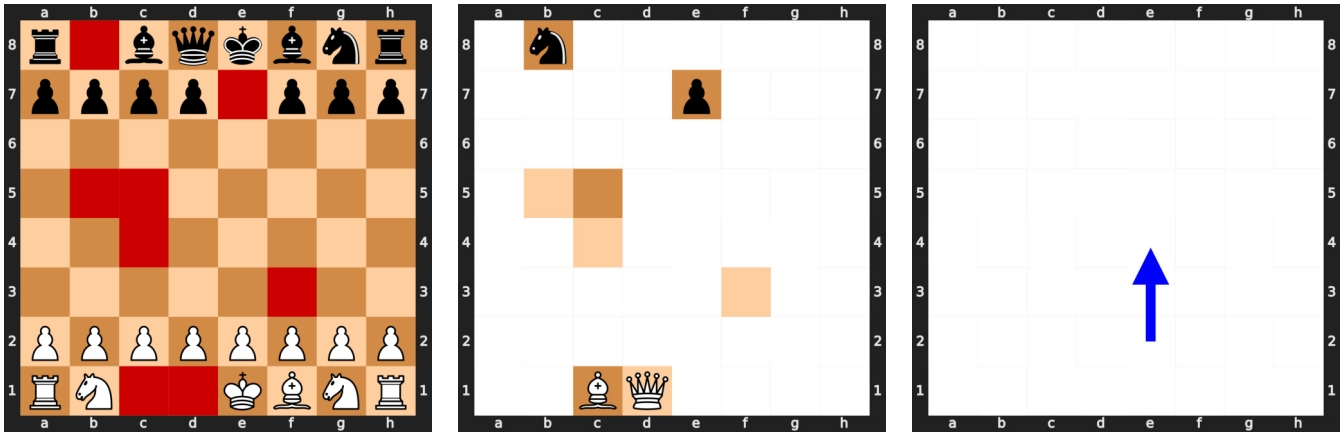
$$R(\hat{r}) = \begin{cases} \max\left(\mu, \hat{r} - \alpha \min\left(1, \left(\frac{\hat{r}-\mu}{\delta}\right)^\gamma\right)\right) & \hat{r} \geq \mu \\ \min\left(\mu, \hat{r} + \beta \min\left(1, \left(\frac{\mu-\hat{r}}{\delta}\right)^\gamma\right)\right) & \hat{r} < \mu \end{cases} \tag{8}$$

with empirically tuned coefficients $\alpha = 200$, $\beta = 400$, $\gamma = 2$, $\delta = 550$. This formulation applies progressively stronger corrections to predictions farther from μ, counteracting the observed shift toward the mean caused by limited solving attempts.

IV. Results and Discussion

Our experimental evaluation addresses the effectiveness of our pretraining strategies, GlickFormer v2's performance relative to state-of-the-art baselines, and the impact of post-hoc calibration. All validation results use our stratified validation set while test results report official competition metrics.

A. Evaluation Protocol



We compare three pretraining strategies: from-scratch training (baseline), masked-only pretraining ($\lambda_{\text{pol}} = 0$), and our multitask approach ($\lambda_{\text{pol}} = 0.1$). Baseline comparisons include GlickFormer v1 [1] and the bread emoji 2024 solution [4]. Note that both our approach and bread emoji used similar validation strategies with sampling from training data. All models are evaluated on our validation set unless otherwise specified.

B. Pretraining Effectiveness

Table I demonstrates the progressive improvements from our pretraining strategy. Masked-only pretraining reduces validation MSE by 22.3% compared to from-scratch training (44.9k vs. 57.8k). Our multitask approach further improves performance by 10.4% over masked-only pretraining (40.2k vs. 44.9k), confirming that combining reconstruction with policy prediction provides richer representations for difficulty assessment.

TABLE I: Pretraining ablation on validation set

Pretraining Strategy	Validation MSE	Difference
No pretraining (from scratch)	*57.8k*	-
Masked squares only	*44.9k*	-22.3%
Multitask	**40.2k**	**-10.4%**

(a) Masked input board (b) Reconstruction target (c) Policy prediction target

Fig. 1: Multitask pretraining objectives: (a) Input board with randomly masked squares (red); (b) Target state for masked-square reconstruction; (c) Target solution move (arrow) for policy prediction.

C. Validation Set Comparisons

Table II compares GlickFormer v2 against key baselines on our validation set. Our approach reduces MSE by 50.2% compared to GlickFormer v1 and by 13.9% compared to Woodruff et al. [4], demonstrating significant improvements over state-of-the-art approaches.

TABLE II: Validation set comparison with baselines

Method	Validation MSE	Difference
GlickFormer v1	80.8k	-
Woodruff et al. (SotA)	46.7k	-
GlickFormer v2 (ours)	**40.2k**	**-50.2% vs v1** **-13.9% vs SotA**

D. Competition Results and Calibration Impact

GlickFormer v2 achieved third place in the 2025 competition with a test MSE of 55.9k. The top-performing teams secured first and second place with MSEs of 52.3k and 54.4k respectively. To quantify the impact of post-hoc calibration, we evaluated its effect on a preliminary test dataset (subset of official test data). This analysis revealed calibration was critical for performance - without it, our MSE increased by 38.6% to 81.6k, demonstrating its importance for addressing distribution shifts in the full competition environment. The close margin between top 5 solutions (52.3k - 61.1k) highlights the competitiveness of this year's challenge, with our approach placing solidly within this range.

E. Key Findings

Analysis reveals several important insights. Masked-only pretraining provides significant gains over from-scratch training, reducing validation MSE by 22.3%. Our multitask approach yields a further 10.4% improvement over masked-only pretraining, confirming the value of combining reconstruction with policy prediction. Post-hoc calibration proves essential for test performance, preventing a 38.6% MSE degradation. Overall, our solution achieves a 50.2% improvement over our previous entry [1] while reducing training time by >80% through architectural simplifications.

The integration of Maia solve-rate priors contributed substantially to our 50.2% improvement over GlickFormer v1, highlighting the value of human-aligned signals in puzzle difficulty modeling. This demonstrates that encoding domain-specific human behavior patterns through pretrained engines provides crucial complementary information beyond board-state analysis alone.

V. Conclusion

GlickFormer v2 demonstrates that spatial-only transformers with targeted pretraining can effectively predict chess puzzle difficulty. The model's novel multitask pretraining strategy, combining masked-square reconstruction with solution policy prediction, significantly outperforms both training-from-scratch and masked-only pretraining baselines. By incorporating human-centric priors through Maia solve-rate predictions and addressing distribution shifts via post-hoc calibration, the approach maintains effectiveness across varied evaluation environments.

Our solution achieved third place in the FedCSIS 2025 Challenge: Predicting Chess Puzzle Difficulty —- Second Edition, showcasing the potential of efficient architectures combined with strategic pretraining.

For future work, this pretraining framework could be adapted for other chess-specific tasks such as value and policy prediction in chess engines. Additional research directions include enhancing robustness to distribution shifts through domain adaptation techniques and refining temporal modeling approaches for complex multi-move puzzles.

APPENDIX: UNCERTAINTY-MASKING SIDE COMPETITION

After the main leaderboard closed, the organizers announced an additional task focused on uncertainty estimation. Each team was asked to submit a binary mask over the test set marking exactly 10% of instances deemed most problematic. During scoring, the organizers replaced model predictions with the ground-truth values on the masked subset and recomputed the test metric. Let $[P]$ denote the *perfect-mask* score for a given team's final submission (i.e., the best possible score if the team had masked the true worst 10%), and let $[N]$ denote the score obtained using the team's submitted mask. The side competition ranked teams by the ratio $[N]/[P]$ (lower is better).

Evaluation Setting

Per the organizers' rules, the submitted 10% mask was evaluated on *all three of our final submissions*, using the same mask for each. In our case, these were an uncalibrated prediction run, a prediction run calibrated using the post-hoc rescaling parameters of Woodruff et al., and a prediction run calibrated using the post-hoc rescaling parameters used in this paper. The organizers computed the score across these three final submissions according to the side-competition protocol.

Method

Our approach leverages the post-hoc distribution calibration $R(\cdot)$ (Eq. (8)) to construct a simple, model-agnostic uncertainty proxy. For each test puzzle i, we compute a *calibration sensitivity*

$$\delta_i \;=\; \left|\hat{r}_i^{\mathrm{raw}} - R(\hat{r}_i^{\mathrm{raw}})\right|, \tag{9}$$

where $\hat{r}_i^{\mathrm{raw}}$ is the uncalibrated prediction and $R(\hat{r}_i^{\mathrm{raw}})$ is the calibrated one. Intuitively, δ_i measures how much calibration "needs to move" a prediction to account for the rating-distribution shift (caused by limited solving attempts in the test environment). Large δ_i values occur predominantly at the distribution tails (very easy/very hard puzzles), which are known to exhibit higher instability. We rank puzzles by δ_i and mark the top 10% as the uncertainty mask. This design purposely targets cases where calibration most alters the prediction, and was explicitly intended to reduce error on the uncalibrated submission.

Outcome

This calibration-sensitivity mask achieved the lowest $[N]/[P]$ ratio among all participating teams, winning the side competition. Our ratio was:

$$\frac{[N]}{[P]} = 1.426,$$

which gave us **1st place** out of 9 teams that decided to participate in this additional task. For our final submitted mask:

$$[N] \approx 61.49k, \quad [P] \approx 43.12k.$$

Beyond its simplicity and robustness (no additional training or ensembling), the method aligns tightly with our main-system calibration: it explicitly targets those instances where calibration exerts the largest corrective effect, which empirically coincide with the most uncertain test cases under the competition's setting.

***Abstract*—We detail the `bread emoji` team's submission to the FedCSIS 2025 Predicting Chess Puzzle Difficulty Challenge. Our solution revolved around improving our submission from the previous competition by incorporating a new puzzle metadata feature and optimizing our implementation to allow for larger model ensembles and more stable training. Similar to our submission from last year, our system has two stages: learning a strong predictor for the LICHESS dataset and then rescaling the distribution using an empirically-guided post-processing step to fit it to the smaller and noisier competition dataset.**

Our submission placed second with a $\sim$3.9% gap in mean squared error (MSE) from first place [1].[1]

I. Introduction

THIS paper introduces our team's (`bread emoji`) submission to Predicting Chess Puzzle Difficulty - Second Edition, a competition hosted by FedCSIS. This was an open-to-the-public online machine learning competition that challenged teams to come up with novel solutions for predicting the difficulty (represented by the GLICKO2 rating system [2]) of a chess puzzle, given the initial board state, the winning moves, and a small set of metadata for each puzzle.

We participated in last year's iteration of this competition, placing first by a significant margin [3][4]. Our solution to this year's competition iterated on last year's solution, and we cover our updated methodologies in this paper. Overall, our solution placed second out of 71 teams, narrowly missing out on first place by $2k$ MSE ($<4\%$).

II. Competition Background

A chess puzzle is an initial board state and sequence of moves that lead to one side of the board gaining a significant material or strategic advantage over the other in a chess game. Puzzles are created primarily by algorithms that parse actual human vs. human games on online chess websites and find interesting move sequences. They are then added to a game server that serves players a continuous stream of puzzles to play against. Both the puzzle and the player have a rating, which are both updated by player wins and losses, according to the GLICKO2 rating system.

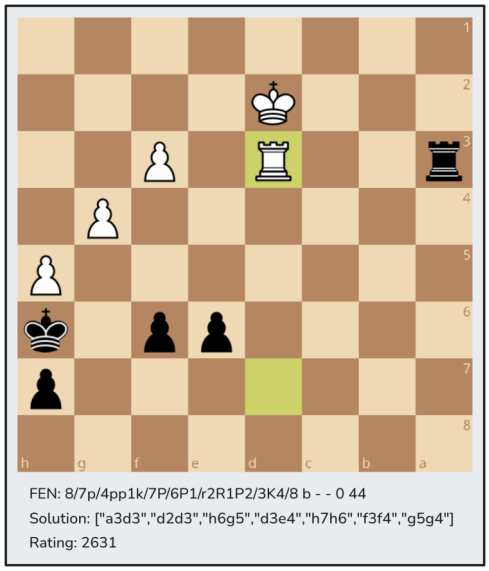

Fig. 1: An example puzzle from the LICHESS database. The most basic information required is the initial position (given in `FEN` format), the solution (from which we can generate a sequence of boards), and the puzzle rating (which we are trying to predict). However, the LICHESS and competition datasets provide some additional puzzle metadata. The theme of this puzzle is to convert white's blunder (capturing the pawn on `d3`, which starts the puzzle) into a winning pawn endgame via zugzwang. The algebraic solution is `♖xd3?? ♜d3+ ♔xd3 ♚g5 ♔e4 ♟h6! ♙f4+ ♚xg4`, after which black has an overwhelming pawn advantage.

Figure 1 gives an example from the LICHESS database.[2]

A. LICHESS *Dataset*

The training dataset given by the competition is a list of over 4.5 million puzzles taken from LICHESS. This is a snapshot of the free-to-download, updated-monthly puzzle dataset taken several months prior to the start of the competition. This dataset contains per-puzzle metadata that is the same as the

[2]https://database.lichess.org/#puzzles

prior iteration of this competition (we point the reader to [3], [4]) with the addition of a set of "success probabilities" computed by the MAIA2 neural chess engine.

B. MAIA2 *Success Probabilities*

This year's competition introduces new metadata in the form of success probabilities generated by MAIA2, a neural chess engine designed to mimic human play (Section III-B). Each value corresponds to the estimated likelihood that a player of a given skill level would successfully complete the puzzle according to the move distributions predicted by 22 different variations of the MAIA2 model [1]. These probabilities were included as scalar features, indexed by their model configurations and were provided for both the LICHESS and competition datasets by the organizers.

III. NEURAL CHESS MODELS

Here, we briefly introduce the families of neural chess models that we use as the backbone for our system. These models differ from classical chess models in that they are trained entirely on data without any hand-crafted features. In particular, we utilize MAIA and MAIA2, which are a family of neural models that are designed to mimic human players of various strengths, and LEELA, an open-source reimplementation of the ALPHAZERO neural chess system. This is not an exhaustive set of neural chess engines, and we point the interested reader to [5] for an overview.

A. MAIA

MAIA is a set of neural chess models that are trained to mimic players of a given rating (for ratings 1100 to 1900 in increments of 100) [6]. Each model has the same architecture—a chain of 6 convolutional blocks with residual connections, followed by a value and policy head—that takes a board representation as input and produces a policy and value score which encode the probability distribution over next moves and the evaluation of the position, respectively.

B. MAIA2

MAIA2 builds upon the ideas of MAIA, but with two key differences. First, the models are no longer segmented by rating; they now take the player ratings as input. And second, the model includes a new rating-board attention layer, which injects rating information into the board representation [7]. The board input and output representations are also different than MAIA, but the training objective is the same.

MAIA2 comes in two flavors, RAPID and BLITZ, denoting the training data used to train it, and the default parameters chunk player ratings into 11 buckets (1050 to 2050).

C. LEELA

LEELA is an open source implementation of the ALPHAZERO neural chess engine [8], [9]. The most modern iteration of LEELA uses a transformer backbone, but we opted to continue using the original model (as we did in [3]), which uses a convolutional backbone. LEELA was trained via self-play to be as strong as possible and has SMALL, MEDIUM, and LARGE variants.

IV. OUR SYSTEM

Our general approach mirrors our implementation from the prior competition [3]. In short, we use neural chess board embedders to extract latent representations of the boards in a puzzle. These are fed into an RNN to produce a puzzle representation, which is then combined with puzzle metadata and passed to a regression MLP. Our solution for this challenge differs from our previous solution in a few details, including an updated, optimized implementation and some architectural and modeling differences. Here, we review the main architectural components of our system and in Section VI-A, we discuss the application of this system to the actual competition challenge.

A. Board and Puzzle Embedders

We again use the MAIA and LEELA neural chess engine family as our neural chess embedding backbone. These are large, convolutional models that ingest board representations (i.e., bitboards representing piece positions and castling metadata) and produce a series of policy and value scalars that are used during min-max tree search in a chess engine. We truncate the models by removing the policy and value heads and take the output of the last convolutional block as the latent vector representation of a given board state.

We point the reader to Figure 10 of [6] (in the Supplemental section) which shows the MAIA architecture. Our latent representation is the vector that is produced by the convolutional block directly before the model is split into the two heads (and we use the analogous vector for the LEELA family, which has a similar architecture [8][9]).

However, puzzles are inherently sequential and variable length. Thus, after extracting latent representations of each board-state in a puzzle, we combine them into a puzzle representation by feeding them into an RNN to produce a single, vector representation.

B. Board Metadata

The LICHESS dataset comes with a large amount of additional metadata other than just the puzzle information. For example, it contains themes (e.g. mate-in-two, pin, etc.), popularity, the game it was drawn from, and more. This metadata may be helpful for modeling purposes, so our architecture allows for injecting representations of the metadata into the latent representation of the puzzle. The competition dataset, however, contains only the explicit puzzle information and the set of precomputed MAIA2 puzzle probabilities (Section II-B), so much of the metadata that is available during training is not immediately helpful since we do not have access to the same metadata during inference.

In our final architecture, we use only puzzle length and MAIA2 puzzle probabilities as metadata features. For the former, we produced a categorical representation of puzzle length (e.g., puzzles of length 2, 4, ..., 16) and used an embedding table to extract the learned metadata representation corresponding to the length of the given puzzle. For the latter, which consists of 22 scalar values, we produce a vector

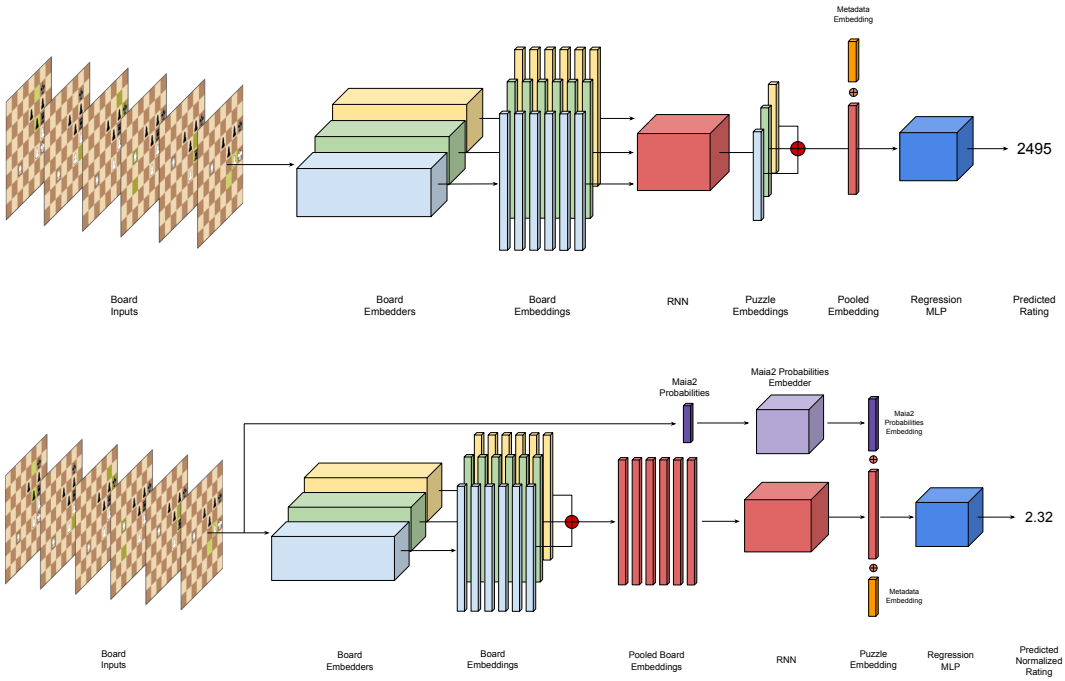

Fig. 2: The model architecture used in the previous competition (top) [3] and the system in this paper (bottom).

embedding by constructing a 22-length vector and passing it through a small MLP to produce a latent representation.

We note one feature, puzzle themes, that is present in the LICHESS dataset but not the competition dataset. However, the LICHESS theme tagging algorithm is open-source[3] and can be used to tag the competition dataset. At least one team in the first iteration of this competition tagged the competition dataset so that the feature could be used during inference [10], however, we did not experiment with including this metadata.

The metadata representations are concatenated to the output of the RNN to produce the final puzzle representation.

C. Rating Prediction as Regression

Once a latent vector representation of the board and its metadata has been formed, we use it to predict the GLICKO2 rating of the puzzle—a simple regression task. We use a three layer, dense MLP with `relu` activations and dropout to learn a mapping from a puzzle representation to its scalar rating.

D. Ensembled Embeddings

Like in [3], we do not restrict ourselves to having a single neural board embedder in a model. Instead, we allow multiple neural board embedders to independently produce board representations which are then combined to form an ensembled board representation. The intuition behind this is that different models have different strengths and weaknesses due to their training objectives and so their latent representations of the board may be complementary and lead to better modeling.

[3]https://github.com/ornicar/lichess-puzzler

Our architecture allows for arbitrarily many board embedders and can mix MAIA and LEELA embeddings.

V. ARCHITECTURAL AND MODELING DIFFERENCES FROM OUR SUBMISSION TO THE PRIOR CONTEST [3]

Despite using the same initial framework as in [3], we implemented a number of architectural and modeling changes (other than the inclusion of the new MAIA2 features) that improved our system's performance. Figure 2 shows the major differences between the two systems.

A. RNN Implementation

In the previous iteration of this competition we manually implemented the RNN in our model architecture. Regardless of puzzle input length, we truncated or padded to 10 boards and then used a hand-written RNN loop. This was slow, had many wasted computations (in that many puzzles have less than 10 boards, but the padded boards were processed anyway), and had some undesirable modeling properties (in theory, models should learn to ignore the padding boards, but they can still "wash out" the signal of non-padding boards, especially when the puzzle is very short).

We replaced our implementation with the PYTORCH RNN implementation, which is faster, uses less memory, and, by using packed tensors, only processes non-padding boards. In a benchmark, we observed a $>4\times$ runtime speed-up when using the PYTORCH RNN compared to our hand-written RNN.

B. Board Pooling

Recall that we have several board embedders that each produce a sequence of latent board representations for each board

(a) Results from the previous competition, taken directly from [3]. These do not include MAIA2 features and use the previous iteration of our architecture. Note that the bottom row is an output-ensemble of embedding-ensemble models.

Model	MSE
MAIA-1300	$56.5k$
MAIA-1500	$57.5k$
MAIA-1700	$57.9k$
LEELA-SMALL	$65.5k$
LEELA-MED	$66.1k$
MAIA-1300 + LEELA-SMALL	$65.4k$
MAIA-1300 + LEELA-MED	$50.8k$
MAIA-{1300, 1500, 1700}	$56.0k$
MAIA-{1300, 1500, 1700} + [MAIA-1300 + LEELA-SMALL] + [MAIA-1300 + LEELA-MED]	$46.7k$

(b) Results for our updated architecture, which includes MAIA2 features. Note that all of these are embedding-ensembled models. The right column is the same model configuration but with an additional LEELA-SMALL embedder.

Model	MSE	
		+ LEELA-SMALL
MAIA-1100	$41.2k$	$41.3k$
MAIA-1500	$41.6k$	$41.3k$
MAIA-1700	$42.2k$	$42.1k$
MAIA-{1100, 1500}	$41.7k$	$38.9k$
MAIA-{1100, 1700}	$40.3k$	$38.7k$
MAIA-{1500, 1700}	$39.7k$	$39.3k$
MAIA-{1100, 1500, 1700}	$39.2k$	**38.3k**

TABLE I: Results on the LICHESS dataset using different model configurations, including from our solution to the previous competition. Each model configuration's MSE is the average of 3 copies of the model. The best performing model is **bolded**.

state in the puzzle and our goal is to somehow combine all of them into a single puzzle representation. In [3], we achieved this by first computing a puzzle vector for each embedder (by processing that embedder's board representations with the RNN) then (mean) pooling the resulting vectors.

In our updated implementation, we reverse this process. We now use the embedders to compute each board state, then (mean) pool all of the analogous board representations before passing it through an RNN.

This has two main benefits. First, it allows for different embedders' board representations to be "mixed" earlier in the model pipeline, which should allow the model to better incorporate the different representations. And second, the board embeddings are processed in parallel in a giant batch, but the RNN inherently involves a non-parallelization, sequential process. Thus, by pooling the embeddings before the RNN layer, we reduce the number of non-parallelizable operations to just a single RNN call, which massively speeds up training and inference runtimes.

Due to the runtime speed up and lower memory requirements of the combination of pre-RNN board pooling and the PYTORCH RNN implementation, we were able to increase our training batch sizes and observed more stable training and faster convergence.

C. Regression Target

Recall that the primary objective of this competition is to predict a puzzle's GLICKO2 rating, which is a non-negative scalar, and try to minimize MSE. In [3], we simply predicted this scalar value directly. Since the ratings can be higher than 3000, the squared errors of predictions can be very large, which leads to training instability due to large gradients.

In our updated version, we instead computed the mean μ and standard deviation σ of the clean LICHESS dataset and scaled the ratings as $r_n = \frac{r-\mu}{\sigma}$ to produce a normalized rating (which was used in the MSE objective). During inference, we reverse the normalization by predicting a normalized rating $\hat{r}_n$ and recovering the predicted rating $\hat{r} = \sigma \times \hat{r}_n + \mu$. This resulted in more stable training and faster convergence.

VI. RESULTS

Overall, our updated model architecture and training scheme, coupled with the addition of MAIA2 probability metadata, led to significantly more accurate models on the LICHESS dataset. Table I shows the results of our prior solution (taken directly from [3]) and a subset of the model configurations we trained for our final submissions.

We note that, across the board, the updated models have substantially lower MSE, despite having similar parameter counts. Most clearly, we can compare models which have the same embedding configurations and thus the salient differences are our new architecture and the MAIA2 metadata (regrettably, we did not perform MAIA2 ablation tests).

For example, comparing the MAIA-1500 model from the previous competition to the MAIA-1500 model from this competition, we observe a $\sim 16k$ reduction in MSE (a 27.7% reduction), despite having similar parameter counts.

Perhaps unsurprisingly, we find that our largest ensemble, MAIA-{1100, 1500, 1700} + LEELA-SMALL, performed the best — achieving $38.3k$ MSE on the LICHESS test set, which is an $8.4k$ (18.0%) reduction in MSE over the best, multi-ensembled model from our submission to the prior competition. Ensembling all of the models that we trained for this competition (i.e., the entire set of models from the right two tables of Table I) reached $36.1k$ MSE corresponding to a $2.2k$ (5.7%) reduction in MSE over the best individual model from this competition and a $10.6k$ (22.7%) reduction over the multi-ensembled model from the last competition.

A. Fitting to the Competition Dataset

Like in [3], we found that models that performed well on the clean LICHESS dataset did not necessarily perform well on the competition dataset, as there are significant differences between the competition distribution and the LICHESS dataset distribution (for example, see Figure 1 of [4]).

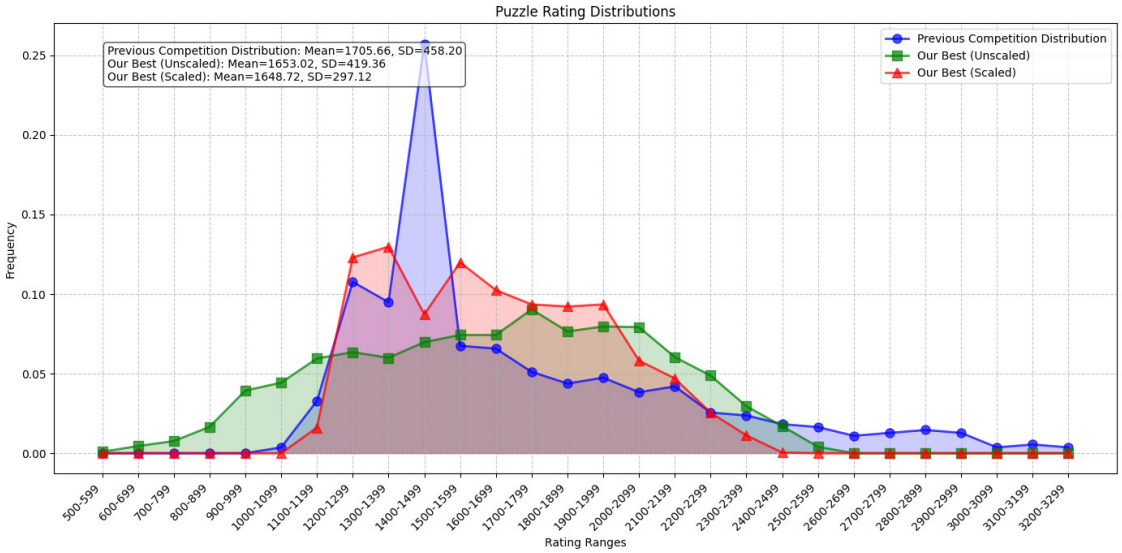

Fig. 3: An overlay of the competition test set's distribution (blue) as reported in the prior competition's writeup [4], our best model's predictions before scaling (green), and our best, scaled result (red). Notice that they have significantly different shapes, implying that accurately modeling one is not a guarantee of accurately modeling another.

We again used the strategy of producing as good of a model as possible on the LICHESS dataset and then rescaling it to fit what we expected the competition dataset to look like.

Previously, we used a simulator that estimated, given a set of players and puzzles for which we had gold-standard rating information, what the distribution of puzzle ratings would look like after each puzzle had been played by a subset of N random players. This was designed to mimic the competition server, which matched players with puzzles randomly (i.e. not matching players and puzzles of similar skill level) and, at the time, did not have many plays-per-puzzle. We used these findings to guide our search for a rescaling function that could map our predicted ratings to what we would expect that puzzle to be rated in the low-play competition-server regime.

We followed the same procedure in this iteration, by using rescaling functions that attempted to reshape our distribution of predicted competition puzzle ratings to be more centered around what we believed the mean competition rating to be.

First, as a baseline, we noted that this year's competition dataset was a subset of the previous year's competition dataset. Thus, we simply reused our winning solution from [3] after filtering out the removed puzzles. On the preliminary competition dataset from last year, our winning solution had $49.1k$ MSE. However, the same solution scored $64.1k$ MSE, indicating that the current iteration of the competition dataset is significantly different than the prior version.

We first performed binary search over the set of possible ratings (between 0 and 3000) for the value that minimized MSE on the preliminary competition dataset when we used it as a constant prediction (i.e., we predicted the same value for all puzzles). The value that minimizes this function gives the mean of the dataset (and we can also recover the standard deviation), approximately $\mu \approx 1650$.

We then used post-processing rescaling steps to try to reshape our predicted output distribution to a distribution that had similar properties to what we expected the competition dataset to have and settled on rescaling functions of the form:

$$\text{SCALE}(r) = \begin{cases} o_u + \frac{\log(c_1 r)}{c_2} & r > 0 \\ o_l - \frac{\log(c_1' r)}{c_2'} & r \leq 0 \end{cases}$$

where r is the normalized predicted rating $\frac{\hat{r}-\mu}{\sigma}$ and o_u, c_1, and c_2 are rescaling hyperparameters that we searched over for when our predicted rating was above the mean (and likewise for o_l, c_1', and c_2' when it is below the mean). We separated these so that we could control the shape of both sides of the output distribution, as we found it was not symmetric. The normalized predicted rating is mapped back into the raw rating space after rescaling.

The differences between the prior competition dataset, our model's (unscaled) predictions on the competition dataset, and our best solution's scaled predictions is shown in Figure 3.

VII. THINGS WE TRIED THAT DID NOT WORK

Like in [3], once our core pipeline was finished, we experimented with several variants but found that none provided gains over our baseline.

A. *RNN → Transformer*

One goal of our updated implementation was to improve the model's runtime performance in order to improve training speed and performance by increasing the batch size and parameter count. A major bottleneck is the RNN layer (particularly in the older, hand-written implementation that pooled boards after the RNN), since it is inherently sequential and cannot

be parallelized. We experimented with replacing this layer with a small transformer model, which has the benefit of increased parallelization and the ability to explicitly inspect the representations of every board in a puzzle simultaneously and learn a weighting for their interactions. We hoped that this would improve both the model's runtime and quality, but we instead found that it massively reduced the modeling performance, even at similar parameter counts.

We experimented with several variations, including stacking several layers of transformers and adjusting the transformer's internal hidden dimension (both within a fixed parameter budget), but we were not able to match the RNN baseline.

B. MAIA2 *Board Embeddings*

We experimented with adding MAIA2 as a board embedder by using the output of the board-rating attention layer as the latent board representation. As the MAIA2 model requires player ratings as input, but the competition dataset does not provide this metadata (the LICHESS dataset does include it), we experimented with several different schemes to select a reasonable rating. For example, we performed a hyperparameter search over all pairs (p_1, p_2) where p_1, p_2 were ratings in the MAIA2 rating buckets to see if some pair worked well. We additionally tried using the ratings as a form of self-ensembling, by simply selecting several rating pairs as hyperparameters and then computing the latent representation of the board for each pair and averaging them.

None of these schemes were effective and we found that models using MAIA2 embeddings were substantially worse than those using MAIA. This is potentially due to the comparatively small output dimension of the rating-board attention layer of MAIA2 (1024) compared to the convolutional block layers of MAIA (4096), which means that it carries less signal when used in the downstream task.

Since MAIA2 also uses a sequence of convolutional blocks as a backbone before the attention layer, we could have used the output of that as well, but we did not experiment with this.

C. Alternative Loss Functions

Our baseline model uses MSE loss as the primary loss function in order to mimic the competition objective. However, as noted in [3], our best performing models had relatively high MSE (40k+ and 50k+ on the LICHESS dataset and the preliminary competition dataset, respectively). Thus, we hypothesized that "small" errors (for example, those with absolute error of less than 180, which would have a squared error of at most 34k) were less important than large errors (e.g., predicting 1800 when the true rating was 2500, corresponding to a squared error of 490k).

We experimented a with piecewise loss, where the model was penalized more harshly for larger errors. For example, we considered loss functions with the basic form:

$$\mathcal{L}(\hat{r}, r) = \begin{cases} (\hat{r} - r)^2, & \text{if } |\hat{r} - r| \leq T \\ (\hat{r} - r)^4, & \text{otherwise,} \end{cases}$$

where r and $\hat{r}$ are the (unnormalized) true and predicted ratings, respectively, and T is some threshold (180, in the example above, though we used normalized rating thresholds in the actual implementation). We also tried more stratified loss functions (e.g. with multiple thresholds and loss scaling functions), but did not observe any improvements.

***Abstract*—Estimating the difficulty of chess puzzles provides a rich testbed for studying human–computer interaction and adaptive learning. Building on recent advances and the FedCSIS 2025 Challenge, we address the task of predicting chess puzzle difficulty ratings using a multi-source representation approach. Our approach integrates pre-trained neural embeddings of board states, solution move sequences, and engine-derived success probabilities. These heterogeneous features are fused via dedicated embedding and projection layers, followed by a multi-layer perceptron regressor. Post-processing calibration and model ensemble further enhance robustness and generalization. Experiments on the FedCSIS 2025 dataset demonstrate that our method effectively leverages both structural and empirical information, achieving strong predictive performance. Our approach achieved fifth place on the final official leaderboard, highlighting the effectiveness of combining neural representations with domain-specific probabilistic features for robust chess puzzle difficulty prediction.**

***Index Terms*—Human-Computer Interaction, Chess Puzzle Difficulty, Multi-Source Feature Fusion, Representation Learning, Ensemble Learning**

I. Introduction

Chess has served not only as a competitive arena, but also as a richly structured and controlled testbed for exploring the foundations of human–computer interaction. From Deep Blue's brute-force victory over Kasparov [1] to AlphaZero's self-taught superhuman play [2], each algorithmic milestone has advanced a deeper goal: understanding how machines can model, anticipate, and ultimately support human cognitive behavior. Contemporary online chess platforms now record every move, reaction time, and mistake across millions of human–machine interactions. These data enable a direct estimation of puzzle difficulty from behavioral patterns. Predicting chess puzzle difficulty thus emerges as a core task that bridges cognitive science, adaptive learning, and recommender system design.

While chess has long served as a model system for cognitive research, it is in the advent of modern online platforms that has enabled large-scale, quantitative analysis. Lichess [1] is a widely used open-source online chess platform that provides millions of user-generated chess puzzles. The difficulty of each puzzle is quantified using rating systems originally designed for human players. The most common systems include the Elo rating [3], which updates a player's rating based on game outcomes, and the Glicko [4] and Glicko-2 [5] systems, which further incorporate rating volatility and adjust more dynamically to player performance. On Lichess, each puzzle receives a Glicko-2 rating that reflects its empirical difficulty for the average user, with accuracy improving as more players attempt the puzzle.

Building on the IEEE BigData 2024 Cup [6], which demonstrated the utility of feature-rich and neural approaches for chess puzzle difficulty prediction [7–12], the FedCSIS 2025 Challenge [13] introduces both a larger dataset and new data modalities. The main objective remains to predict the difficulty rating of a chess puzzle using its initial board state and solution moves. However, in contrast to the first edition, the FedCSIS 2025 Challenge provides 22 precomputed engine-based success probabilities per puzzle, generated by Maia-2 models [14] to simulate human move likelihoods across different player ratings and types of rating. This addition eliminates the need for costly local engine simulations and facilitates more equitable benchmarking of model designs. With a training set of over 4.5 million puzzles, FedCSIS 2025 offers an enriched setting for advancing research in chess puzzle difficulty prediction.

In this study, we propose a multi-source neural representation approach for predicting chess puzzle difficulty. Our approach integrates heterogeneous information from pre-trained board state embeddings, solution move sequences, and a 22-dimensional vector of engine-estimated success probabilities. These complementary features are jointly fused and embedded through dedicated projection layers, followed by a multi-layer perceptron regressor to predict the rating. To further enhance robustness and address distributional shifts, we apply post-processing calibration and ensemble models trained under diverse settings. This design leverages both the structural and empirical dimensions of puzzle difficulty, leading to improved predictive performance and generalization.

The remainder of this paper is organized as follows: Section II analyzes the dataset and outlines the preprocessing pipeline. Section III describes the proposed approach. Section IV details the experimental setup and results. Section V discusses findings, limitations, and potential ways to improve in future work. Section VI concludes the paper.

II. Data Analysis

A comprehensive understanding of the dataset structure is essential for designing robust prediction models in this challenge. Table I provides an overview of the principal features included in the competition dataset. Each chess puzzle is uniquely identified by a `PuzzleId` and is characterized by several core components: the board position specified in Forsyth–Edwards Notation (FEN), the solution sequence encoded in Portable Game Notation (PGN), and a 22-dimensional vector of engine-estimated success probabilities (`SuccessProb`), which represents projected solve rates across diverse player rating groups and game types. The `Rating` field denotes the puzzle's Glicko-2 difficulty rating [5], which serves as the primary target variable for model training.

TABLE I
Summary of Features in the Challenge Dataset

Field Name	Description	Type
PuzzleId	Unique identifier	String
FEN	Board position	String
Moves	Solution in PGN	String
SuccessProb	Success probabilities	Float
Rating	Glicko-2 puzzle rating (Target)	Integer
RatingDeviation	Uncertainty in rating	Integer
Popularity	Upvotes minus downvotes	Integer
NbPlays	Number of attempts	Integer
Themes	Puzzle motif tags	String
GameUrl	Lichess game provenance	String
OpeningTags	Opening classification	String

In addition to these core fields, the training data comprises several auxiliary metadata attributes. These include the rating uncertainty (`RatingDeviation`), popularity score (`Popularity`), total number of attempts (`NbPlays`), thematic tags (`Themes`), and optional fields such as the original game URL (`GameUrl`) and opening classification (`OpeningTags`). This rich set of features enables multi-faceted analysis and facilitates the construction of both neural and feature-based models.

TABLE II
Comparison of Training and Test Datasets

Property	Training Set	Test Set
Instances	4,557,000	2,235
Features	PuzzleId, FEN, Moves, SuccessProb, RatingDeviation, Popularity, NbPlays, Themes, GameUrl, OpeningTags	PuzzleId, FEN, Moves, SuccessProb
Target	Rating	-

Table II presents a comparative summary of the training and test datasets used in this challenge. The training set contains 4,557,000 puzzle instances, while the test set contains 2,235 instances. Notably, the test set is restricted to the core features: `PuzzleId`, `FEN`, `Moves`, and `SuccessProb` with the ground-truth `Rating` field hidden to facilitate unbiased model evaluation. Consequently, additional metadata present in the training set, such as `RatingDeviation`, `Popularity`, and `Themes`, must be excluded from the feature set during model development to ensure strict compatibility between training and inference conditions.

The structure of the dataset, characterized by both structural descriptors and empirical engine-based probabilities, enables the exploration of diverse modeling strategies. The inclusion of precomputed success probabilities is particularly noteworthy, as it reduces the computational barrier for participants and provides valuable prior information for puzzle difficulty prediction, especially for those without access to sufficient local computational resources.

Although the dataset provides a comprehensive set of structural and empirical features, ensuring the reliability of the target variable is crucial for robust model training. In particular, the rating uncertainty (`RatingDeviation`) quantifies the confidence of each puzzle's Glicko-2 difficulty estimate and varies substantially across puzzles.

Puzzles exhibiting high rating uncertainty generally correspond to unstable or unreliable difficulty estimates, often resulting from insufficient player attempts or inconsistent solution patterns. To improve data quality and label reliability, all puzzles with a `RatingDeviation` greater than 90 were excluded from the training set. This threshold, which aligns with established practice in prior studies, effectively reduces label noise by filtering out puzzles with highly variable ratings.

After this preprocessing step, the size of the training set decreased from approximately 4.56 million to 3.53 million puzzles. The resulting dataset, comprising high-quality and reliable labels, was used for model training. This preprocessing pipeline enhances the stability of the learning process and ensures that subsequent modeling are grounded in representative data.

III. Methodology

Figure 1 presents an overview of the proposed solution pipeline for chess puzzle difficulty prediction. The overall methodology consists of several key components: multi-source feature embedding, a neural regressor for rating prediction, post-processing calibration, model ensemble, and uncertainty estimation. Each component is described in detail below.

A. Feature Embedding

Our approach integrates three complementary sources of information for each chess puzzle: the board state encoded in Forsyth–Edwards Notation (FEN), the solution move sequence represented in Portable Game Notation (PGN), and a 22-dimensional vector of engine-estimated success probabilities (`SuccessProb`). The FEN string offers a detailed, lossless description of the board configuration, while the PGN sequence captures the temporal progression of solution moves. The `SuccessProb` vector summarizes the predicted probability of a successful solve across various player rating brackets and type of rating (rapid or blitz), as precomputed by the MAIA2 neural engine [14].

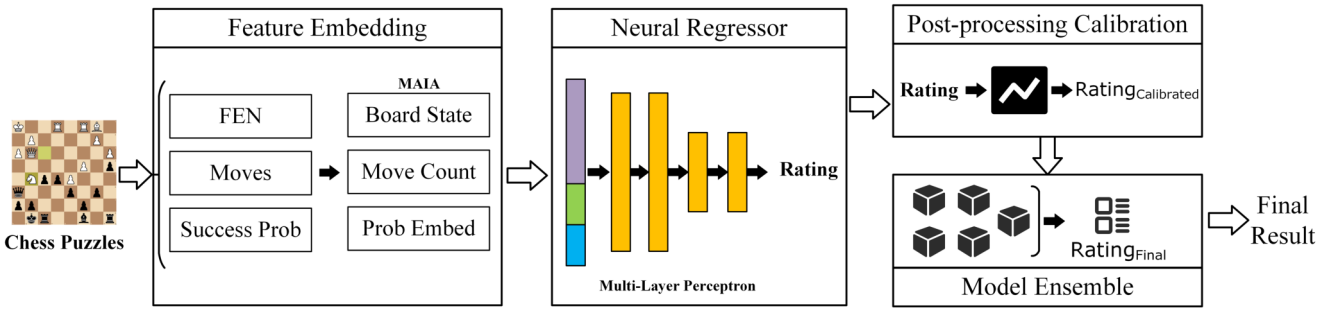

Fig. 1. Overview of proposed approach

To comprehensively capture both the structural and sequential aspects of each puzzle, we generate a sequence of consecutive board states by iteratively applying the solution moves to the initial FEN. Each intermediate position is embedded using a pre-trained Maia neural network, which is specifically trained to emulate human move preferences at defined skill levels [15]. For each board state, we extract a neural embedding from the penultimate hidden layer of the Maia model. These embeddings are mapped into a unified latent space and combined to form a comprehensive representation of the puzzle's solution trajectory.

The solution length is discretized and encoded as a learnable embedding, enabling the model to incorporate information about puzzle complexity. Simultaneously, the `SuccessProb` vector is embedded through a two-layer feedforward network with ReLU activation to produce a dense embedding representing empirical difficulty. Finally, concatenating the aggregated board embedding, the move count embedding, and the success probability embedding yields a unified embedding vector. This multi-source representation integrates structural configuration, sequential solution dynamics, and empirical difficulty priors, providing a rich input for downstream prediction.

B. Neural Regressor

The aggregated feature vector is processed by a multi-layer perceptron regressor designed to capture complex nonlinear relationships between the fused feature embeddings and puzzle difficulty. The architecture comprises a sequence of fully connected layers with progressively decreasing dimensionality, interleaved with ReLU activation functions and dropout regularization to enhance generalization and mitigate overfitting. This deep regression network enables the model to learn intricate mappings from multi-source representations to difficulty ratings. The final output is a single scalar representing the predicted Glicko-2 rating for the given puzzle.

C. Post-processing Calibration

To mitigate the distributional shift between the training set and the competition test data, we employ a simulation-inspired nonlinear rescaling technique [7] to adjust the raw predictions of the neural regressor. This post-processing step compresses prediction values at the distributional extremes while preserving ratings near the empirical mean, thereby reducing the impact of outliers. The calibration function is defined as follows:

$$\hat{r} = \mu - \frac{1+\text{sign}(r-\mu)}{2} \cdot H \cdot \max\left(1, \left|\frac{r-\mu}{D}\right|^4\right) + \frac{1-\text{sign}(r-\mu)}{2} \cdot L \cdot \min\left(1, \left|\frac{r-\mu}{D}\right|^4\right) \quad (1)$$

where $\mu = 1900$ denotes the empirical mean rating, $H = 200$ and $L = 250$ control the scaling magnitude for over- and underestimations respectively, and $D = 1000$ determines the scale at which the rescaling effect saturates. These hyperparameters are selected based on prior studies [7] and further validated through our empirical experience in this challenge.

This calibration strategy aims to improve the alignment between predicted and true rating distributions. By explicitly correcting for known biases in the rating aggregation process, the rescaling aims to make the predicted difficulty ratings more robust.

D. Model Ensemble

To further enhance model robustness and predictive performance, we employ an output-level ensemble strategy. Specifically, multiple base models are trained independently using board embeddings generated from different Maia engine variants, each emulating human play at a distinct ELO rating. The final prediction is computed by averaging the outputs from all base models:

$$\text{Rating}_{\text{final}} = \frac{1}{N}\sum_{i=1}^{N} \text{Model}_i(\text{Input}), \quad (2)$$

where N is the total number of ensembled models. This approach leverages complementary perspectives of models trained on different skill levels and effectively reduces the variance of individual predictions. Ensembling not only mitigates overfitting and model-specific biases but also enhances the model's ability to generalize across puzzles of varying complexity. This strategy is particularly effective in domains where task difficulty spans a wide spectrum and individual models may excel in different sub-regions of the input space.

E. Uncertainty Estimation

To further enhance model reliability and provide interpretable confidence assessments for each prediction, we propose an ensemble-based uncertainty estimation strategy. Specifically, for each test instance, we aggregate the prediction outputs from all base models within the ensemble and compute the standard deviation of these predictions as a proxy for epistemic uncertainty, reflecting the degree of disagreement among ensemble members.

Formally, let $y_i^{(j)}$ denote the prediction for the i-th test sample by the j-th base model in the ensemble, where $j = 1, \ldots, M$. The uncertainty score for the i-th sample is quantified as the standard deviation across the ensemble outputs:

$$\sigma_i = \sqrt{\frac{1}{M} \sum_{j=1}^{M} \left(y_i^{(j)} - \bar{y}_i \right)^2}, \tag{3}$$

where $\bar{y}_i$ represents the mean prediction for the i-th sample. A higher standard deviation σ_i indicates greater predictive uncertainty, as it signals increased model disagreement regarding the sample's difficulty.

In accordance with the challenge requirements, we rank all test samples by their uncertainty scores and flag the top K instances (where K corresponds to 10% of the test set, i.e., $K = 223$ for 2235 samples) using a binary mask. By leveraging the diversity inherent in the ensemble, this strategy systematically identifies predictions with elevated risk of error.

IV. Experiment and Result

A. Experiment Setup

1) Environment: The experimental environment is based on Ubuntu 22.04, equipped with an NVIDIA RTX 3090 GPU (24 GB VRAM). The CPU is an Intel Xeon Gold 6330 operating at 2.00 GHz, complemented by 90 GB of system memory.

2) Toolkit: The implementation is based on Python 3.12, with PyTorch 2.5.1 used for neural network construction and training. CUDA 12.4 is utilized to accelerate GPU computations and enhance overall computational efficiency.

3) Evaluation Metric: The metric for performance evaluation is the Mean Squared Error (MSE), consistent with the official evaluation criterion of the FedCSIS 2025 Challenge.

B. Experiment Result

We conducted a comprehensive set of experiments to evaluate the effectiveness of our approach for chess puzzle difficulty prediction. Table III summarizes model performance on the public leaderboard, measured in terms of MSE. All results correspond to the official public test set provided by the competition platform [16].

As a baseline, we implemented a LightGBM regressor utilizing handcrafted chess features extracted from the board state, move sequence, and basic positional statistics. Feature extraction was performed using the `python-chess` library, which provides utilities for parsing FEN and PGN representations and computing relevant game attributes. This model achieved an MSE of 104703.66, serving as the baseline for subsequent neural network-based approaches.

To investigate the impact of learned representations, we incorporated pre-trained neural board embeddings derived from various Maia engine variants. Employing MAIA-1300 embeddings without the inclusion of organizer-provided success probability vectors resulted in an MSE of 91689.69. Incorporating the success probability features further reduced MSEs for the MAIA-1300, MAIA-1500, and MAIA-1700 models to 82582.37, 85625.50, and 81570.99, respectively, thereby underscoring the complementary value of empirical priors.

To address distributional shift and enhance calibration, we applied a post-processing rescaling procedure to the model outputs, as described in Section III-C. This adjustment led to further improvement, with MSEs decreasing to 76986.22 for MAIA-1300, 78155.64 for MAIA-1500, and 79688.41 for MAIA-1700.

Subsequently, ensemble averaging across the MAIA-1300, MAIA-1500, and MAIA-1700 models yielded an MSE of 75915.97. Our final approach, which ensembles board embeddings from five Maia variants (MAIA-1100, MAIA-1300, MAIA-1500, MAIA-1700, and MAIA-1900) and combines calibrated outputs with success probability features, achieved the best observed performance, attaining an MSE of 67071.66 on the public leaderboard.

TABLE III
Performance Comparison of Different Methods on Public Leaderboard

Method	Public MSE
Handcrafted Features + LightGBM (Baseline)	104703.66
MAIA-1300 (w/o SuccessProb)	91689.69
MAIA-1300	82582.37
MAIA-1500	85625.50
MAIA-1700	81570.99
MAIA-1300 + Post-processing	76986.22
MAIA-1500 + Post-processing	78155.64
MAIA-1700 + Post-processing	79688.41
MAIA-1300/1500/1700 Ensemble	75915.97
MAIA-1100/1300/1500/1700/1900 Ensemble	**67071.66**

The results clearly demonstrate that leveraging pre-trained neural embeddings, incorporating empirical success probabilities, and ensembling the outputs of individually calibrated models together yield substantial improvements over traditional handcrafted feature-based models. The progressive reduction in MSE observed through our stepwise model enhancements highlights the additive value of each component in our solution. Ultimately, our final ensemble approach achieved a marked performance gain relative to classical models. These findings confirm the effectiveness of multi-source feature fusion and neural representation learning for chess puzzle difficulty prediction.

C. Uncertainty Estimation Result

To quantitatively evaluate the effectiveness of our uncertainty estimation strategy, we participated in the additional uncertainty mask task organized as part of the challenge. In this task, each team was required to submit a binary mask identifying the most uncertain 10% of the test puzzles. Let P denote the perfect score, obtained by replacing the predictions for the 10% most erroneous test cases with their ground-truth values, and let N denote the score achieved using the submitted mask. The evaluation metric is defined as:

$$\rho = \frac{N}{P} \tag{4}$$

Our submitted mask achieved a ratio of $\rho = 1.589$, ranking **3rd** among participating teams. On the official leaderboard, this corresponded to a score of approximately 55234, compared with the theoretical lower bound of 34766 under a perfect mask. The results show that our proposed uncertainty estimation strategy provides a reliable means of identifying error-prone cases, with potential for further refinement.

V. Discussion

Our experimental results reveal several insights and limitations that warrant further investigation. While handcrafted features extracted from the board state and move sequences provide a valuable baseline for chess puzzle difficulty prediction, they are inherently limited in their ability to capture the full complexity of positional and sequential information. Models based solely on such features consistently underperform relative to deep neural architectures, likely due to their inability to represent the nuanced dynamics encoded in FEN strings and move sequences, both of which are essential for accurate difficulty modeling.

Nevertheless, prior work and our own attempts indicate that carefully engineered handcrafted features, if effectively integrated into neural network architectures, may offer complementary benefits. However, our straightforward approach to merging these features with neural embeddings did not yield performance improvements, suggesting that more advanced integration strategies, such as attention-based models, may be necessary to unlock the full potential of hybrid feature sets.

Due to computational constraints and time limitations, our current study utilized only five Maia pre-trained model variants, corresponding to targeted ELO levels of 1100, 1300, 1500, 1700, and 1900. Each Maia variant is designed to emulate the play style of human users at its specific rating level, thereby enabling the model to capture a spectrum of human skill profiles. Nonetheless, this approach may not fully represent the diversity of the solver population. Future research should consider integrating all available Maia models, spanning ELO 1100 to 1900, to achieve finer granularity in modeling player abilities. Such comprehensive ensembles could provide a more nuanced simulation of the human skill continuum and further improve prediction robustness.

In summary, our findings underscore the importance of both high-capacity neural architectures and the principled fusion of domain-specific features for robust chess puzzle difficulty prediction. Advancing this field will require continued research into sophisticated feature integration strategies and more comprehensive utilization of human-like engine ensembles, ultimately paving the way for models with enhanced generalization and interpretability.

VI. Conclusion

In this work, we investigated chess puzzle difficulty prediction using a multi-source feature fusion approach based on neural embedding techniques, within the context of the FedCSIS 2025 Challenge. Our approach integrates pre-trained Maia board embeddings, solution move sequences, and success probabilities generated by the MAIA2 engine. These heterogeneous information sources are combined within a unified neural regression model. Results on the official public leaderboard demonstrate that incorporating empirical priors derived from chess engines, neural network-based representations, model ensemble, and post-processing calibration leads to improved performance over traditional feature-based baselines.

In addition, we acknowledge the overarching goal of the knowledgepit competition series [17–20], which is to evaluate the skills of data scientists through carefully designed tasks [16]. Beyond its evaluative role, the knowledgepit provides an excellent platform for testing novel methodologies, comparing approaches under common benchmarks, and advancing the broader data science community.

Acknowledgment

We thank the organizers of the FedCSIS 2025 Challenge for their efforts in hosting this competition and maintaining a fair and engaging environment.

***Abstract*—We summarize the results of the FedCSIS 2025 machine learning competition organized on the knowledgepit.ai online platform. We recall the competition's goals corresponding to estimations of the chess puzzle difficulty levels, we refer to the winning solutions, and we also compare the scope of this year's competition (and particularly the data available to competition participants) with its previous edition associated with the IEEE BigData 2024 conference. Finally, we discuss the new functionality of the knowledgepit.ai platform, which enables competition participants to submit additional uncertainty masks reflecting their assessment of test cases that are mostly problematic for their machine learning models.**

***Index Terms*—Human-Computer Interaction, Chess, Machine Learning Competitions, Uncertainty in Machine Learning**

I. Introduction

THE FedCSIS 2025 machine learning competition continues the successful blueprint established in the IEEE BigData 2024 edition [1], held at the knowledgepit.ai platform as well, addressing the challenge of predicting chess puzzle difficulty ratings from board configurations and solution sequences. While the core task remains unchanged – estimating Glicko-2 ratings that reflect human-perceived difficulty rather than engine-optimal evaluations – this second edition introduces significant enhancements in both data quality and modeling capabilities. The competition attracted 42 teams who collectively submitted 1185 solutions, with eight of the top ten teams contributing technical papers describing their approaches.

The primary innovations in this edition address key limitations of the previous competition. First, we integrated 22 precomputed success probability features generated by the Maia-2 model [2], providing participants with standardized human-aligned difficulty indicators across multiple rating bands and time controls. Second, we substantially improved test set quality through expanded data collection and a novel fairness algorithm that ensured balanced solving attempts across all puzzles, eliminating the rating convergence issues that plagued the first edition, where many puzzles remained clustered around the 1500 initialization value. These improvements resulted in more reliable ground truth labels and enabled more sophisticated modeling approaches, as evidenced by the winning solutions' creative use of ensemble methods, transformer architectures, and domain-specific feature engineering.

Beyond the core regression task, this competition pioneers a new dimension in machine learning competitions through the introduction of uncertainty masks – an extra challenge where participants identify the 10% of test cases their models find most problematic. This extension represents a step toward more interpretable and reliable machine learning systems, addressing the growing need for models that can communicate their (un)certainty levels alongside predictions.

The next sections describe the related work (Section II), the dataset (Section III), and the competition setup (Section IV). Further, we analyze the submitted solutions (Section V), discuss prediction errors and masking strategies of the top teams (Section VI), and conclude with implications for future competitions and research directions (Section VII).

II. Related Work

The challenges of the assessment of chess puzzle difficulty were discussed in our paper related to the first edition of this competition [1]. We also refer to [3]–[5] where the Top 3 solutions submitted to the first edition were reported.

The importance of machine learning competitions was also discussed in our previous papers [6]–[10]. In particular, we investigated possibilities of utilizing such competitions to build a platform for automatic evaluation of skills of data scientists [11]. As already mentioned, the new idea of extending the format of knowledgepit.ai competitions with uncertainty masks corresponds to that aspect of our research as well.

This new aspect of our competitions corresponds to an important topic in machine learning [12]. Although the most problematic cases for machine learning models are not necessarily the most "uncertain" ones, measures of uncertainty are often used, e.g., in active learning [13] and model diagnostics [14]. In our research, we estimate a given object's uncertainty using a neighborhood of cases having the same or similar values over subsets of attributes that are significant to the given model or decision problem [15]. The attribute selection mech-

anism described in [15] was also applied to build a benchmark machine learning model for this particular competition.

III. New Chess Puzzle Dataset

This competition builds upon the dataset foundation established in the previous IEEE BigData 2024 edition [1], while introducing a more robust test set and a significant enhancement to support more sophisticated modeling approaches.

A. Core Dataset Structure

Similarly to the previous edition, the dataset consists of chess puzzles with basic fields including PuzzleId, FEN (board position), Moves (puzzle solution), and the target Rating to be predicted. The training dataset retains the extra metadata fields from the original competition: RatingDeviation, Popularity, NbPlays, Themes, GameUrl, and OpeningTags.

B. Success Probability Features

The primary innovation in this edition is the addition of 22 success probability features generated using the Maia-2 model. Unlike the original Maia models that required separate trained models for each rating group [16], Maia-2 employs a unified architecture that jointly models success probabilities across all skill levels [2]. This model takes as input the chess position, player rating, and game type (rapid or blitz), outputting predicted success probabilities for solving the puzzle. Specifically, the Success_prob fields represent the estimated probability that a player of a given rating level and game type would correctly solve each puzzle. These 22 fields cover different rating ranges and both rapid and blitz time controls, providing participants with rich, model-generated features that capture human solving patterns across the skill spectrum.

Inspired by the innovative approaches observed in the top solutions from the previous competition [3]–[5], this enhancement aimed to provide participants with features that better capture the human element of puzzle-solving difficulty. Rather than requiring each team to independently extract chess engine evaluations for millions of puzzles, the Maia-2-generated success probabilities offer a standardized set of features that encode human-like assessment of puzzle difficulty across different skill levels.

C. Improved Test Set Quality

A significant improvement over the previous competition relates to the quality and distribution of puzzle attempt data. The IEEE BigData 2024 competition suffered from insufficient rating convergence in the test set, with many puzzles remaining near their initialized rating of 1500 due to limited solving attempts [1]. To address this limitation, the FedCSIS 2025 edition implemented two key enhancements:

- Expanded data collection: A larger pool of chess players was recruited to solve puzzles, resulting in substantially more solving attempts across the test set.
- Fairness algorithm: A novel algorithm was integrated into our lichess fork that prioritized presenting puzzles with fewer total attempts (regardless of correctness) to users. This ensured a more balanced distribution of solving attempts across all puzzles, leading to better rating convergence and more reliable ground truth labels.

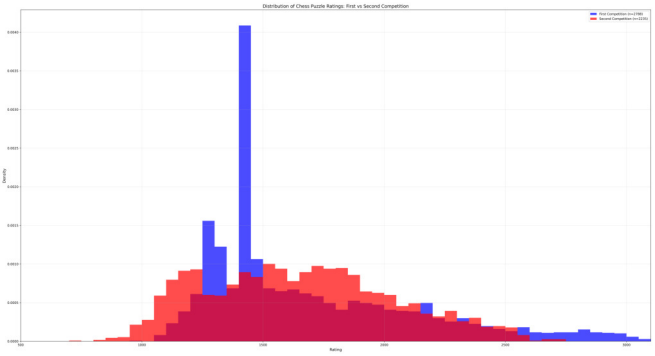

Fig. 1: Distribution of puzzle ratings in test sets: First competition (IEEE BigData 2024, blue) vs. Second competition (FedCSIS 2025, red). The first edition shows a pronounced spike at 1500 (the initialization value), while the second edition exhibits a more natural distribution with better rating convergence across the full spectrum.

Figure 1 illustrates the dramatic improvement in rating distribution quality. The first competition's test set (blue) exhibits a sharp peak around 1500—the default initialization value—indicating that many puzzles received insufficient solving attempts to converge to their true difficulty. In contrast, the FedCSIS 2025 test set (red) displays a smoother, more naturally distributed profile spanning from approximately 800 to 3000, demonstrating successful rating convergence. This improvement directly translates to more reliable ground truth labels for model evaluation.

IV. Competition Task

The core regression task of the FedCSIS 2025 Challenge remained fundamentally the same as in the first edition [1], requiring participants to predict difficulty ratings for chess puzzles based on their FEN board states and PGN solution sequences. The primary difference was the dataset size, which contained 2283 puzzles after removing those with fewer than 10 solving attempts during data annotation. As before, predictions were evaluated using Mean Squared Error (MSE) between predicted ratings $\hat{y}_i$ and ground-truth ratings y_i, computed as:

$$\text{MSE} = \frac{1}{n}\sum_{i=1}^{n}(y_i - \hat{y}_i)^2, \tag{1}$$

where n denotes the number of test samples.

A novel extension to this edition introduced an uncertainty estimation task, whereby participants were invited to submit binary masks identifying the 10% of test puzzles for which their predictions were most likely to be erroneous. The mask $M \in \{0,1\}^N$ required each participant to flag exactly 10% of the test set as uncertain, with $M_i = 1$ indicating high uncertainty for puzzle i and the constraint $\sum_{i=1}^{N} M_i = N \times 0.1$. The

TABLE I: Top 10 submissions in the FedCSIS 2025 knowledgepit.ai competition. The evaluation metric was the mean squared error – the lower Final (and preliminary, Pre.) score, the better. The Subs column reflects the total number of submissions. The Mask column reports the uncertainty ratio – again, the lower, the better (the best score bolded). Eight out of Top 10 teams submitted conference papers describing their solutions. Nine teams participated in the additional uncertainty mask contest.

Rank	Team	Paper	Final	Pre.	Subs	Mask	Approach
1	ousou	[17]	**52.3k**	**55.4k**	89	1.64	Fine-tuned Maia-2 embeddings combined with other features through LightGBM, ensembled via CatBoost with linear scaling.
2	bread emoji	[18]	54.4k	58.2k	240	1.71	Two-stage approach with ensembled neural chessboard embedders, pre-RNN board pooling, and logarithmic rescaling.
3	transformer_enjoyer	[19]	55.9k	58.9k	117	**1.43**	Spatial transformer with masked-square reconstruction and solution policy prediction, rescaling borrowed from [3].
4	ToDoFindATeamName	–	57.5k	61.5k	136	–	–
5	Cyan	[20]	61.0k	67.1k	93	1.59	Multi-variant ensemble of Maia embeddings, solution sequences, and engine success probabilities with nonlinear calibration.
6	neuro	[21]	62.6k	66.5k	81	1.68	Four-stage pipeline with Elo-banded base models, gradient boosting, structural calibration via failure distributions, and ensemble averaging.
7	xyz	[22]	62.7k	66.6k	25	1.70	Three-stage pipeline with four Elo-banded MLP base models, stacking ensemble, and structure-aware residual correction.
8	DML	[23]	63.0k	66.7k	73	1.65	Three-stage pipeline combining GB models, multi-modal CNN with EfficientNetB3-rendered board images, and XGB residue stacking.
9	Ru	[24]	67.5k	70.4k	53	1.62	Three-stage pipeline with MobileNetV2 board images, LightGBM residual refinement, and adjustments based on failure distribution.
10	Feiwyth	–	68.1k	70.7k	17	1.58	–

rationale was that by replacing the predicted ratings at these masked positions with their ground-truths, the evaluation could assess a model's ability to identify its own confidence.

The uncertainty masks were evaluated using the Uncertainty Ratio metric, defined as:

$$\mathrm{UR} = \frac{\mathcal{N}}{\mathcal{P}}, \tag{2}$$

where $\mathcal{N}$ represents the New Score (MSE after replacing masked predictions with ground truth) and $\mathcal{P}$ represents the Perfect Score (the minimum achievable MSE if the 10% highest-error samples were perfectly identified and masked). An optimal uncertainty ratio approaches 1.0, indicating perfect identification of the most erroneous predictions. For example, a ratio of 1.2 would indicate that the submitted mask captured errors that, when corrected, achieved 83.3% (1/1.2) of the theoretically optimal improvement, demonstrating reasonably good uncertainty estimation while leaving room for improvement in identifying the truly most difficult cases.

V. Competition Overview

Table I presents the top 10 submissions in the FedCSIS 2025 knowledgepit.ai competition, where teams competed to predict chess puzzle difficulty using mean squared error as the evaluation metric. Nine of the top 10 teams submitted conference papers describing their solutions and participated in the additional uncertainty mask contest.

We refer to Table I and papers [17]–[24] for detailed descriptions of particular competition solutions. In general, the best-performing models leveraged pretrained neural chess embeddings – particularly from the Maia family of models designed to mimic human play at various skill levels – combined with ensemble methods and gradient boosting techniques. The winning team achieved an MSE of 52.3k by fine-tuning Maia-2 embeddings and combining them with other features through LightGBM, followed by CatBoost ensembling with linear scaling. The second-place team (54.4k MSE) employed a two-stage approach with ensembled neural chessboard embedders and pre-RNN board pooling, while the third-place team (55.9k MSE) utilized spatial transformers with masked-square reconstruction. A common pattern across successful approaches was the use of multi-stage pipelines: initial feature extraction via neural board embeddings (Maia-1, Maia-2, or Leela), intermediate refinement through gradient boosting methods (LightGBM, XGBoost, or CatBoost), and final calibration via post-processing techniques addressing distributional shifts.

For uncertainty estimation, most teams developed mask prediction strategies that identified the least reliable predictions, achieving uncertainty ratios between 1.43 and 1.71. The transformer_enjoyer team achieved the best uncertainty ratio of 1.43 despite placing third overall, suggesting that model confidence estimation and raw prediction accuracy represent distinct challenges. Several approaches also incorporated the competition-provided Maia-2 success probabilities – precomputed estimates of puzzle completion likelihood for players at different skill levels – as auxiliary features, though their integration strategies varied considerably across teams.

VI. Error Analysis and Masking Strategies

A. Analysis of Prediction Errors

We conducted several post-hoc analyses of the rating prediction task. Figure 2 shows prediction errors by puzzle difficulty. A U-shaped pattern is visible: models perform worse on very easy (< 1000) and very hard (> 2400) puzzles, while medium-difficulty puzzles are predicted more accurately. This behavior is consistent with the MSE objective, which emphasizes outliers at both ends of the scale.

We then analyzed performance as a function of rating uncertainty (Figure 3). Prediction errors increase monotonically with the Glicko rating deviation of puzzles, indicating that puzzles with higher inherent rating uncertainty are systematically

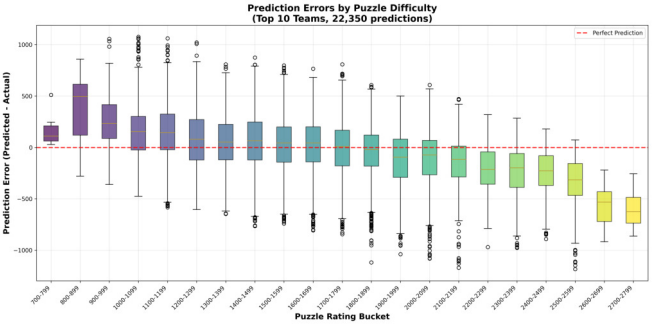

Fig. 2: Prediction errors by puzzle difficulty.

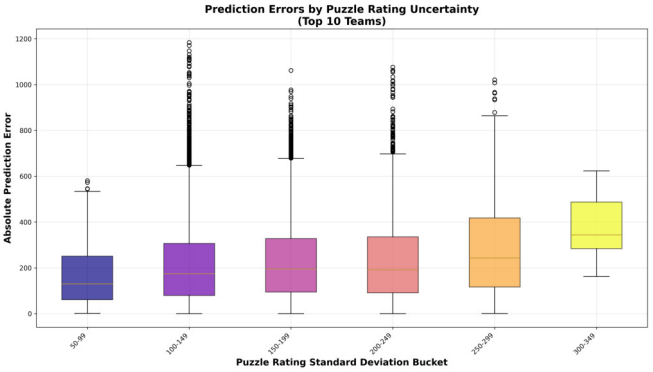

Fig. 3: Prediction errors by rating uncertainty.

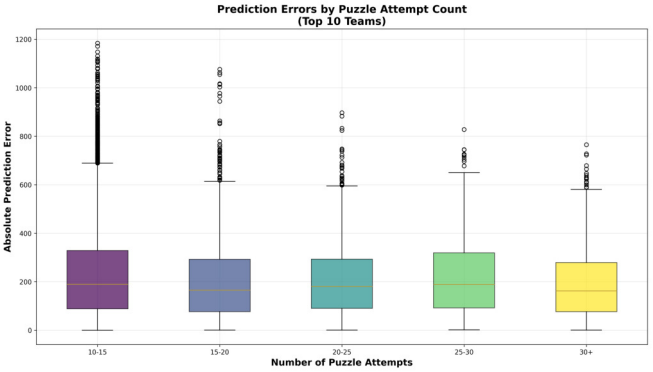

Fig. 4: Prediction errors by the number of attempts during data annotation phase.

harder to model. This suggests that rating deviation, rather than the number of attempts, is a more reliable signal for deciding how well a puzzle's difficulty has been established.

Finally, we investigated whether the number of puzzle attempts during tagging correlates with error (Figure 4). We found no significant trend: puzzles with 10–15 attempts yield error levels comparable to those with 30 or more attempts. Taken together, these findings imply that once a puzzle's Glicko deviation has stabilized, additional attempts provide little benefit. Thus, rating deviation should guide tagging efforts more directly than attempt count.

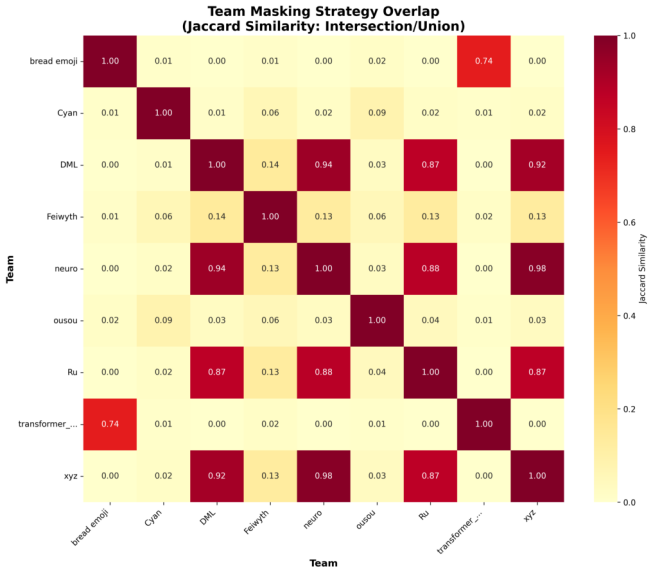

Fig. 5: Jaccard similarity matrix showing overlap between teams' masking strategies.

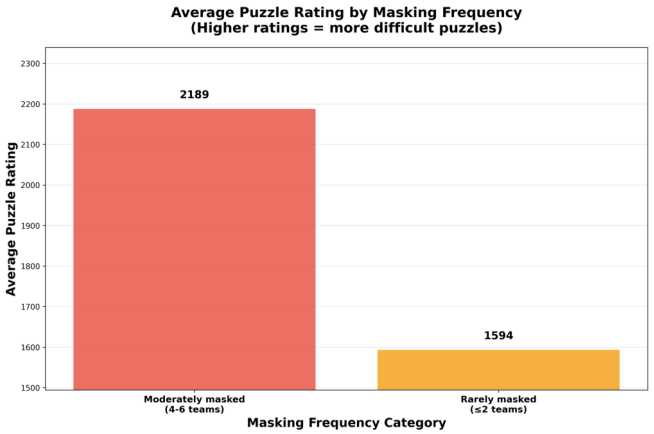

Fig. 6: Puzzle characteristics grouped by masking frequency across teams.

B. *Masking Strategy Analysis*

We next examined the masking strategies employed by teams, focusing both on the convergence of approaches and the characteristics of commonly excluded puzzles. Figure 5 shows the Jaccard similarity between teams' masking choices. Several teams converged on remarkably similar strategies, with DML, neuro, Ru, and xyz achieving similarity scores of 0.87–0.98. This suggests that these teams independently identified a common set of problematic puzzles. By contrast, teams such as bread emoji and transformer_enjoyer pursued more distinctive approaches, showing consistently lower overlap with others.

Beyond team overlap, we analyzed which puzzles were most frequently masked (Figure 6). A clear trend emerges: puzzles targeted by many teams tend to be significantly more difficult ($\approx$ 2200) than those rarely masked ($\approx$ 1600). This indicates

that masking was not random but systematically biased toward high-difficulty puzzles, which teams collectively judged as less reliable or harder to model.

VII. Conclusions

The FedCSIS 2025 knowledgepit.ai competition highlighted the effectiveness of combining neural chess embeddings with ensemble methods and calibration strategies for predicting puzzle difficulty. The top-performing teams consistently employed multi-stage pipelines in which pretrained embeddings such as Maia-2 served as the foundation for downstream boosting models and refined scaling. Despite differences in architecture, a recurring theme was the integration of multiple feature sources – ranging from engine success probabilities to solution policy predictions – followed by systematic post-processing. The additional mask contest further demonstrated that raw predictive accuracy and confidence estimation are distinct goals – while the winning team achieved the lowest MSE overall, the strongest uncertainty modeling was achieved by a different team. This emphasizes the importance of addressing not only point prediction but also model reliability.

Post-hoc analyses of prediction errors revealed consistent patterns across submissions. Errors followed a U-shaped trend with respect to puzzle difficulty, increasing at both extremes of the scale, while rating deviation emerged as a more reliable indicator of prediction uncertainty than attempt count. These findings suggest that puzzle ambiguity, as quantified by Glicko deviation, poses a fundamental barrier to modeling accuracy and that additional attempts beyond stabilization yield limited benefit. Overall, the competition illustrates the dual challenges of modeling puzzle difficulty and quantifying uncertainty, pointing to promising directions for future research in hybrid modeling and calibrated confidence estimation.

In the future, we intend to embed the mechanism of uncertainty masks into all challenges held at the knowledgepit.ai platform – not only as additional tasks but as the main competition objectives. This is because the ability to identify the hardest cases in the data is the key element of advanced machine learning processes [13], and therefore, we need to develop tools for measuring whether the competition participants possess the appropriate skills in this regard [11]. While doing this, however, we need to remember that uncertainty measures are not necessarily the only way to identify those most problematic cases for machine learning models.

As another future topic, encouraged by the aforementioned fact that most of the successful teams relied heavily on non-trivial feature engineering, we are going to further improve our benchmark competition model, this time taking into account also the attributes gathered from papers [17]–[24], organizing them within semantically meaningful groups, and deriving ensembles of their subsets as proposed in [15].

Acknowledgments

This research was co-funded by Smart Growth Operational Programme 2014-2020, financed by European Regional Development Fund, in frame of project POIR.01.01.01-00-1070/21, operated by National Centre for Research and Development in Poland. We are also grateful to chess players who helped us with the difficulty ratings of puzzles in the test data.
