DEAR Reader, it is our pleasure to present to you Proceedings of the 2015 Federated Conference on Computer Science and Information Systems (FedCSIS), which took place in Łódź, Poland, on September 13–16, 2015. Each of the papers, found in this volume, was refereed by at least two referees and the acceptance rate of full (regular) papers was 24.01% (91 papers out of 379 submissions).

FedCSIS 2015 was organized by the Polish Information Processing Society (Mazovia Chapter), Wrocław University of Economics, Systems Research Institute Polish Academy of Sciences and Łódź University of Technology. FedCSIS was organized in technical cooperation with: IEEE Computer Society, IEEE Region 8, IEEE SMC Technical Committee on Computational Collective Intelligence, Computer Society Chapter Poland, Gdańsk Computer Society Chapter, Poland, Polish Chapter of the IEEE Computational Intelligence Society (CIS), ACM Special Interest Group on Applied Computing, European Alliance for Innovation (EAI), Łódź ACM Chapter, Committee of the Computer Science of the Polish Academy of Sciences, Polish Operational and Systems Research Society, Mazovia Cluster ICT and Eastern Cluster ICT Poland. Furthermore, the 10th International Symposium Advances in Artificial Intelligence and Applications (AAIA'15) was organized in technical cooperation with: International Fuzzy Systems Association, European Society for Fuzzy Logic and Technology, International Rough Set Society and Polish Neural Networks Society.

FedCSIS 2015 consisted of the following events:

- AAIA'15—10th International Symposium Advances in Artificial Intelligence and Applications
  - AIMaVIG'15—1st International Workshop on Artificial Intelligence in Machine Vision and Graphics
  - AIMA'15—5th International Workshop on Artificial Intelligence in Medical Applications
  - ASIR'15—5th International Workshop on Advances in Semantic Information Retrieval
  - LQMR'15—1st Workshop on Logics for Qualitative Modelling and Reasoning
  - WCO'15—8th Workshop on Computational Optimization
- CSS—Computer Science & Systems
  - BCPC'15—1st International Workshop on Biological, Chemical and Physical Computations
  - CANA'15—8th Computer Aspects of Numerical Algorithms
  - IWCPS'15—2nd International Workshop on Cyber-Physical Systems
  - MMAP'15—8th International Symposium on Multimedia Applications and Processing
  - WAPL'15—5th Workshop on Advances in Programming Languages
- ECRM—Education, Curricula & Research Methods
  - DS-RAIT'15—2nd Doctoral Symposium on Recent Advances in Information Technology
- iNetSApp'15—3rd International Conference on Innovative Network Systems and Applications
  - EAIS'15—2nd Workshop on Emerging Aspects in Information Security
  - SoFAST-WS'15—4th International Symposium on Frontiers in Network Applications, Network Systems and Web Services
  - WSN'15—4th International Conference on Wireless Sensor Networks
- IT4MBS—Information Technology for Management, Business & Society
  - ABICT'15—6th International Workshop on Advances in Business ICT
  - AITM'15—13th Conference on Advanced Information Technologies for Management
  - ISM'15—10th Conference on Information Systems Management
  - IT4L'15—4th Workshop on Information Technologies for Logistics
  - KAM'15—21st Conference on Knowledge Acquisition and Management
- JAWS—Joint Agent-oriented Workshops in Synergy
  - ABC:MI'15—10th Workshop on Agent Based Computing: from Model to Implementation
  - MAS&S'15—9th International Workshop on Multi-Agent Systems and Simulations
  - SEN-MAS'15—4th International Workshop on Smart Energy Networks & Multi-Agent Systems

Furthermore, an AAIA'15 Data Mining Competition, focused on "Recognition of activities carried out by first responders at a fire scene based on body sensor network readings" has been organized. Its results constitute a separate section in these proceedings. Awards for the winners of the contest were sponsored by: Mazovia Chapter of the Polish Information Processing Society.

Each event constituting FedCSIS had its own Organizing and Program Committee. We would like to express our warmest gratitude to members of all of them for their hard work attracting and later refereeing 379 submissions.

FedCSIS 2015 was organized under the auspices of Prof. Lena Kolarska-Bobińska, Minister of Science and Higher Education, Andrzej Halicki, Minister of Administration and Digitization, Prof. Michał Kleiber, President of the Polish Academy of Sciences, Witold Stępień, Marshal of Łódź Province, Hanna Zdanowska, Mayor of the City of Łódź, and Prof. Stanisław Bielecki, Rector of Łódź University of Technology.

FedCSIS was sponsored by the Ministry of Science and Higher Eduction, Intel and Samsung.

***Abstract*—The usage of Unmanned Aerial Vehicles (UAVs) is increasing day by day. In recent years, UAVs are being used in increasing number of civil applications, such as policing, fire-fighting, etc in addition to military applications. Instead of using one large UAV, multiple UAVs are nowadays used for higher coverage area and accuracy. Therefore, networking models are required to allow two or more UAV nodes to communicate directly or via relay node(s). Flying Ad-Hoc Networks (FANETs) are formed which is basically an ad hoc network for UAVs. This is relatively a new technology in network family where requirements vary largely from traditional networking model, such as Mobile Ad-hoc Networks and Vehicular Ad-hoc Networks. In this paper, Flying Ad-Hoc Networks are surveyed along with its challenges compared to traditional ad hoc networks. The existing routing protocols for FANETs are then classified into six major categories which are critically analyzed and compared based on various performance criteria. Our comparative analysis will help network engineers in choosing appropriate routing protocols based on the specific scenario where the FANET will be deployed.**

***Index Terms*—UAV networks, MANET, VANET, FANET, Routing protocols**

## I. Introduction

UNMANNED aerial vehicle (UAV) systems can fly independently or can be operated distantly. The usage of UAVs is increasing day by day. Earlier, UAVs were simple remotely piloted aircrafts and mostly used for military operations / applications. However, in recent years, UAVs are being used in increasing number of civil applications, such as policing and fire-fighting, non-military security work, etc.

The use of single-UAV system is very common, but using a group of small UAVs has become advantageous. Nonetheless, multi-UAV systems have some exclusive challenges and one of the most important design issues is the communication. There are many advantages of multi-UAV systems, such as

- Economical: The installation and maintenance cost of small UAVs are much less than that of a large UAV [1].
- Flexibility: Single UAV have limited coverage area, hence coverage rate is low [2]. However, multi-UAV systems can adapt to the situation easily.
- Continuity: If the UAV operation (operated by one UAV) fails in a mission, it cannot proceed. However, if a UAV goes off in a multi-UAV system, the operation can be survived through other UAVs.
- Faster: It has been shown that the missions can be completed faster with a higher number of UAVs [3].
- Higher accuracy: Instead of one large radar cross-section, multi-UAV systems produce very small radar cross-sections which are more accurate and crucial for military applications [4].
- Sustainable: Multi UAVs are more sustainable than single UAV system.
- Easy to solve: Multi-UAVs sometime can be solved recursively, which is much easier than single UAV system.

Multi-UAV systems have several issues. In a single-UAV system, a ground base station or a satellite is used for communication. Sometimes, communication link is established between the UAV and an airborne control system. In every case, single-UAV communication link is established between the UAV and the infrastructure. When the number of UAVs increases in the unmanned aerial systems, designing effective network architectures becomes a crucial issue.

There are some UAVs, those connect with a ground base station; others can connect to satellites, thereby realizing the UAV-to-UAV communication through the infrastructure. However, there are several design limitations with the infrastructure-based approach. First of all, each UAV must be equipped with an exclusive and complex hardware in order to communicate with a ground base station or a satellite. Reliability of the communication is the second issue. Another problem is the range restriction among the UAVs and the ground base station. If a UAV is outside the coverage area of the ground station, it becomes disconnected.

To resolve all the above mentioned issues, an alternative solution for multi-UAV systems is required to create an ad-hoc network among the UAVs, which is called FANET. In FANET, only a subset of UAVs can interconnect with the ground station or the satellite and all UAVs constitute an ad-hoc network. In this way, the UAVs can communicate with one another in addition to the ground station.

FANET is basically a special form of MANET/VANET. There are also certain differences between FANET and the traditional ad-hoc networks. Mobility degree of FANET nodes is much higher than that of MANET or VANET nodes. While typical MANET and VANET nodes are walking human beings or vehicles, respectively, FANET nodes fly in the sky. Due to high mobility of FANET nodes, the topology changes more frequently than the network topology of a typical MANET or even VANET. FANET needs peer-to-peer connections for

978-83-60810-66-8/$25.00©2015, IEEE

synchronization and relationship of UAVs. It is required to collect data from the environment and to transmit to the command & control center, as in wireless sensor networks [5]. Hence, FANET must support both peer-to-peer communication and converge cast traffic at the equivalent time. The distances among FANET nodes are much higher than in MANETs or VANETs [6]; so higher range of communication is needed. Multi-UAV systems may include different types of sensors, and each sensor may require different data distribution approaches.

There exist a few studies on UAV networks [7]–[11]. In [7], authors discussed Unmanned Aircraft System (UAS) where wireless communication is performed through IEEE 802.11b/g and Dynamic Source Routing (DSR) protocol was used as the routing protocol. In [8], a net-centric communication process is described with full command and control architecture for a heterogeneous unmanned aircraft system (in a small topology). In [9], authors discussed several networking issues related to delay-tolerant mobile ad-hoc network architecture. However, none of these works have provided a comprehensive survey of the routing issues of FANET networks. A survey [10] was performed on Flying ad-hoc network where FANET application scenario are discussed. It also discusses the FANET Communication protocols that consist of Physical, MAC, Network, Transport and Cross-layer architectures. FANET network layer has been discussed briefly in [11] where it is proposed that with a small modification on the routing protocols (used for VANET and MANET), they can be used in FANET architecture. However, none of these works [10], [11] have provided a comprehensive survey of the routing issues of FANET networks.

The main *objective* of this paper is to explain FANET as a distinct ad hoc network family and to introduce unique challenges, design constraints and routing issues in FANETs.

The *contributions* of this paper are (i) presenting different challenges and issues of FANET design, (ii) classifying existing routing protocols for FANET, and (iii) critically analyzing and comparing them based on various performance criteria.

Our comparative analysis will help network engineers in choosing appropriate routing protocols based on the specific scenario where the FANET will be deployed.

The rest of the paper is organized as follows. In Section II, we present several FANET designing issues. In Section III, we provide an extensive evaluation of the existing FANET routing protocols. In Section IV, we provide a comparative study among the six basic protocols of FANETs, followed by a discussion of open problems for FANET research in Section V. Finally, Section VI has the concluding remarks.

## II. FANET Design Issues

FANET is a new form of MANET where the nodes are UAVs. So a single-UAV systems cannot form a FANET, and valid only for multi-UAV systems. Again all multi-UAV systems do not form a FANET. UAV communication should create an ad-hoc network between UAVs to create FANET. Therefore, if the communication between UAVs fully relies on UAV-to-infrastructure links, it cannot be classified as a FANET [10].

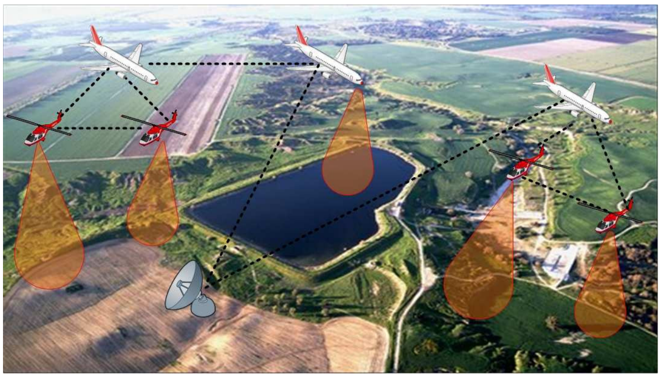

Fig. 1. A FANET scenery of multi-UAV systems.

In Fig. 1, a detailed multi-UAV system is shown. There are several area where FANET linked researches are studied under dissimilar names. Like, aerial robot team [12], aerial sensor network [13]–[15], but exact FANET base study is less interest in this topics. UAV ad hoc network [16] is totally a unique topic, which is thoroughly associated to FANETs. In fact, there is no major change between the existing UAV ad-hoc network researches and the above FANET definition. However, FANET term instantly prompts that it is a specialized form of MANET and VANET. This is why it is called Flying Ad-Hoc Network, FANET.

*FANET vs. traditional ad-hoc networks:*
Wireless ad hoc networks are categorized permitting to their application, positioning, communication and assignment intentions. By characterization, FANET is a form of MANET, and there are many mutual design thoughts for MANET and FANET. FANET can also be classified as a subset of VANET, which is also a subgroup of MANET.

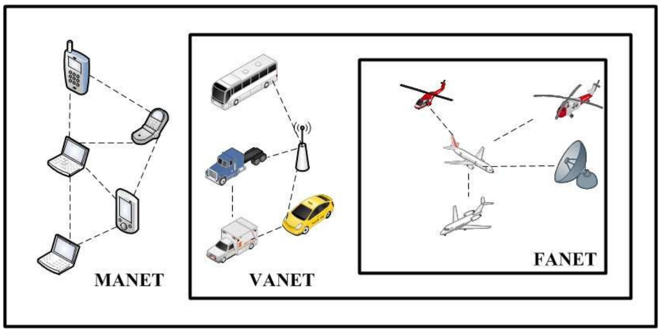

Fig. 2. MANET, VANET and FANET.

This affiliation is shown in Fig. 2. FANET shares common characteristics with these networks, and it also has some unique design challenges. Table I presents a comparison among FANET, VANET and MANET. In the following subsections, the differences among FANET and the existing wireless ad hoc networks are explained in details.

TABLE I
COMPARISON AMONG FANET, VANET AND MANET.

| Ad-Hoc network Types<br>Criteria | FANET | VANET | MANET |
|---|---|---|---|
| Node mobility | High compactness | Medium compactness | Low compactness |
| Mobility model | Usually predetermined, but special mobility models for independent multi-UAV systems | Steady | Arbitrary |
| Node density | Low thickness | Medium thickness | Low thickness |
| Topology change | Rapid and speedy | Average speed | Slow and steady |
| Radio propagation model | High above the ground level,LoS (Line of Sight) is accessible for most of the cases | Close to ground, LoS is not accessible for all cases | Very close to ground, LoS is not accessible for all cases |
| Power consumption and network lifetime | Needed for mini UAVs, but not needed for small UAVs | Not needed | Need of energy efcient protocols |
| Computational power | Very big | Average | Limited |
| Localization | GPS, AGPS, DGPS, IMU | GPS, AGPS, DGPS | GPS |

### A. Node mobility

Node mobility issues are the most significant difference between FANET and the other ad hoc networks. MANET node movement is comparatively slow when it is compared to VANET. In FANET, the nodes mobility degree is much higher than in the VANET and MANET. According to [6], a UAV has a speed of 30–460 km/h, and this situation results in several challenging communication design problems [17].

### B. Mobility model

MANET nodes move on a definite territory, VANET nodes move on the highways, and FANET nodes fly in the sky. In multi-UAV systems, the flight plan is not fixed, if a multi-UAV system uses predefined flight plans it may not be successful, because of the environmental deviations or operation updates, the flight plan may need to be recalculated.

### C. Node density

Node density is defined as the average number of nodes in a unit area. FANET nodes are normally spread in the sky, and the distance between UAVs can be several kilometers even for small multi-UAV systems. As a result of this, FANET node density is much lower than in the MANET and VANET.

### D. Topology change

Due to higher mobility degree, FANET topology changes more regularly than MANET and VANET topology. When a UAV fails, the links that the UAV has been involved in also failed and it results in a topology update. Another factor that affects the FANET topology is the link outages. Because of the UAV schedules and variations of FANET node distances, link quality changes very quickly, and it also causes link outages and topology changes [18].

### E. Radio propagation model

FANET and the other ad hoc network operating environments affect the radio propagation characteristics. MANET and VANET nodes are very close to the ground, and in many cases, there is no line of-sight between the sender and the receiver. Radio signals are mostly affected by the geographic structure. Again, FANET nodes those are away from the ground can be driven remotely and in maximum case; there is a line-of sight between UAVs [10].

### F. Power consumption and network lifetime

Developing energy efficient communication protocols is a major part to increase the network lifetime. Particularly, while the battery-powered computing devices in MANETs; system developers have to pay extra attention to the energy efficient communication protocols. However, FANET communication hardware is powered by the energy source of the UAV. This means FANET communication hardware has no power resource problem as like in MANET.

### G. Computational power

MANET nodes are battery powered small computers such as laptops, PDAs and smart phones. Because of the size and energy constraints, the nodes have only limited computational power. On the other hand VANETs and FANETs support devices with high computational power.

### H. Localization

In MANET, GPS is generally used to receive the coordinates of a mobile communication terminal, and maximum time, GPS is enough to regulate the location of the nodes. In VANET, for a navigation-grade GPS receiver, there is about 10–15 m accuracy, which can be satisfactory for route guidance. Because of the high velocity and dissimilar mobility models of multi-UAV systems, FANET needs highly accurate localization data with smaller time intervals. GPS provides position information at one second interval, and it may not be adequate for certain FANET protocols.

## III. FANET NETWORKING PROTOCOLS

There exists many routing protocols for wireless and ad-hoc networks, such as pre-computed routing, dynamic source routing, on demand routing, cluster based routing, flooding, etc. FANET is a sub-class of VANET and MANET networks. Therefore, MANET routing protocols are initially chosen and tested for FANET. Due to the UAV-specific issues, such as, rapid changes in link quality, most of these protocols are not directly applicable for FANET networks. Hence, in order to implement this new networking model, some definite adhoc networking protocols have been implemented and some previous ones have been adapted. These protocols can be classified into six major categories:

- **Static protocols**, having fixed routing tables (no need to refresh these tables).
- **Proactive protocols**, have periodically refreshed routing tables.
- **Reactive protocols** (also called on-demand protocols) discover paths for messages on demand.
- **Hybrid protocols** that use both proactive and reactive protocols.
- **Position/Geographic Based protocols** that use position or area coverage.
- **Hierarchical protocols** that use hierarchy model for routing.

With the help of all these routing protocols, a FANET can actively discover new paths among the communicating nodes.

## A. Static Routing Protocols

In static routing protocol, a routing table is calculated and uploaded to UAV nodes before an assignment, and cannot be updated during the operation; this is why it is called static. UAVs in this protocol have a constant topology [19]. Here every node communicates with a limited numbers of UAVs or ground stations, and it only preserves their information. In case of a failure (of a UAV or ground station), for updating the tables, it is essential to wait until the assignment is finished. As a result there are no fault tolerant approach for dynamic environments in static routing protocols.

*1) Data Centric Routing:* UAVs wireless communication support one to many data transmission which is similar to one-to-one data transmission [20], [21]. This method is selected when the data is requested by a number of nodes, and data distribution is done by on-demand algorithms. Data-centric routing is a favorable model of routing mechanism and can be adjusted for FANET [22], [23].

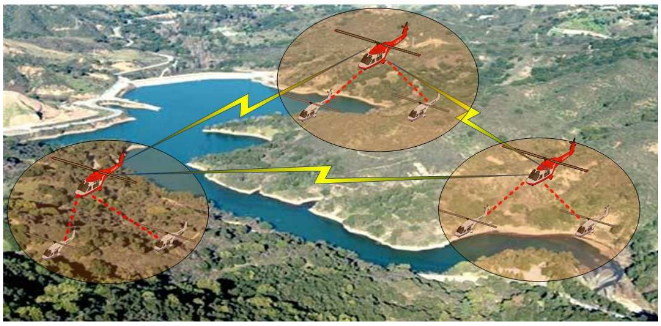

Fig. 3. Data centric routing model in FANET.

Data demand and gathering are done by data attributes instead of sender and receiver nodes' IDs. As shown in Fig. 3, this model is usually skillful with cluster infrastructure.

In this model, the consumer node (either ground node or a UAV) broadcasts queries (such as ”get video of area X if there is a change of more than % 3”) as contribution message in order to collect particular data from a precise area. Routing is done with respect to the content of data. Data aggregation algorithms may be used for energy efficient data broadcasting. This routing executes three scopes of decoupling:

- *Space decoupling*: Communicating parties can be anywhere.
- *Time decoupling*: Data can be transmitted to the subscribers instantly or later.
- *Flow decoupling*: Delivery can be accomplished constantly.

This model can be chosen when the system contains a small number of UAVs on a planned path, which involves minimum assistance.

*2) Multi-Level Hierarchical Routing:* Organizing UAV networks hierarchically a number of clusters needs to operate in different mission areas, as shown in Fig. 4. Each cluster has a cluster head (CH), which will represent the whole cluster; this separate cluster can perform different activities. Each CH is in connection with the upper/lower layers (ground stations, UAVs, satellites, etc.) directly or indirectly. To broadcast data and control info to other UAVs in the cluster, CH should be in direct communication range of other UAVs in cluster.

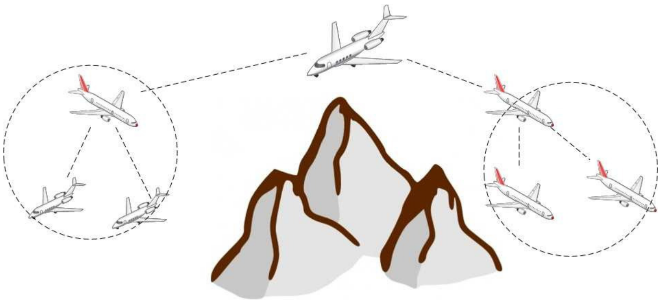

Fig. 4. Multi-Level Hierarchical routing model in FANET

This model is better if UAVs are controlled in changed swarms, the mission area is huge, and several UAVs are used in the network.

*3) Load Carry and Deliver Routing:* In this model, a UAV loads data from a ground node; then the data is being carried to the destination by flying; and at the end the data reached to the destination ground node.

The main objectives of load carry and deliver routing is to maximize throughput and increase the security. But the main drawback of this protocol is whenever the distance of communicating parts growth, the transmission delay becomes tremendously huge and unendurable. To solve this problem multi-UAVs system can be developed so that it decreases transmission delay as well as the distance among UAVs.

## B. Proactive Routing Protocols

Proactive routing protocols (PRP) use tables to store all the routing in the network. The main advantage of proactive routing is that it stores the latest information of the routes; therefore, it is easy to choose a route from the sender to the receiver, as a result transmission delay can be minimized. But, there are some disadvantages of this protocol.

$First$, there are lot of messages are being exchange between nodes, therefore bandwidth optimization is not possible. For this reason PRPs are not suitable for highly mobile and/or larger networks. $Second$, when the topology change or connection failure occurs, PRP shows a slow reaction.

*1) Directional Optimized Link State Routing:* This protocol is based on the well known Optimized Link State Routing Protocol (OLSR) [24]. One of the most important factors that affect the OLSR performance is to select multipoint relay (MPR) nodes. The sender node selects a set of MPR nodes so that the MPR nodes can cover two hop neighbors. One of the most crucial design issues for OLSR is the number of MPRs, which effects the delay dramatically. Simulation studies [25] showed that DOLSR can reduce the number of MPRs with directional antennas.

*2) Destination Sequenced Distance Vector:* This protocol mainly uses the Bellman Ford algorithm with slight modifications for ad hoc networks. In DSDV, each node saves a routing table (with sequence number) for all other nodes, not just for the neighbor nodes [26]. Whenever the topology of the network changes, these changes are circulated by the protocol to update devices. To eliminate routing-loops and to identify the latest route, DSDV uses sequence numbers, which are allocated by destination nodes. The route which has higher sequence number is selected.

The main advantages of DSDV are easy algorithm and the usage of sequence numbers, which guaranteed the protocol to be loop free. Again, it has some drawbacks. For an upto date routing table, each node periodically broadcast routing table updates, which brings overhead to the network.

*3) Topology Broadcast based on Reverse-Path Forwarding:* This protocol use Dynamic Source Routing (DSR) [27]. The main advantage to choose DSR is its reactive configuration. The source tries to find a path to a destination, only if it has data to send. Main drawback of this protocol is the topology is unstable when the nodes are highly mobile.

### C. Reactive Routing Protocols

Reactive Routing Protocol (RRP) can be referred as on demand routing protocol. If there is no connection between two nodes, there is no need to calculate a route between them. The concept RRP is came to overcome the overhead problem of PRP.

There are two different messages in this protocol: Route_Request messages and Route_Reply messages. Route_Request messages are created and transmitted by flooding to the network by the source node, and the destination node responses to this message with a Route_Reply message. RRP is bandwidth efficient, because there is no periodic messaging. Main drawback is it takes long time to find the route; as a result high latency may occur.

*1) Dynamic Source Routing:* Dynamic Source Routing (DSR) is designed for wireless mesh networks [28]. In DSR, the source node broadcasts a route request message to its neighbor nodes. In the entire communication route, there can be many route request messages. So, to avoid mix-up, the source node added a distinctive request_id. If the source node is not capable to use its present route (changes in the network topology), then the route repairs mechanism is triggered. This routing protocol was implemented by Brown et al. in [29] and they found finding a new route in UAV network with DSR can be frustrating.

*2) Ad-hoc On-demand Distance Vector:* Ad-hoc On-demand Distance Vector (AODV) has almost the similar on-demand features with DSR. The only difference is routing table maintenance [30].

In DSR each node can store multiple entries in the routing table for each destination while in AODV; there is a single record for each destination. Another difference in DSR, the data packets transfer the complete path between source and the destination nodes. But in AODV, the source node only stores the next-hop information consistent to each data communication.

AODV routing protocol consists of $three$ phases: route discovery, packet transmitting and route maintaining.

*3) Time-slotted on-demand Routing:* Time-slotted on-demand routing protocol is proposed in [31] for FANETs. Basically it is time-slotted version of AODV. Time-slotted on-demand protocol uses dedicated time slots in which only one node can send data packet. Although it increases the use of network bandwidth but mitigates the packet collisions and ensure packet delivery.

### D. Hybrid Routing Protocols

To overcome the limitations of previous protocol Hybrid routing protocol (HRP) is introduced. Reactive routing protocols needs extra time to discover route and proactive routing protocols has huge overhead of control messages both can mitigate in HRP. HRP is appropriate for large networks. A network can be divided into a number of zones where intra-zone routing used proactive method while inner-zone routing uses reactive method [11].

*1) Zone Routing Protocol:* Zone Routing Protocol (ZRP) is based on the concept of zones [32]. In this protocol, each node has a different zone. The zone is defined as the set of nodes whose minimum distance is predefined radius $R$. So, the zones of neighboring nodes intersect. The routing inside the zone is called as intra-zone routing, and it uses proactive method. If the source and destination nodes are in the same zone, the source node can start data communication instantly. When the data packets need to send outside the zone the inter-zone routing is used and reactive method is applied.

*2) Temporarily Ordered Routing Algorithm:* Temporarily Ordered Routing Algorithm (TORA) routers only preserve info about adjacent routers [33]. TORA mainly uses a reactive routing protocol but it also use some proactive protocol. It constructs and preserves a Directed Acyclic Graph (DAG) from the source node to the destination. TORA does not use a shortest path solution, sometime longer routes used to reduce network overhead. Each node has a parameter value termed as "height" in DAG, which is unique for each node. Data flow as a fluid from the higher nodes to lower. It is structurally loop-free because data cannot flow to the node that has higher value [11].

### *E. Position/Geographic Based Routing Protocols*

Position-based routing needs information about the physical position of the contributing nodes in the network. Generally, each node calculates its own location through the use of GPS or some other type of positioning facilities. Position based routing is primarily motivated by two subjects, $(i)$ A position facility is used by the sender of a packet to decide the position of the destination and $(ii)$ A forwarding approach used to forward the packets.

*1) Greedy Perimeter Stateless Routing:* Greedy Perimeter Stateless Routing (GPSR) is a position based protocol, have several advantages over proactive and reactive routing protocols. Shirani et al. developed a simulation framework to study the position-based routing protocols for FANETs [34]. The outcome of the study is that GPSR can be used for compactly positioned FANETs. But, reliability is the major issue of this protocol. For this another method, like face routing, can be used to achieve more reliability.

*2) Geographic Position Mobility Oriented Routing:* The traditional position-based protocols only depend on the location information of the nodes. But, geographic position mobility oriented routing predicts the movement of UAVs with $Gaussian - Markov$ mobility model, and uses this information to guess the next hop.

### *F. Hierarchical Routing Protocols*

In hierarchical routing protocols the choice of proactive and of reactive routing depends on the hierarchic level. The routing is primarily established with some proactive planned routes and then helps the request from by triggered nodes through reactive protocol at the lower levels. The main drawbacks of this protocol are: complexity and addressing scheme which response to traffic request as a result it hang the interconnecting factors.

*1) Mobility prediction clustering:* It operates on the dictionary of Trie-structure calculation algorithm and link termination time mobility model to guess network topology updates. In this way, it can build more constant cluster formations [35].

*2) Clustering algorithm of UAV networking:* It constructs the clusters on the ground, and then updates the clusters through the mission in the multi-UAV system [36].

## IV. Comparative study

As mentioned earlier, there exist six basic protocols for FANET. In this section, we critically analyze and compare these basic FANET protocols. Table II presents the comparative study among these six FANET routing protocols: static, proactive, reactive, hybrid, position/geographic based and hierarchical protocols. We explain each of the comparison criteria in more details in this section:

### *A. Main Idea*

The main idea for static protocol is routing information is fixed for a specific mission and loaded into the UAVs before the mission. Proactive protocol stores the current route information into the table. Reactive protocol is on demand protocol; when the source asks for destination route, it calculates the route. Hybrid protocol is a combination of both proactive and reactive protocols. Position/geographic protocol uses GPS or other location service to calculate the route. Hierarchical protocols uses hierarchy model to find route.

### *B. Complexity*

For static protocol, complexity is relatively low because destination is fixed. However, for proactive, reactive and hybrid protocol, complexity is medium. In case of topology change, route finding becomes more complex in proactive protocol. For position-based protocol, finding route becomes difficult if the location service is poor. In an urban area, hierarchical protocol is useful but its setup is not so simple.

### *C. Route*

In case of static protocol, route is fixed throughout the mission. For all other protocols, routes are dynamic.

### *D. Topology size*

Static protocol is used for fixed mission. As a result, if the topology size is large, there is chance of topology change. Hence, static protocol is suitable for small networks. Proactive protocol is a table-driven protocol; hence, if the number of UAVs increases, their corresponding routing table entries also increases. Thus, proactive protocol is suited for small networks. For hybrid protocols, intra-zone routing is usually fixed and small sized. Position based and hierarchical protocols are used in larger network.

### *E. Memory size*

In static protocols, the whole routing information is uploaded into the UAVs before the mission. As a result, it requires large memory space. If the number of nodes increases, the table size grows larger. Thus, proactive protocol requires larger memory. Reactive protocol is source driven; hence, when source is required to find route, it is activated, requiring less memory. Position-based protocol caches the coordinates of each UAV, thereby requireing large memory space. Hierarchical protocol uses hierarchical structure whose memory requirement is low.

### *F. Fault tolerant*

In FANETs, mission route or topology change is a very common scenario. However, static protocols do not support this scenario. Therefore, fault tolerance is absent in this protocol. However, every other protocol has some fault tolerance.

TABLE II
COMPARISONS AMONG THE BASIC ROUTING PROTOCOLS IN FANETS.

| Criteria \ Different Protocol Types | Static Protocols | Proactive Protocols | Reactive Protocols | Hybrid Protocols | Position/Geographic Based Protocols | Hierarchical Protocols |
|---|---|---|---|---|---|---|
| Main Idea | Static routing table | Table driven protocols | On demand protocol | Combination of proactive and reactive protocols | Position-based protocol | Protocol maintained through hierarchy |
| Complexity | Low | Medium | Average | Average | High | High |
| Route | Static | Dynamic | Dynamic | Dynamic | Dynamic | Dynamic |
| Topology size | Small network | Small network | Large network | Both small and large network | Large network | Large network |
| Memory size | High | High | Low | Medium | High | Low |
| Fault tolerant | Absent | Present | Present | Mostly present | Present | Present |
| Bandwidth Utilization | Maximum | Minimum | Maximum | Medium | Minimum | Maximum |
| Convergence Time | Fast | Slow | Mostly fast | Average | Average | Average |
| Signalling Overhead | Absent | Present | Present | Present | Present | Present |
| Communication Latency | Low | Low | High | High | Low | High |
| Mission Failure Rate | High | Low | Low | Very low | Very low | Very low |
| Popularity | Less | Medium | Medium | High | Less | High |
| Application | Fixed mission | Dynamic mission | Dynamic mission | Dynamic mission | Dynamic mission | Dynamic mission |

### G. Bandwidth utilization

Static protocols are used in small network where topology is fixed; as a result, bandwidth utilization is high in this protocol. Proactive protocols have to send hello messages periodically in the network. Therefore, this protocol requires more bandwidth. Reactive protocols are source driven, requiring less bandwidth. For hybrid protocols, bandwidth utilization is medium. Position based protocol send source location as extra information; hence, bandwidth consumption rate is higher. Hierarchical protocols use limited bandwidth as each UAV is connected to upper level UAVs.

### H. Convergence time

In the static protocol, destination is predetermined. As a result route finding time is minimal. Proactive protocol searches the destination node after each topology change, resulting in larger converge time. Reactive protocols usually find route much faster but if topology changes, this protocol takes more time than normal case. Hybrid, position based and hierarchical protocols usually take average time to converge.

### I. Signalling overhead

Other than static protocols, each protocol (proactive, reactive, hybrid, position based and hierarchical) have signaling overheads, such as hello message in proactive protocols, route request and route reply message in reactive protocols, etc.

### J. Communication latency

Static, proactive and position based protocols have low communication latency since the distance between the UAVs in these protocols is small. Reactive, hybrid and hierarchical protocols have higher latency because UAV-to-UAV and UAV-to-ground station distance is much higher in these protocols.

### K. Mission failure rate

Topology and route change are common phenomena in FANETs.Other than static protocols, each protocol has backup strategy for topology change. Only static protocols do not have any strategy when topology or route changes, as a result mission failure rate is very high in this protocol.

### L. Popularity

Static protocols is not fault tolerant and position based protocols need extra mechanism to find the positions of the UAVs. This is why, these two protocols are least popular. Rest of the protocols are much more popular.

### M. Applications

Static protocols are used in missions where mission objective and topology are fixed. Hierarchical protocols are mostly used in military operations where communication is difficult. Previously, most of the protocols were used in military operations. However, use of UAVs have increased day by day. As a result, many civil operations are now conducted by multi-UAVs systems. For this reason, all the protocols are being modified so that these protocols can be used in normal and civil operations.

## V. OPEN RESEARCH PROBLEMS

Existing MANET and VANET routing protocols cannot satisfy all the FANET routing requirements. Therefore, routing is one of the most important and challenging issues for FANETs. In this section, we list a few open research issues regarding routing in flying ad hoc networks.

### A. P2P UAV communications

In FANET, movements of UAVs are very fast, resulting in very rapid network topology change. Hence, data routings among the UAVs are challenging. The routing protocols should be capable of updating routing tables dynamically. Peer-to-peer communication is crucial for cooperative synchronization and collision anticipation of multi-UAV systems. FANET can collect information from the environment as in wireless sensor networks, which is a different traffic configuration. Developing a peer-to-peer communication and converge cast traffic can be an attractive topic in FANETs. Data centric routing for FANETs is another encouraging approach which is still unexplored.

### B. Regulations for civilian UAVs

The uses of UAVs are increasing day by day and now it has become a part of most of countries national airspace system. However, most of the existing air principles do not allow UAV operations in civil airspace. This is the biggest obstruction to the development of Unmanned Arial Systems in civilian areas. As a result, distinctive rules and guidelines to integrate UAV flights into the national airspace need to be deployed urgently.

### C. Robust FANET algorithms

In a large area mission and multi-UAV operations, dynamic changes (such as addition / deletion of UAVs, fixed and dynamic threats, etc.) can occur. Therefore, robust algorithms with dynamic route adjustments are compulsory to coordinate the fleets of UAVs. It is essential for FANET to support qualities of services (QoS) so that it can protect against some predetermined service performance constraints, such as delay, bandwidth, jitter, packet loss, etc.

### D. UAV placement

The sizes of mini-UAVs are small and they carry limited payloads, for example single radar, infrared camera, thermal camera, image sensor, etc. Therefore, different sensors can be merging-up with different UAVs; or one UAV can be integrated with a thermal camera and another with image sensor. Regarding this, UAV placement to reduce energy consumption is still an open issue.

### E. FANET standardization

FANET uses various wireless communication bands, such as, VHF, UHF, L-Band, C-band, Ku-Band, etc. [11] which are also used in different application areas, such as GSM networks, satellite communications. For reducing congestion problem, FANETs require standardization. FANET should connect to integrate with a Global Information Grid (GIG) as one of the main information platforms to increase its efficiency.

### F. Coordination of UAVs with Manned aircraft

In the future, flights of UAVs with other manned aircraft are likely to increase. Coordination of these two will ensure the destruction of opponent aircraft with minimal losses. Therefore, the association of UAVs and manned aircraft should be in a networked environment.

## VI. Conclusion

Unmanned Aerial Vehicles have promising role in a large operation zone with complicated missions. For the region that are reasonably isolated from the ground and to accomplish complex tasks, UAVs require cooperation with one another and need a quick and easy deploying network system. Multi-UAV system reduces the operation accomplishment time and increases reliability of the system for airborne operations when compared to a single-UAV system. To apply networking in non-LOS, urban, aggressive, and noisy environment, multi-UAV system is very effective and accurate.

Communication is one of the most challenging issues for multi-UAV systems. In this paper, ad hoc networks among the UAVs, i.e, FANETs are surveyed along with its key challenges compared to traditional ad hoc networks. The existing routing protocols for FANETs are classified into six major categories which are then critically analyzed and compared based on various performance criteria. Finally, we list several open research issues related to FANET routing protocols to inspire researchers work on these open problems.

# The Cognitive Cycle

John F. Sowa

*Abstract*—**In the twenty years from first grade to a PhD, students never learn any subject by the methods for which machine-learning algorithms have been designed. Those algorithms are useful for analyzing large volumes of data. But they don't enable a computer system to learn a language as quickly and accurately as a three-year-old child. They're not even as effective as a mother raccoon teaching her babies how to find the best garbage cans. For all animals, learning is integrated with the cognitive cycle from perception to purposeful action. Many algorithms are needed to support that cycle. But an intelligent system must be more than a collection of algorithms. It must integrate them in a cognitive cycle of perception, learning, reasoning, and action. That cycle is key to designing intelligent systems.**

## I. Theories of Learning and Reasoning

THE nature of the knowledge stored in our heads has major implications for educating children and for designing intelligent systems. Both fields organize knowledge in teachable modules that are presented in textbooks and stored in well structured databases and knowledge bases. A systematic organization makes knowledge easier to teach and to implement in computer systems. But as every student discovers upon entering the workforce, "book learning" is limited by the inevitable complexities, exceptions, and ambiguities of engineering, business, politics, and life. Although precise definitions and specifications are essential for solving problems in mathematics, science, and engineering, most problems aren't well defined. As Shakespeare observed, "There are more things in heaven and earth, Horatio, than are dreamt of in your philosophy."

During the past half century, neuroscience has discovered a great deal about the organization of the human brain and its inner workings. But each discovery has led to far more questions than answers. Meanwhile, artificial intelligence developed theories, tools, and algorithms that have been successfully applied to practical applications. Both neuroscience and AI have been guided by the centuries of research in other branches of cognitive science: philosophy, psychology, linguistics, and anthropology.

One explanation of learning that has been invented and reinvented in various guises is the *apperceptive mass* or dominant system of ideas. It was suggested by Leibniz, elaborated by Johann Friederich Herbart [5], and had a strong influence on educational psychology [31]:

> There is a unity of consciousness — attention, as one might call it — so that one cannot attend to two ideas at once except in so far as they will unite into a single complex idea. When one idea is at the focus of the consciousness it forces incongruous ideas into the background or out of consciousness altogether. Combined ideas form wholes and a combination of related ideas form an apperceptive mass, into which relevant ideas are welcomed but irrelevant ones are excluded… If information is to be acquired as easily and as rapidly as possible, it follows that in teaching one should introduce new material by building upon the apperceptive mass of already familiar ideas. Relevant ideas, then, will be most easily assimilated to the apperceptive mass, while irrelevant ideas will tend to be resisted and, consequently, will not be assimilated as readily.

In AI, versions of semantic networks from the 1960s [20] to the 1990s [8] resemble Herbart's apperceptive mass. In fact, the implementations exhibit many of the properties claimed by educational psychologists [26]. Piaget and his colleagues in Geneva observed children and analyzed the *schemata* they used at various ages [19]. They showed that learning progresses by stages, not by a series of database updates. At each stage, the brain *assimilates* new information to its existing structures. When the complexity of the information grows beyond the capacity of the structures at one stage, a minor revolution occurs, and a new schema is created to reorganize the mental structures. The later, more abstract *conceptual* schemata are derived by generalizing, building upon, and reorganizing the *sensorimotor* schemata formed in infancy and early childhood.

Rumelhart and Norman [23] used the term *accretion* for Piaget's assimilation of new information to the old schemata. They split Piaget's notion of *accommodation* in two stages of *tuning* and *restructuring*:

- *Accretion.* New knowledge may be added to episodic memory without changing semantic memory. It corresponds to database updates that state new facts in terms of existing categories and schemata.
- *Schema tuning.* Minor changes to semantic memory may add new features and categories, generalize old schemata to more general supertypes, and revise priorities or defaults.
- *Restructuring.* As episodic memory becomes more complex, a major reorganization of semantic memory may be needed. Completely new schemata and concept types may represent old information more efficiently, support complex deductions in fewer steps, and make drastic revisions to old ways of thinking and acting.

Restructuring is responsible for the *plateau effect*: people quickly learn a new skill up to a modest level of proficiency; then they go through a period of stagnation when study and practice fail to show a noticeable improvement; suddenly,

978-83-60810-66-8/$25.00©2015, IEEE

they break through to a new plateau where they again progress at a rapid rate — until they reach the next plateau. Restructuring is the creative discovery. When a person attains a new insight, a sudden revolution reorganizes the old information in the new categories and schemata.

The paradigms that psychologists have proposed for human learning have their counterparts in AI. In 1983, a review of machine learning [3], distinguished three historical periods, each characterized by its own paradigm for learning:

- *Stimulus-response*. In the late 1950s and early 60s, *neural nets* and *self-organizing systems* were designed to start from a neutral state and build up internal connections solely by reinforcement and conditioning.
- *Induction of concepts*. A higher form of learning is the induction of new types of categories from the data. It started in the 1960s with clustering and concept learning techniques, and it can be integrated with every learning system, formal or informal.
- *Knowledge-intensive learning*. Before a system can learn anything new, it must already have a great deal of initial knowledge. Most methods of restructuring are compatible with knowledge-intensive learning.

One of the first steps in restructuring is categorization: selecting new concept types, mapping percepts to those types, and assigning the types to appropriate levels of the type hierarchy. A more radical alteration of schemata is a leap into the unknown. It requires someone to abandon comfortable old ways of thought before there is any reassurance that a new schema is better. To explain how such learning is possible, Charles Sanders Peirce [17] proposed the reasoning method of *abduction*, which operates in a *cognitive cycle* with observation, induction, abduction, deduction, testing, action — and repeat:

- Deduction is logical inference by formal reasoning or plausible reasoning.
- Induction involves gathering and generalizing new data according to existing types and schemata.
- Abduction consists of a tentative guess that introduces a new type or schema, followed by deduction for exploring its consequences and induction for testing it with reality.

An abduction is a hunch that may be a brilliant breakthrough or a dead end. The challenge is to develop a computable method for generating insightful guesses. Beforehand, a guess cannot be justified logically or empirically. Afterwards, its implications can be derived by deduction and be tested against the facts by induction. Peirce's logic of pragmatism integrates the reasoning methods with the twin gates of perception and purposeful action.

## II. Deep Learning

Educational psychologists, who were strongly influenced by Herbart, Piaget, and William James, distinguish *deep learning* as a search for meaning from *surface learning* as the memorization of facts. Although their definitions are not sufficiently precise to be implemented in AI systems, surface learning corresponds to accretion, and deep learning corresponds to schema tuning and restructuring.

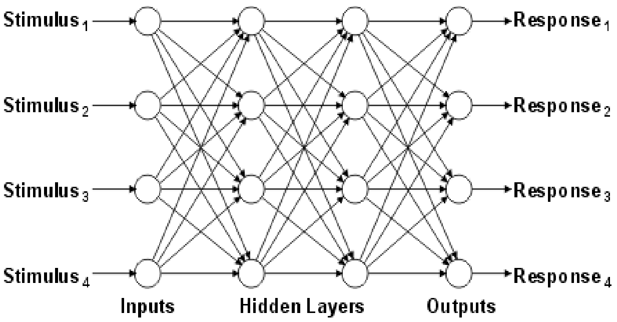

Fig 1. A neural net for connecting stimuli to responses

Educational psychologists considered behaviorism *rat psychology*. But Thorndike [29], a former student of William James, used animal experiments to develop a stimulus-response theory, which he called *connectionism*: rewards strengthen the S-R connections, and punishments weaken them. In 1943, McCulloch and Pitts [13], a neurophysiologist collaborating with a logician, designed a theoretical model of neural nets that were capable of learning and computing any Boolean function of their inputs. To implement a version, Rosenblatt used potentiometers to change weights on the links of a net called a *perceptron* [22]. Later neural nets were implemented by programs on a digital computer.

Behaviorist methods of operant conditioning suggested neural-net methods of learning by *backpropagation*. Figure 1 shows a neural net with stimuli entering the layer of nodes at the left. The nodes represent neurons, and the links represent axons and dendrites that propagate signals from left to right. In computer simulations, each node computes its output values as a function of its inputs. Whenever a network generates an incorrect response to the training stimuli, it is, in effect, "punished" by adjusting weights on the links, starting from the response layer and propagating the adjustments backwards toward the stimulus layer.

Figure 1 is an example of a multilayer feedforward neural network. The original perceptrons had just a single layer of nodes that connected inputs to outputs. With more layers and the option of cycles that provide feedback from later to earlier nodes, more complex patterns can be learned and recognized. After a network has been trained, it can rapidly recognize and classify patterns. But the training time for backpropagation increases rapidly with the number of inputs and the number of hidden layers.

Many variations of algorithms and network topologies have been explored, but the training time for a network grew exponentially with the number of layers. A major breakthrough for *deep belief networks* was a strategy that reduced the training time by orders of magnitude. According to Hinton [6], the key innovation was "an efficient, layer by layer procedure" for determining how the variables at one layer depend on the variables at the previous layer.

> Deep belief nets are learned one layer at a time by treating the values of the latent variables in one layer, when they are being inferred from data, as the data for training the next layer. This efficient, greedy learning can be followed by, or combined with, other learning procedures that fine-tune all of the weights to improve the generative or discriminative performance of the whole network.

With this strategy, the time for training a network with *N* layers depends on the sum of the times for each layer, not their product. As a result, deep belief nets can quickly learn and recognize individual objects, even human faces, in complex street scenes.

The adjective *deep* in front of *belief network* introduced an ambiguity. The term *deep learning*, which the educational psychologists had used for years, implies a human level of understanding that goes far beyond pattern recognition. Enthusiastic partisans of the new methods for training neural networks created an ambiguity by adopting that term. To avoid confusion, others use the more precise term *deep neural network* (DNN). The remainder of this article will use the acronym DNN for methods that use only the neural networks. For hybrid systems that combine a DNN with other technologies, the additional methods and the roles they play are cited.

The Stanford NLP group led by Christopher Manning has been in the forefront of applying statistical methods to language analysis. By combining DNNs for scene recognition with statistical NLP methods, they relate objects in a scene to sentences that describe the scene — for example, the sentence *A small crowd quietly enters the historic church* and the corresponding parts of the scene [25]. But to derive implications of the sentences or the scenes, they use a variation of logic-based methods that have been used in AI for over 40 years [9]. Some of those methods are as old as Aristotle and Euclid. Others were developed by Peirce and Polya [28].

DNNs are highly successful for static pattern recognition. Other techniques, such as hidden Markov models (HMMs), are widely used for recognizing time-varying sequences. For a dissertation under Hinton's supervision, Navdeep Jaitly developed a DNN-HMM hybrid for speech recognition [7]. His office mate, Volodymyr Mnih, combined DNNs with a technique, called *Q-learning*, which uses patterns from two or more time steps of a neural net to make HMM-like predictions [30]. By using DNNs with Q-learning, Mnih and his colleagues at DeepMind Technologies designed the DQN system, which learned to play seven video games for the Atari 2600: Pong, Breakout, Space Invaders, Seaquest, Beamrider, Enduro, and Q*bert [15]. DQN had no prior information about the objects, actions, features, or rules of the games. For each game, the input layer receives a sequence of screen shots: 210×160 pixels and the game score at each step. Each layer learns features, which represent the input data for the next layer. The final layer determines which move to make for the next time step based on patterns in the current and previous time steps.

When compared with other computer systems, DQN outperformed all other machine learning methods on 6 of the 7 games. Its performance was better than a human expert on Breakout, Enduro, and Pong. Its score was close to human performance on Beamrider. But Q*bert, Seaquest, and Space Invaders require long-term strategy. On those games, DQN performed much worse than human experts. Yet the results were good enough for Google to buy the DeepMind company for $400 million [21].

In a critique of DNNs [11], the psycholinguist Gary Marcus wrote "There is good reason to be excited about deep learning, a sophisticated machine learning algorithm that far exceeds many of its predecessors in its abilities to recognize syllables and images. But there's also good reason to be skeptical... deep learning takes us, at best, only a small step toward the creation of truly intelligent machines."

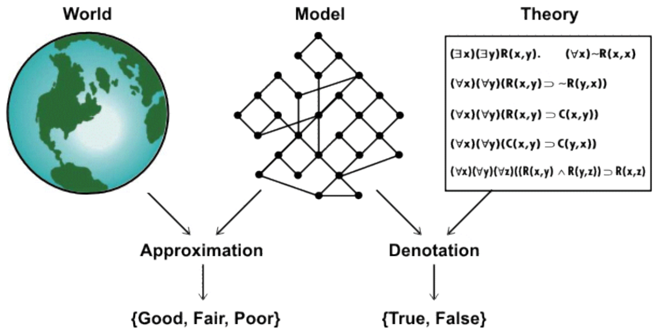
Advocates of DNNs claim that they embody "a unified theory of the human cortex" that holds the key to all aspects of intelligence. But Marcus observed "They have no obvious ways of performing logical inferences, and they are also still a long way from integrating abstract knowledge, such as information about what objects are, what they are for, and how they are typically used. The most powerful AI systems, like Watson, the machine that beat humans in Jeopardy!, use techniques like deep learning as just one element in a very complicated ensemble of techniques." After a discussion with Peter Norvig, director of Google Research, Marcus reported that "Norvig didn't see how you could build a machine that could understand stories using deep learning alone."

## III. Models and Reality

Language, thought, and reality are systems of signs. They are related to the world (or reality), but in different ways. Humans and other animals relate their internal signs (thoughts and feelings) to the world by perception and purposeful action. They also use their sensorimotor organs for communicating with other animals by a wide range of signs, of which the most elaborate are human languages, natural or artificial. Cognitive scientists — philosophers, psychologists, linguists, anthropologists, neuroscientists, and AI researchers — have used these languages to construct an open-ended variety of models and theories about these issues.

As Charles Sanders Peirce observed, all the models, formal and informal, have only two things in common: first, they consist of signs about signs about signs...; second, they are, at best, fallible approximations to reality. As engineers say, all models are wrong, but some are useful. To illustrate the relationships, Figure 2 shows a model as a Janus-like structure, with an engineering side facing the world and an abstract side facing a theory.

On the left is a picture of the physical world, which contains more detail and complexity than any humanly conceivable model or theory could represent. In the middle is a mathematical model that represents a domain of individuals **D** and a set of relations **R** over individuals in **D**. If the world had a unique decomposition into discrete objects and relations, the world itself would be a universal model, of which all correct models would be subsets. But the selection of a domain and its decomposition into objects depend on



World
Model
Theory
(∃x)(∃y)R(x,y).  (∀x)~R(x,x)
(∀x)(∀y)(R(x,y) ⊃ ~R(y,x))
(∀x)(∀y)(R(x,y) ⊃ C(x,y))
(∀x)(∀y)(C(x,y) ⊃ C(y,x))
(∀x)(∀y)(∀z)((R(x,y) ∧ R(y,z)) ⊃ R(x,z)
Approximation
Denotation
{Good, Fair, Poor}
{True, False}

Fig 2. A model that relates a theory to the world

the intentions of some agent and the limitations of the agent's measuring instruments. Even the best models are approximations to a limited aspect of the world for a specific purpose.

The two-stage mapping from theories to models to the world can reconcile a Tarski-style model theory with the fuzzy methods of Lotfi Zadeh [34]. In Tarski's models, each sentence has only two possible truth values: {T,F}. In fuzzy logic, a sentence can have a continuous range of values from 0.0 for certainly false to 1.0 for certainly true. Hedging terms, such as likely, unlikely, very nearly true, or almost certainly false, represent intermediate values. The two-stage mapping of Figure 2 can accommodate an open-ended variety of models and methods of reasoning. In addition to the Tarski-style models and the fuzzy approximations, it can represent engineering models that use any mathematical, computational, or physical methods for simulating a physical system. For robot guidance, the model may represent the robot's current environment or its future goals. For mental models, it could represent the virtual reality that people have in their heads.

No discrete model can be an exact representation of a physical system. But discrete models can exactly represent a digital computation or a mathematical game such as chess, checkers, or go. In fact, the game of checkers has a far deeper strategy than any of those Atari games. But in 1959, Art Samuel wrote a program that learned to play checkers better than he could [24]. He ran it on an IBM 704, a vacuum-tube computer that had only 144K bytes of RAM and a CPU that was much slower than the Atari. Yet it won one game in a match with the Connecticut state checkers champion.

For the learning method, Samuel used a weighted sum of features to evaluate each position in a game. His algorithm was equivalent to a one-layer neural net. But the program also tested each evaluation by looking ahead several moves. During a game, it maintained an exact model of each state of the game. By searching a few moves ahead, it would determine exact sequences, not the probabilities predicted by an HMM. In the match with the human expert, Samuel's program found the winning move when the human made a mistake.

Samuel's program was a hybrid of a statistical learning method with an exact model for positions in the game. Many chess-playing programs use a similar hybrid, but the programs that model game positions are completely different. Some AI researchers have claimed that to exhibit a human level of intelligence, a *general game playing system* should be be able to learn multiple games without special programming for each one [4]. But the criterion of "special programming" is unclear:

- The rules for games of strategy, such as bridge, chess, and go can be learned in a day. But mastery requires years.
- Many people have become good amateur players of all three games, but no one has ever reached a world-class mastery of more than one. Grandmasters in those games begin early in life, preferably before puberty, and devote many hours per week to reach a world-class level.
- Early learning is also necessary for native mastery of languages, musical performance, gymnastics, and other complex skills. Mentoring by a master is also critical. That concentrated study could be considered a kind of special programming.

## IV. The Cognitive Cycle

The human brain is a complex hybrid of multiple components with different kinds of representations interacting at various stages during the processes of learning and reasoning. After many years of research in the design and implementation of AI systems, Minsky [14] argued that no single mechanism, by itself, can adequately support the full range of functions required for a human level of intelligence:

> What magical trick makes us intelligent? The trick is that there is no trick. The power of intelligence stems from our vast diversity, not from any single, perfect principle. Our species has evolved many effective although imperfect methods, and each of us individually develops more on our own. Eventually, very few of our actions and decisions come to depend on any single mechanism. Instead, they emerge from conflicts and negotiations among societies of processes that constantly challenge one another.

Evidence from fMRI scans supports Minsky's hypothesis. Mason and Just [12] studied 14 participants who were learning the internal mechanisms of four devices: a bathroom scale, a fire extinguisher, an automobile braking system, and a trumpet. For all 14 participants, the brain regions involved in learning how each device worked progressed through the same stages:

> (1) initially, the representation was primarily visual (occipital cortex); (2) it subsequently included a large parietal component; (3) it eventually became cortically diverse (frontal, parietal, temporal, and medial frontal regions); and (4) at the end, it demonstrated a strong frontal cortex weighting (frontal and motor regions). At each stage of knowledge, it was possible for a classifier to identify which one of four mechanical systems a participant was thinking about, based on their brain activation patterns.

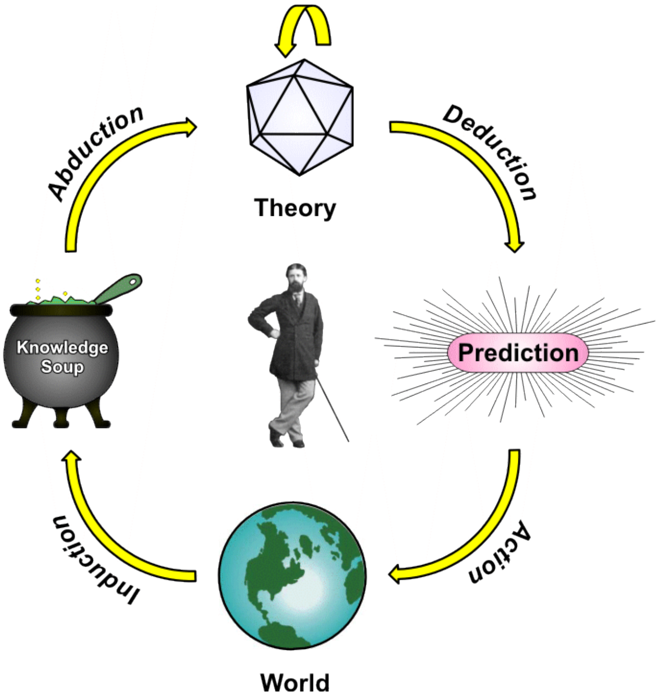


Fig 3. Peirce's cycle of pragmatism

In the first stage, the visual cortex recognized and encoded the visual forms and details of each device. In the second stage, the parietal lobes, which represent cognitive maps or schemata, involved "imagining the components moving." The third stage involved all lobes of the cortex. The medial frontal cortex, which has sensorimotor connections to all parts of the body, suggests that the participants were "generating causal hypotheses associated with mental animation." Finally, the frontal cortex seemed to be "determining how a person (probably oneself) would interact with the system."

An educational psychologist would not find the studies by Mason and Just to be surprising. But a partisan of DNNs might find them disappointing. DNNs may be useful for simulating some aspects of intelligence, but AI and cognitive science have developed many other useful components. In the book *Deep Learning*, the psychologist Stellan Ohlsson reviewed those developments and systematic ways of integrating them [16]. Ohlsson defined learning as "nonmonotonic cognitive change," which "overrides experience" by

- creating creating novel structures that are incompatible with previous versions,
- adapting cognitive skills to changing circumstances, and
- testing those skills by acting upon the environment.

Ohlsson cites Peirce's logic of pragmatism [17] and adopts Peirce's version of abduction as the key to nonmonotonic reasoning. The result is similar to Peirce's cycle of pragmatism (Figure 3).

In Figure 3, the pot of knowledge soup represents the highly fluid, loosely organized accumulation of memories, thoughts, fantasies, and fears in the mind. The arrow of induction represents new observations and generalizations that are tossed in the pot. The crystal at the top symbolizes the elegant, but fragile theories that are constructed by abduction from chunks in the knowledge soup. The arrow above the crystal indicates the process of belief revision, which uses repeated abductions to modify the theories. At the right is a prediction derived from a theory by deduction. That prediction leads to actions whose observable effects may confirm or refute the theory. Those observations are the basis for new inductions, and the cycle continues.

Learning is the process of accumulating chunks of knowledge in the soup and organizing them into theories — collections of consistent beliefs that prove their value by making predictions that lead to successful actions. Learning by any agent — human, animal, or robot — involves a constant cycling from data to models to theories and back to a reinterpretation of the old data in terms of new models and theories. Beneath it all, there is a real world, which the entire community of inquirers learns to approximate through repeated cycles of induction, abduction, deduction, and action.

The cognitive cycle is not a specific technology, such as a DNN, an HMM, or an inference engine. It's a framework for designing hybrid systems that can accommodate multiple components of any kind. Ohlsson, for example, is a psychologist who had collaborated with AI researchers, and he was inspired by Peirce's writings to design systems based on a cognitive cycle that is similar to Figure 3. James Albus was an engineer who studied neuroscience to get ideas for designing robots [1]. Although he had not studied Peirce, he converged on a similar cycle. Majumdar and Sowa [10] did study Peirce, and they adopted Figure 3 as their foundation. Each of the five arrows in Figure 1 may be implemented in a variety of different methods, formal or informal, crisp or fuzzy, statistical or symbolic, declarative or procedural.

In the conclusion of an article about statistical modeling, the statistician Leo Breiman stated an important warning [2]:

> Oddly, we are in a period where there has never been such a wealth of new statistical problems and sources of data. The danger is that if we define the boundaries of our field in terms of familiar tools and familiar problems, we will fail to grasp the new opportunities.

Another statistician, Martin Wilk [33], observed "The hallmark of good science is that it uses models and 'theory' but never believes them." The logician Alfred North Whitehead stated a similar warning about grand theories of any kind [2]: "Systems, scientific and philosophic, come and go. Each method of limited understanding is at length exhausted. In its prime each system is a triumphant success: in its decay it is an obstructive nuisance."

The cognitive cycle is a metalevel framework. It relates the methods of reasoning that people use in everyday life and scientific research. The cycle is self correcting. Every prediction derived in one cycle is tested in the next cycle. Although perfect knowledge is an unattainable goal, repeated cycles can converge to knowledge that is adequate for the purpose. That is the logic of pragmatism.

# 10th International Symposium Advances in Artificial Intelligence and Applications

THE AAIA'15 will bring researchers, developers, practitioners, and users to present their latest research, results, and ideas in all areas of artificial intelligence. We hope that theory and successful applications presented at the AAIA'15 will be of interest to researchers and practitioners who want to know about both theoretical advances and latest applied developments in Artificial Intelligence. As such AAIA'15 will provide a forum for the exchange of ideas between theoreticians and practitioners to address the important issues.

## Topics

Papers related to theories, methodologies, and applications in science and technology in this theme are especially solicited. Topics covering industrial issues/applications and academic research are included, but not limited to:

- Knowledge Management
- Decision Support Systems
- Approximate Reasoning
- Fuzzy Modeling and Control
- Data Mining
- Web Mining
- Machine Learning
- Combining Multiple Knowledge Sources in an Integrated Intelligent System
- Neural Networks
- Evolutionary Computation
- Nature Inspired Methods
- Natural Language Processing
- Image Processing and Interpreting
- Applications in Bioinformatics
- Hybrid Intelligent Systems
- Granular Computing
- Architectures of Intelligent Systems
- Robotics
- Real-world Applications of Intelligent Systems
- Rough Sets

## Professor Zdzislaw Pawlak Best Paper Awards

We are proud to announce that we will continue the tradition started during the AAIA'06 Symposium and award two "Professor Zdzislaw Pawlak Best Paper Awards" for contributions which are outstanding in their scientific quality. The two award categories are:

- Best Student Paper - for graduate or PhD students. Papers qualifying for this award must be marked as "Student full paper" to be eligible for consideration.
- Best Paper Award for the authors of the best paper appearing at the Symposium.

Candidates for the awards can come from AAiA and all workshops organized within its framework (i.e. AIMaViG, AIMA, ASIR, CEIM, LQMR, WCO).

In addition to a certificate, each award carries a prize of 300 EUR provided by the Mazowsze Chapter of the Polish Information Processing Society.

## IFSA Award for Young Scientist

During the Advances in Artificial Intelligence and Applications (AAIA) Symposium, the International Fuzzy Systems Association (IFSA) Best Paper Award for Young Scientist, will be presented.

Candidates for the awards can come from AAiA and all workshops organized within its framework (i.e. AIMaViG, AIMA, ASIR, CEIM, LQMR, WCO).

***Abstract*—Recurrent drift, as a specific type of concept drift, is characterised by the appearance of previously seen concepts. Therefore, in those cases the learning process could be saved or at least minimized by applying an already trained classification model. In this paper we propose Fuzzy-Rec, a framework that is able to deal with recurrent concept drifts by means of a repository of classification models and a similarity function.**

**Fuzzy logic is used in the framework to implement the similarity function needed to compare different classification models. This is a crucial aspect when dealing with drift recurrence, as long as some measure must be implemented to determine which model better fits a previously seen context. As it can be seen in the experimentation results of this paper, this fuzzy similarity function provides excellent results both in synthetic and real datasets. As a conclusion, we can state that the introduction of fuzzy logic comparisons between models could lead to a better efficient reuse of previously seen concepts, saving computational resources by applying not just equal models, but also similar ones.**

## I. Introduction

TRADITIONAL data stream classification [1] aims to learn a classification model from a stream of training records in order to use it later to predict the class of unlabeled records with high accuracy. Most of these kinds of classification models lack an efficient adaptation to the environment where they are implemented which, in most cases, is constantly changing. For this reason, coping with the improvement and adaptation of classification algorithms on data streams is still a great challenge, as long as data stream mining imposes some requirements that have to be accomplished, namely: maintaining an efficient behaviour in the system, i.e. stable computational and memory load; while providing suitable quality in the classification process, i.e. high accuracy of predictions.

Concept drift is known as the intrinsic changes that occur on the data being processed during data-mining tasks. These changes might be caused by data distribution alterations or by the appearance of a new context that alters the relations among the data attributes. Keeping this scenario in mind, different concept drift techniques have been extensively applied to cope with changes in the underlying distribution of records over time, allowing classification models to be able to adapt their behaviour when needed [2, 3, 4].

Moreover, it is common in real-world data streams for previously seen concepts to reappear [5]. This represents a particular case of concept drift [6], known as recurring concepts [7]; [8]; [5]; [9]; [10]. An adequate management of recurrent concept drifts would lead to a better overall data stream learning and classification processes efficiency and efficacy.

Some real cases where concept recurrence is likely to appear are:

1) Product recommendation systems. Drift in these kind of systems is usually related to fashion trends, economy fluctuations or other hidden context. Anyway, in the first two causes recurrence it is likely to reappear. This is due to the fact that fashion and economy trends reappear during time. A system able to deal with concept recurrence could save some precious training time by means of reusing previously seen recommendation models.
2) Weather prediction. The changes that occur in weather predictions are usually recurrent according to the seasons. Therefore, prediction models that deal well with a specific season could be reused latter on time.
3) Intrusion detection systems. An intrusion detection system (IDS) is a typical monitoring problem which aims to detect cyber incidents. In this case, a trained classification model could send alerts to the operator when a malfunction in the system occurs. A concept drift in an IDS means that the system is behaving in a different way from that expected. But that different behaviour may be caused by a new kind of intrusion that is probably taking place, or because the system monitored is changing in a controlled environment (no intrusion is taking place). If we were able to store all the patterns that represent the different situations of the system monitored (its concepts), we could reuse previously seen models easily.
4) Fraud detection. A similar situation like the one explained in the case of IDS, would be the case of a set of systems dealing with fraud detection. Fraud detection systems are able to detect misbehaviours on

978-83-60810-66-8/$25.00©2015, IEEE

a big amount of data. In this kind of scenarios drift is usually related to economy variations or seasons. As in the previous cases, the detection of drift recurrence could aid in the performance and precision values of the prediction mechanism.

Therefore, there are situations in which a new training is not needed, as the new concept is equal or similar to a previous one. In those cases we could reuse a previously-trained model, saving computation costs and thus providing an efficient method to undertake this new context.

Extending this idea, in this work we propose Fuzzy-Rec as a novel data-stream learning system to help in the process of recurrent concept drift management. In situations where concepts reappear we propose to use a fuzzy similarity function to help in the process of getting the most similar model in a specific context. Some approaches already exist for that goal, but they refer to crisp logic based on true/false values. We assume that a similarity function based on fuzzy logic [11] would improve the similarity process, also allowing us to obtain a better knowledge of what is happening in that process. Furthermore a fuzzy logic similarity function could be adapted for each situation, depending on the feature space of the data stream or on the computational capabilities of the system.

This is a crucial aspect to improve the storing process in the repository effectively. When a model has to be stored in the repository, it is required to know if the concept that the model is representing is recurrent or not. In case of a recurrent concept, it should not be stored, as there are already previous models representing it.

In order to calculate the fuzzy similarity level between models, two main features have been used in this work: i) the level of accuracy of the different models involved regarding a specific set of instances; ii) the number of instances used to train the different models, as a measure of maturity and stability of the model. This process helps the system as a whole to save memory consumption, as long as just the models needed are stored in the repository. In this way, the proposed mechanism makes it feasible to work with complex data-stream environments where an overloaded repository would make it difficult to achieve a suitable quality of the system.

To the best of our knowledge, this is the first work to deal with concept drift by means of the use of fuzzy logic to predict similar previously seen concepts.

Experiments performed with different real and synthetic datasets show that Fuzzy-Rec provides similar precision results when comparing it with other approaches.

The rest of the paper is organized as follows. In Section II, we summarize related work on concept drift and fuzzy logic, which is followed in Section III by the preliminaries of the approach where the motivation, challenges and problem definition are stated. Furthermore, in Section IV, we propose Fuzzy-Rec as a solution to work in recurring concept drift environments, with a detailed description of its components and the algorithm used. Section V presents the results obtained by the experimentation phase. Finally Section VI presents the main conclusions and discussion of future lines of research.

## II. Related Work

The approach that we propose in this paper relies on the storage of previously learnt concepts. A fuzzy similarity function is used to retrieve a previously built model which is similar to the current one.

Consequently, in this section we review and compare our proposal with methods that address the problems of: recurring concepts, change detection and conceptual equivalence.

A recent review of the literature related to the problem of concept drift can be found in [4]. Moreover, a review on the challenges for adaptative learning systems have been published in [12].

### A. Recurring Concepts

There have been several techniques developed to achieve the challenge that arises when dealing with concept drift, be they algorithms adaptations or wrapper mechanisms. New algorithms have recently appeared [1, 2, 3, 4, 5, 13, 14], but some other related challenges have received far less attention. Such is the case of situations where the same concept or a similar one reappears, and a previous model could be reused to enhance the learning process in terms of accuracy and processing time [7, 8, 10, 15, 16].

In this way, most existing proposals do not exploit this and have to learn new concepts from scratch even if they are recurrent. However, there are some solutions that deal with concept recurrence, as is the case of the work presented by Ramamurthy and Bhatnagar [15]. In this research, the authors present an ensemble approach that exploits concept recurrence, using a global set of classifiers learned from sequential data chunks. If no classifier in the ensemble performs better than the error threshold, a new classifier is learned and stored to represent the current concept. The classifiers with better performance on the most recent data form part of the ensemble for labeling new records. In [17] and [18] an ensemble mechanism is used to deal with concept drift. Similarly, in [8] an ensemble is also used, but incremental clustering is performed to maintain information on historical concepts. In this way, the proposed framework captures batches of examples from the stream into conceptual vectors. Conceptual vectors are clustered incrementally according to their distance and for each cluster a new classifier is learnt. Classifiers in the ensemble are then learnt using the clusters. Recently [19] proposed Learn++.NSE, an extension of [20] for nonstationary environments, Learn++.NSE is also an ensemble approach that learns from consecutive batches of data without making any assumptions on the nature or rate of drift. The classifiers are combined using dynamic weight majority and the major novelty is on the weighting function that uses the classifiers time-adjusted accuracy on current and past environments. To deal with resource constraints [21] proposes a novel algorithm to manage a pool of classifiers when learning recurring concepts. The main drawback of these methods, apart from the computational process time needed, is the need of constantly train the models used being them recurrent or not.

More sophisticated approaches that use drift detection [3] have also been proposed to address concept recurrence, such as [7, 10]. These approaches store learned models and reuse them when a similar concept reappears in the stream, thus avoiding the effort necessary to relearn a previously observed concept. The method proposed by Yang et al. [10] consists of using a proactive approach to recurring concepts, which means reusing a concept from the concept history. This concept history is represented as a Markov chain which allows the most probable concept to be selected according to a given transition matrix. The approach proposed by Gama and Kosina [7] uses the drift detection method presented in [3] to identify stable concepts and it also memorizes learned classifiers that represent these concepts. After a change is detected in situations of recurrence, referees are used to choose the most appropriate classifier to be reused (i.e., the referee prediction on the applicability of the classifier is greater than a pre-defined threshold). [22] is a recent work on drift detection which uses a control chart to monitor the misclassification rate of the data stream classifier. RCD [23] is a recent recurring concept drift framework that uses a non-parametric multivariate statistical tests to check for recurrence. [24] proposes a semi-supervised recurring concept learning algorithm that takes advantage of unlabelled data.

In the approach proposed in [16] context-concept relationships are learnt from the concept history. A model from a previously learnt concept associated with a particular context is reused in situations of recurrence. Moreover, the proposed method does not require the partition of the dataset into small batches. The concept representations are learnt by a base learner algorithm from an arbitrary number of records. These concept boundaries are determined when a drift detection method signals a change/drift. To improve [16], which relies on a single classifier to deal with recurring concepts, the use of ensembles has been proposed in [25].

### B. Change Detection

Although online learning systems are able to adapt to evolving data without any additional change detection mechanism, the advantage of explicit change detection is providing information about the intrinsic dynamics of the process generating data. In this way, the change detection module characterizes the techniques and mechanisms for drift detection. One advantage of detection models, is that they can provide a meaningful description (indicating the change-points or small time-windows where the change occurs) and the quantification of changes. They may be divided into two different approaches:

- Monitoring the evolution of performance indicators [5]. Some indicators (e.g., performance measures, properties of the data, etc.) are monitored over time. In the work presented in [26] the monitoring of three performance indicators (accuracy, recall, and precision) has been proposed. Furthermore, a highly referenced work that uses this approach is the FLORA family of algorithms developed by [5].
- Monitoring distributions on two different time-windows. A reference window, which usually summarizes past information, and a window over the most recent records. The work proposed by [27] uses statistical tests based on Chernoff bound to determine if the samples drawn from two probability distributions are different and then decide if a concept change occurred. Also [28, 29, 30] approaches are based on monitoring two different time-windows.

[3] and [9] approaches monitor the error-rate of the learning algorithm to find drift events. In [3], when the learning process error-rate increases above certain pre-defined levels, the method signals that the underlying concept has changed. Alternatively [31] uses the distribution of the distances between classification errors to signal drift. If the distance, which results from more consecutive errors is above pre-defined threshold, the underlying concept must be changing and an event is triggered. The basic adaptation strategy after drift is detected is to discard the old model and learn a new one to represent the new underlying concept [3, 31].

### C. Conceptual equivalence

To determine whether a certain model represents a new concept or a reappearing one, a similarity measure is required. The current work is an improvement of the *Conceptual equivalence* measure proposed by Yang et al. [9] where a fuzzy logic function [32] is used to better represent the relationship between different concepts.

## III. Problem Definition and Preliminaries

This section provides the necessary background to understand Fuzzy-Rec system. We start by motivating and defining the problem, including some basic definitions to understand the basics of the solution proposed as well as the main challenges we are dealing with in this paper.

From now on we assume that the data streams that are used as input in the Fuzzy-Rec model are already preprocessed and adapted to work well with incremental data stream classification processes. In this way, we can then assume that we do not need to preprocess the data streams, this work being out of the scope of this paper.

### A. Motivation

Data stream mining algorithms must come up with the problem of having to keep in memory just a limited number of records to train their models. That is why these algorithms have to cope with the task of processing each training record only once, while maintaining a suitable quality on the resulting model. This is the main difference from traditional data mining algorithms, where multiple passes over data are common.

In particular, that leads to classification techniques on data streams where models have to be learned incrementally with each incoming record. With the availability of these kinds of models, it is feasible to predict the class of unlabeled records anytime from an early stage. Obviously, the more training records the better precision values obtained.

However, in scenarios where the data distribution changes the accuracy of the classification is expected to decrease. In these cases, to continuously maintain the quality of the models, it is also important for them to be able also to detect and adapt anytime to changes in the underlying concept that they represent [2].

One of the causes of changes in the underlying concept may be recurrence, as a particular case of concept drift [5, 7, 8, 10]. In those cases, a previously learned concept is expected to reappear.

We envisage that recognizing and predicting already learned concepts might help the system to better adapt to future changes where these concepts reappear. With that recognition task in place, it would be possible for the algorithms to avoid relearning something from scratch that has been already learned [5, 7, 8, 10, 16]. This same idea has been already explored in [16], where concepts are able to be saved in a repository.

However in our approach we propose a fuzzy based mechanism to decide about similarity of models, improving the storage of the models. As a result, by means of a good similarity selection, the number of instances needed for the training process is expected to decrease.

### B. Preliminaries

*1) Learning with Concept Drift:* Let $X$ be the space of attributes with its possible values; $Y$ the set of possible discrete class values. Let $D$ be the data stream of training records arriving sequentially $X_i = (\vec{x_i}\ , y_i)$ with $x_i \in X$ (feature space) and $y_i \in Y$, where $\vec{x_i}$ is a vector of the attribute values and $y_i$ is the (discrete) class label for the $i^{th}$ record in the stream. In order to train a base learner based on a classification model $m$ incrementally, these records are processed by $m$ with the goal of predicting the class label of a new record $\vec{x} \in X$, so that $m(\vec{x}) = y \in Y$.

As stated in [9], the concept term is more subjective than objective. That is why in the scope of this paper a concept is represented by the learning results of the classification algorithm used as a base learner, such a Hoeffding Tree [33].

In this field, we consider that a stable concept has been learned when the records used during a given period $k$ are independently and identically distributed according to a probability distribution $P_k(x, y)$. In these situations where concept change, $P_k(x, y) \neq P_{k+1}(x, y)$.

*2) Recurring Concepts :* A recurring concept change can be detected when the input records during a period $k$ are generated based on the same distribution as a previously observed period, in a way that $P_k(x, y) = P_{k-j}(x, y)$. To deal with these kinds of situation, the model $m_k$ learned from a certain period $k$ could be saved to be reused later if it is needed. This would avoid the need to learn a new model representing the same concept as $m_k$. With this solution the continuous learning process improves its behaviour, not requiring a previously learned concept to be learnt from scratch. In addition this approach needs fewer training records to be processed than other approaches that do not deal with recurrent concepts. However, to better calculate whether a concept is recurrent or not, a similarity function is usually used. This is the case of the similarity function proposed in [9], which is the starting point in developing the new fuzzy similarity method proposed in this paper.

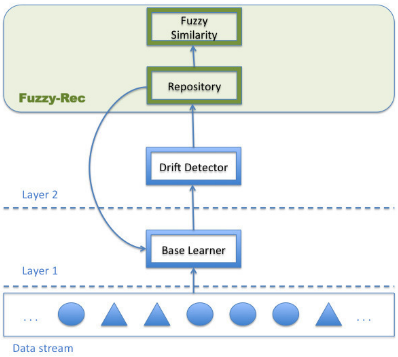

Fig. 1. Fuzzy-Rec Components

### C. Challenges

The main challenges we deal with in this paper are:

- Arranging a fuzzy similarity function in order to better calculate the level of similarity between different concepts.
- Improving the precision values of similar recurrent methods.
- Reducing the number of instances needed to train the classification model.

Fuzzy-Rec faces the aforementioned challenges by means of a fuzzy function to deal with concept similarities evaluation.

### D. Fuzzy-Rec

The main elements of Fuzzy-Rec, as depicted in figure 1, are:

- A repository of previously seen models.
- A concept similarity function based on fuzzy logic. This function is used to determine the level of similarity between concepts. This fuzzy similarity function is crucial to solve the problem of deciding not just which is the most suitable model, but also if the storage of a specific model in the repository is required.

This is therefore a substantial improvement in the work presented in [16], where the problem of concept drift in recurring scenarios was solved in a similar way also by using a repository of concepts and a crisp similarity function.

The proposed Fuzzy-Rec system allows us to better deal with recurrent situations in a classification problem in data streams, helping the evolving base learner to adapt to drifts. Hence the Fuzzy-Rec system is a feasible tool to be used in a wide range of real application scenarios.

We propose a concept similarity function that uses fuzzy logic and it is based on that presented in [9]. This function is defined by the following parameters:

- A conceptual degree of equivalence based on the matching of two different models classifying many instances,

even when their classifications are both wrong. It is not therefore an accuracy equivalence, but a measure of the level of both models to classify in the same way.
- A measure that represents the difference in the number of records used to train each model. This parameter is intended to provide a measure on the maturity and stability of the model.

From the aforementioned two parameters, a fuzzy [34] similarity value is estimated from a previously defined set of rules, making it possible to obtain the poor, average or high values.

There are two situations where a similarity function is required:

1) A model must be stored in the repository of previously trained concepts: in this case the fuzzy similarity function is used to assess the need to store a new model. If there is a similar model in the repository, storing a similar one would not improve the quality of the classification process while unnecessarily increasing the memory consumption.
2) A drift is taking place and it is time to decide whether the new concept is recurrent or not: in this case, the system has been training two different models in parallel to adapt to the drift in a recurrent way (the current model and a new one).

## IV. Implementation of Fuzzy-Rec

As in the case of the MRec system proposed in [16], Fuzzy-Rec can be seen as a two-layer framework:

1) A basic layer where an incremental learning algorithm is able to represent the underlying concept by means of a classification model.
2) An extended layer in which detection and adaptation to concept changes takes place. The detection of recurrent concepts is implemented in this layer. It is also at this level where Fuzzy-Rec implements its fuzzy similarity mechanism.

To provide an in depth knowledge of the implementation of the Fuzzy-Rec system proposed in this paper, first the learning process is described in section IV-A, whereas the description of the fuzzy similarity concepts is presented in section IV-C.

### A. The Learning Process

The on-line learning process for the proposed learning system, as well as the method to detect and adapt to recurrent concepts are detailed in Algorithm 1. The process proceeds as follows:

- It continuously processes the records $X_i = \{\vec{x}, y\}$ with $\vec{x} \in X$ as they appear in the Data Stream.
- In line 3, *currentClassifier* represents the base learner classifier that is currently being used to classify unlabeled records. Its prediction $y$, being right or wrong, on $X_i$ is passed to the drift detection method used to identify the suitable drift level (*stable, warning or drift* ), as explained in IV-B.
- If the process is at the normal level (line 7), the base learner represented by the *currentClassifier* is updated with the new training record. This is the same behaviour as in any other traditional data mining model ready to work with data streams.
- In the case of a warning level (line 8), if the repository does not have the *currentClassifier*, or a similar way as referred to in IV-C, the *currentClassifier* is stored. Still at this level (lines 12 and 13), a $newLearner$ is updated with the training record; the training record is also added to a $warningWindow$. The $warningWindow$ contains the latest records (which should belong to the most recent concept), and will also be used to calculate the conceptual equivalence and estimate the accuracy of models stored with the current concept.
- When drift is signalled (line 14), until there are enough records (i.e., stability period) in the $warningWindow$ the $newLearner$ is updated. When the stability period is over (line 18) it is compared with repository models in terms of conceptual equivalence as stated in IV-C. If the current underlying concept is recurrent a stored model from the repository is used to represent the recurring underlying concept, otherwise the $newLearner$ is used. It is important to remark that the benefit of implementing a previously seen model is that it does not need to be trained again, as it is supposed to be a stable model. When using the newLearner, it needs to be constantly trained during the learning process as it is still an immature model. Therefore, if newLearner is used there is not a decrease in the number of training instances needed. However, the risk of reusing a not suitable recurrent model is still latent. In those cases, the accuracy of the classification base learner would drop.
- A false alarm (line 24) case is used when a warning is signaled but then the learner returns back to normal without achieving drift. In those cases, both the $warningWindow$ and the $newLearner$ are cleared.

In short, the Fuzzy-Rec system can be seen as a continuous learning process with the following steps:

1) The base learner processes the incoming records from data streams by means of an incremental learning algorithm to generate a decision model $m$ representing the underlying concept. The model $m$ will be used to classify unlabelled records.
2) A drift detection method is continuously monitoring the error-rate of the learning algorithm [3]. When the error-rate goes beyond some predefined levels, the drift detection method signals a *warning* (possible drift) or a *drift*.
3) Throughout the life cycle of the system, two different cases may be used to adapt to changes in the underlying concept: i) the concept similarity method detects that the underlying concept is new, and the base learner has to learn it by processing the current incoming labelled records in an incremental way. ii) the (fuzzy) concept

**Algorithm 1** Data Stream Learning Process

```
Require: Data stream $DS$, ModelRepository $MR$
repeat
    Get next record $X_i$ from $DS$;
    prediction = currentClassifier.classify($X_i$);
    DriftDetection.update(prediction);
    switch DriftDetection.level
    case Normal
    currentClassifier.train($X_i$);
    case Warning
    if $\neg MR.containsSimilar(currentClassifier)$ then
        MR.store(currentClassifier);
    end if
    WarningWindow.add($X_i$);
    newLearner.train($X_i$);
    case Drift
    repeat
        WarningWindow.add($X_i$);
        newLearner.train($X_i$);
    until $WarningWindow.size > \tau$ //Stability Period
    if $\neg MR.containsSimilar(newLearner)$ then
        currentClassifier = newLearner;
    else
        currentClassifier = MR.getEquivalent(newLearner);
    end if
    case FalseAlarm
      WarningWindow.clear();
      newLearner.delete();
    end switch
until END OF STREAM
```

similarity method detailed in IV-C detects that the underlying concept is recurrent, and a previous model is applied.

### *B. Drift Detection Mechanism*

The Fuzzy-Rec system needs to know when a concept drift is taking place from the behaviour of a base learner. For this purpose Fuzzy-Rec uses the method proposed by Gama el al. [3]. From this method, it is important to remark the following characteristics:

- The system assumes the observation of periods of stable concepts followed by changes that lead to new stable periods with different underlying concepts.
- The error-rate of the base learning algorithm is considered as a random variable from a sequence of Bernoulli trials.
- The general form of the probability of detecting an error is given by means of a binomial distribution.
- Three different drift levels are defined to manage concept changes: stable or at a control level, warning level and drift or out of control level. These levels represent the confidence of the mechanism of having detected a concept drift.

It also important to note that other similar methods can be used to detect change detections in concepts. Since the Fuzzy-Rec system has been developed as a wrapper mechanism, the specific method used for it is transparent, so it is not necessary to change the learning process.

Having detected a change in the underlying concept, there are some situations in which a concept recurrence appears. In these cases it is worth anticipating to the reappearing concept, in order to improve the learning process efficiency [16]. In order to do so, a concept similarity method must be used.

### *C. Concept Similarity*

To determine whether a certain model represents a new concept or a reappearing one, a similarity measure is required. In this paper, the *Conceptual equivalence* measure is developed by means of a fuzzy logic system [35] where two variables are used to calculate the similarity between two models.

The term “fuzzy logic” was introduced in [34], and is a way of representing many-valued logic, allowing approximate reasoning to be applied through the definition of variables with several truth ranges (from 0 to 1) and rule sets. A rule set determines which fuzzy operator must be used in each case.

By means of using fuzzy logic, it is easy to deal with the concept of partial truth, where a truth value may range from completely true to completely false. In fuzzy logic applications it is common to use linguistic variables to facilitate the implementation of rules and truth values. In this way, a linguistic variable may have several truth values in the same system. These truth values can be seen as subranges of a continuous variable.

In the proposed Fuzzy-Rec system, three linguistic variables are defined:

- The variable $equal\_classified$, used to represent the similarity in the classification precision behaviour of two different models, may take the values: poor, good and excellent.
- The variable $diff\_training$, used to represent the difference that exist in the number of training records used between two different models, may take the values: small and big.
- The variable $similarity$, a variable use to calculate the output of the fuzzy system based on the aforementioned variables, may take the values: poor, average and high.

Therefore, it is assumed to get a value of “high” when calculating the $similarity$ variable, although in some cases the range could be lowered to “average” values, depending on the characteristics of the dataset used.

The variable $equal\_classified$ is based on the method proposed by Yang et al. [9] to calculate its conceptual equivalence. In our case, as it has been outlined, the equivalence between two models when dealing with classification similarity is just one parameter of the global fuzzy function. This parameter is calculated as follows:

1) Given two classification models $m_1$,$m_2$ and a sample dataset $D_n$ of $n$ records, it is possible to calculate for each instance $X_i$=($\vec{x_i}$ , $y_i$) a score, score($D_n$) = +1 if (prediction($m_1(\vec{x_i})$) = prediction($m_2(\vec{x_i})$))

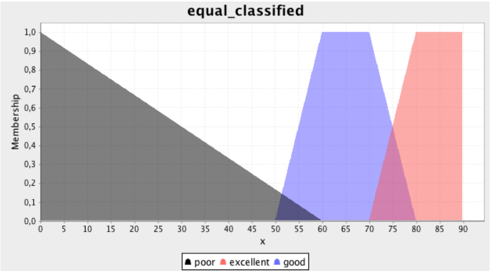

Fig. 2. Membership function of "equal_classified"

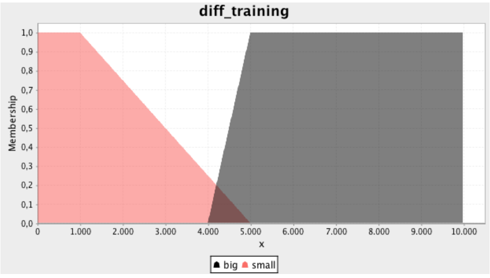

Fig. 3. Membership function of "diff_training"

2) score($D_n$) is used to represent the degree of equivalence in the classification process between $m_1$ and $m_2$.
3) The final classification equivalence $ce$ value, that is a continuous value score with range [0,1], is calculated by

$$ce = \frac{score(D_n)}{N}$$

Depending on the value of $ce$, $equal\_classified$ will take one or another membership value, as represented in the figure 2, where we can see the values this variable may take. The larger the output value of $ce$, the higher the degree of classification equivalence. For the records in $D_n$ it compares how $m_1$ and $m_2$ classify the records. As in [9], the similarity in the classification processes is not necessarily related to the accuracy attribute. This means that two models that present low accuracy for a set of records will have a high $ce$ value, and therefore a high $equal\_classified$ value.

As regards the variable $diff\_training$, its value represents the difference in the number of instances used to train each model we are trying to compare. In figure 3 we can see the values this variable may take.

The rule set implemented to develop the fuzzy logic inference is defined as follows:

1) IF $equal\_classified$ IS $poor$ OR $diff\_training$ IS $big$ THEN $similarity$ IS $poor$;
2) IF $equal\_classified$ IS $good$ AND $diff\_training$ IS $big$ THEN $similarity$ IS $poor$;
3) IF $equal\_classified$ IS $good$ AND $diff\_training$ IS $small$ THEN $similarity$ IS $average$;
4) IF $equal\_classified$ IS $excellent$ AND $diff\_training$ is $big$ THEN $similarity$ is $average$;
5) IF $equal\_classified$ IS $excellent$ AND $diff\_training$ is $small$ THEN $similarity$ is $high$;

Finally, a defuzzification method [35] is needed to get a crisp value of the variable measured. In the case of Fuzzy-Rec, "Center Of Gravity" is the method used to calculate the final value of the $similarity$ variable representing the conceptual equivalence, it being a very popular method in which the "center of mass" of the result provides the crisp value.

From the crisp value returned by the defuzzification method, we evaluate if it is above a predefined threshold. In that case, we assume that the models are similar and thus represent the same underlying concept.

It is important to highlight that without the existence of such a fuzzy method the similarity process should be more naive, being able to integrate just one of the aforementioned variables in the process. As a consequence, a biased classification model with a short life cycle but a high performance could be selected as similar to a more mature and stable model. The fuzzy similarity function implemented in Fuzzy-Rec avoids these kind of behaviours, strengthening the similarity process.

## V. Experiments

In order to validate the Fuzzy-Rec method, and taking into account that Fuzzy-Rec is an extension of the MRec method cited in [16], two different experiments have been developed:

1) Experiment 1: The goal of this experiment is to prove that the precision of Fuzzy-Rec is similar to the MRec method, and no worse than other methods able to deal with concept drift. In order to do so, accuracy and kappa statistic measures are evaluated.
2) Experiment 2: The goal of this experiment is to prove that the training instances needed by Fuzzy-Rec when drifts appear are fewer than the ones needed when using MRec.

In addition a statistical analysis has been developed to validate the results provided by the execution of experiments 1 and 2.

To sum up, the main goal of this experimentation phase is to test the feasibility of using a fuzzy similarity procedure to determine similar previously seen concept drifts.

### A. Parameters setting

To develop the aforementioned experiments, both synthetic and real datasets have been used. A description of the different datasets applied is presented below. Regarding the similarity threshold values needed both for the MRec and Fuzzy-Rec methods, the experiments were developed setting high similarity values; in the specifica case of MRec, a threshold of 0.9 value was used; in the case of Fuzzy-Rec, a similarity value of 0.9 after defuzzification was used. This similarity threshold must be established to afford the comparison process between models. This is important because we must assure that the reused models really fit the context of the data during the learning process. Hence, lower values of the similarity threshold would lead to reuse models that may be not appropriate to the new concept in course. In contrast, higher values would make MRec and Fuzzy-Rec to look for previously seen models that really fit the concept represented by data. In situations where noise could be present in the data, it is important to set higher similarity threshold values to avoid misconceptions.

Regarding the number of classifiers stored in the repository, 10 was the value set for both experiments.

Below a description of the different datasets used during the experimentation phase is made.

### B. Datasets

*1) SEA dataset:* This synthetic dataset is made up of 1.8M instances, representing two drifts repeated for three times. Specifically this dataset was created by means of the following methodology:

1) Create a dataset with 2 concept drifts, changing from SEA function 1 to function 4.
2) Create a dataset with 2 concept drifts, changing from SEA function 2 to function 3.
3) Merge the previous files for three times in a global dataset to ensure that concepts are mixed and may appear in any time during the execution of the dataset.

*2) Hyperplane dataset:* A different synthetic dataset with gradual drifting concepts was created based on a moving hyperplane. A hyperplane in d-dimensional space is denoted by equation: $\sum_{i=1}^{d} a_i x_i = a_0$. Instances are labeled as positive if $\sum_{i=1}^{d} a_i x_i \geq a_0$, and as negative if $\sum_{i=1}^{d} a_i x_i < a_0$. Hyperplanes have been used to simulate time-changing concepts because the orientation and the position of the hyperplane can be changed in a smooth manner by changing the magnitude of the weights [13]. This dataset contains 170,000 instances and it represent different recurrent drifts. Taking into account that some noise has been introduced to the dataset, a threshold value of 0.9 is set to ensure that the reused models really fit the concept represented by the data when drifts happen.

*3) Electricity dataset:* The Electricity Market Dataset (Elec2) [36] is a real dataset that uses data collected from the Australian New South Wales Electricity Market, where the electricity prices are not stationary and are affected by the market supply and demand. The market demand is influenced by context such as season, weather, time of the day and central business district population density. In addition, the supply is influenced primarily by the number of on-line generators, whereas an influencing factor for the price evolution of the electricity market is time. During the time period described in the dataset, the electricity market was expanded with the inclusion of adjacent areas (Victoria state), which led to more elaborate management of the supply as oversupply in one area could be sold interstate.

The Elec2 dataset contains 45,312 records obtained from 7th May 1996 to 5th December 1998, with one record for each half hour (i.e., there are 48 instances for each time period of one day). The class label identifies the change in the price related to a moving average of the last 24 hours. As shown in [36], the dataset exhibits substantial seasonality and is influenced by changes in context. Taking into account that this dataset is expected to have gradual or soft drifts, a similarity threshold of 0.9 is used for this dataset in order to force both MRec and Fuzzy-Rec to reuse just the models associated to concepts really similar to the new appearing one in case of a drift.

*4) Sensor dataset:* Sensor stream [37] is a real dataset that contains information (temperature, humidity, light, and sensor voltage) collected from 54 sensors deployed in Intel Berkeley Research Lab. The whole stream contains consecutive information recorded over a 2 months period (1 reading per 1-3 minutes) which makes a total of 2,219,803 instances. The learning task of the stream is to correctly identify which of the 54 sensors is associated to the sensor information read. The goal of this experiment is to effectively detect and adapt to the multiple concept drifts that this dataset contains.

Taking into account that recurrent drifts are expected to appear in this dataset, a similarity threshold of 0.9 is set in order to force both MRec and Fuzzy-Rec to use previously seen models just in case there were a high level of certainty of equivalence between concepts.

### C. Environment

The implementation of the Fuzzy-Rec learning system was developed in Java, using the MOA [38] environment as a test-bed. The specific fuzzy similarity function implemented in Fuzzy-Rec was developed using jFuzzyLogic [39].

During the execution of the different experiments, the following MOA evaluation features were established:

1) The *Prequential-error* method [38] as the main evaluation technique. When using this evaluator, each individual example can be used to test the model before it is used for training, and from this the accuracy can be incrementally updated. Therefore, the results presented in tables I and II have been gathered in this way.
2) The *Naive Bayes* [40] class as base learner.
3) The *SingleClassifierDrift* class as the method in charge of detecting drifts. This class implements the drift detection method of [3] and adapts to drift by learning a new classifier (i.e., discards previous concept representations).

It is important to note that no distributed environment has been available for the execution of the experimentation phase.

In order to develop the statistical analysis R [41] software was used with the “coin” and “multcomp” packages. Taking into account that when comparing several methods over multiple datasets a post-hoc analysis is desired, in this case the post-hoc tests have been developed using the Wilcoxon-Nemenyi-McDonald-Thompson test [42], using the code of [43].

### D. Results

A description of the results obtained during the execution of the different experiments presented in the beginning of section V is made below. All the experiments have been executed on the datasets presented in section V-B, and comparisons are made with the following methods:

1) MRec with Naive Bayes class as base learner.
2) The RCD method presented in [23] also using Naive Bayes.

*1) Experiment 1:* The goal of this experiment was to prove that the precision values (accuracy and kappa statistic) provided by Fuzzy-Rec were better to the ones provided by the MRec and RCD methods.

As it can be seen in table I, when testing the electricity dataset MRec and Fuzzy-Rec improve the RCD precision values, both behaving in a similar way. This is caused by an application of the same recurrent concepts, so in this case the fuzzy similarity function does not improve the precision values. However, in this case it is demonstrates that in the worst case Fuzzy-Rec provides similar precision values to MRec.

In the case of the sensor dataset, Fuzzy-Rec improves the precision values of MRec by applying a better selection of previously seen models. As long as the difference of training instances between models is one of the variables used when comparing models in Fuzzy-Rec, this allows a more precise choice. Due to the fact that MRec does not make use of such variable, it is using in some cases possible similar models that do not count with enough training records, and therefore the similarity process is biased. When comparing Fuzzy-Rec to RCD in this dataset, similar results are obtained.

When using the SEA dataset there is a big difference on the precision values of Fuzzy-Rec when comparing it with MRec method. The reason of this behaviour is the same than before: the fuzzy similarity function allows to make more precise choices of previously seen models. Also in this case the values obtained when using RCD are similar to Fuzzy-Rec.

Lastly, in the case of the hyperplane dataset Fuzzy-Rec is the method that provides better precision results, improving the behaviour of both RCD and MRec methods.

To sum up, we can conclude in this experiment that Fuzzy-Rec provides similar or even better precision values than MRec or RCD methods in all cases. There are no situation in which Fuzzy-Rec behaves worst than the other methods assessed.

*2) Experiment 2:* The goal of this experiment is to prove that the training instances needed by Fuzzy-Rec when drifts appear are fewer than the ones needed when using MRec and RCD.

The results of this experiments are shown in table II. We can see that except in the case of SEA dataset, Fuzzy-Rec needs fewer training instances than RCD. Comparing these results to the one presented in the previous experiment, we can state that Fuzzy-Rec makes a more efficient use of training instances, improving the precision values of RCD. The reason why Fuzzy-Rec needs more instances when using SEA dataset is due to the high threshold value established to determine similarity. This threshold forces the method to reuse models with a high similarity, which is not reached for this dataset. However, as it has been shown in table I, the precision values are similar to RCD.

Lastly, when comparing the training instances needed by Fuzzy-Rec with the ones needed by MRec, we can see that there are just some slightly differences. As in the previous case, the unique exception is when using the SEA dataset, because of the aforementioned reasons. However, although the instances usage is similar, when comparing these results with the precision values of the previous experiment (see table I), we can conclude that Fuzzy-Rec makes an optimal selection of previously seen models. It is important to note the case of MRec when dealing with SEA dataset, because comparing it with Fuzzy-Rec we can see that although the former makes a lower use of training instances, the precision values obtained drop significantly; in contrast, Fuzzy-Rec while needing more instances provides the better precision results among all the methods assessed. The behaviour of MRec and Fuzzy-Rec with SEA dataset reinforce the idea that the latter provides a more appropriate selection of similar models.

## VI. Conclusions and Future Lines of Research

In this paper the Fuzzy-Rec system, has been described as a mechanism to deal with concept drift in recurring situations.

The main contributions of Fuzzy-Rec are:

1) The implementation of a new similarity concept function using fuzzy logic techniques, which helps in the assessment of similarity between concepts in an improved way.
2) The development of Fuzzy-Rec as a wrapper mechanism, allowing it to be used in an easy way with different base learners and drift detector methods. Furthermore, this wrapper mechanism allows the behaviour of the similarity concept function to be parametrized depending on the needs of each dataset or real-world environment.

Fuzzy-Rec has been tested on different synthetic and real datasets, and comparisons have been made with other similar context-aware algorithms able to deal with drift recurrence. The main conclusions obtained from those experiments are that:

- Fuzzy-Rec is the method that provides the better balance between training instances needed and precision values obtained.
- Fuzzy-Rec needs a low rate of training instances as long as it reuses previously seen models.
- The fuzzy similarity function helps to find the most appropriate model without loosing precision.
- Fuzzy-Rec does not decrease the precision values when comparing it with similar methods.

Future lines of research are: i) analysis of a loss function to penalize bad similarity calculus; ii) implementation of a common fuzzy similarity function in distributed environments.

In both cases, an improvement on precision values is foreseen.

***Abstract*—Decision tree is a widely used technique to discover patterns from consistent data set. But if the data set is inconsistent, where there are groups of examples (objects) with equal values of conditional attributes but different decisions (values of the decision attribute), then to discover the essential patterns or knowledge from the data set is challenging. We consider three approaches (generalized, most common and many-valued decision) to handle such inconsistency. We created different greedy algorithms using various types of impurity and uncertainty measures to construct decision trees. We compared the three approaches based on the decision tree properties of the depth, average depth and number of nodes. Based on the result of the comparison, we choose to work with the many-valued decision approach. Now to determine which greedy algorithms are efficient, we compared them based on the optimization and classification results. It was found that some greedy algorithms ($Mult\_ws\_entSort$, and $Mult\_ws\_entML$) are good for both optimization and classification.**

## I. Introduction

OFTEN in a decision table, we have different examples with the different values of decision and we call such table as a consistent decision table or single-valued decision table. But it is pretty common in real life problems to have inconsistent decision tables where there are groups of examples (objects) with equal values of conditional attributes and different decisions (values of the decision attribute).

In this paper, instead of the group of examples with equal values of conditional attribute, we consider only one example for this group and attach the set of decisions to it. We will call such tables as many-valued decision tables.

In the rough set theory [1], generalized decision ($GD$) has been used to handle inconsistency. In this case, an inconsistent decision table is transformed into the many-valued decision table and after that, each set of decisions has been encoded by a number (decision) such that equal sets are encoded by equal numbers and different sets by different numbers (see Figure 1). We have also used another approach named the most common decision ($MCD$) which is derived from the concept of using most common value in case of missing value [2]. Instead of a group of equal examples with (probably) different decisions, we consider one example given by values of conditional attributes and we attach to this example the most common decision for examples from the group (see Figure 1).

Fig. 1: Transformation of inconsistent decision table $T^0$ into decision tables $T^0_{MVD}$, $T^0_{GD}$ and $T^0_{MCD}$

In our approach, we can say that for a given example, we have multiple decisions that can be attached to the example but the goal is to find a single decision for each example. We refer this approach as many-valued decision ($MVD$) approach (see Figure 1). This approach is used for classical optimization problems (finding a Hamiltonian circuit with the minimum length or finding nearest post office [3]) where we have multiple optimal solutions but we have to give only one optimal output.

We studied a greedy algorithm for construction of decision trees for many-valued decision tables using the heuristic based on the number of boundary subtables in [4]. Besides, we have studied this algorithm in the cases of most common decision, and generalized decision approaches in [5]. In addition to this, we studied various greedy algorithms as well as dynamic programming algorithm to minimize the average depth in [6], minimize depth in [7], and as well as minimize size of the constructed decision tree in [8].

978-83-60810-66-8/$25.00©2015, IEEE

This paper is a continuation of the current research. We have compared three approaches $MVD$, $MCD$, and $GD$ by comparing the complexity of constructed decision trees. We choose $MVD$ approach based on the result of the comparison. After that, we have shown the average relative difference between greedy algorithm results and optimal results obtained by dynamic programming algorithms for the depth, average depth, and number of nodes of the constructed decision trees. Subsequently, we compare the performance of the classification error rates among classifiers constructed by the various greedy algorithms. We have presented results in the form of critical difference diagram [9] as well as average error rates using data sets from UCI ML Repository [10] and KEEL [11] repository. Finally, we found some of the greedy algorithms are in the top list for both optimization and classification tasks.

## II. Related Works

In literature, these types of tables are often referred as multi-label decision tables [12]. These tables are found in the problem of semantic annotation of images and videos, music categorization into emotions, functional genomics (gene and protein functions), and text classification (news article, email, bookmarks). There are two ways to solve the classification problem from these data sets: first one is algorithm adaptation method where usual classification methods are adapted or modified to handle multi-label data, and the second one is the problem transformation method where the multi-label data set is transformed into single label data set to work with usual classification methods without any modification of the algorithm. These papers solve the inconsistency of the decision table by dividing full set of decisions into relevant and irrelevant decision set for each example. The goal is to find the relevant set of decisions for unknown object.

There is another way to handle inconsistency which is mentioned in different names in literature: partial learning [13], ambiguous learning [14], and multiple label learning [15]. In this learning problem, each example is associated with multiple labels but only one label is correct, and all others are incorrect. The goal is to find out which label is correct. In [13], [15], the authors shows probabilistic methods to solve the learning problem whereas in [14], the author used standard heuristic approach to exploit inductive bias to disambiguate label information.

Our approach of $MVD$ is different from the above mentioned approaches in two ways:
- we assume that all our decisions are correct and there is no incorrect decisions attached with any of the examples,
- we assume that it is enough to find out one decision from the set of decisions rather than the relevant set of decisions.

Therefore, one can use our approach when it is enough to find one decision from the set of decisions.

## III. Preliminaries

### A. Many-valued Decision Table

A *many-valued decision table*, $T$ is a rectangular table whose rows are filled by nonnegative integers and columns are labeled with conditional attributes $f_1, \ldots, f_n$. If we have strings as values of attributes, we have to encode the values as nonnegative integers. There are no duplicate rows, and each row is labeled with a nonempty finite set of natural numbers (set of decisions). We denote the number of examples (rows) in the table $T$ by $N(T)$.

TABLE I: A many-valued decision table $T'$

$T' =$

| $f_1$ | $f_2$ | $f_3$ | |
|---|---|---|---|
| 0 | 0 | 0 | {1} |
| 0 | 1 | 1 | {1,2} |
| 1 | 0 | 1 | {1,3} |
| 1 | 1 | 0 | {2,3} |
| 0 | 0 | 1 | {2} |

If there is a decision which belongs to all of the set of decisions attached to examples of $T$, then we call it a *common decision* for $T$. We will say that $T$ is a *degenerate* table if $T$ does not have examples or it has a common decision. We give an example of degenerate table in the Table II where 1 is the common decision.

TABLE II: A degenerate many-valued decision table

$T'' =$

| $f_1$ | $f_2$ | $f_3$ | |
|---|---|---|---|
| 0 | 0 | 0 | {1} |
| 0 | 1 | 1 | {1,2} |
| 1 | 0 | 1 | {1,3} |

A table obtained from $T$ by removing some examples is called a subtable of $T$. We denote a *subtable* of $T$ which consists of examples that at the intersection with columns $f_{i_1}, \ldots, f_{i_m}$ have values $a_1, \ldots, a_m$ by $T(f_{i_1}, a_1), \ldots, (f_{i_m}, a_m)$. Such nonempty tables (including the table $T$) are called separable subtables of $T$. For example, if we consider subtable $T'(f_1, 0)$ for table $T'$, it will consist of examples $1, 2$, and $5$. Similarly, $T'(f_1, 0)(f_2, 0)$ subtable will consist of examples $1$, and $5$.

TABLE III: Example of subtables of many-valued decision table $T'$

$T'(f_1, 0) =$

| $f_1$ | $f_2$ | $f_3$ | |
|---|---|---|---|
| 0 | 0 | 0 | {1} |
| 0 | 1 | 1 | {1,2} |
| 0 | 0 | 1 | {2} |

$T'(f_1, 0)(f_2, 0) =$

| $f_1$ | $f_2$ | $f_3$ | |
|---|---|---|---|
| 0 | 0 | 0 | {1} |
| 0 | 0 | 1 | {2} |

We denote the set of attributes (columns of table $T$), such that each of them has different values by $E(T)$. For example, if we consider table $T'$, $E(T') = \{f_1, f_2, f_3\}$. Similarly, $E(T'(f_1, 0)) = \{f_2, f_3\}$ for the subtable $T'(f_1, 0)$, because the value for the attribute $f_1$ is constant in subtable $T'(f_1, 0)$. For $f_i \in E(T)$, we denote the set of values from the attribute $f_i$ by $E(T, f_i)$. As an example, if we consider table $T'$ and attribute $f_1$, then $E(T', f_1) = \{0, 1\}$.

The minimum decision which belongs to the maximum number of sets of decisions attached to examples of the table

$T$ is called the *most common decision* for $T$. For example, the most common decision for table $T'$ is 1. Both 1 and 2 appears 3 times in the sets of decisions, but 1 is the most common decision as it is the minimum. We denote the number of examples for which the set of decisions contains the most common decision for $T$ by $N_{mcd}(T)$.

### *B. Decision tree*

A *decision tree* over $T$ is a finite tree with root in which each terminal node is labeled with a decision (a natural number), and each nonterminal node is labeled with an attribute from the set $\{f_1, \ldots, f_n\}$. A number of edges start from each nonterminal node which are labeled with the values of that attribute (e.g. two edges labeled with 0 and 1 for the binary attribute) .

Let $\Gamma$ be a decision tree over $T$ and $v$ be a node of $\Gamma$. We denote $T(v)$ as a subtable of $T$ that is mapped for a node $v$ of decision tree $\Gamma$. If the node $v$ is the root of $\Gamma$ then $T(v) = T$ i.e. the subtable $T(v)$ is the same as $T$. Otherwise, $T(v)$ is the subtable $T(f_{i_1}, \delta_1) \ldots (f_{i_m}, \delta_m)$ of the table $T$ where attributes $f_{i_1}, \ldots, f_{i_m}$ and numbers $\delta_1, \ldots, \delta_m$ are respectively nodes and edge labels in the path from the root to node $v$. We will say that $\Gamma$ is a decision tree for $T$ if $\Gamma$ satisfies the following conditions:
- if $T(v)$ is degenerate then $v$ is labeled with the common decision for $T(v)$,
- otherwise $v$ is labeled with an attribute $f_i \in E(T(v))$. In this case, $k$ outgoing edges from node $v$ are labeled with $a_1, \ldots, a_k$ where $E(T(v), f_i) = \{a_1, \ldots, a_k\}$.

An example of a decision tree for the table $T$ can be found in Fig. 2. If the node $v$ is labeled with the nonterminal attribute $f_3$, then subtable $T(v)$ corresponding to the node $v$ will be the subtable $T(f_1, 0)$ of table $T$. Similarly, the subtable corresponding to the node labeled with 2 will be $T(f_1, 0)(f_3, 1)$ and here 2 is the common decision.

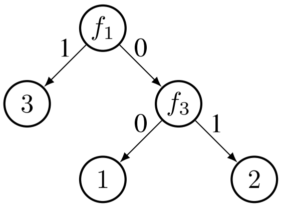

Fig. 2: Decision tree for the many-valued decision table $T'$

### *C. Impurity Functions and Uncertainty Measures*

In greedy algorithm, we need to choose attributes to partition the decision table into smaller subtables until we get degenerate table which then be used to label the terminal node. To choose which partition to consider for tree construction, we need to evaluate the quality of partition by impurity function. We assume that, the smaller the impurity function value, the better is the quality of partition. Impurity function can be calculated based on uncertainty measures for the considered subtables corresponding to the partitions. If we have a common decision, then there is no uncertainty in the data, and uncertainty measure is zero, otherwise uncertainty measure is positive.

**Algorithm 1** Greedy algorithm $A_I$

```
Input: A many-valued decision table $T$ with conditional attributes $f_1, \ldots, f_n$.
Output: Decision tree $A_I(T)$ for $T$.
  Construct the tree $G$ consisting of a single node labeled with the table $T$;
  while (true) do
    if No one node of the tree $G$ is labeled with a table then
      Denote the tree $G$ by $A_I(T)$;
    else
      Choose a node $v$ in $G$ which is labeled with a subtable $T'$ of the table $T$;
      if $U(T') = 0$ then
        Instead of $T'$ mark the node $v$ with the common decision for $T'$;
      else
        For each $f_i \in E(T')$, compute the value of the impurity function $I(T', f_i)$; Choose the attribute $f_{i_0} \in E(T')$, where $i_0$ is the minimum $i$ for which $I(T', f_i)$ has the minimum value; Instead of $T'$ mark the node $v$ with the attribute $f_{i_0}$; For each $\delta \in E(T', f_i)$, add to the tree $G$ the node $v_\delta$ and mark this node with the subtable $T'(f_{i_0}, \delta)$; Draw an edge from $v$ to $v_\delta$ and mark this edge with $\delta$.
      end if
    end if
  end while
```

*1) Uncertainty Measures:* Uncertainty measure $U$ is a function from the set of nonempty many-valued decision tables to the set of real numbers such that $U(T) \geq 0$, and $U(T) = 0$ if and only if $T$ is degenerate.

Let $T$ be a many-valued decision table having $n$ conditional attributes, $N = N(T)$ examples and its examples be labeled with sets containing $m$ different decisions $d_1, \ldots, d_m$. For $i = 1, \ldots, m$, let $N_i$ be the number of examples in $T$ that has been attached with sets of decisions containing the decision $d_i$, and $p_i = N_i/N$. Let $d_1, \ldots, d_m$ be ordered such that $p_1 \geq \cdots \geq p_m$, then for $i = 1, \ldots, m$, we denote by $N_i^{'}$ the number of examples in $T$ such that the set of decisions attached to example contains $d_i$, and if $i > 1$ then this set does not contain $d_1, \ldots, d_{i-1}$, and $p_i^{'} = N_i^{'}/N$. We have the following four uncertainty measures (we assume $0 \log_2 0 = 0$):

- Misclassification error: $me(T) = N(T) - N_{mcd}(T)$. It measures difference between total number of examples and number of examples with most common decision.
- Sorted entropy: $entSort(T) = -\sum_{i=1}^{m} p_i^{'} \log_2 p_i^{'}$ ([14]). First we sort the probabilities for all decisions. After that, for each example, keep the decision having maximum probability and discard others. Then we calculate entropy for this modified decision table.
- Multi-label entropy: $entML(T) = 0$, if and only if $T$ is

degenerate, otherwise, it is equal to $-\sum_{i=1}^{m}(p_i \log_2 p_i + q_i \log_2 q_i)$, where, $q_i = 1 - p_i$. ([16]).

- Absent: $abs(T) = \prod_{i=1}^{m} q_i$, where $q_i = 1 - p_i$. It measures the multiplication of all absent probability $q_i$'s.

*2) Impurity Functions:* Let $U$ be an uncertainty measure, $f_i \in E(T)$, and $E(T, f_i) = \{a_1, \ldots, a_t\}$. The attribute $f_i$ divides the table $T$ into $t$ subtables: $T_1 = T(f_i, a_1), \ldots, T_t = T(f_i, a_t)$. We now define three types of impurity function $I$ which gives us the impurity $I(T, f_i)$ of this partition.

- Weighted max ($wm$):
  $I(T, f_i) = \max_{1 \le j \le t} U(T_j)N(T_j)$.
- Weighted sum ($ws$):
  $I(T, f_i) = \sum_{j=1}^{t} U(T_j)N(T_j)$.
- Multiplied weighted sum ($Mult\_ws$):
  $I(T, f_i) = (\sum_{j=1}^{t} U(T_j)N(T_j)) \times \log_2 t$.

## IV. Greedy Algorithms for Decision Tree Construction

Let $I$ be an impurity function based on the uncertainty measure $U$. The greedy algorithm $A_I$, for a given many-valued decision table $T$, constructs a decision tree $A_I(T)$ for $T$ (see Algorithm 1).

It constructs decision tree sequentially in a top-down fashion. It greedily chooses one attribute at each step based on the considered impurity function. We have total 12 (= 4 × 3) algorithms. The complexities of these algorithms are polynomially bounded above by the size of the tables.

## V. Data Sets

We consider five decision tables from UCI Machine Learning Repository [10]. There were missing values for some attributes which were replaced with the most common values of the corresponding attributes. Some conditional attributes have been removed that take unique value for each example. For the sake of experiments, we removed from these tables more conditional attributes. As a result, we obtained inconsistent decision tables which contain equal examples with equal or different decisions. The information about obtained inconsistent (represented as many-valued decision) tables can be found in Table IV. These modified tables have been renamed as the name of initial table with an index equal to the number of removed conditional attributes.

We also consider five decision tables from KEEL [11] multi-label data set repository. Note that, these tables are already in many-valued decision format. The information about these table can be found in Table V. The decision table 'genbase' has one attribute with unique value for each example and therefore, it was removed, and renamed as 'genbase-1'.

Table IV and V also contain the number of examples (column "Row"), the number of attributes (column "Attr"), the total number of decisions (column "Label"), the cardinality of decision (column "$lc$"), the density of decision (column "$ld$"), and the spectrum of this table (column "Spectrum"). The decision cardinality, $lc$, is the average number of decisions for each example in the table. The decision density, $ld$, is the average number of decisions for each example divided by the total number of decisions. If $T$ is a many-valued decision table with $N$ examples $(x_i, D_i)$ where $i = 1, \ldots, N$, then $lc(T) = \frac{1}{N}\sum_{i=1}^{N}|D_i|$, where $|D_i|$ is the cardinality of decision set in $i$-th example, and $ld(T) = \frac{1}{|L|}lc(T)$, where $L$ is the total number of decisions in $T$. Spectrum of a many-valued decision table is a sequence $\#1$, $\#2, \ldots$, where $\#i$, $i = 1, 2, \ldots$, is the number of examples labeled with sets of decisions with the cardinality equal to $i$. For some tables (marked with * in Table V), the spectrum is too long to fit in the page width. Hence, we show what allows in the page width limit.

## VI. Comparison of Three Approaches

We compared the three approaches $MVD$, $MCD$, and $GD$ to handle inconsistency. We have published the results of the comparison using the decision tree complexity (depth, average depth and number of nodes) in [17]. For the sake of the discussion, we reproduced the result in Table VI for the above 10 decision tables using the algorithm $A_I$ (see Algorithm 1) which uses misclassification error uncertainty measure and weighted sum impurity type.

Data sets from KEEL are already in $MVD$ format. These tables are converted into formats $MCD$ (in this case, the first decision is selected from the set of decisions attached to a row) and $GD$ by the procedure described in Section I. Conversely, inconsistent tables from UCI ML Repository were converted into $MVD$, $MCD$ and $GD$. We then used such data sets to construct decision trees by the algorithm $A_I$, and further we listed the depth, average depth and number of nodes in the constructed decision trees. Note that, we interpreted single valued decision tables, i.e. $T_{GD}$, $T_{MCD}$, as many-valued decision tables where each row is labeled with a set of decisions that has one element. Hence, we can apply the same algorithm for all three cases.

Table VI shows the result of depth, average depth and number of nodes for decision trees $A_I(T_{MVD})$, $A_I(T_{GD})$ and $A_I(T_{MCD})$. Moreover, we took average among the 10 data sets. Since, the result varies in the range of the parameter, we took the normalized average. The normalization has been done by taking the value and dividing by the maximum of three approaches. For example, the maximum depth of the three approaches for the table 'bibtex' is 43. Then the normalized depth of $MVD$ approach will be 39/43 = 0.91. Similarly, the normalized depth of $MCD$ approach will be 42/43 = 0.98, and for $GD$ will be 1.

If we look at the result, the $MVD$ approach in many cases gives minimum depth, average depth and number of nodes. When we took the normalized average, this claim is pretty clear. If our goal is to represent knowledge from the given data using the decision tree, we should use $MVD$ approach as it produces simpler trees compared to other approaches. Therefore, we have used $MVD$ approach for the rest of the paper.

TABLE IV: Characteristics of modified UCI inconsistent data represented in $MVD$ format

## VII. Decision Tree Optimization

We can optimize the depth, average depth and number of nodes of the constructed decision tree based on dynamic programming algorithms as shown in [6], [8], [7]. It builds all possible separable subtables from the root to the leaf. After that, it considers all possible decision trees by the bottom up approach based on the given criteria of minimizing depth or average depth, or number of nodes. We have compared the average relative difference (in %) $ARD = \frac{greedy-optimal}{optimal} \times 100$ between the sub-optimal results from the greedy algorithms and optimal result from the dynamic programming algorithm. ARD shows how close the greedy result compared to the optimal solution. We have produced the ARD results in Table VIIa, VIIb and VIIc for 3 top algorithms from 12 algorithms (see Section IV).

TABLE VII: ARD (in %) between results of greedy and dynamic algorithms

| Algorithm | $ARD$ |
|---|---|
| $ws\_entSort$ | 4.58 |
| $ws\_entML$ | 5.47 |
| $ws\_me$ | 6.03 |

(a) Average depth

| $Mult\_ws\_entML$ | 21.22 |
| $Mult\_ws\_entSort$ | 24.58 |
| $ws\_abs$ | 25.03 |

(c) Number of nodes

## VIII. Decision Tree Classifier

The examples in the many-valued decision table $T$ have been attached with sets of decisions $D \subset L$ where $L$ is the set of all possible decisions in the table $T$. We denote $D(x)$ as the set of decisions attached to the example $x$. If $X$ is the domain of the examples to be classified, the goal is to find a classifier $h : X \to L$ such that $h(x) = d$, where $d \in D(x)$, that means to find a decision from the ground truth set of decisions attached to the example. To solve the problem, we use decision tree as our model. We construct different kinds of decision trees using various impurity functions.

### A. Evaluation Measure

Here we use the common evaluation measure of classification error percentage. Let us assume, we have unknown instance $x'$ and corresponding decision set is $D(x')$. The classifier $h$ is applied on the new instance $x'$ and it gives the decision $d = h(x')$. If $d \in D(x)$ then $error(x') = 0$, otherwise $error(x') = 1$. Let us assume, we have total $M$ unknown instances to classify, then the error rate will be $\frac{1}{M}\sum_{i=1}^{M} error(x_i)$.

### B. Methodology

Let $T$ be a many-valued decision table with conditional attributes $f_1, \ldots, f_n$, and the decision attribute $D$. We have to divide the initial subtable into three subtables: training subtable $T_1$, validation subtable $T_2$, and test subtable $T_3$. The subtable $T_1$ is used for construction of initial classifier. The subtable $T_2$ is used for pruning of the initial tree. Let $\Gamma$ is a decision tree for $T_1$. For each node $v$ of $\Gamma$, we construct a subtable $T_1(v)$ of the table $T_1$. If $v$ is the root, then $T_1(v) = T_1$, otherwise $T_1(v) = T_1(f_{i_1}, a_1)\ldots(f_{i_m}, a_m)$ where $f_{i_1}, \ldots, f_{i_m}$ are the conditional attributes attached to nodes of the path from the root of $\Gamma$ to $v$, and $a_1, \ldots, a_m$ are numbers attached to edges of this path.

We denote $\alpha(v) = U(T_1(v))/U(T_1)$, where $U(T_1)$ is the misclassification error uncertainty of table $T_1$. Let $\Gamma$ contain $t$ nonterminal nodes, and $v_1, \ldots, v_t$ be all nonterminal nodes of $\Gamma$ in an order such that $\alpha(v_1) \leq \alpha(v_2) \ldots \leq \alpha(v_t)$. For any $i \in \{1, \ldots, t-1\}$, if $\alpha(v_i) = \alpha(v_{i+1})$ then the distance from the root of $\Gamma$ to $v_i$ is at least the distance from the root to $v_{i+1}$. We now construct a sequence of decision trees $\Gamma_0, \Gamma_1, \ldots, \Gamma_t$ where $\Gamma_0 = \Gamma$ (initial tree). The procedure of such decision tree construction is described below in an inductive way:

Let assume that, for some $i \in 0, \ldots, t-1$, the decision tree $\Gamma_i$ is already constructed. We now construct the decision tree $\Gamma_{i+1}$ from the decision tree $\Gamma_i$. Let $D$ be a subtree of $\Gamma_i$ with the root $v_{i+1}$. We remove all nodes and edges of $D$ from $\Gamma_i$ with the exception of $v_{i+1}$. After that, we transform the node $v_{i+1}$ into a terminal node which is labeled with the most common decision for $T_1(v_{i+1})$. As a result, we obtain the decision tree $\Gamma_{i+1}$.

For $i = 0, \ldots, t$, we used the decision tree $\Gamma_i$ to calculate the classification error rate for the table $T_2$. We choose the tree $\Gamma_i$ which has the minimum classification error rate (in case of tie, we choose the tree with smaller index). Now this tree can be used as the final classifier and we can evaluate the test error rate by using this tree to classify the examples in table $T_3$.

## IX. Statistical Comparison of Greedy Algorithms

To compare the algorithms statistically, we used Friedman test with the corresponding Nemenyi post-hoc test as suggested in [9]. Let we have $k$ greedy algorithms $A_1, \ldots, A_k$ for constructing trees and $M$ decision tables $T_1, \ldots, T_M$. For each decision table $T_i$, $i = 1, \ldots, M$, we rank the algorithms $A_1, \ldots, A_k$ on $T_i$ based on their performance scores of classification error rates, where we assign the best performing algorithm the rank of 1, the second best rank 2, and so on. We break ties by computing the average of ranks. Let $r_i^j$ be the rank of the $j$-th of $k$ algorithms on the decision table $T_i$. For $j = 1, \ldots, k$, we correspond to the algorithm $A_j$ the average rank $R_j = \frac{1}{M} \cdot \sum_{i=1}^{M} r_i^j$. For a fixed significance level $\alpha$, the performance of two algorithms is significantly different if the corresponding average ranks differ by at least the critical difference $CD = q_\alpha \sqrt{\frac{k(k+1)}{6M}}$ where $q_\alpha$ is a critical value for the two-tailed Nemenyi test depending on $\alpha$ and $k$.

## X. Classification Results

We used 3-fold cross validation to separate test and training data set for each decision table. The data set is divided into 3 folds, we run the experiment for 3 times. At $i$-th ($i = 1, 2, 3$) iteration, $i$-th fold is used as the test subset, and the rest of data is partitioned randomly into train (70%) and validation subset (30%). The validation subset is used to prune the trained tree. We successively prune the nodes of the trained decision tree model based on the accuracy of the classifier from validation data set unless its accuracy is maximum. After pruning, we used trained decision tree model to predict the decisions for test data sets. For each fold, we repeat the experiment 5 times and take the average of 5 error rates.

We have four uncertainty measures ($me$, $abs$, *entSort*, *entML*) and three types of impurity functions ($ws$, $wm$, *Mult_ws*). So, 12 greedy algorithms have been compared. We show the names of the algorithms as combined name of heuristic and impurity function types separated by '_' in CDD. For example, if the algorithm name is *wm_me*, this means it uses $wm$ as a type of impurity function and $me$ as uncertainty measure. Figure 3 shows the CDD containing average rank for each algorithm on the $x$-axis for significance level of $\alpha = 0.05$. The best ranked algorithm are shown in the leftmost side of the figure. When Nemenyi test cannot identify significant difference between some algorithms, then those are clustered (connected).

It is clear that, *Mult_ws_abs* is the best ranked algorithm to minimize the test error. We have shown classification error rate for each data sets for the three best ranked algorithm in Table VIII as well as the average error rate (AER) among all the data sets. We can see that for most of the data sets *Mult_ws_abs* gives minimum error rate than others. On average it gives the best result. We have also shown the overall execution time for the three best ranked algorithm in the Table IX and found that the *Mult_ws_entML* algorithm is faster than other algorithms.

Also note that, the *Mult_ws_entML* algorithm is the best for minimizing the number of nodes in the tree (see Section VII), and it is also one of the top algorithms for minimizing the classification error rates. Also there are two algorithms (*Mult_ws_entML*, and *Mult_ws_entSort*) for minimizing number of nodes in the tree intersects with the same two algorithms for minimizing the classification error rates. This result is interesting as we can relate the classification and optimization problem. It looks like the quality of classification is connected with the quality of minimizing the number of nodes.

## XI. Conclusion

We studied three different approaches to handle inconsistent decision tables and found $MVD$ approach performs better. We also have created different greedy algorithms based on various uncertainty measures and impurity types to construct decision trees, and compared the results with the optimal results. Finally, we compared these greedy algorithms statistically for classification task to get best ranked classifier and considered also the average error rate across all data sets. We found that $Mult\_ws\_abs$ gives lowest classification error rate than others for most of the data sets. We also found $Mult\_ws\_entML$ algorithm is faster than other top algorithms and also good for both classification and optimization of number of nodes.

In the future, our goal is to construct ensemble of decision trees to work with larger data sets efficiently. Also we are planning to consider more sophisticated pruning methods based on Pareto-optimal points using dynamic programming algorithms.

*Abstract*—**Two algorithms for building classification trees, based on Tsallis and Rényi entropy, are proposed and applied to customer churn problem. The dataset for modeling represents highly unbalanced proportion of two classes, which is often found in real world applications, and may cause negative effects on classification performance of the algorithms. The quality measures for obtained trees are compared for different values of α parameter.**

## I. Introduction

DECISION trees are powerful and very popular tools for different classification tasks [1]-[3]. The attractiveness of this technique is due to the fact that they create rules that can be easily interpreted. Decision trees use some statistical property called information gain to measure the classification power of the input attributes on classification problem as the difference between the entropy before and after a decision. Entropy computation is used to generate simple decision trees, in terms of the structure, with effective classification, since tree size reduction depends on the attribute selection. For this purpose, usually Shannon entropy is used, but other entropy formulas, such as Rényi [4] and Tsallis [5] entropy, can also be applied. Here, a comparative study based on Rényi and Tsallis entropy is described taking into account the issue of imbalance in the class distribution. We used data from telecommunication industry to predict loss of customers to competitors what is known as customer churn. In this dynamical and liberal market customers can choose among cellular service providers and actively migrate from one service provider to another. This problem is especially interesting due to the fact that the portion of churning customers in business practice is low, between 1% and 5%, depending on the country and type of the telecommunication service.

The comparison of the trees is carried out by taking into account different values of α parameter and set of the following measures: classification accuracy, area under the ROC curve, lift, and number of leaves in a tree as complexity measure.

In the next section properties of Rényi and Tsallis entropies are described. The data used in this study are described in the third section. The empirical analysis and comparison of the entropies is shown in fourth section. This type of analysis is especially interesting for decision trees because of the high dimensionality of telecommunication data. Conclusions are given in the last section.

## II. Theoretical framework

In this paper we assume that observations may belong to two given classes and for the classification we use a modified algorithm similar to C4.5 [6] to construct a binary tree in R environment [7].

As a general measure of diversity of objects, a Shannon entropy is often used which is defined as [8]:

$$H_s = -\sum_{i=1}^{n} p_i \log p_i, \tag{1}$$

where $p_i$ is the probability of occurrence of an event $x_i$ being an element of the event $X$ that can take values $x_i,\ldots,x_n$. The value of the entropy depends on two parameters: (1) disorder (uncertainty) and is maximum when the probability $p_i$ for every $x_i$ is equal; (2) the value of n. Shannon entropy assumes a tradeoff between contributions from the main mass of the distribution and the tail. To control both parameters two generalizations were proposed by Rényi [4] and Tsallis [5].

The Rényi entropy is defined as:

$$H_R = \frac{1}{1-\alpha}\log\left(\sum_{i=1}^{n} p_i^{\alpha}\right), \tag{2}$$

where parameter $\alpha$ is used to adjust the measure depending on the shape of probability distributions.

The Tsallis entropy is defined as:

$$H_R = \frac{1}{\alpha-1}\left(1-\sum_{i=1}^{n} p_i^{\alpha}\right). \tag{3}$$

With Shannon entropy, events with high or low probability have equal weights in the entropy computation. However, using Tsallis entropy, for $\alpha > 1$, events with high probability contribute more than low probabilities for the entropy value [9]. Therefore, the higher is the value of $\alpha$, the higher is the contribution of high probability events in the final result. Furthermore, increasing $\alpha$ parameter $(\alpha \to \infty)$ makes the Rényi entropy determined by events

978-83-60810-66-8/$25.00©2015, IEEE

with higher probabilities, and lower values of $\alpha$ coefficient $(\alpha \to 0)$ weigh the events more equally, no matter of their probabilities.

The Tsallis and Rényi entropies were successfully applied to many diverse practical problems, showing their high usefulness for accurate classification. For instance, in [10] the authors applied both entropies for variable selection in computer networks intrusion detection, analyzing models detection capabilities while providing a set of attributes coming from the network traffic. Their results showed that selecting attributes based on Rényi and Tsallis entropies can achieve better results as compared to Shannon entropy.

Modified C4.5 decision trees based on Tsallis and Rényi entropies have been tested on several high-dimensional microarray datasets in [11]. The results showed that use of non-standard entropies may be highly recommended for this kind of data.

In [12] the authors addressed the question whether the Rényi entropy is equally suit-able to describe systems with q-exponential behavior, where the use of the Tsallis entropy is relevant. The study confirmed that in this case Tsallis entropy is a more suitable choice than Rényi entropy.

Some other studies considered image segmentation based on Tsallis and Rényi-entropies [13]. Their conclusion was that entropic segmentation can give good results but is highly related to an appropriate choice of the entropic index $\alpha$.

## III. The churn dataset

Customer churn is a term used in the telecommunication industry to describe the customer movement from one provider to another, and the churn management strategy is a process aimed to retain profitable customers [14]. Every year telecommunication industry suffers from a substantial loss of valuable customers to competitors. In this liberal market customers can migrate between telecommunication operators freely. The motivation for churn research is based on the fact that it costs more to recruit new customers than to retain existing ones, especially those high profitable customers. The other motivation is the fact that the average churn at cellular providers is about 25% per year in Europe, according to [15], what means that one fourth of the customers' base is lost each year.

In order to check the performance of the proposed entropies, we conducted the simulations based on the data collection known as "Cell2Cell: The Churn Game" [16] derived from the Center of Customer Relationship Management at Duke University, USA. The data constitute a representative slice of the entire customer database, be-longing to an anonymous company operating in the sector of mobile telephony in the United States.

The data contains 71047 observations, wherein each observation corresponds to the individual customer. For each observation 78 variables are assigned, of which 75 potential explanatory variables are used for models construction. All explanatory variables are derived from the same time period, except the binary dependent variable (the values 0 and 1) labeled as "churn", which has been observed in the period from 31 to 60 days later than the other variables. In the collection there is an additional variable "calibrat" to identify the learning sample and test sample, comprising 40000 and 31047 observations, respectively. Learning sample contains 20000 cases classified as churners (leavers) and 20000 cases classified as non-churners. In the test sample, which is used to check the quality of the constructed model, there is only 1.96% of customers who quit. Such a small percentage of the modeled class can be often found in the business practice.

## IV. Analysis and results

### A. Accuracy measures

To compare the trees obtained for different values of $\alpha$ we define a set of three measures. These are: (1) AUC (area under the ROC curve), (2) Lift and, (3) Lv (number of leaves in a tree). The first two measures are related to efficiency and effectiveness of the tree and they have been often used for evaluation of classification models in the context of e.g. credit scoring [17], income and poverty determinants [18] or customer insolvency and churn [19]. The last measure Lv expresses a complexity of the tree as the number of its leaves. In this study we will favor small trees which usually lead to simple and general rules, thus having an advantage over other models. Therefore, a good tree will be characterized by the high accuracy of AUC and lift as well as the relatively small number of leaves. In other words we would like to obtain small but efficient structures for churn classification.

Since we deal with a problem of binary classification, the model yields two results: positive and negative. There are four possible outcomes, as shown in Table 1.

In order to construct AUC measure we need to define two indicators: $Tpr = TP / (\mathrm{TP+FP})$, $Fpr = FP / (\mathrm{FP}+T\,\mathrm{P})$ as well as a ROC curve. As mentioned earlier, each tree's node and leaf has a class assigned based on the share of churn classes. If the share exceeds the decision threshold, usually set to 0.5, a node or a leaf gets a class churn=1 assigned, otherwise class churn=0.

TABLE 1.
CONFUSION MATRIX FOR BINARY CLASSIFICATION

| **Predicted** | **Observed** | |
|---|---|---|
| | Positives | Negatives |
| Positives | True Positives (TP) | False positives (FP) |
| Negatives | False Negatives (FN) | True Negatives (TN) |

Defined indicators can be calculated for various values of the decision threshold. The increase of the threshold from 0 to 1 will yield to a series of points ( $Fpr$ , $Tpr$ ) forming the curve with $Tpr$ on horizontal axis and $Fpr$ on vertical axis. The curve is named receiver operating characteristics, ROC [20], [21]. The AUC measure is an area under the ROC curve which can be calculated using trapezoidal rule. Theoretically $AUC \in [0;1]$ and the larger the AUC the closer is the model to the ideal one and the better is its performance.

The lift measure is dictated by the economic considerations, because the telecom operator does not direct the retention campaign to a wide customer base, but focuses on a small percentage of approximately 1-2% of the customer database on a monthly basis, characterized by the highest probability of resignation. For instance, having the total number of customers of approximately 10 million, a group of 1% of customers is equal to 100 thousand customers per month, which would receive the retention offer.

The required input for lift calculation is a validation dataset that has been “scored" by assigning the estimated churn probability to each case. Next, the churn probabilities are sorted in descending order and for a given customers percentage, the measure is calculated in the following manner (for the first percentile) [22]:

$$Lift_{0.01} = \frac{TP_{0.01}}{TP} \tag{4}$$

The lift measure shows how much more likely we are to receive positive responses (detecting churn customers) in comparison to a random sample of customers.

### B. Experiments

Rényi and Tsallis entropy were compared to each other using the modified C4.5 algorithm for decision tree construction which has been applied to churn dataset. The modification of the algorithm concerned mainly the pruning part. The listing *Generate_decision_tree* presents the tree growing algorithm.

```
Algorithm: Generate_decision_tree
Input: training samples D, list of attributes L,
attribute_selection_method
Output: decision tree

Create a node N
if D has the same class C then
  return N as leaf node with class C label
if L is empty then
  return N as leaf node with class label that is the most class in D
Choose test-attribute a that has the most Gain-Ratio using attribute_selection_method
Give node N with test-attribute label
Find an optimal split that splits D into subsets D_i ($i = 1, ..., k$)
foreach $i = 1$ to $k$ do
  Add branch in node N to test-attribute = $a_i$
   Make partition for sample D_i from samples where test-attribute = $a_i$
  if D_i is empty then
    attach leaf node with the most class in D
       else attach node that generate by Generate_decision_tree(D_i, attribute-list, test-attribute)
endfor
return N
```

The algorithm is recursively called so that it works from the bottom of the tree upward, removing or replacing branches to minimize the predicted error on the validation dataset.

In order to obtain the optimal split while growing the tree (see part of the pseudo-code above) the gain ratio should be calculated. The listing *Prune* outlines the pruning process.

The algorithm is recursively called so that it works from the bottom of the tree up-ward, removing or replacing branches to minimize the predicted error on the validation dataset.

The decision trees were trained on training samples which reflected two designs: (1) learning on the balanced dataset (equal proportion of churn and non-churn classes); (2) learning on the imbalanced dataset with the churn rate of 1.96%. Both designs were then checked on the validation sample in which the churn rate was equal to 1.96%, as observed in real population. We considered α starting from 0.5 to 10 by 0.5.

The results obtained on the validation datasets are collected in Tables 2-3. The best results and corresponding values of α parameter differ in each case and can be summarized as follows:

i. Training the trees on the balanced dataset resulted in better classification performance;

ii. The Rényi entropy based trees trained on imbalanced dataset generated the splits only for α equal to 1 and 1.5; all the other α resulted in no split (Lv=1)

iii. In general, the Tsallis entropy based trees provided better generalization (smaller number of leaves) and the highest lift (3.612);

iv. The Rényi entropy based trees provided complex tree structures with questionable generalization abilities (although the high AUC observed).

v. The Shannon based tree trained on the balanced dataset resulted in high AUC and high lift; however the tree was very complex. The tree trained on the imbalanced dataset did not generate any splits.

The structure of the best tree, in terms of the lift, trained on the balanced dataset using Tsallis entropy is presented in Fig. 1. The tree has 27 leaves on 7 levels (including the root). Each node and each leave has indicated: decision rule, class (TRUE – if churn was observed and FALSE otherwise), and percentage of objects belonging to the majority class.

The first variable used for split was *EQPDYAS* (number of days of the current equipment). If the value of *EQPDYAS* was greater than 302 then the probability of churn increased, forming a group in which the percentage of churners amounted to 56.9%. On the other levels of the tree it was observed that the following variables were useful for detecting churners: *MONTHS* (months in service), *MOU* (mean monthly minutes of use), *RETCALLS* (number of calls previously made to retention team), *RECCHRGE* (mean total recurring charge), *RETACCPT* (number of

```
Algorithm: Prune
Input: node with an attached subtree, validation samples W
Output: pruned tree

    leafError = estimated leaf error on W
    if node is a leaf then
      return leaf error
    else
      subtreeError = $\sum_{N_i \in children(\text{node})} \Pr une(N_i)$
      branchError = error if replaced with most frequent branch
      if leafError is less than branchError and subtreeError then
        make this node a leaf
        error = leafError
      else if
        branchError is less than leafError and subtreeError then
        replace this node with the most frequent branch
        error = branchError
      else
        error = subtreeError
      return error
end
```

previous retention offers accepted), *PEAKVCE* (mean number of in and out peak voice calls), *DIRECTAS* (mean number of director assisted calls), *MOUREC* (mean unrounded MOU received voice calls), *CHANGEM* (% change in minutes of use), *CALLWAIT* (mean number of call waiting calls), *INCOME* (customer income), *REVENUE* (mean monthly revenue).

The final leaves contained the high proportion of churners ranging from 54.9% to 100%. Three rules lead to the leaves with 100% of churners. These were:

Rule 1 – *EQPDAYS* <= 302 & *MONTHS* <= 10 & *RECCHRGE* <= 37.8775 & *RETACCPT* > 0 & *DIRECTAS* <= 2.2275;

Rule 2 – *EQPDAYS* > 302 & *MONTHS* <= 12 & *RETCALLS* > 0 & *PEAKVCE* > 122.33 & *MOUREC* > 86.35 & *RETACCPT* <= 0;

Rule 3 – *EQPDAYS* > 302 & *MONTHS* > 12 & *MOU* <= 6 & *MOU* > 0 & *EQPDAYS* <= 375 & *CHANGEM* > -3.25.

The results presented in this paper are encouraging and provide high accuracy of classification, when compared to similar studies on this dataset. For example, the authors in [23] as an assessment of the quality of the model, chose lift in the first decile, which was equal to 2.61 for the best model. Finally, in our previous study [24] we obtained lift of 3.11 for the first percentile using C&RT tree on the same dataset, while current study delivers improved results.

## V. SUMMARY AND CONCLUDING REMARKS

In this paper, an evaluation of Rényi and Tsallis entropy applied to customer churn in telecommunication industry is performed. In particular, the modified C4.5 decision tree

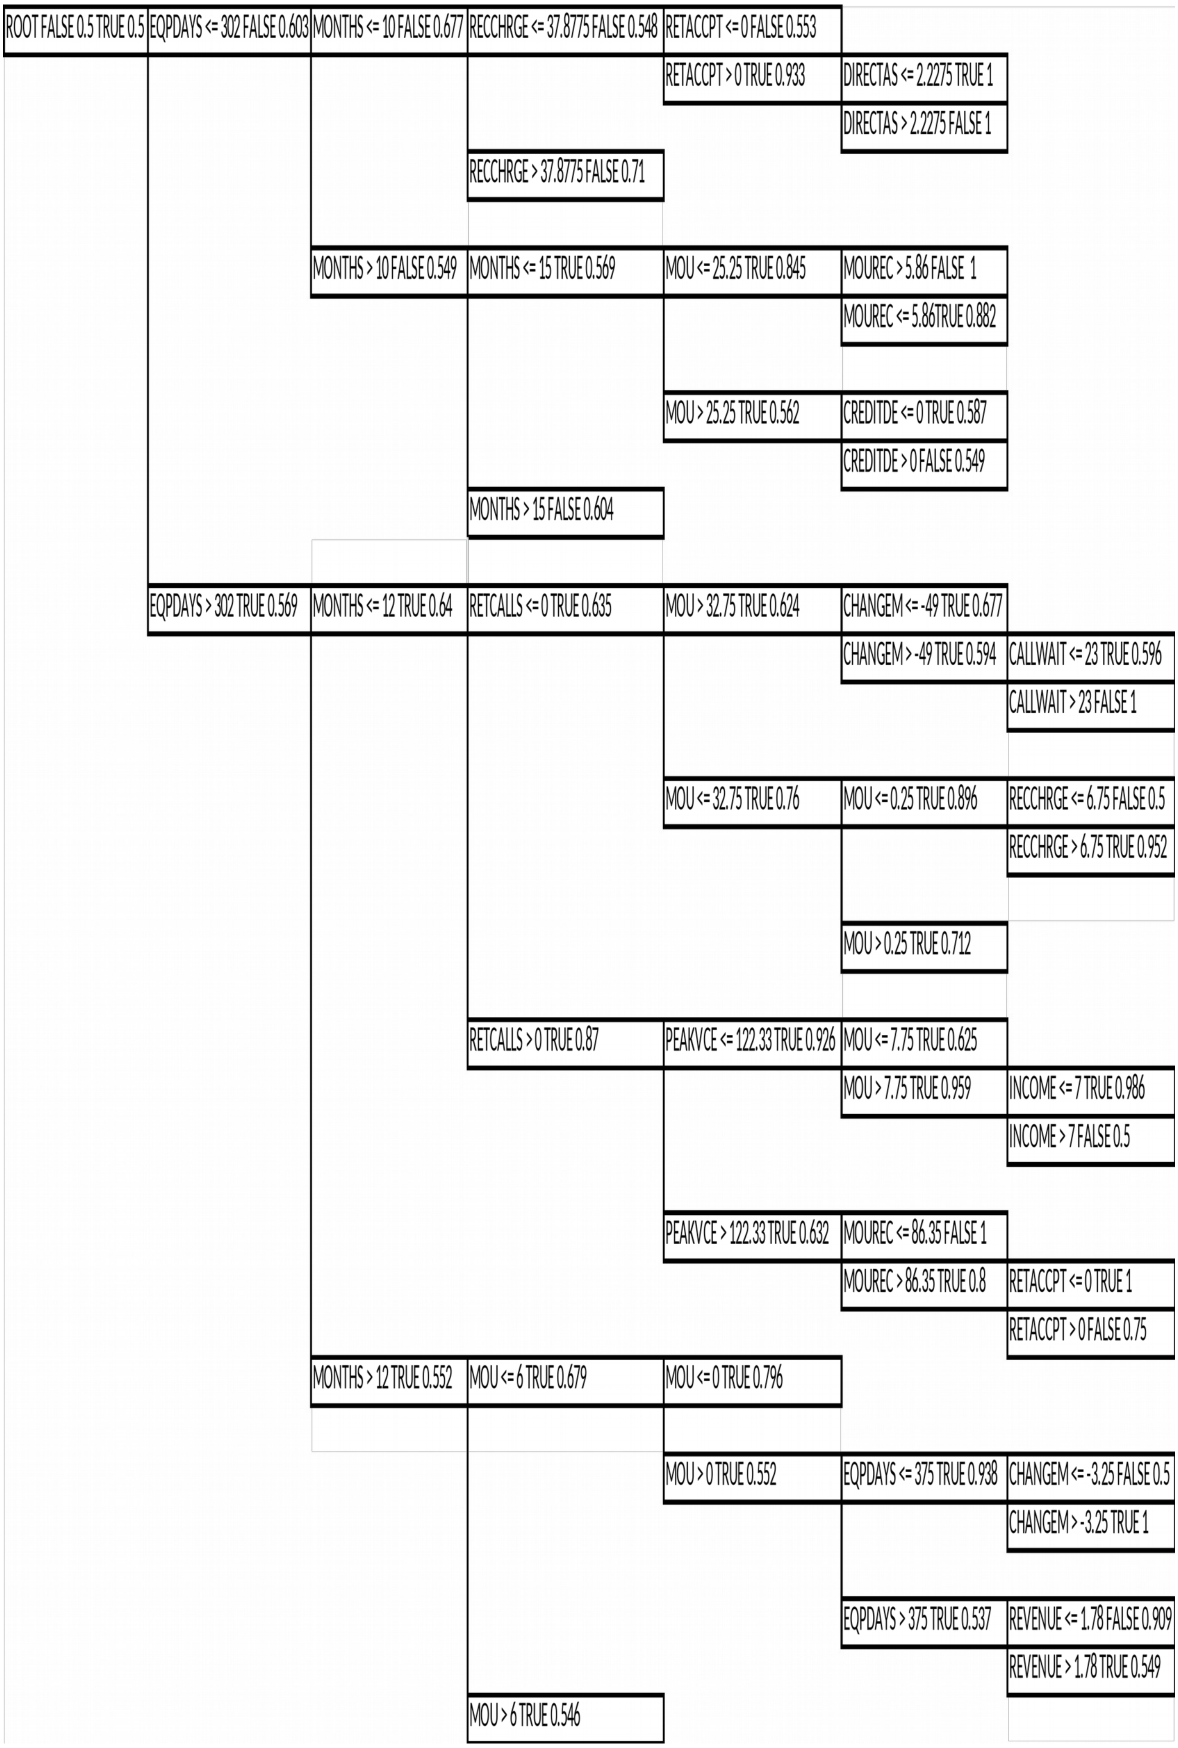

Fig. 1. Decision tree based on Tsallis entropy for α = 6.5 trained on the balanced data.

algorithm was used for classification since it can handle continuous and discrete input variables as observed in the churn dataset.

Additionally, we studied the performance of both entropies in the case of the learning dataset being balanced or imbalanced. The experimental results show that in general, Tsallis and Rényi entropies, with adequate $\alpha$ parameters, can lead to compact and efficient decision trees, with high accuracy measures. We observed that Tsallis entropy provided better generalization since the resulting trees were not as complex as for Rényi case. The study revealed that learning on the balanced learning dataset is beneficial for the final results. Finally, the use of Tsallis and Rényi entropies makes analysis more flexible than standard approach, e.g. Shannon entropy, since it allows for exploration of the tradeoff between the probability of different classes and the overall information gain.

## Acknowledgment

The computations were performed partially employing the computational resources of the Interdisciplinary Centre for Mathematical and Computational Modeling at the Warsaw University (Computational Grant No. G59-31).

***Abstract*—Equality is fundamental notion of logic and mathematics as a whole. If computer-supported formalization of knowledge is taken into account, sooner or later one should precisely declare the intended meaning/interpretation of the primitive predicate symbol of equality. In the paper we draw some issues how computerized proof-assistants can deal with this notion, and at the same time, we propose solutions, which are not contradictory with mathematical tradition and readability of source code. Our discussion is illustrated with examples taken from the implementation of the MIZAR system.**

## I. Introduction

THE ROLE of equality in mathematics is indispensable. Linear equations represented and accompanied by graphs seem to be one of the primary mathematical exercises for children, where also recognizing which objects are identical is important. Finding solutions for systems of equations [2], formulas for calculating integrals, values of various mathematical functions, etc., is the basic mathematical activity all engineers are familiar with. Hence it is not surprising that equational provers were one of the primary computerized tools developed for use by mathematicians, after offering simple numerical tools and methods – in fact also based on equality since they essentially handle sequences of equalities.

As a mathematical proof, a proof in a computerized system is just a sequence of proof steps, we could expect that it can be discovered automatically within a reasonable universe of discourse. Typically, a proof search explodes exponentially if the universe and/or the method is not properly chosen. Essentially the process of finding an equational proof is fairly simple. Given sets of equalities can be merged to define a substitution operation by iteration. E.g., in cases when the equalities are between terms and variables, or imply such equalities that can be derived, the substitution operation is the result of (1) (simultaneous) substitution of terms for corresponding variables, according to the given equalities, and (2) iterating this process on results. The iteration step (2) can lead to the target or fail if sooner or later the equalities became too complex to handle. The idea is to have a handy set of underlying techniques for machine learning and to restrict the field of expansions.

The results are always tempting, as after identifying two objects as equal – no matter how different they seem to have been – all knowledge about one of them applies to the other also. Moreover, from the moment of identifying objects, it does not matter with which of them we are dealing, properties discovered for one of them automatically carry over to the other one. Thus, identifying objects as equal can make certain work (e.g., in some non-procedural or extensional work) just easier. Depending on the mathematical context or computational environment, the use of the quality predicate may not be so simple as they look, and saying that two objects are equal we often mean certain level of *abstraction* which is the core of mathematics.

Informally the notion of equality is clear, but following [19] we cannot be sure about that:

> *... when it comes to a crisis of rigorous argument, the open secret is that, for the most part, mathematicians who are not focussed on the architecture of formal systems per se, mathematicians who are consumers rather than providers, somehow achieve a sense of utterly firm conviction in their mathematical doings, without actually going through the exercise of translating their particular argumentation into a brand-name formal system.*

Developers of computerized proof-assistants must be prepared for such exercises, furthermore – they have to provide tools for solving them. Our paper is a result of some thoughts presented in [7] and [3]. However, we are focusing not on computer algebra systems as in [7], and also not on the role of equality in mathematical education (although mathematical proof-assistants are definitely useful in this area). We started from the place where [7] posed some important questions: the area where automated reasoning and computer algebra can interact, and we went ahead of discussions, focusing on real-life implementations of the theoretical ideas: how the automatic proof-checker can cope with the predicate of mathematical equality and corresponding predicate symbol of equality. For our work in this paper, we have chosen MIZAR proof-checker described in [1]. The MIZAR system is much closer to automated theorem prover, although some basic elements of computer algebra are also implemented. In this sense this discussion is a kind of a counterpart of Davenport's research from the viewpoint of MIZAR proof-checker.

Essentially, all with the exception of the very basic MIZAR examples are of our authorship: the first author is mainly responsible for the formalization of lattice theory, rough and fuzzy sets [26], [37], the second author's work is on hard-coding of new MIZAR constructions (e.g. reductions), while the third author delivered examples from abstract algebra. We

978-83-60810-66-8/$25.00©2015, IEEE

hope then that our paper is much more than a theoretic discussion on selected issues on the usage of equality predicates.

The structure of the paper is as follows. At the beginning we draw some initial remarks on the properties of the equality and show how one can solve equational problems with the help of a computer, not necessarily in a fully readable way. Then we focus on the MIZAR system, explaining the implementation of the equality both from purely logical point of view, and extensionally, in set theory (including two extensions: rough and fuzzy sets). Section VI starts the discussion on specific implementation issues in MIZAR: analysis of terms, properties, and built-in computations. In Section XII, based on the concrete example, we show how the discussed techniques work to find the compromise between readability and writability, and then we present the statistics of the use of described constructions in MIZAR Mathematical Library (MML). The final part is devoted to the discussion of the structural understanding of the equality, where injections and isomorphisms are typically used by mathematicians.

## II. Equational Characterization

The importance of equational characterization is obvious – varieties are defined in this way. Among equationally defined classes of algebras, we can find all well-known problems solved with the help of powerful provers, with the Robbins problem [21] (the alternative set of axioms for Boolean algebras) and its solution by EQP/OTTER as the most prominent example. And even if Robbins problem's importance for Boolean algebras is not crucial, this specific set of axioms is quite interesting. E.g., we can point out many problems in lattice theory (presented as short equational bases) solved as a by-product of this computerized system achievement [9].

Absolute equality has the following properties defining it as equivalence relation between the objects in the considered universe of discourse (i.e., domain of objects):

- reflexivity,
- symmetry, and
- transitivity.

Furthermore, the absolute equality should satisfy the so-called Leibniz's Law (or identity of indiscernibles), which is a kind of closure with respect to properties or substitution property.

> *Two objects $x$ and $y$ are equal if for every predicate $P$ we have $P(x)$ if and only if $P(y)$, that is, $x$ and $y$ are equal if they cannot be distinguished using predicates.*

This is an intuitively clear definition, however hard to check, in particular in proof assistants – one can ask *which* universe of discourse should be taken. On the other hand, in some sense, the equality can be treated just like ordinary predicate.

## III. Automation – The Initial Approach

If we are not aware of all fears of the precise meaning and all shades of mathematical equality, we can see its use with computer knowledge systems very flawlessly. We can use equational provers e.g. in the area of lattice theory (as EQP/Prover9 was very successful in this domain), which gives representation of various mathematical areas – topology, algebra, logic, geometry, etc.

Remembering that lattices are structures

$$\langle L, \sqcup, \sqcap \rangle$$

where both binary operations $\sqcup$ and $\sqcap$ are commutative, associative, and satisfy the absorption laws, given as axioms, we can obtain

$$a \sqcup a = a$$

as a result of the six axioms. Essentially, the easy proof (sometimes credited to Dedekind) doesn't need them all, although caused some confusion (e.g., early versions of lattice axiomatics included both idempotences as additional axioms). We can easily obtain a proof using any equational prover. Let us stick to our favourite Prover9 – the direct successor of OTTER:

```
formulas(assumptions).
x ^ y = y ^ x.
x ^ (y ^ z) = (x ^ y) ^ z.
x ^ (x v y) = x.
x v y = y v x.
x v (y v z) = (x v y) v z.
x v (x ^ y) = x.
end_of_list.
```

pushing all the axioms into the assumptions and the desired equality into the goals:

```
formulas(goals).
x v x = x.
end_of_list.
```

and after a while one can get the answer, which is maybe not very readable for a human, but definitely assures us that the proven formula is true.

```
1   x v x = x.         [goal].
5   x ^ (x v y) = x.   [assumption].
9   x v (x ^ y) = x.   [assumption].
10  c1 v c1 != c1.     [deny(1)].
22  x v x = x.         [para(5(a,1),9(a,1,2))].
23  $F.                [resolve(22,a,10,a)].
```

Even for the reader unfamiliar with Prover9 syntax [20] it is clear that only two axioms are really needed. Bigger proofs are not that readable and additional transformations are useful to show the essence of the proof. In the column on the right hand side in square braces one can note the so-called *tactics* used in the proof search – among assumptions and goals, `deny` denotes the denial of the goal (Prover9 uses proofs by contradiction, then paramodulation and resolution is done). Essentially, the more readable counterpart of the proof given by Prover9 is the following *proof object* which contains concrete proof steps.

```
(5 (input) (= (meet v0 (v v0 v1)) v0) NIL)
(9 (input) (= (v v0 (meet v0 v1)) v0) NIL)
(10 (input) (not (= (v (c1) (c1)) (c1))) NIL)
(24 (instantiate 5 ((v0 . v100)))
     (= (meet v100 (v v100 v1)) v100) NIL)
(25 (instantiate 9 ((v0 . v100)
     (v1 . (v v100 v1))))
      (= (v v100 (meet v100 (v v100 v1))) v100)
      NIL)
(26 (paramod 24 (1) 25 (1 2))
     (= (v v100 v100) v100) NIL)
(22 (instantiate 26 ((v100 . v0)))
     (= (v v0 v0) v0) NIL)
(27 (instantiate 22 ((v0 . (c1))))
     (= (v (c1) (c1)) (c1)) NIL)
(23 (resolve 27 () 10 ()) false NIL)
```

## IV. The Mizar System

Formalization of mathematics is a practise of mathematics, or specific mathematical activity, by using a formal language suitable for computerized systems [36]. Here, we mean that a practise of mathematics means acts of proving theorems and correctness of definitions according to classical logic and Zermelo-Fraenkel set theory. Such activity, obviously without the use of computers, is dated back to Peano and Bourbaki, and typically, all areas of mathematics use specific, more-or-less formal languages. Computer certification of mathematics can be useful for many reasons – computers open new possibilities of information analysis and exchange, they can help to discover new proofs or to shed some light on approaches from various perspectives. With the help of such automated proof assistants one can observe deeper connections between various areas of mathematics.

Even if formalization of mathematics (even outside any computerized assistants) could potentially depend only on specific logical layer, set-theoretical counterpart is often, or typically, indispensable in practical applications (of course, one can imagine expressing e.g. Zermelo theorem in terms of pure predicates as Rasiowa and Sikorski mentioned in their *The Mathematics of Metamathematics* [30], but we aim at practically useful programs). Essentially then, alongside with logical connectives, e.g. equivalence, a mathematical system can include equality relation or predicate. Its characteristic properties are those commonly accepted in equivalential logics – reflexivity, symmetry, and transitivity, as we mentioned before.

As the testbed of our considerations we have chosen the MIZAR system, developed by the team we are members of. It was created in the early 1970s in order to assist mathematicians in their work. Now the system consist of three main parts: (1) a special formal language, in which mathematics can be expressed. This language is close to the vernacular used by human mathematician [14]. When used, the language expressions can be automatically checked for grammatical correctness; (2) the software, which verifies the correctness of formalized knowledge, in the classical logical framework; and last, but not least, (3) a huge collection of certified mathematical knowledge – the MML.

Here, we can quote the source written in MIZAR file HIDDEN containing basic built-in properties of primitives – one can see reflexivity and symmetry for the equality. Unfortunately, there is no *transitivity* property implemented for predicates in MIZAR, hence it was hard-coded by the developers of the system.

```
definition let x,y be object;
  pred x = y;
  reflexivity;
  symmetry;
end;
```

In fact, as HIDDEN is one of the two axiomatic files in the MML (the second one is TARSKI, which will be mentioned in the next section), there are no proofs for these properties. The formal language in our examples with MIZAR is pretty close to the every-day language in ordinary mathematics. For precise syntax details, we refer to [1].

## V. Set-theoretic Equality and Its Extensions

If we have primitives for chosen set theory, namely the notion of a set and a primitive set-theoretic membership predicate $\in$, we can express the equality of sets in terms of $\in$ and logical connectives (including quantifiers). Clasically, it is done via extensionality.

$$\forall_X \forall_Y (X = Y \Leftrightarrow (\forall_x (x \in X \Leftrightarrow x \in Y)))$$

```
theorem :: TARSKI:2 :: Extensionality
  (for x being object holds
    x in X iff x in Y) implies
      X = Y;
```

The implication in the opposite direction is provided by the implementation of the system. But obviously, this equality predicate is by no means *new* one. Of course, the above theorem can be read as the form of Leibniz's Law.

Although the notion of the equality of objects is quite concrete, its specific realizations are strongly dependent on how the object is mathematically defined. An illustrative example could be the notion of a rough set [26] treated formally in [8]. On the one hand, rough sets can be defined as the classes of equivalence with respect to a certain relation (it's really meaningless here that numerous generalizations are described in the literature, and partitions are hardly used nowadays in real-life applications of rough set theory). In such approach, two rough sets are equal if the families of subsets are equal (taken componentwise). Thus, we can define the alternative rough equality as below. It is coherent with the equality of ordered pairs, but not necessarily with families of subsets.

```
definition
  let A be Approximation_Space,
      X, Y be Subset of A;
  pred X _=^ Y means
:: ROUGHS_1:def 16
  LAp X = LAp Y & UAp X = UAp Y;
  reflexivity;
  symmetry;
end;
```

Note that the symbol of the rough equality predicate is not the ordinary =, but _=^ denoting the equality of lower and upper approximations. Earlier, we introduced similar predicates in cases of single approximations only [13], [10].

One can consider another approach, credited to Iwiński [16] – rough sets can be viewed as a pair of approximation operators – the lower and the upper one. Within a fixed approximation space, two sets are equal if both approximations are equal (from the very foundational part we can quote Kuratowski's definition of an ordered pair as

$$(a, b) = \{\{a, b\}, \{a\}\}),$$

but majority of mathematicians explore an usual equality of underlying elements.

Here we only mention that even if rough and fuzzy sets have much in common, the equality of fuzzy sets in MIZAR is not that harmless. Because in MML fuzzy sets are corresponding membership functions, their equality is just set-theoretic equality. For formal approach to fuzzy sets, see [11].

## VI. EQUATIONAL CALCULUS IN MIZAR

Equational calculus is mainly performed by a dedicated module EQUALIZER which computes the congruence closure over the collection of equalities accessible at a given inference, where the congruence closure of a relation $R$ defined on a set $A$ is the minimal *congruence relation* (a relation that is simultaneously reflexive, symmetric, transitive, and compatible) containing the original relation $R$. In other words, $R$ is congruence iff it is an equivalence relation satisfying

$$\forall_{x_1,x_2,y_1,y_2 \in A} (x_1, x_2) \in R \Leftrightarrow (y_1, y_2) \in R.$$

The computed congruence closure is used by the MIZAR CHECKER to detect a possible contradiction and to refute the inference (MIZAR is a disprover; by using a technique similar to adding the negation of the goal to the list of available premises can be observed in line 10 of the Prover9 proof in Section III), which can happen if one of the following cases holds

- there are two premises of the form $P[x]$ and $\neg P[y]$ and $x$, $y$ are congruent, or
- there is a premise of the form $x \neq y$ when $x$, $y$ are congruent;

where two elements $x$ and $y$ are congruent, if the pair $(x, y)$ belongs to the congruence closure.

There are many possible sources of equalities, which can be taken into account during the analysis of a given inference. They can be grouped into the following categories:

- occurring explicitly in a given inference,
- term expansions (`equals`),
- properties,
- term reductions,
- term identifications,
- arithmetic,
- type changing (`reconsider`),
- others, e.g. processing structures.

Some of them are of very basic character (e.g. arithmetic), two last ones are extremely dependent on the MIZAR language specification of objects (in this case, structures and type changing statements), but the remaining five are of very general character, and we can easily remap them with the ordinary human reasoning.

The following is an example of a very basic case of equalities, which are stated in the statement to be proved, e.g.:

```
theorem
  for a,b being Element of INT.Ring
    for c,d being Integer st a = c & b = d
      holds a + b = c + d;
```

In the following section(s), we give examples of equalities for the listed categories, at least for those that are not-so-intuitively clear.

## VII. TERM EXPANSIONS AND TERM REDUCTIONS

There are two MIZAR strategies based on substitutions – they act dually in a sense that one of them increases the length of the formula (measured by the number of characters), the other goes in the opposite direction preventing a little bit from uncontrolled growth of terms.

### A. Expansions

One of the methods for defining new functors can use the following syntax:

```
definition
  let $x_1$ be $\theta_1$, $x_2$ be $\theta_2$, ..., $x_n$ be $\theta_n$;
  func $\otimes(x_1, x_2, \ldots, x_n)$ -> $\theta$ equals :ident:
    $\tau(x_1, x_2, \ldots, x_n)$;
  coherence
  proof
    thus $\tau(x_1, x_2, \ldots, x_n)$ is $\theta$;
  end;
end;
```

which introduces a new functor $\otimes(x_1, x_2, \ldots, x_n)$ which is equal to $\tau(x_1, x_2, \ldots, x_n)$. Such definitions, whenever terms $\otimes(x_1, x_2, \ldots, x_n)$ occur in an inference, allow the VERIFIER to generate equalities

$$\otimes(x_1, x_2, \ldots, x_n) = \tau(x_1, x_2, \ldots, x_n).$$

For example,

```
definition
  let x,y be Complex;
  func x - y -> Complex equals
    x + (-y);
  coherence;
end;
```

causes that all instantiations of terms `x-y` are expanded to `x+(-y)`. As a gain of such expansions, for example, the equality `a-b-c = a+(-b-c)` is a direct consequence of associativity of addition. It holds because the term `a-b` is expanded to the term `a+(-b)`, and the term `a-b-c` is expanded to the term `a-b+(-c)`, and both give `a+(-b)+(-c)`. On the other hand, the term `-b-c` is expanded to the term `-b+(-c)`, which creates the term `a+(-b+(-c))`, that is, the associative form of `a+(-b)+(-c)`. An important feature of this kind of term expansions is that it is "a one-way" expansion, in the sense, that terms $\otimes(x_1, x_2, \ldots, x_n)$ are expanded to $\tau\,(x_1, x_2, \ldots, x_n)$ , but not vice-versa. The reason of such treatment is to avoid ambiguity of expansions and over-expanding terms.

### *B. Term Reductions*

Another method of imposing the EQUALIZER to generate extra equalities based on terms occurring in processed inferences are *term reductions*, presented in [17], with the following syntax:

```
registration
  let $x_1$ be $\theta_1$, $x_2$ be $\theta_2$, ..., $x_n$ be $\theta_n$;
  reduce $\tau_1(x_1, x_2, \ldots, x_n)$ to $\tau_2(x_1, x_2, \ldots, x_n)$;
  reducibility
  proof
    thus $\tau_1(x_1, x_2, \ldots, x_n)$ = $\tau_2(x_1, x_2, \ldots, x_n)$;
  end;
end;
```

Term reductions can be used to simplify terms to their proper parts of terms (sub-terms). This simplification relies on matching terms existing in the processed inference with left-side terms of all accessible reductions, and whenever the EQUALIZER meets an instantiation $\sigma$ of the term $\tau_1(x_1, x_2, \ldots, x_n)$, it makes $\sigma$ equal to its sub-term equivalent to $\tau_2(x_1, x_2, \ldots, x_n)$.

The restriction about simplifying terms to their proper subterms, not to any arbitrarily chosen terms, is to fulfill the general rule established for the system, that the EQUALIZER does not generate extra terms and does not expand the universe of discourse.

An example of a possible reduction could be reducing the first power of a complex number to the number (`c` is a subterm of `c|^1`).

example

```
registration
  let c be Complex;
  reduce c|^1 to c;
  reducibility;
end;
```

Reducing the zero power of a number to one is not allowed (`1` is not a sub-term of `c|^0`) – as in the source code below – as a result the following error will be output in a comment (“`::`” starts a comment).

prohibited use of a reduction

```
registration
  let c be Complex;
  reduce c|^0 to 1;
::>        *257
  reducibility;
end;

::> 257: Right term must be
::>      a sub-term of the left term
```

Reductions are recently implemented and their impact on the library is not very big yet. First of all, we can imagine even very complicated reductions, which can be useful in very exceptional cases. The main aim is to reflect human reasoning rather than to force unusual calculations, even if they are straightforward for the machine.

## VIII. PROPERTIES

*Properties* in MIZAR are special formulas, which can be registered while defining functors, see [1], [23]. MIZAR supports `involutiveness` and `projectivity`, for unary operations, and `commutativity` and `idempotence`, for binary operations. If a property is registered for some functor, the EQUALIZER processes appropriate equalities adequate to the property, where for `involutiveness` the equality is

$$f(f(x)) = x,$$

for `projectivity` it is

$$f(f(x)) = f(x),$$

for `commutativity` it is

$$f(x, y) = f(y, x),$$

and for `idempotence`

$$f(x, x) = x.$$

## IX. TERM IDENTIFICATIONS

In mathematics, there are different theories, which at some of their parts are about the same objects. For example, when one considers complex numbers and extended real numbers (reals augmented by $+\infty$ and $-\infty$) and discusses basic operations on such numbers (like addition, subtraction, etc.), it can be quickly recognized that if the numbers are reals, the results of these operations are equal to each other. That is, there is no difference, if one adds reals in the sense of complex numbers or in the sense of extended real numbers. Therefore, pairs of such operations could be identified on appropriate sets of arguments.

MIZAR provides a special construction for such identifications [4] with syntax:

```
registration
  let $x_1$ be $\theta_1$, $x_2$ be $\theta_2$, ..., $x_n$ be $\theta_n$;
  let $y_1$ be $\Xi_1$, $y_2$ be $\Xi_2$, ..., $y_n$ be $\Xi_n$;
  identify $\tau_1(x_1, x_2, \ldots, x_n)$ with $\tau_2(y_1, y_2, \ldots, y_n)$
   when $x_1$ = $y_1$, $x_2$ = $y_2$, ..., $x_n$ = $y_n$;
  compatibility
  proof
   thus $x_1$ = $y_1$ & $x_2$ = $y_2$ & ... & $x_n$ = $y_n$
     implies $\tau_1(x_1, x_2, \ldots, x_n)$ = $\tau_2(y_1, y_2, \ldots, y_n)$;
  end;
end;
```

and, whenever the EQUALIZER meets an instantiation $\sigma$ of the term $\tau_1(x_1, x_2, \ldots, x_n)$, it makes $\sigma$ equal to the appropriate instantiation of $\tau_2(y_1, y_2, \ldots, y_n)$. A gain of using such identifications is that all facts proven about $\tau_2(y_1, y_2, \ldots, y_n)$ are applicable for $\tau_1(x_1, x_2, \ldots, x_n)$, as well.

An example of identification taken from the MIZAR MATHEMATICAL LIBRARY could be the lattice of real numbers with operations `min`, `max` as the infimum and supremum, respectively, of two elements of the lattice, see [5].

```
registration
  let a,b be Element of Real_Lattice;
  identify a "\/" b with max(a,b);
  compatibility;
  identify a "/\" b with min(a,b);
  compatibility;
end;
```

By having such identifications declared, i.e., registered, as `registration`, reasonings about the lattice operations can automatically use facts about real numbers. For example, the associativity of the supremum is a direct consequence of the associativity of the maximum: `max(max(a,b),c) = max(a,max(b,c))`

A less obvious example of such term identifications is connection of lower and upper approximations of rough sets with the topological interior and topological closure, respectively, see [12]. The problem is that the topological closure coincides with the notion of the upper approximation (both possess Kuratowski closure's properties), but topological spaces and approximation spaces are formally distinct structures. We can lift both into some other common one.

```
registration
  let T be with_equivalence
    naturally_generated non empty TopRelStr;
  let A be Subset of T;
  identify LAp A with Int A;
  identify UAp A with Cl A;
end;
```

The latter registration would allow for mixed use of the lower approximation instead of interior operator and vice versa. Here the mathematician's understanding of the identification is as isomorphism (or an analogon) instead of equality.

## X. BUILT-IN COMPUTATIONS

Another source of equalities processed by the EQUALIZER are special built-in procedures for processing selected objects. Generating equalities by these routines is controlled by the environment directive **requirements**, see [23]. In our interest are two procedures dealing with boolean operations on sets (`BOOLE`) and basic arithmetic operations on complex numbers (`ARITHM`).

### *A. Requirements `BOOLE`*

```
X \/ {} = X;    X /\ {} = {};    X \ {} = X;
{} \ X = {};    X \+\ {} = X;
```

### *B. Requirements `ARITHM`*

```
x + 0 = x;    x * 0 = 0;    1 * x = x;
x - 0 = x;    0 / x = 0;    x / 1 = x;
```

Moreover, requirements `ARITHM` provides procedures for solving systems of linear equations over complex numbers.

## XI. TYPE CHANGING STATEMENTS

It is quite common situation, when one object can be treated as an element of different theories or different structures. For example, the empty set is the empty set in set theories, but it is also the zero number is some arithmetics. In computerized mathematics, to allow systems to distinguish and understand symbols clearly and to avoid ambiguity, it is often required to express types of objects explicitly.

MIZAR provides a special rule (**reconsider**) for forcing the system to treat a given term as if its type was the one stated.

For example, to consider the number 0 as an element of the field of real numbers (for example, to prove that it is the neutral element of its additive group), one can state

```
  reconsider z = 0 as Element of F_Real;
```

The equality `z = 0` is obviously processed by the EQUALIZER.

## XII. EXAMPLE WITH AUTOMATIZATION

In this section we present an example how all described above techniques can automatize reasoning and make proofs shorter or even make theorems obvious. The working example (about elements of the additive group of real numbers `G_Real`) with all automatizations switched-off and all basic proof steps written within the proof is as follows:

```
theorem
  for a being Element of G_Real holds
    a + 0.G_Real = a
  proof
    let a be Element of G_Real;
    reconsider x = a as Real;
B:  0 in REAL by XREAL_0:def 1;
A:  0.G_Real = the ZeroF of G_Real
                by STRUCT_0:def 6
      .= In(0,REAL) by VECTSP_1:def 1
      .= 0 by B,SUBSET_1:def 8;
    thus a + 0.G_Real
      = (the addF of G_Real).(a,0.G_Real)
                by ALGSTR_0:def 1
     .= addreal.(a,0.G_Real) by VECTSP_1:def 1
     .= x + 0 by A,BINOP_2:def 9
     .= x by ARITHM:1
     .= a;
  end;
```

while the theorem is obvious when all provided mechanism are utilized.

The equality

```
  a + 0.G_Real =
    (the addF of G_Real).(a,0.G_Real);
```

is a consequence of the "equals" expansion of the definition:

```
definition
  let M be addMagma;
  let a,b be Element of M;
  func a+b -> Element of M equals
:: ALGSTR_0:def 1
  (the addF of M).(a,b);
end;
```

The equality `a + 0.G_Real = x + 0` is a consequence of the equality `x = a` (reconsider), the equality `0.G_Real = 0` and the term identification:

```
registration
  let a,b be Element of G_Real, x,y be Real;
  identify a+b with x+y
  when a = x, b = y;
  compatibility by BINOP_2:def 9;
end;
```

The equality `0.G_Real = 0` is a consequence of the "equals" expansion of the definition:

```
definition
  let S be ZeroStr;
  func 0.S -> Element of S equals
:: STRUCT_0:def 6
  the ZeroF of S;
end;
```

and the "equals" expansion of the definition:

```
definition
  func G_Real -> strict addLoopStr equals
:: VECTSP_1:def 1
  addLoopStr (# REAL,addreal,In(0,REAL) #);
end;
```

and the term reduction:

```
registration
  let r be Real;
  reduce In(r,REAL) to r;
  reducibility;
end;
```

The equality `x + 0 = x` is a consequence of built-in calculations over complex numbers. Finally, the equality `x = a` is a trivial consequence of the "reconsider".

What is especially useful, the distribution of MIZAR contains programs which detect if the reference (or the proof step) is really necessary for the checker. Alternatively, we can test by brute force if the construction is useful in a specific case: adding an environment directive to the preamble of the article [25] and call the cleaning utilities; if no changes will be done, the directive is deleted. Of course, there is no need to add all directives to all articles (some of them can be just from another area of mathematics), note also that even useful constructions, say expansions, can significantly slown down the proof checking by expanding the universe of discourse.

An illustrating example was the splitting of the equality of sets into two inclusions: it is useful, but even if, according to the von Neumann construction, all natural numbers are sets, the expansion of the equality of numbers into two inclusions isn't especially feasible (even if mathematically reasonable, but who would prove inclusions like $2 \subseteq 3$, perhaps besides the person interested in the arithmetic of ordinals?).

Every MIZAR article contains a preamble with the list of files from MML which will be used. There are 10 keywords for that (and respectively, 10 environment directives). We focus only on those tightly connected with our paper, mainly of three items:

- registrations, responsible for various registrations of clusters, including reductions and identifications;
- equalities, which allow to expand definitions given by `equals`;
- requirements, which turn on (mainly arithmetical or set-theoretic) calculations.

With all the automatics switched on, one can obtain the formula from the third section

```
a "\/" a = a;
```

as a result of declared reduction (or alternatively, the `idempotence` property). This however cannot be enough for a human user who wants to see what is really going on here, i.e.:

```
a "\/" a = (a "/\" (a "\/" a)) "\/" a
                              by LATTICES:def 9
        .= a by LATTICES:def 8;
```

where both definitions are actually axioms – the absorption laws defined in the form of attributes.

Of course, the equality can be introduced in a non-explicit way as in the examples of problems of purely equational character. Remember that one can, apart from the above considerations, register the following cluster:

```
registration
  let X be set;
  cluster X \ X -> empty;
  coherence;
end;
```

which is effectively equivalent to

```
  X \ X = {};
```

adding it automatically as one of the premises to every inference where applicable. Remember that in order to assure the needed identification, one should not use the reduction ($\emptyset$ is not a sub-term of `X \ X`).

```
registration
  let T be TopSpace,
      A be 1st_class Subset of T;
  cluster Border A -> empty;
end;
```

To quote less straightforward example, in the area of rough sets (expressed in Isomichi style) it can be the identification of first class subsets with crisp sets, consequently their borders are the empty sets as the set-theoretic difference $A \setminus A$. The explanation and the details of the corresponding implementation of rough sets can be found in [13].

## XIII. Some Statistics

We illustrate our discussion by the number of concrete constructions used within the MML by Table I.

Table II shows how often selected properties are declared (and proved) in MML. The numbers however can be more or less accidental: authors can just omit a property when developing some theories, and can state it in a form of explicit formula, or just the proof of it can be too complex. In Table

Table I
OCCURRENCES OF BASIC CONSTRUCTIONS IN MML

| Construction | keyword | occurrences |
|---|---|---|
| type changing statements | `reconsider` | 66115 |
| equalities | `equals` | 3678 |
| identifications | `identify` | 172 |
| reductions | `reduce` | 139 |

Table II
OCCURRENCES OF PROPERTIES IN MML

| Property | occurrences |
|---|---|
| `commutativity` | 150 |
| `idempotence` | 18 |
| `involutiveness` | 36 |
| `projectivity` | 20 |

III, we listed how many times in MIZAR articles (among 1240 in total in the whole MML) selected properties were used. We have chosen among three areas: basic set theory, arithmetic of complex numbers, and some properties of pairs. Even if MML is based on ZFC set theory, the calculations are used very extensively.

Here we can point out the scale we refer to. There are about 11 thousand definitions and 55 thousand theorems proven in MML. This is contained among 2 million lines of code (about 90 MB of mathematical texts). One can ask a question why the commutativity of the set-theoretic union is used less often than that of set-theoretic intersection. Similar (although dual) issue with arithmetic is clear: the complex addition is just used more frequently. Symmetric difference $X \dot{-} Y$ is just of marginal interest and, which can be also a kind of explanation after deeper research, it is defined as equal to the combination of the other operations, namely $X \dot{-} Y = (X \setminus Y) \cup (Y \setminus X)$, where the commutativity of $\cup$ (understood automatically) can do some useful work.

## XIV. VARIOUS MATHEMATICAL EQUALITIES

Equality in mathematics has many facings; of course there are the usual identities $x = y$, such as for example $2+1 = 3$ or $(x+1)^2 = x^2+2x+1$. Note however, that even in these cases equality depends on the domain we are working in: $2+1 = 3$ is true in $\mathbb{Z}$ but not in $\mathbb{Z}_2$. The second equation can be seen as an equation between (real) numbers or between polynomials (not necessarily) over the real numbers.

Table III
THE NUMBER OF CONCRETE USES OF PROPERTIES

| Property | No. of Mizar articles | No. of implicit uses |
|---|---|---|
| $X \cup Y = Y \cup X$ | 483 | 4721 |
| $X \cap Y = Y \cap X$ | 547 | 6232 |
| $X \dot{-} Y = Y \dot{-} X$ | 7 | 57 |
| $a + b = b + a$ | 670 | 9548 |
| $ab = ba$ | 429 | 5734 |
| $\{x, y\} = \{y, x\}$ | 118 | 857 |

There are other kinds of equality. Among the most important ones is identifying objects of a given structure with respect to a certain property. Formally, this is described by an equivalence relation $r$, for example $r_p(x, y)$, if $x$ and $y$ are integers such that $x$ mod $p$ = $y$ mod $p$. This in particular is applied when, for example, constructing $\mathbb{Z}_p$, the integers modulo $p$: All integers leaving the same remainder when dividing them by $p$ are identified using the equivalence relation $r_p$. Formally, equivalence classes with respect to $r_p$ are built, and these are the elements of $\mathbb{Z}_p$ – on which the usual operations are defined. Using this construction $\mathbb{Z}_p$ does not contain any numbers, this is later achieved by "identifying an equivalence class with a number", so that $\mathbb{Z}_p = \{0, 1, \ldots, p-1\}$ is used. Note, however, that this formally also means "changing the operations of $\mathbb{Z}_p$ appropriately" to match with elements of $\{0, 1, \ldots, p-1\}$.

In some sense this last step – going from equivalence classes to non-negative integers smaller than $p$ – can be seen as changing the representation of the integers modulo $p$. In fact it does not matter whether we consider $\mathbb{Z}_p$ as a set of equivalence classes or as $\{0, 1, \ldots, p-1\}$. Aside from the names of the objects, the two structures are the same: The objects behave the same way, that is, the effect of the operations is identical.

This in fact is the most important kind of mathematical equality: The two structures are isomorphic, that is there exists a (bijective) function $i$ from $\mathbb{Z}_p$ to $\{0, 1, \ldots, p-1\}$ respecting the domain's operations, i.e. $i(x+y) = i(x) + i(y)$, and similarly for all other operations of $\mathbb{Z}_p$. From a mathematical point of view, this completely defines an equality in the sense of the first section: Properties discovered for one of the structures automatically carry over to the other one. In a proof-assistant, this however is not that obvious. First of all, both structures must have been constructed in the prover to describe the isomorphism. This is not always the case and is often technical and tedious, or impossible. Moreover, by having a property/theorem for one of the isomorphic structures, usually some work remains to be done in order to have the same property/theorem for the other one. For example $\mathbb{Z}_p$ is a field, if $p$ is prime. Proved in one of the isomorphic structures, carrying it over to the other one requires to translate the property with the help of the isomorphism $i$. Here of course the theorem that $i(x*y) = i(x)*i(y)$, where $y$ is the inverse of $x$ does the trick. The interesting discussion from the category theorist's point of view is given in [19].

Observe that our discussion here is not in contradiction with the Leibniz's Law mentioned at the beginning of our paper. Such an identity of indiscernibles does not coincide with equality via isomorphisms. For example, a field is prime, if it does not have any proper subfield. One could now expect that two isomorphic fields are either both prime or not. This, however, is not the case as the isomorphic fields $K(X)$ and $K(X^2)$ show. We will therefore mostly deal with equality via isomorphisms.

## XV. Data Structure Equality

From a computer scientist's view, the equality is not that easy as Leibniz's Law could suggest. Almost immediately one observes that, e.g. in a programming language, it is quite a difference whether the objects to be equal are just plain numbers or more structured objects such as arrays or trees. For short, equality, and consequently its handling, heavily depends on the object's types. In programming languages, of course, there exist a number of techniques allowing users to exactly define equality of objects of a given type, e.g. via type classes in Haskell [32]. In general, intelligent systems should be able to handle equalities of different kinds, even delivered by external tools [24].

Proof assistants dealing with the notion of a mathematical proof, therefore, should provide means for equalities occurring in mathematics. In mathematics, however, the notion of equality is much more elaborated. To give an easy example, two functions $f$ and $g$ are equal if their domain $D$ and codomain $C$ are equal, and if $f(x) = g(x)$, for all $x \in D$. Of course, this apparent incoherence can be easily explained considering natural hierarchy of notions many mathematicians don't use in their proofs. For example, in typical set-theoretic approaches, functions are just binary relations of a special type, and relations are subsets of the Cartesian product, which is a set of corresponding ordered pairs. Here equality takes into account not only two/four additional sets, but also equality of a – possibly infinite – number of objects of another type.

When it comes to structures, such as e.g. groups, fields or topologies, equality becomes even more sophisticated. This is not only due to the growing complexity of the objects; mathematicians have developed a special style of informal handling with various kinds of equality. The point is that, in proof assistants, each kind of equality between objects of a given type has to be formally defined, in order to prove that two objects of that type are equal.

## XVI. Isomorphisms and Inclusions

For a given field $F$, one can build the ring of polynomials $F[X]$. Actually, while the construction applies to arbitrary rings, our formalization work, however, concentrates on field theory, so we restrict ourselves to fields here. Elements of $F[X]$ – polynomials over $F$ – are basically functions from the natural numbers into $F$, hence obviously different from elements of $F$. Consequently, $F \subseteq F[X]$ cannot hold from a formal point of view. In particular one cannot prove this with the ordinary definition of $\subseteq$. Even if this would be possible, note that $F \subseteq F[X]$ here means not that $F$ is a subset of $F[X]$, but that $F$ is a subfield of $F[X]$, that is addition and multiplication of $F[X]$ are taken into account. Nevertheless, [35] states the following

> *We regard $F \subseteq F[X]$ by identifying the element $a \in F$ with the constant polynomial $a \in F[X]$, and observe that under this identification the units of $F[X]$ are precisely the nonzero elements of $F$.*

What is hidden in this statement, is the application of a mapping $i$ sending an element $a \in F$ to the constant polynomial $p(X) = a$. The mapping $i$ is an isomorphism between $F$ and its $i$-image in $F[X]$ (which is a subfield of $F[X]$). Thus, identifying $a$ with $a(x)$ actually means replacing the image of $i$ with $F$, which then formally gives an isomorphic copy $C$ of $F$ under the isomorphism $i$, such that $C \subseteq F[X]$:

```
theorem
  for F being Field
   ex R being Ring st
     R, Polynom-Ring F are_isomorphic &
       F is a Subfield of R;
```

and

```
theorem
  for F being Field,
      a being Element of F holds
    a|F is Unit of Polynom-Ring F
      iff a is non zero;
```

This is nice and handy, because it allows to work with the easier objects of $F$ when appropriate. In a proof assistant, however, it gives rise to quite a number of additional work and theorems: one has to define $i$.

Working with polynomials, however, is not the same in isomorphic polynomial rings, even if we restrict ourselves to polynomial rings over isomorphic fields. One has to apply the isomorphism $i$ to translate from one into the other. Note, that formally $i \circ p$ is an extension of $i$ transforming $p \in F[X]$ into a polynomial over $E$, that is $i$ is applied to all of $p$'s coefficients:

```
theorem
  for F, E being Field,
      p being Polynomial of F,
      x being Element of F,
      i being Isomorphism of F,E holds
    i(p(x)) = (i p)(i x);

theorem
  for F, E being Field,
      p being Polynomial of F,
      x being Element of F,
      i being Isomorphism of F,E holds
    p(x) = 0.F iff (i p)(i x) = 0.E;
```

Things can get even worse. The quotient field $F[X]/<p(X)>$, for a irreducible polynomial $p$, formally consists of equivalence classes $[q(X)]_{<p(X)>}$, where $q(X) \in F[X]$ – this is the field in which $p(X)$ has a root. However, in [35], after showing that $F[X]/<p(X)>$ is a field, the author states:

> *... to give an explicit description of the field $E = F[X]/<p(X)>$. Let $p(X) \in F[X]$ be an irreducible polynomial of degree $n$, $p(X) = a_nX^n + \cdots + a_0$. By taking representatives of equivalence classes we may regard*
>
> $$E = \{g(X) \in F[X] \mid deg\ g(X) < n\}$$
>
> *as a set. Addition in $E$ is the usual addition of polynomials, while multiplication in $E$ ...*

Actually, this means only that $E$ with the new defined operations is isomorphic to $F[X]/{<}p(X){>}$. Afterwards, the following consequence is drawn in [35]:

> *If $\pi : F[X] \longrightarrow F[X]/{<}p(X){>}$ is the canonical projection, then $\pi|_F$ is an injection, and using this we also regard $F \subseteq F[X]/{<}p(X){>}$.*

## XVII. Conclusion

Even if mathematicians have developed and used some human "mechanisms of obviousness", for hundreds of years, new technologies impose the need for new standards. Computerized systems should undoubtfully deliver the answers of some human questions and to construct models, which cannot be created by hand in a reasonable time – this is the testbed for computer algebra systems and model finders. Proof assistants, in order not to break human standards, should however support the traditional way of thinking, so there is a place for finding a reasonable balance between writability and readability of the source code, as we believe the Mizar system can deliver. We hope that we convinced the reader that the problem of the equality treatment is harder than it looks like at the very first sight, and if automated proof-assistants are taken into account, we should take care on something more than what we called absolute equality – Davenport's data structure equality.

***Abstract*—Cognitive radio (CR) technology has emerged as a promising solution to many wireless communication problems including spectrum scarcity and underutilization. To enhance the selection of channel with less noise among the white spaces (idle channels), the a priory knowledge of Radio Frequency (RF) power is very important. Computational Intelligence (CI) techniques cans be applied to these scenarios to predict the required RF power in the available channels to achieve optimum Quality of Service (QoS). In this paper, we developed a time domain based optimized Artificial Neural Network (ANN) and Support Vector Regression (SVR) models for the prediction of real world RF power within the GSM 900, Very High Frequency (VHF) and Ultra High Frequency (UHF) FM and TV bands. Sensitivity analysis was used to reduce the input vector of the prediction models. The inputs of the ANN and SVR consist of only time domain data and past RF power without using any RF power related parameters, thus forming a nonlinear time series prediction model. The application of the models produced was found to increase the robustness of CR applications, specifically where the CR had no prior knowledge of the RF power related parameters such as signal to noise ratio, bandwidth and bit error rate. Since CR are embedded communication devices with memory constrain limitation, the models used, implemented a novel and innovative initial weight optimization of the ANN's through the use of compact differential evolutionary (cDE) algorithm variants which are memory efficient. This was found to enhance the accuracy and generalization of the ANN model.**

***Index Terms*—Cognitive Radio; Primary User; Artificial Neural Network; Support Vector Machine; Compact Differential Evolution; RF Power; Prediction.**

## I. Introduction

DUE TO the current static spectrum allocation policy, most of the licensed radio spectrum are not maximally utilized and often free (idle) while the unlicensed spectrum are overcrowded. Hence the current spectrum scarcity is the direct consequence of static spectrum allocation policy and not the fundamental lack of spectrum. The first bands to be approved for CR communication by the US Federal Communication Commission (FCC) because of their gross underutilization in time, frequency and spatial domain are the very high frequency and ultra-high frequency (VHF/UHF) TV bands [1] [2] [3]. In this paper, we focused on the study of real world RF power distribution in some selected channels (54MHz to 110MHz, 470MHz to 670MHz, 890MHz to 908.3MHz GSM up-link, 935MHz to 953.3MHz GSM down-link) within the VHF/UHF bands, FM band, and the GSM 900 band. The problem of spectrum scarcity and underutilization, can be minimized by adopting a new paradigm of wireless communication scheme. Advanced Cognitive Radio (CR) network or Adaptive Spectrum Sharing (ASS) is one of the ways to optimize our wireless communications technologies for high data rates in a dynamic environment while maintaining user desired quality of service (QoS) requirements. CR is a radio equipped with the capability of awareness, perception, adaptation and learning of its radio frequency (RF) environment [4]. CR is an intelligent radio where many of the digital signal processing that were traditionally done in static hardware are implemented via software. Irrespective of the definition of CR, it has the followings basic features: observation, adaptability and intelligence. CR is the key enabling tool for dynamic spectrum access and a promising solution for the present problem of spectrum scarcity and underutilization. Cognitive radio network is made up of two users i.e. the license owners called the primary users (PU) who are the incumbent legitimate owners of the spectrum and the cognitive radio commonly called the secondary users (SU) who intelligently and opportunistically access the unused licensed spectrum based on some agreed conditions. CR access to licensed spectrum is subject to two constrains i.e on no interference base, this implies that CR can use the licensed spectrum only when the licensed owners are not using the channel (the overlay CR scheme). The second constrain is on the transmitted power, in this case, SU can coexist with the PU as long as the interference to the PU is below a given threshold which will not be harmful to the PU nor degrade the QoS requirements of the PU (the underlay CR network scheme) [5] [1]. There are four major steps involved in cognitive radio network, these are: spectrum sensing, spectrum decision, spectrum sharing, and spectrum mobility [6] [7].

978-83-60810-66-8/$25.00©2015, IEEE

In spectrum sensing, the CR senses the PU spectrum using either energy detector, cyclostationary features detector, cooperative sensing, match filter detector, eigenvalue detector, etc to sense the occupancy status of the PU [8]. Based on the sensing results, the CR will take a decision using a binary classifier to classify the PU channels (spectrum) as either busy or idle there by identifying the white spaces (spectrum holes or idle channels). Spectrum sharing deals with efficient allocation of the available white spaces to the CR (SU) within a given geographical location at a given period of time while spectrum mobility is the ability of the CR to vacate the channels when the PU reclaimed ownership of the channel and search for another spectrum hole to communicate. During the withdrawal or search period, the CR should maintain seamless communication. Many wireless broadband devices ranging from simple communication to complex systems automation, are deployed daily with increasing demand for more, this calls for optimum utilization of the limited spectrum resources via CR paradigm. Future wireless communication device should be enhanced with cognitive capability for optimum spectrum utilization. CRs are embedded wireless communication devices with limited memory, thus in this paper, we utilized the power of compact differential evolutionary (cDE) algorithm which is memory efficient, to develop an optimized ANN and SVR model for the prediction of real world radio frequency (RF) power. RF power traffics is a function of time, geographical location (longitude and latitude), height above the sea level (altitude) and the frequency or channels properties. Since our experiment is conducted at a fixed geographical location and at constant height, the inputs of the ANN and SVR consist of only past RF power samples, current time domain information and frequency (channel) while the output is the predicted current RF power in decibel (dB) (i.e. the current RF power is modelled as a function of time, frequency and past RF power samples) hence forming a nonlinear time series prediction model. ANN and SVR models were adopted because of the dynamic nonlinearity often associated with RF traffic pattern, coupled with random interfering signals or noise resulting from both artificial and natural sources. The use of sensitivity analysis as detailed in Section VIII for the determination of the optimum number of past recent RF power samples to be used as part of the input of the ANN or SVR for prediction of current RF power, results into a more compact, robust, accurate, and well generalized models. The proposed algorithm used a priori data to enable the system to avoid noisy channels. The prior knowledge of the RF power allowed the cognitive radio to predictively select channels with the least noise among those that were unused or free. This would allow for a reduced utilization of radio resources including transmitted power, bandwidth, and in turn maximizing the usage of the limited spectrum resources. The data used in this study was obtained by capturing real world RF data for two months using Universal Software Radio Peripheral 1 (USRP 1). The digital signal processing and capturing of the data were done using gnuradio which is a combination of Python for scripting and C++ for signal processing blocks; while the models design and prediction were done in Matlab. The experiment was conducted at Centre for Computational Intelligence, De Montfort University, UK, located very close to Leicester city centre.

Many prediction models used in CR radio uses known RF related parameters as their inputs of which licensed owners will not be willing to dispose such information to CR users. Some of the models are based on explicit mathematical model which may be different from real world situation as highlighted in Section II. Some of the prediction models aim at prediction of spectrum holes, but the fact that spectrum holes (vacant channels) are known does not depict any information about the best channel to be used among the idle channels as the noise level is not flat for all the channels. Thus the major contribution of our model is that it can be used for Rf power prediction where the CR has no prior knowledge of any RF power related parameter. This will enable the CR to avoid noisy channels. The model is trained and tested using real world data. Also instead of training the ANN using back propagation algorithms (BPA) which often lack optimality due to premature convergent, the weights of the ANN are initially evolves using cDE and then fine tune using BPA, this was found to produce a more accurate and generalized model as compared with the one trained using only BPA. SVR was also examined using different kernels and we come up with the model that is more appropriate for our studied location.

The rest of this paper is consist of the following sections. Section II consist of previously presented related research in this field. This will be followed by Section III and Section V, that gives brief description of neural network and the optimization algorithms implemented. Experimental details are discussed in Section VII. The paper is concluded with Section IX, which discusses the results of the experiments, Section X gives the summary of the findings.

## II. Related Work

There are different types and variants of Computational Intelligence (CI) and machine learning algorithms that can be used in CR such as genetic algorithms for optimization of transmission parameters [9], swarm intelligence for optimization of radio resource allocation [10], fuzzy logic system (FLS) for decision making [11] [12], neural network and hidden Markov model for prediction of spectrum holes; game theory, linear regression and linear predictors for spectrum occupancy prediction [13] , Bayesian inference based predictors, etc. Some of the CI methods are used for learning and prediction, some for optimization of certain transmission parameters while others for decision making [14]. TV idle channels prediction using ANN was proposed in [15], however, data were collected only for two hours everyday day (5pm to 7pm) within a period of four weeks, this is not sufficient to capture all the various trends associated with TV broadcast. Also, identifying the idle channels does not depict any spatial or temporal information of the expected noise and/ or level of interference based on the channels history which is vital in selecting the channels to be used among the idle channels. Spectrum hole prediction using Elman recurrent artificial neural network (ERANN) was proposed in [16]. It uses the cyclostationary features of modulated signals to determine the presence or absence of primary signals while the input of the ERANN consists of time instances. The inputs and the target output used in the training of the ERANN and prediction were modelled using ideal multivariate time series equations, which are often different from real life RF traffics where PU signals can be embedded in noise and/ or interfering signals. Traffic pattern prediction using seasonal autoregressive integrated moving-average (SARIMA) was proposed for reduction of CRs hopping rate and interference effects on PU while maintaining a fare blocking rate [17]. The model (SARIMA) does not depict any information about the expected noise power.

Fuzzy logic (FL) is a CI method that can capture and represent uncertainty. As a result it has been used in CR research for decision making processes. In [11] an FL based decision-making system with a learning mechanism was developed for selection of optimum spectrum sensing techniques for a given band. Among these techniques are matched filtering, correlation detection, features detection, energy detection, and cooperative sensing. Adaptive neural fuzzy inference system (ANFIS) was used for prediction of transmission rate [18]. This model was designed to predict the data rate (6, 12, 24, 36, 48 and 54 Mbps) that can be achieved in wireless local area network (WLAN) using a 802.11a/g configuration as a function of time. The training data set was obtained by generating a random data rate with an assigned probability of occurrence at a given time instance, thus forming a time series. In this study, real world RF data wasn't used. More importantly, the research did not take into account the dynamic nature of noise or interference level which can affect the predicted data rates. Semi Markov model (SMM) and continuous-time Markov chain (CTMC) models have also been used for the prediction of packet transmission rates [19]. This avoids packet collisions through spectrum sensing and prediction of temporal WLAN activities combined with hoping to a temporary idle channel. However, SMM are not memory efficient, neither was there any reference made to the expected noise level among the inactive (idle) channels to be selected. An FL based decision system was modeled for spectrum hand-off decision-making in a context characterized by uncertain and heterogeneous information [12] and fuzzy logic transmit power control for cognitive radio. The proposed system was used for the minimization of interference to PU's while ensuring the transmission rate and quality of service requirements of secondary users [20]. The researcher did not, however, include any learning from past experience or historical data. An exponential moving average (EMA) spectrum sensing using energy prediction was implemented in [21]. The EMA achieved a prediction average mean square error (MSE) of 0.2436 with the assumption that the channel utilization follow exponential distribution with rate parameter $\lambda = 0.2$ and signal to noise (SNR) of 10dB; RF real world data was not used in their study. Within this paper we demonstrate the use of SVR and an ANN trained using cDE for prediction of real world RF power of selected channels within the GSM band, VHF and UHF bands. An optimized ANN model was produced by combining the global search capabilities of cDE algorithm variants and the local search advantages of back-propagation algorithms (BPA). The initial weights of the ANN were evolved using cDE after which the ANN was trained (fine tune) more accurately using back-propagation algorithms. This methodology demonstrates the application of previously acquired real world data to enhance the prediction of RF power to assist the implementation of CR applications. The meta parameters that govern the accuracy and generalization SVR model were evolves using cDE.

## III. Artificial Neural Network

Artificial Neural Networks (ANN) are composed of simple elements operating in parallel. These elements are inspired by biological nervous systems [22], [23]. Due to the dynamic nonlinearity often associated with RF traffic pattern, coupled with random interfering signals or noise resulting from both artificial and natural sources, a fully connected multilayer perceptron (MLP) ANN with two hidden layers was used in this study. The input layer was cast into a high dimensional first hidden layer for proper features selection. The activation functions used in the two hidden layers are nonlinear hyperbolic tangent functions (1), and a linear symmetric straight line (2) is used for the output activation function. Implementation with other activation functions were also adopted, but this choice gave a better promising results. The nonlinear hyperbolic tangent functions introduced a nonlinear transformation into the network. The hidden layers serve as a feature detector i.e. during the training; they learn the salient attributes (features) that characterizes the training data. The ANN is trained using compact differential evolutionary algorithms variants after which the weights are further fine tuned using backpropagation algorithm (BPA). The training objective function is the minimization of the mean square error (MSE) i.e. the synaptic weights and biases were updated every epoch to minimize the MSE. A supervised batch training method was used with 60% of the data used for training the ANN, 20% for validation and 20% for testing the trained ANN. In this study, the back propagation algorithm is used as a local searcher, thus the learning rate was kept low at 0.01. The inputs of the ANN consist of seven past recent RF power, and time domain data of varying rates of change i.e. second, minute, hour, week day (1 to 7), date day (1 to at most 31), week in a month (1 to 5), and month while the output gives the power in Decibels (dB). Each input of the time domain, enables the ANN to keep track with the trend of RF power variation as a function of that particular input. The current RF power is modelled as a nonlinear function of recent past RF power samples and current time, thus forming a nonlinear time series model. The number of past samples to be used (in this study 7) for reliable prediction and efficient memory management was obtained experimentally as detailed in Section VIII. The actual past RF power (not the predicted RF power) samples fed at the input of the ANN, coupled with the long time training information captured via the time domain inputs, results in a robust ANN model that adapt well to the present trend of RF power variation. In this paper we designed three ANN models. The first model is shown in Fig 1; it consists of only one output neuron and is dedicated for RF power prediction of only one channel which implies that each channel will have its own dedicated ANN. To circumvent this problem, we designed two models for RF power prediction in multiple channels. The second model depicted in Fig 2 is used for prediction of RF power in many channels (for this study is 20 channels) but one at a time. It has only one output neuron, but in addition to the time and past RF power samples inputs, it has another inputs representing the channels. The output neurons of the third (parallel) model is equal to the number of channels to be considered Fig 3. The parallel model is used for simultaneous prediction of RF power in multiple channels given the current time instant and past RF power samples as inputs. For the parallel model, if 7 recent past samples of each of the channels were used as distinct feedback inputs, there will be a total of $7N$ feedback inputs; where $N$ is the number of channels Fig 3; and the training will be computationally expensive. These large feedback inputs ware reduced to 7 by using their average.The data used in this study were obtained by capturing real world RF signals within the GSM 900, VHF and UHV TV and FM bands for a period of two months. In all the models, no RF power related parameters such as signal to noise ratio (SNR), bandwidth, and modulation type, are used as the input of the ANN. Thus making the models robust for cognitive radio application where the CR has no prior knowledge of these RF power related parameters.

Artificial neural network architecture can be broadly classified as either feed forward or recurrent type [22]. Each of these two classes can be structured in different configurations. A feed forward network is one in which the output of one layer is connected to input of the next layer via a synaptic weight, while the recurrent type may have at least one feedback connection or connections between neurons within the same layer or other layers depending on the topology (architecture). The training time of the feed forward is less compared to that of the recurrent type but the recurrent type has better memory capability for recalling past events. Four ANN topologies were considered: feed forward (FF), cascaded feed forward (CFF), feed forward with output feedback (FFB), and layered recurrent (LR) ANN.

The accuracy and level of generalization of ANN depend largely on the initial weights and biases, learning rate, momentum constant,training data and also the network topology. In this paper, the learning rate and the momentum were kept constant at 0.01 and 0.008 respectively while the initial weights and biases were evolved using compact differential evolutionary algorithm variants. The first generation initial weights and biases were randomly generated and constrained within the decision space of -2 to 2. After 1000 generations, the ANN weights and biases were initialized using the elite i.e. the most fittest solution (candidate with the least MSE, obtain using test data) and then train further using backpropagation algorithm (BPA) to fine tune the weights as detailed in the training Section VI-A. Thus producing the final optimized ANN model.

$$F(x) = b \cdot tanh(ax) = b(\frac{e^{ax} - e^{-ax}}{e^{ax} + e^{-ax}}) \tag{1}$$

$$F(x) = mx + c \tag{2}$$

Where the intercept $c = 0$ and the gradient $m$ is left at Matlab default while the constants $a$ and $b$ are assigned the value 1.

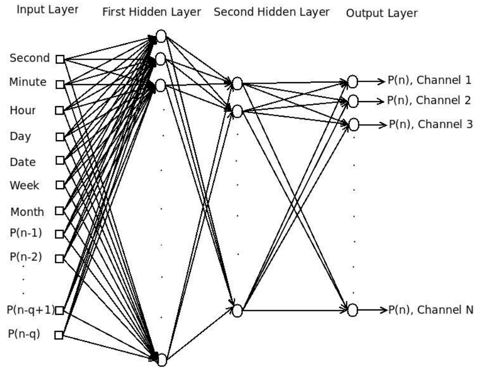

Fig. 3: Multiple channels, parallel outputs ANN model

Where $n$ is a time index, $P(n-1), P(n-2), \cdots, P(n-q)$ are the past $q$ RF power samples while $P(n)$ is the current predicted RF power.

## IV. Support Vector Machine

Support vector machine (SVM) used for regression is often known as support vector regression (SVR). In SVR, the input space $x$ is first mapped onto a high $m$ dimensional feature space by means of certain non-linear transformation (mapping), after which a linear model $f(x, w)$ is constructed in the feature space as shown in (4), [22]. Many time series regression prediction models uses certain lost functions during the training phase for minimization of the empirical risk, among these loss functions are mean square error, square error and absolute error. In SVM regression, a different loss function called $\varepsilon$-insensitive loss proposed in [24] [25], is used. When the error is within the threshold $\varepsilon$, it is considered as zero, beyond the threshold $\varepsilon$, the loss function (error) is computed as the difference between the actual error and the threshold as depicted in (5). The empirical risk function of support vector regression is as shown in (6). The gaol of SVR model is to approximate an unknown real-value function depicted by (3). Where $x$ is a multivariate input vector while $y$ is a scalar output, and $\delta$ is independent and identically distributed (i.i.d.) zero mean random noise or error. The model is estimated using a finite training samples $(x_i, y_i)$ for $i = 1, \cdots, n$ where $n$ is the number of training samples. For this study, the input vector $x$ of the SVR model consist of past recent RF power, current time and frequency while the scalar output $y$ is the current power in Decibels (dB).

$$y = r(x) + \delta \tag{3}$$

$$f(x, w) = \sum_{j=1}^{m} w_j g_j(x) + b \tag{4}$$

Where $g_j(x),\ j = 1, \cdots, m$ refer to set of non-linear transformations, $w_j$ are the weights and $b$ is the bias.

$$L_\varepsilon(y, f(x, w)) = \begin{cases} 0 & \text{if } |y - f(x, w)| \le \varepsilon \\ |y - f(x, w)| - \varepsilon & \text{otherwise} \end{cases} \tag{5}$$

$$R_{emp}(w) = \frac{1}{n} \sum_{i=1}^{n} L_\varepsilon(y_i, f(x_i, w)) \tag{6}$$

Support vector regression model is formulated as the minimization of of the following objective functions, [22]:

$$\text{minimise} \quad \frac{1}{2}\|W\|^2 + C\sum_{i=1}^{n}(\xi_i + {\xi_i}^*) \tag{7}$$

$$\text{subject to} \quad \begin{cases} y_i - f(x_i, w) - b \le \varepsilon + {\xi_i}^* \\ f(x_i, w) + b - y_i \le \varepsilon + \xi_i \\ \xi_i, {\xi_i}^* \ge 0, \quad i = 1, \cdots, n \end{cases} \tag{8}$$

The non-negative constant $C$ is a regularization parameter that determined the trade off between model complexity (flatness) and the extend to which the deviations larger than $\varepsilon$ will be tolerated in the optimization formulation. It controls the trade-off between achieving a low training and validation error, and minimizing the norm of the weights. Thus the model generalization is partly dependent on C. The parameter C enforces an upper bound on the norm of the weights, as shown in (9). Very small value of C will lead to large training error while infinite or very large value of C will lead to over-fitting resulting from large number of support vectors, [26]. The slack variables $\xi_i$ and ${\xi_i}^*$ represent the upper and lower constrains on the output of the system. These slack variables are introduced to estimate the deviation of the training samples from the $\varepsilon$-sensitive zone thus reducing model complexity by minimizing the norms of the weights, and at the same time performing linear regression in the high dimensional feature space using $\varepsilon$-sensitive loss function. The parameter $\varepsilon$ controls the width of the $\varepsilon$-insensitive zone used to fit the training data. The number of support vectors used in constructing the support vector regression model (function) is partly dependent on the parameter $\varepsilon$. If $\varepsilon$-value is very large, few support vectors will be selected, on the contrary, bigger $\varepsilon$-value results in a more generalized model (flat estimate). Thus both the complexity and the generalization capability of the network depend on its value. One other parameter that can affect the generalization and accuracy of a support vector regression model is the kernel parameter and the type of kernel function used as shown in (11) to (14).

There are three meta-parameters or hyperparameters that determine the complexity, generalization capability and accuracy of support vector machine regression model, these are the $C$ Parameter, $\varepsilon$ and the kernel parameter $\gamma$, [27], [28], [29]. Optimal selection of these parameters is further complicated due to the fact that they are problem dependent and the performance of the SVR model depends on all the three parameters. There are many proposals how these parameters can be chosen. It has been suggested that these parameters should be selected by users based on the users experience, expertise and a priori knowledge of the problem, ( [24], [25], [30], [31]). This leads to many repeated trial and error attempts before getting the optimums if possible, and it limit the usage to only experts. In this study, we used cDE to evolves the three meta parameters of the SVR model. SVR optimization problem constitute a dual problem with a solution given by

$$f(x) = \sum_{i=1}^{s} (\alpha_i - \alpha_i^*) K(x, x_i) + b \tag{9}$$

The dual coefficients in (9) are subject to the constrains $0 \le \alpha_i \le C$ and $0 \le \alpha_i^* \le C$. Where $s$ is the number of support vectors, $K(x, x_i)$ is the kernel function, $b$ is the bias, while $\alpha$ and $\alpha^*$ are Lagrange multipliers. The training samples $x$ with non-zero coefficients in (9) are called the support vectors. The general expression for the kernel is depicted in (10). Any symmetric positive definite function, which satisfies Mercers Conditions [22] can be used as kernel function. In this study, four kernel were used, i.e. the Radial Basis Function (RBF), Gaussian Radial Basis Function, Exponential Radial Basis Function kernel and Linear kernel given by (11), (12), (13), and (14) respectively, [22]. In this study, we designed two SVR models for each kernel, one of the model shown in Fig. 4 is dedicated for prediction of RF power of only one channel or resource block which implies that each channel will have it own model; the second model shown in Fig. 5 has an additional channel input thus it can be used for prediction of RF power in many channels but one at a time.

$$K(x, x_i) = \sum_{j=1}^{m} g_j(x) g_j(x_i) \tag{10}$$

$$K(x, x_i) = e^{(-\gamma\|x - x_i\|^2)} \tag{11}$$

$$K(x, x_i) = e^{(-\frac{\|x - x_i\|^2}{2\sigma^2})} \tag{12}$$

$$K(x, x_i) = e^{(-\frac{\|x - x_i\|}{2\sigma^2})} \tag{13}$$

$$K(x, x_i) = x^T x_i + c \tag{14}$$

The adjustable constant parameter $c$ of the linear kernel was set to 0 while the kernel parameters $\sigma$ and $\gamma$ were evolved using cDE algorithm variants.

Where $n$ is a time index, $P(n-1), P(n-2), \cdots, P(n-q)$ are the past $q$ RF power samples while $P(n)$ is the current predicted RF power.

## V. Optimization Algorithms

A brief description of the optimization algorithms implemented are presented in this section. We combine the global search capability of compact differential evolutionary algorithms with the single solution local search advantages of BPA to evolve the weights and biases of the optimized ANN model as described in the training, Section VI-A.

### A. Differential Evolution

Base on the original definition, DE are population based direct search algorithms used to solve continuous optimization problems [32] [33]. DE aims at evolving $NP$ population of $D$ dimensional vectors which encodes the $G$ generation candidate solutions $X_{i,G} = \{X_{i,G}^1, \cdots X_{i,G}^D\}$ towards the global optimum, where $i = 1, \cdots, NP$. The initial candidate solutions at $G = 0$ are evolves in such a way as to cover the decision space as much as possible by uniformly randomizing the candidates within the search domain using (15), [32].

$$X_{i,G} = X_{min} + rand(1,0) \cdot (X_{max} - X_{min}) \tag{15}$$

Where $i = 1, \cdots NP$. $X_{min} = \{X_{min}^1 \cdots X_{min}^D\}$, $X_{max} = \{X_{max}^1 \cdots X_{max}^D\}$ and $rand(1,0)$ is a uniformly distributed random number between 0 and 1.

### B. Mutation

For every candidates solution (individuals or target vectors) $X_{i,G}$ at generation $G$, a mutant vector $V_{i,G}$ called the provisional or trial offspring is generated via certain mutation schemes. The mutation strategies implemented in this study are as shown in (16) to (20), [32]:

- DE/rand/1:
$$V_{i,G} = X_{r_1,G} + F \cdot (X_{r_2,G} - X_{r_3,G}) \tag{16}$$
- DE/best/1:
$$V_{i,G} = X_{best,G} + F \cdot (X_{r_1,G} - X_{r_2,G}) \tag{17}$$
- DE/rand-to-best/1:
$$V_{i,G} = X_{i,G} + F \cdot (X_{best,G} - X_{i,G}) + F \cdot (X_{r_1,G} - X_{r_2,G}) \tag{18}$$
- DE/best/2
$$V_{i,G} = X_{best,G} + F \cdot (X_{r_1,G} - X_{r_2,G}) + F \cdot (X_{r_3,G} - X_{r_4,G}) \tag{19}$$
- DE/rand/2
$$V_{i,G} = X_{r_5,G} + F \cdot (X_{r_1,G} - X_{r_2,G}) + F \cdot (X_{r_3,G} - X_{r_4,G}) \tag{20}$$

Where the indexes $r_1$, $r_2$, $r_3$, $r_4$ and $r_5$are mutually exclusive positive integers and distinct from $i$. These indexes are generated at random within the range $[1\ PN]$. $X_{best,G}$ is the individual with the best fitness at generation $G$ while $F$ is the mutation constant.

### C. Cross Over

After the mutants are generated, the offspring $U_{i,G}$ are produced by performing a crossover operation between the target vector $X_{i,G}$ and its corresponding provisional offspring $V_{i,G}$. The two crossover schemes i.e. exponential and binomial crossover are used in this study for all the cDE algorithm variants implemented [34]. The binomial crossover copied the $jth$ gene of the mutant vector $V_{i,G}$ to the corresponding gene (element) in the offspring $U_{i,G}$ if $rand(0,1) \leq CR$ or $j = j_{rand}$. Otherwise it is copied from the target vector $X_{i,G}$ (parent). The crossover rate $Cr$ is the probability of selecting the offspring genes from the mutant while $j_{rand}$ is a random number in the range $[1\ D]$, this ensure that at least one of the offspring gene is copied from the mutant. The binomial crossover is represented by (21), [32]:

$$U_{i,G}^j = \begin{cases} V_{i,G}^j & \text{if} \quad (rand(0,1) \leq Cr \quad \text{or} \quad j = j_{rand}) \\ X_{i,G}^j & \text{otherwise} \end{cases} \tag{21}$$

For exponential crossover, the genes of the offspring are inherited from the mutant vector $V_{i,G}$ starting from a randomly selected index $j$ in the range $[1\ D]$ until the first time $rand(0,1) > Cr$ after which all the other genes are inherited from the parent $X_{i,G}$. The exponential crossover is as shown in Algorithm 1, [32].

*Algorithm 1:* Exponential Crossover

```
$U_{i,G} = X_{i,G}$
generate $j = randi(1, D)$
$U^j_{i,G} = V^j_{i,G}$
$k = 1$
**while** $rand\,(0, 1) \leq Cr$ AND $k < D$ **do**
    $U^j_{i,G} = V^j_{i,G}$
    $j = j + 1$
    **if** $j == n$ **then**
        $j = 1$
    **end if**
    $k = k + 1$
**end while**
```

**end**

### D. Selection Process

After every generation, the fitness function of each offspring $U_{i,G}$ and the corresponding parent $X_{i,G}$ are computed. A greedy selection schemes is used in which if the fitness function of the offspring is less than or equal to that of it parent, the offspring will replace the corresponding parent in the next generation otherwise the parent will be maintained among the next generation individuals. At the end of the generation, the most fittest individual (global best) among the final evolved solutions is selected. The DE algorithm pseudocode is depicted in Algorithm 2.

*Algorithm 2:* Differential Evolution

```
Generate an initial population $X_{G=0}$ of $Np$ individuals.
Evaluate fitness of each individuals (solutions).
**while** termination condition is not met (Generation) **do**
    **for** $i = 1$ to $Np$ **do**
        Evaluate parent ($X_{i,G}$) fitness .
        Generate trial offspring $V_{i,G}$ by mutation using (16).
        Generate offspring $U_{i,G}$ by either binomial crossover or exponential crossover.
        Evaluate offspring ($U_{i,G}$) fitness
    **end for**
    **for** $i = 1$ to $Np$ **do**
        Selection Process:
        Form the next generation solutions by selecting the best between parents and their offspring
    **end for**
**end while**
```

**end**

## VI. Compact Differential Evolution

Compact differential evolution (cDE) algorithm is achieved by incorporating the update logic of real values compact genetic algorithm (rcGA) within DE frame work [35] [36] [37]. The steps involves in cDE is as follows: A (2 x n) probability vector **PV** consisting of the mean $\mu$ and standard deviation $\sigma$ is generated. where $n$ is the dimensionality of the problem (in this case the number of weights and biases). At initialization, $\mu$ was set to 0 while $\sigma$ was set to a very large value 10, in order to simulate a uniform distribution. A solution called the elite is sampled from the **PV**. At each generation (step) other candidate solutions are sampled from the **PV** according to the mutation schemes adopted as described in Section V-B, e.g. for DE/rand/1 three candidate solutions $X_{r_1}$, $X_{r_2}$ and $X_{r_3}$ are sampled. Without lost of generality, each designed variable $X_{r_1}[i]$ belonging to a candidate solution $X_{r_1}$, is obtained from the **PV** as follows: For each dimension indexed by $i$, a truncated Gaussian probability density function (PDF) with mean $\mu[i]$ and standard deviation $\sigma[i]$ is assigned. The truncated PDF is defined by (22). The CDF of the truncated PDF is obtained. A random number rand(0,1) is sampled from a uniform distribution. $X_{r_1}[i]$ is obtained by applying the random number rand(0,1) generated to the inverse function of the CDF. Since both the PDF and CDF are truncated or normalized within the range [-1, 1]; the actual value of $X_{r_1}[i]$ within the true decision space of [a, b] is obtain as $(X_{r_1}[i] + 1)\frac{(b-a)}{2} + a$. The mutant (provisional offspring) is now generated using the mutation schemes. The offspring is evolved by performing a crossover operation between the elite and the provisional offspring as described in Section V-C. The fitness value of the offspring is computed and compare with that of the elite. If the offspring outperform the elite, it replaces the elite and declare the winner while the elite the loser; otherwise the elite is maintained and declare the winner while the offspring the loser. In this study, the fitness function is the MSE obtain using the test data. The weights and the biases of the ANN are initialized with the offspring and the MSE is obtain, this is repeated using the elite. The one with the least MSE is the winner. The **PV** is updated using (23) and (24). Hence in cDE, instead of having a population of individuals (candidates solutions) for every generation as in normal DE, the population are represented by their probability distribution function (i.e. their statistics), thus minimizing the computational complexity, amount of memory needed, and the optimization time. The psuedocode of cDE is as shown in Algorithm 3, [35].

$$PDF(\mu[i], \sigma[i]) = \frac{e^{\frac{-(x-\mu[i])^2}{2\sigma[i]^2}}\sqrt{\frac{2}{\pi}}}{\sigma[i](erf(\frac{\mu[i]+1}{\sqrt{2}\sigma[i]}) - erf(\frac{\mu[i]-1}{\sqrt{2}\sigma[i]}))} \tag{22}$$

$$\mu^{t+1}[i] = \mu^t[i] + \frac{1}{N_P}(Winner[i] - loser[i]) \tag{23}$$

$$\sigma^{t+1}[i] = \sqrt{(\sigma^t[i])^2 + \delta[i]^2 + \frac{1}{N_P}(Winner[i]^2 - loser[i]^2)} \tag{24}$$

where $\delta[i]^2 = (\mu^t[i])^2 - (\mu^{t+1}[i])^2$ , $t =$ steps or generations, $N_P$ is a vitual population and $erf$ is the error function.

*Algorithm 3:* Compact Differential Evolution Pseudocode

```
generation t=0
** PV Initialization **
**for** $i = 1$ to $n$ **do**
    Initialize $\mu[i] = 0$
    Initialize $\sigma[i] = 10$
**end for**
Generate the elite by means of **PV**
**while** buget condition **do**
    ** Mutation **
```

```
        Generate 3 or more individuals according to the mutation schemes e.g. $X_{r_1}$, $X_{r_2}$ and $X_{r_3}$ by means of **PV**
        Compute the mutant $V = X_{r_1} + F \cdot (X_{r_2} - X_{r_3})$
        ** Crossover **
        $U = V$, where $U =$ offspring
        for $i = 1 : N$ do
            Generate rand(0,1)
            if $rand(0, 1) > Cr$ then
                $U[i] = elite[i]$
            end if
        end for
        ** Elite Selcetion **
        [ Winner Loser] $= compete(U, elite)$
        if $U ==$ Winner then
            $elite = U$
        end if
        ** PV Update **
        for $i = 1 : n$ do
            $\mu^{t+1}[i] = \mu^t[i] + \frac{1}{N_P}(Winner[i] - loser[i])$
            $\sigma^{t+1}[i] = \sqrt{(\sigma^t[i])^2 + \delta[i]^2 + \gamma[i]^2}$
            Where: $\delta[i]^2 = (\mu^t[i])^2 - (\mu^{t+1}[i])^2$
            $\gamma[i]^2 = \frac{1}{N_P}(Winner[i]^2 - loser[i]^2)$
        end for
        $t = t + 1$
    end while
end
```

### A. Training of ANN and SVM

The objective function in this study is the MSE of the optimized ANN computed using the test data. After every generation, the offspring $U_G$ and the $elite$ are used to set the weights and biases of the ANN and the MSE of the ANN models are obtain using the test data. The use of the test data (data not known by the ANN nor used to train it) for computation of the fitness function (MSE) does not only result in a more accurate network but also a more robust and generalized ANN model. A greedy selection schemes is used in which if the MSE of the offspring is less than or equal to that of the elite, the offspring will replace the elite in the next generation otherwise the elite will be maintained. At the end of the generations, the most fittest candidate solution i.e. the final evolved elite; is used to initialize the weights and biases of the ANN which is further trained using back propagation algorithms (BPA) to fine tune the weights to produce the final optimized ANN model. The cDE is run for 1000 generations. The fine tuning of the ANN weights using BPA was constrained within a maximum of 200 epoch and 6 validation fails, i.e the training stop if any of these constrain thresholds is satisfied. One of the desirable feature of BPA is it simplicity but it often converges slowly and lack optimality as it can easily be trapped in a local optimum leading to premature convergent. Many approaches has been adopted to solve the problem of premature convergent associated with BPA such as the introduction of momentum constant, varying of the learning rate and retraining of the network with new initial weights. To circumvent the problem of premature convergent, and to have a robust ANN that is well generalized, we combine the global search advantages of cDE optimization algorithm and the local search capability of single solution BPA to evolve the weights and biases of the ANN. The combination of the global search capabilities of cDE and the local search advantages of BPA to evolve the weight and biases of ANN have proving to be superior to using only the famous BPA for this problem. The cDE algorithm pseudocode is depicted in Algorithm 3.

In constract to the training of ANN using BPA, the training of SVM is optimal with the optimality rooted in convex optimization. This desired feature of SVM is obtained at the cost of increased computational complexity. The fact that the training of SVM is optimal does not implies that the evolved machine will be well generalized or have a good performance. The optimality here is based on the chosen meta parameters ( i.e. $C$ parameter, $\varepsilon$ and the kernel parameter $\gamma$), the type of kernel function used and the training data. We used the same randomization cDE optimization algorithm variants to evolve the SVM meta parameters while the weights and bias of the SVM were evolves via convex optimization. At each generation, the meta parameters are set using each candidate solution, and the corresponding weights and bias are computed. In order to estimate how the SVM will generalize to an independent dataset (test data), we use two fold cross validation commonly known as holdout method. This has the advantage of having both large training and validation datasets, and each data point is used for both training and validation on each fold. The training data is randomly divided into two sets e.g. $A$ and $B$ of equal size. The SVM was trained on $A$ and test on $B$, after which it is trained on $B$ and test on $A$, the average of the MSE for the two test was used as the fitness function for the given sets of meta parameters. At the end of the generations, the SVM is reconstructed using the most fittest meta parameters and tested on the test datasets (data not known by the SVM nor used to train it).

## VII. Experiment and Simulation Data

The datasets used in this study were obtained by capturing real world RF signals using universal software radio peripheral 1 (USRP 1) for a period of two months. The USRP are computer hosted software-defined radios with one motherboard and interchangeable daughter board modules for various ranges of frequencies. The daughter board modules serve as the RF front end. Two daughter boards, SBX and Tuner 4937 DI5 3X7901, having a continuous frequency ranges of 4MHz to 4.4GHz and 50 MHz to 860 MHz respectively, were used in this research. The daughterboard perform analog operations such as up/down-conversion, filtering, and other signal conditioning while the motherboard perform the functions of clock generation and synchronization, analog to digital conversion (ADC),digital to analog conversion (DAC), host processor interface, and power control. It also decimate the signal to a lower sampling rate that can easily be transmitted to the host computer through a high-speed USB cable where the signal is processed by software. For TV channels with channels bandwidth of 8 MHz, we divided the channels into subchannels (resource block) each consisting of 500 KHz bandwidth. To ensure that no spectral information was lost, we used a sample frequency of 1MHz and obtained 1024 samples for each sample time. For GSM 900 and FM band with a bandwidth of 200 KHz, we used 1MHz sample frequency and 512 samples for each sample time. The power was obtained using both the time and frequency domain data. For the frequency domain, after passing the signal through the channel filter, the signal was windowed using a hamming window in order to reduce spectral leakage. The stream of the data was converted to a vector and decimated to a lower sampling rate that can easily be processed by the host computer at run time using the inbuilt decimation block in gnu-radio. This is then converted to the frequency domain and the magnitudes of the bins were passed to a probe sink. The choice of probe sink is essential because it can only hold the current data and does not increase thereby preventing stack overflow or a segmentation fault. This allows Python to grab the data at run time for further analysis. The interval of time between consecutive sample data was selected at a random value between 5 seconds and 30 seconds. The choice of this range is based on the assumption that for any TV programme, FM broadcast or GSM calls, will last for not less than 5 to 30 seconds. In order to capture all possible trends, the time between consecutive sample data is selected at random within the given range instead of using regular intervals. For the VHF and FM band we captured RF signals from 54MHz to 110MHz and 470 to 670MHz for the VHF TV bands. For the GSM band, 62 down-link channels (935MHz to 953.3MHz) and 62 uplink channels (890MHz to 908.3MHz) were captured. The real world RF data was divided into three subsets, randomly selected with 60% used for training the ANN, 20% for validation and 20% for testing the trained ANN model. The training or estimation data were the only known data sources used in training the ANN. The test data set was unknown to the network i.e. they are not used in training the network rather are used in testing the trained ANN as a measure of the generalization performance of the ANN model. The ANN design, optimization and the simulation were done in Matlab while the capturing of the data and the signal processing were implemented using gnu-radio which is a combination of Python and C++.

## VIII. Delayed Inputs Sensitivity Analysis

In order to examine how many numbers of recent past RF power samples are needed as feedback inputs for reliable prediction, and to have a model with reduced dimensionality of input vector, we carried out a sensitivity analysis. One way of evaluating the importance (significance) of an input in ANN is to measure the Change Of MSE (COM) when the input is deleted or added to the neural network [38]. In this study, the COM method is adopted with the time domain inputs unaltered, and the actual past RF power are added to the input one after the other starting from the most recent one. The ANN is trained with $i$ delay inputs (past RF power samples) and the MSE $MSE_i$ is evaluated. The network is retrained with $i+1$ delayed inputs, the MSE $MSE_{i+1}$ is obtained and the change in the MSE, $\delta_{mse} = MSE_{i+1} - MSE_i$ is computed as a means of evaluating the importance of the $i+1$ delay input, for $i = [0 \cdots q]$, where $q$ is the total number of past samples used; see Fig 1. Note, $\delta_{mse}$ is not computed relative to the MSE obtained when all the $q$ delayed inputs are used as in normal COM method, due to the fact that we don't know the required number of delay inputs $q$ at the start of the experiment; in this case $q$ is obtained by setting a constrain on $\delta_{mse}$. The importance of the inputs are ranked base on the one whose addition causes the largest decrease in MSE as the most important since they are most relevant to the construction of a network with the smallest MSE. In order to justify the importance or ranking of the inputs statistically, for every $i$ inputs delay, the ANN is trained 20 times, each time with a randomly generated initial weights and biases, the average of the 20 $MSE_i$ is used. The ranking using the normalized values of change in average MSE $\delta_{mse}$ as delayed inputs were added is as shown in Fig 7. The graph of the average MSE against number of delayed inputs is as depicted in Fig 6. From Fig 6 and Fig 7, it is obvious that when the number of delay inputs is $> 7$, the change in MSE $\delta_{mse}$, is very small. Thus in this study we decided to use 7 past recent RF power samples as part of the ANN inputs for current RF power prediction, taken into cognition the memory constrain of CR as an embedded device.

## IX. Results

To minimize the MSE of the ANN when tested with the test data, the above listed algorithms were run for 30 independent runs. Each run has been continued with 30000 fitness evaluations for 1000 generations. After a manual tuning of the parameters, the following parameters are used in this study:

- cDE/rand/1/bin, cDE/rand/1/exp, cDE/rand/2/bin, cDE/rand/2/exp, cDE/best/1/bin, cDE/best/1/exp, cDE/best/2/bin, cDE/best/2/exp, cDE/rand-to-best/1/bin and cDE/rand-to-best/1/exp has been run with $F = 0.1$ and $Cr = 0.3$
- BPA has been run with $Epoch = 1200$, $learningrate = 0.01$ $mumentum = 0.008$ the other specifications are shown in Table I.

TABLE I: ANN Models Specification

| | ANN Models | | |
|---|---|---|---|
| | Dedicated one channel | Multiple channels, single output | Multiple channels, parallel output |
| First Hidden Neurons | 5 | 15 | 15 |
| Second Hidden Neurons | 3 | 10 | 10 |
| Output Neurons | 1 | 1 | 20 |
| Number of Channels | 1 | 20 | 20 |

Tables IV and III shows the numerical results in terms of the MSE obtained using the test data (data not known by the ANN nor used in training the ANN). The final results of each algorithm was obtained by taken the average of the MSE (AMSE) for the 30 independent runs and their corresponding standard deviation (STD). From the results, the combination of cDE/rand/1/exp and back propagation algorithm (BPA) outperform all the other algorithms with reference to the FFB ANN model while the combination of cDE/rand/1/bin and BPA is the best for the FF ANN model. These two bests are used as the reference for the Wilcoxon test [39]. A '+' indicate that the reference algorithm outperform the other algorithm while "−" mean that the other algorithm outperform the reference. For this problem, when the Wilcoxon test was perform by changing the reference algorithm, the second best algorithm for the FFB ANN model are cDE/rand-to-best/1/exp and cDE/rand/2/exp; both having the same AMSE and STD of 0.0290 and 0.0005 respectively while for FF ANN model, the second best algorithm is cDE/rand/1/exp. For this problem, the FF ANN model trained using cDE/rand/1/bin and BPA emerge as the best compared with other models (FFB, CFF, LR) and algorithms implemented. This implies that the feedback information may have been captured through the inputs assigned to the 7 recent past RF power samples. Comparing the results depicted in tables IV and III with our previous work detailed in [40]; the use of some of the most recent RF power samples as part of the input vector of the ANN, produces a more accurate and robust ANN model with reduced number of neurons. This form a non-linear time series predictive model. The neurons in the model adopted in this study is approximately half of the ones used in [40], thus it has less parameters (weights and biases) to be optimized. To validate the fact that the combination of these cDE variants of optimization algorithms with the famous BPA to evolves the weights and biases of ANN will produce a more accurate, robust and generalized model than using only BPA; we use the same topology but train with only BPA at constant learning rate of 0.01 and another one with varying learning rate starting from 0.8 and keep on changing with change in MSE using inbuilt Matlab training function traingda. For both models trained with only BPA, each was run 30 times, each run was constrain within a maximum of 1200 epoch and 6 validation fails, the average results is depicted in tables IVand III. For the hybridized training i.e combining cDE with BPA, the cDE is run for 1000 generations and the final best solution (elite) was used to reinitialized the ANN weights and further train using BPA constrained within 200 epoch and 6 validation fails. In almost all cases, the hybridize training outperform the training with only BPA. Fig 8, 9 and 10 shows the prediction graphs of some selected channels using test data. These results depict a good generalization of the three models. For this problem, the combination of the global search capabilities of cDE algorithm variants, and the local search advantages of BPA to evolve the weights of the ANN was found to yield an improved performance as compared to using only the famous BPA.

The prediction results of the dedicated SVR model shown in Fig. 4 is depicted in Table IV. From this result, the exponential kernel with meta parameters evolved using cDE/rand/2/exp seem to be more promising with an average MSE of 0.0226, the next best kernel is the linear kernel with AMSE of 0.0301 using cDE/rand/1/bin variant. For multiple channel, single output SVR model Fig. 5, trained for prediction of RF power of 20 resource blocks or channels, the linear kernel emerge as the best with AMSE of 0.0682 this is followed by the RBF kernel with AMSE of 0.0819. the best hyperparameters are evolved using cDE/rand/1/exp for linear kernel and cDE/rand/1/bin and cDE/rand/2/bin for RBF. The results for FF ANN, multiple channel, single output model is also shown in Table with best model having an AMSE of 0.0818 with weights and biases evolved using cDE/best/2/exp and BPA.

## X. Conclusion

This paper demonstrates the power of ANN to produce a robust time series prediction models for RF power traffics in some selected channels. The combination of the global search capabilities of memory efficient cDE and the local search advantages of single solution BPA to evolves the weights and biases of the ANN prediction models, proved to produce a more robust, accurate and well generalise ANN models than

using only BPA for this problem. For the dedicated one channel model, the ANN outperform the SVR model for all the kernels implemented while for the multiple channels, single output model, only the linear kernel SVR model outperform the ANN. The a priori knowledge of the RF power resulting from either communication signals, noise and/or interferences, is not only applicable to cognitive radio network, but in any wireless communication system for noisy channels avoidance.

***Abstract*—This paper presents the DISESOR integrated decision support system. The system integrates data from different monitoring and dispatching systems and contains such modules as data preparation and cleaning, analytical, prediction and expert system. Architecture of the system is presented in the paper and a special focus is put on the presentation of two issues: data integration and cleaning, and creation of prediction model. The work contains also a case study presenting an example of the system application.**

## I. Introduction

COAL mining is a heavy industry that plays an important role on an energy market and employs hundreds of thousands of people. Coal mining is also an industry, where large amount of data is produced but little is done to utilise them in further analysis. There is also a justified need to introduce a decision support system (DSS) integrating different aspects of coal mine operation in order to maintain continuity of mining.

Currently coal mines are well equipped with the monitoring, supervising and dispatching systems connected with machines, devices and transport facilities. There are also the systems for monitoring natural hazards (methane-, seismic- and fire hazards). All these systems are provided by many different companies, what causes problems with quality, integration and proper interpretation of the collected data. The collected data are used chiefly for current (temporary) visualisation on boards which display certain places in the mine. Whereas, application of domain knowledge and the results of historical data analysis can improve the operator's and supervisor's work significantly. For example, thanks to short-term prognoses about methane concentration, linked with the information about the location and work intensity of the cutter loader, it is possible to prevent emergency energy shutdowns and maintain continuity of mining (the research on this methodology was discussed in [1]). This will enable to increase the production volume and to reduce the wear of electrical elements whose exploitation time depends on the number of switch-ons and switch-offs.

It is possible to see the rising awareness of monitoring systems suppliers who begin to understand the necessity to make the next step in these systems development. Therefore, the companies providing monitoring systems seek their competitive advantage in equipping their systems with knowledge engineering, modelling and data analysis methods. This is a strong motivation to consider a DSS presented in this paper.

The goal of this paper is to present an architecture of the integrated decision support system DISESOR. The system integrates data from different monitoring systems and contains an expert system module, that can utilise domain expert knowledge, and analytical module, that can be applied to diagnosis of the processes and devices and to prediction of natural hazards. The special focus of the paper is put on the data integration and data cleaning issues realised by means of the data warehouse and ETL process. The work also contains a more detailed presentation of the prediction module, which is complemented by a presentation of a simple case of methane concentration prediction in a coal mine.

The contribution of the paper consists of:

- the architecture of the integrated decision support system DISESOR,
- presentation of the approaches to the preparation and cleaning of the data collected by monitoring systems,
- presentation of the prediction module architecture and principles of the module operation,
- case study presenting application of the presented system to methane concentration prediction in a coal mine.

The structure of the paper is as follows. Section II presents the works related to the presented topic. The architecture of the DISESOR system and its data repository are presented in section III. The more detailed descriptions of the data preparation and cleaning and prediction modules are presented in sections IV and V respectively. The case study of methane concentration prediction task is presented in section VI and section VII presents the final conclusions.

## II. Related work

The typical environments deployed in a coal mine are monitoring and dispatching systems. These systems collect a large number of data which can be utilised in further analysis, e.g., on-line prediction of the sensor measurements, which area was surveyed in [2]. The analysis can address different aspects of coal mine operation such as, e.g., equipment failure or natural hazards.

The examples of the research in the field of natural hazards in an underground coal mine cover, e.g., methane concentration prediction and seismic hazard analysis. The research on the prediction of the methane concentrations was presented in [3, 1]. Application of data clustering techniques to seismic hazard assessment was presented in [4]. There are also approaches to prediction of seismic tremors by means of artificial neural networks [5] and rule-based systems [6]. Each research listed above is a stand alone approach not incorporated into any integrated system.

Analytical methods that were mentioned require the data which are extracted, cleaned, transformed and integrated. Decision support systems utilise a data repository of some kind, e.g., a data warehouse [7]. The critical dependence of the decision support system on a data warehouse implementation and an impact of the data quality on decision support is discussed in [8].

There are applications of machine learning methods to diagnostics of mining equipment and machinery presented in literature [9, 10]. Also some initial concepts of the system that processes data streams delivered by the monitoring systems were presented in [11]. However, to the best of the authors knowledge there is no example of the integrated decision support system for monitoring processes, devices and hazards in a coal mine (except the work dealing with DSS for coal transportation [12] which loosely corresponds to the given topic).

## III. System architecture

The general architecture of the DISESOR integrated decision support system is presented in Fig. 1. The architecture of the system consists of data repository and data preparation and cleaning, that are presented in more detail in the following sections, and analytical, prediction and expert system modules shortly presented below, as they are not the main focus of the paper.

### A. Decision support system

The core of analytical, prediction and expert system modules is based on the RapidMiner [13] platform. The RapidMiner environment was customised to the requirements of the non-advanced user by disabling unnecessary options and views. Therefore, an advanced user can use the whole functionality of RapidMiner, whereas the non-advanced user can use such thematic operators as e.g., "Solve a methane concentration prediction issue" or "Solve a seismic hazard issue". Also due to the target application of the system in Polish coal mines the RapidMiner environment was translated into Polish. Finally, RapidMiner was extended in the created application by additional operators wrapping R [14] and MOA (Massive On-line Analysis) [15] environments.

The goal of the Data preparation and cleaning module, which is referred further as ETL2, is to integrate the data stored in data warehouse and process them to the form acceptable by the methods creating prediction and classification models. In other words the ETL2 module prepares the training sets.

Prediction module is aimed to perform incremental (on-line) learning of predictive models or apply classification and prediction models created in analytical module for a given time horizon and frequency of the values measured by the chosen sensors. This module also tracks the trends in the incoming measurements. The created predictive models are adapted to the analysed process on the basis of the incoming data stream and the models learnt on historical data (within the analytical module). The module provides the interfaces that enable the choice of quality indices and their thresholds that ensure the minimal prediction quality. If the quality of predictions meets the conditions set by a user, the predictions will be treated as the values provided by a soft sensor. They can be further utilised by e.g., expert system but also they can be presented to a dispatcher of a monitoring system.

Analytical module is aimed to perform analysis of historical data (off-line) and to report the identified significant dependencies and trends. The results generated by this module are stored in the repository only when accepted by a user. Therefore, this module supports a user in decision-making of what is interesting from monitoring and prediction point of view. It also provides additional information that can be utilised to enrich the knowledge of expert system or that can be utilised to comparative analysis. The module supports identification of changes and trends in the monitored processes and tools and it also enables to compare the operator's and dispatcher's work.

Expert system module is aimed to perform on-line and off-line diagnosis of machines and other technical equipment. It is also aimed to supervise the processes and to support the dispatcher or expert decision-making with respect to both technical condition of the equipment and improper execution of the process. The inference process is performed by means of classical inference based on stringent rules and facts or probabilistic inference based on belief networks. The system contains also a knowledge base editor that allows a user to define such rules and network. The expert system module is currently being developed.

### B. Data repository

Data repository was designed as a data warehouse of a snowflake structure (as some dimensions have multiple levels), that is presented in Fig. 2 in a reduced, general form. The structure of a data warehouse results from the analysis of databases of the existing monitoring systems and the characteristics of the known sensors. The full list of tables with their description is presented in Table I.

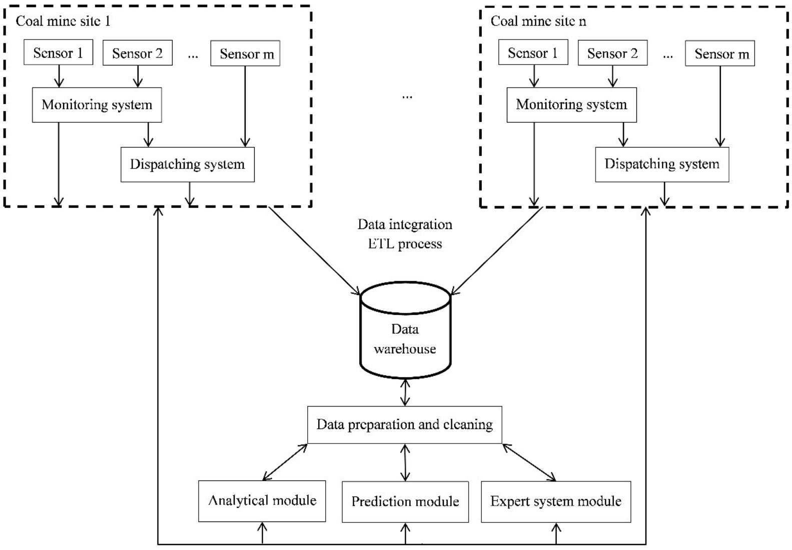

Fig. 1. Architecture of the DISESOR integrated decision support system

| Table | Description |
|---|---|
| Measurement | Value of a measurement |
| State | State of a measurement, e.g., *alarm*, *calibration*, *breakdown* |
| Discretisation | The measured values can be of discrete type |
| Time | Time of a measurement, range $[00:00:00, 23:59:59]$, 1 second resolution |
| Time_category | Category, e.g., *mining* or *no mining* |
| Date | Date of a measurement |
| Location | Location of the measurement source |
| Location_attribute | Characteristics of the given location |
| Location_hierarchy | Hierarchical structure of location |
| Source | Measurement source, e.g., sensor or device |
| Source_attribute | Characteristics of the given source |

TABLE I
TABLES CREATING A DATA WAREHOUSE STRUCTURE.

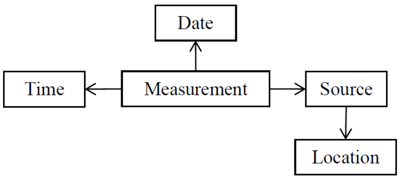

Fig. 2. Simplified schema of data repository

The central table of the data repository is *Measurement* where all the measurements are stored. The dimensions related to the *Measurement* table are *Date*, *Time* and *Source*. *Date* and *Time* describe when the measurement was registered, whereas *Source* describes what registered the given measurement. The *Source* table contains among others such information about sensors/devices as:

- name (e.g., MM256),
- description (e.g., methane meter number 256),
- type name (e.g., methane meter),
- measured quantity (e.g., methane concentration),
- measurement unit (e.g., %CH4),
- name of a system that collects the data (e.g., THOR),
- range of measurements.

The *Source* table is described by means of *Location* dimension, that describes where in a coal mine it is located. The location has hierarchical structure, some sample hierarchy is presented in Fig. 3. The top-most level of hierarchy are formed by coal mine divisions. Divisions consist of seams, which are divided into mining areas. At the bottom of hierarchy there are mining workings.

The data warehouse is loaded with data by means of the ETL process designed for the main monitoring and dispatching systems for coal mining, which are deployed in Poland, Ukraine and China, e.g., THOR dispatching system [16] or Hestia natural hazards assessment system [6]. The ETL process was designed by means of Open Talend Studio [17].

During the tests of the created solution the data warehouse was loaded with 800 million records what resulted in 200 GB of data. Therefore, it enabled the performance tests and optimisation of both the logical data warehouse structure and database management system (PostgreSQL [18]). As a result the *Measurement* data table was partitioned according

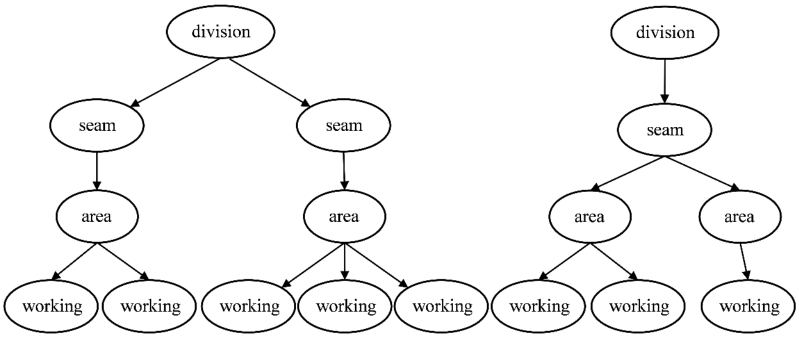

Fig. 3. Location hierarchy in a coal mine

to the months of measurements and the indices for foreign keys in this table were created. On the DBMS side several configuration parameters were adjusted, e.g., shared_buffers, work_mem, maintenance_work_mem, checkpoint_segments, checkpoint_completion_target, effective_cache_size.

## IV. Data preparation and cleaning

The goal of ETL2 module is to deliver integrated data (in a form of a uniform data set) coming from chosen sources (especially sensors) in a chosen time range.

The measurements can be collected with different frequencies. Additionally, some systems collect a new measurement only after significant (defined in a monitoring system) change of the measured value. Table II presents how the measurements of two methanometers can look like when collected directly from the data warehouse. The ETL2 process uniforms the data to the form where each recorded measurement represents the time period defined by a user, e.g., 1 second (Table III).

Output data

Fig. 4. General characteristics of the data processing in ETL2 module

Within the ETL2 module there are also executed procedures of data cleaning, that identify outlier values and impute the missing values. This task is realised both by means of the simple functions presented below and by means of operators available in RapidMiner environment. Also data aggregation (e.g., 10 measurements are replaced with 1 measurement) and manual definition of derived variables (e.g., a new variable can be calculated as a sum of the values of two other variables) are performed by means of the methods included in ETL2 module.

The general scheme of data processing within ETL2 module is presented in Fig. 4.

As a result of the processing performed by means of the ETL2 module we receive a data set that can be either analysed (by means of analytical module), or utilised to prediction model creation (by means of prediction module), or utilised within diagnosis process (by means of expert system). All the phases of processing are performed as separate RapidMiner operators.

In order to select the variables that should be analysed a user can utilise THOR dispatching system 5, where each sensor (and attributes) are presented on a map of the region of interest. The system that is being created enables in turn, data (time-series) visualisation in order to select the time periods, that are the most interesting from the analyst point of view. Fig. 6 presents the visualisation of time-series consisting of several thousands of records. The developed operator creating such visualisation utilises R environment.

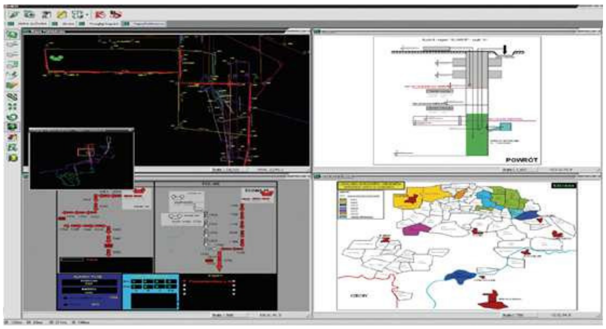

Fig. 5. Visualisation available in THOR dispatching system

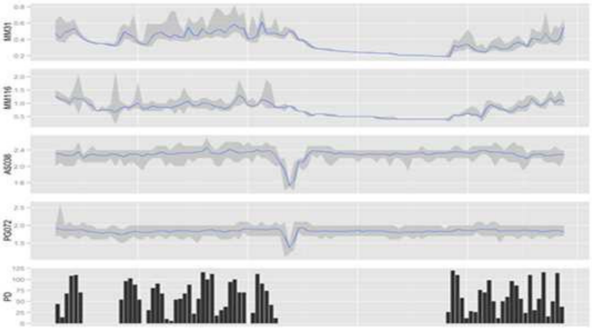

Fig. 6. Visualisation of exemplary time-series: methane concentration, air flow and mining cycle on a chosen longwall

Aggregation of the measurements replaces several values with a single one. The period of aggregation is chosen by a user, who sets a number of measurements that should be aggregated or a time unit defining the windows containing measurements to be aggregated. The following aggregation operators are available for each attribute: average, minimum, maximum, median, dominant, the number of occurrences. For each record being the result of the aggregation there is calculated a weight, that is inversely proportional to the number of missing values existing in the aggregated data. The weight calculation is also based on a weighted average for all the attributes. This approach enables us to reduce the number of missing values in data and introduce weights that can be utilised by the chosen methods (e.g., rule induction).

The operator that imputes missing values performs the analysis of each attribute separately. The following methods of changing the value or imputing the missing value can be utilised:

- a logical expression defining the replacing values (e.g., replace each value <1 with "low state"),
- the way how to receive the replacing values:
  - the value set by a user,
  - the last valid measurement,
  - average of the neighbouring measurements (with the parameter defining the number of neighbours),
  - linear regression of the two points (the last one before missing values section and the first one after this section),
  - linear regression of the data preceding missing values (with the parameter defining the window size).

The maximal number of consecutive missing values that can be imputed is defined as a separate parameter, as imputing the values for the long breaks in the measurements has no practical meaning. Therefore, the resulting data set can still contain missing values. In such case, the analyst can use a number of methods that are able to analyse data with missing values.

Introduction of a new derived variable can cover, among others, introduction of delays (the values of the previous measurements) or calculation of increments and trends (e.g., as an ordinal - increases, decreases). Another operator enables data smoothing by means of different filters (e.g., average, median). Finally, the last operator enables creation of dependent variable (decision variable). Typically, this variable contains the moved forward values of the chosen attribute, what enables to receive a proper prediction horizon. The operator defining the dependent variable has expanded functionality what enables e.g., to define the dependent variable as a maximal value of a given attribute in a defined time interval (e.g., 3 to 6 minutes in advance).

It is also important that within the developed framework the operators can be applied multiple times and in unrestricted order. Moreover, it is possible to pre-process data by means of the operators delivered by RapidMiner, that are dedicated to multidimensional analysis/identification of outliers and missing values (e.g., the operator applying local k-NN to missing values imputation).

When data pre-processing is finished, the whole process is saved according to RapidMiner-XML standard, that was created for the needs of the system. Thereby, the prediction module is able to transform the incoming data to the form that is acceptable by prediction models (see section V).

## V. Prediction module

Prediction module is based on, so called, prediction services. Prediction service is a webservice that predicts values of a variable (discreet or continuous) on the basis of input vector. Prediction service is inseparably connected with a model (regression or classification one) that is the basis of the prediction. The basic scenario of prediction service application is as follows:

1) Client sends a prediction execution request accompanied by a vector of conditional attributes and a timestamp.
2) Service calculates the prediction delivering the vector of conditional attributes as a model input. The attribute values come directly from the monitoring system, because

the data warehouse is not loaded online. The values of the attributes are transformed according to the dedicated ETL2 process to the form acceptable by the prediction model.

3) Service loads the results to a database.

The architecture of the prediction module is presented in Fig. 7.

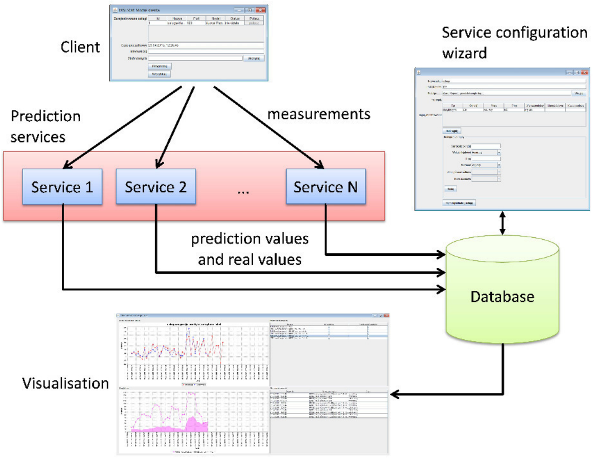

Fig. 7. Architecture and operation of prediction module

Database, which is an internal RapidMiner repository, stores the description of a model and the transformations of the attributes. It also stores the information about training data, the parameters of the minimal model quality and both predicted and real values of dependent variable. Each model adaptation results in a new database entry what makes the history of the changes available to the users.

The predictions can be visualised and compared on a single plot with the real values that are measured. Such visualisation can be performed by a monitoring or dispatching system (e.g., THOR dispatching system), where predicted values are delivered as measurements of a virtual sensor and the values of both sensors (virtual and real) can be easly compared.

It is assumed for the current module version, that if the quality of the predictions decreases below a given threshold, then a new training set is automatically collected. The size of this new data set is the same as size of the original data. The model adaptation is performed by modifying only the parameters of the existing model (the method and algorithm is not changed). Next, the quality of the model is verified on the same data that triggered the model adaptation (these data are not the part of the new training data set). If the quality of the adapted model is satisfactory, then this new model is applied to prediction. Otherwise a message is generated stating that prediction cannot be continued and it is needed to come back to analytical module in order to create a new prediction model.

The configuration wizard enables to define the so-called quality monitoring rules. From the practical point of view there is no point in presenting the minimum model quality by means of the well known measures, such as overall classification accuracy, g-mean, specificity, sensitivity, RMSE (Root Mean Squared Error), MAE (Mean Absolute Error), etc. Therefore, quality monitoring rules are based on: a sliding time-window (e.g., 1 hour) in which the quality is verified, frequency of the prediction calculation (e.g., 1 minute) and the indicators which are typically called *FalsePositive* and *FalseNegative*. The values of these indicators are explicitly defined by a user for each decision class or only for a target class, e.g., corresponding to "danger". Therefore, knowing the values of *FalsePositive* and *FalseNegative*, and a number of predictions that are calculated in a given time-window it is possible to calculate the values of almost all the possible quality measures of prediction model. In case of regression task the module allows so-called insensitivity, what means that the predictions that differ less than the given threshold from the real values are not treated as an error. Additionally, it is possible to define that the values within the given range (e.g., corresponding to the "normal" state) are not counted as errors.

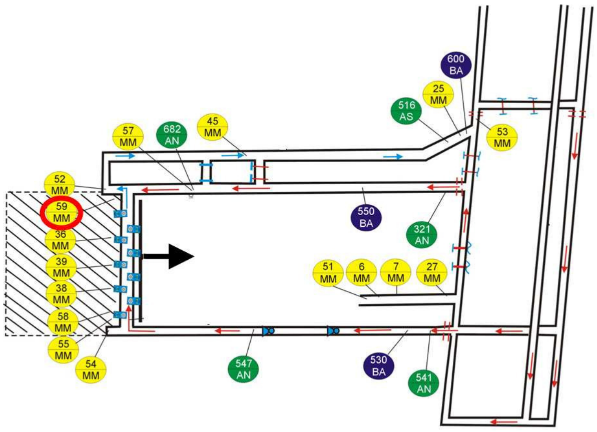

Fig. 8. Topology of the mining area and location of the sensors - MM59 sensor chosen as dependent variable is outlined a thick line

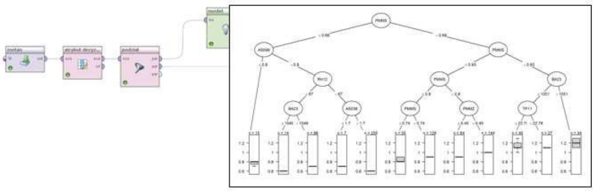

Fig. 9. The process of data preparation and prediction model creation together with the initial regression tree that was created

## VI. Example of the system application to the task of methane concentration prediction in mining excavation

The DISESOR system can be applied to several different tasks solving. This section presents an example, how the system can be utilised to methane concentration prediction.

Methane concentration monitoring is one of the main tasks of the natural hazard monitoring systems in mining industry.

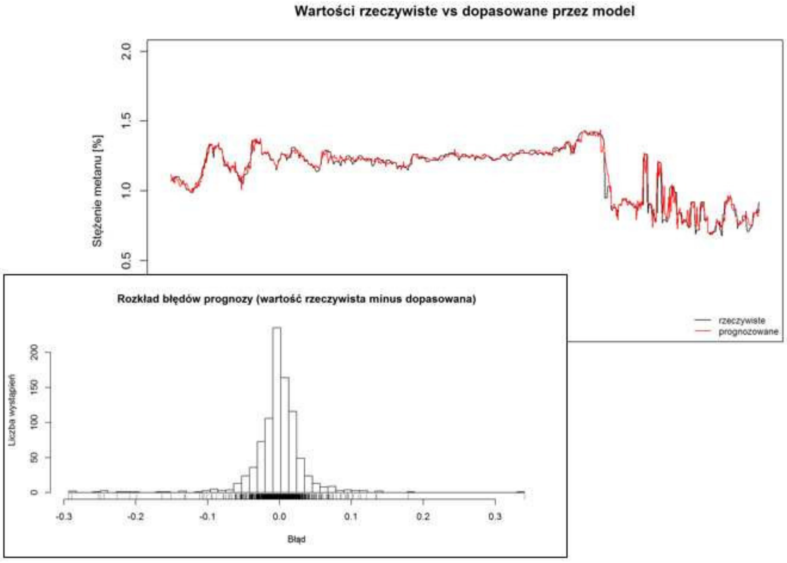

Fig. 10. The plot of the real methane concentration and the predicted maximum concentration together with the histogram of errors that are reported to a user

Such system is in charge of automatic and immediate shutdown of electricity within a given area, if a methane concentration exceeds a given alarm threshold. The power turn-on is possible after a certain time (from 15 minutes to even several hours), when the methane concentration decreases to the acceptable level. This results in large losses associated with downtime of production. Information from a soft (virtual) sensor presenting to a dispatcher the prediction of the methane concentration with a few minute horizon can allow the prevention electricity shut-down or can allow to lower the mining activity and increase the air flow if possible. Therefore, these actions allow to avoid undesirable situations and unnecessary downtimes.

The task of maximal methane concentration prediction with the horizon from 3 to 6 minutes was realised within the DISESOR system. By means of ETL2 module a set of the following sensors was selected: AN321, AN541, AN547, AN682, BA1000, BA603, BA613, BA623, MM11, MM21, MM25, MM31, MM36, MM38, MM39, MM41, MM45, MM52, MM53, MM54, MM55, MM57, MM58, MM59, MM61, MM81. The data were aggregated applying minimum operation to anemometer (AN) measurements, average operation to barometer (BA) measurements and maximum operation to methanometer (MM) measurements. The missing values were imputed applying linear regression method. As a dependent variable MM59 sensor was chosen. A map presenting the topology of the mining area and location of the sensors is presented in Fig. 8.

Analytical module is currently being developed and the analysis presented below is an example of the possible system apllication. Therefore, to create the examplary prediction model the method of regression tree induction was chosen arbitrary. The initial tree was created on the basis of data coming from 1 shift. The model and the list of sensors (variables) together with the defined transformations were forwarded to prediction model running a proper service. The time-window defined for prediction quality monitoring was set to 1 hour and the model adaptation was executed each hour regardless the minimum quality requirements. The adaptation could be executed more often if the minimum quality requirements were not met but there was no such situation. The data that were predicted were delivered on-line by the simulator of THOR system in order to simulate the real stream of measurements.

Fig. 9 presents the process of data preparation and the prediction model creation together with the initial regression tree that was created. Whereas, Fig. 10 presents the plot of the real methane concentration and the predicted maximum concentration together with the histogram of errors that are reported to a user. Currently, the user interface is in Polish as the deployment in Poland was planned in the project. However, the English and Chinese versions are also planned.

## VII. Conclusions

The system that is being developed delivers the solutions for decision support of a dispatcher and process operator. This system is complete as it delivers the tools that can be applied to data storage, processing and preparation, and also to definition of the models based on expert knowledge (expert system) and the models based on the results of both historical and on-line data analysis. Due to the application and proper customisation of existing tools (RapidMiner, R) and development of the proprietary solutions (e.g., ETL2, rule induction and optimisation [19, 20], rough set operators [21] and semantic analysis of data mining processes [22] that are not available in RapidMiner) a user receives a broad set of tools that can be applied to different tasks. Finally, the case study that was presented shows that the system can be practically utilised in a coal mine industry.

# Emotion Monitor - Concept, Construction and Lessons Learned

Agnieszka Landowska
Gdansk University of Technology, Narutowicza St. 11/12, 80-233, Gdansk, Poland
E-mail: nailie@eti.pg.gda.pl

*Abstract*—**This paper concerns the design and physical construction of an emotion monitor stand for tracking human emotions in Human-Computer Interaction using multi-modal approach. The concept of the stand using cameras, behavioral analysis tools and a set of physiological sensors such as galvanic skin response, blood-volume pulse, temperature, breath and electromyography is presented and followed by details of Emotion Monitor construction at Gdansk University of Technology. Some experiments are reported that were already held at the stand, providing observations on reliability, accuracy and value the stand might provide in human-systems interaction evaluation. The lessons learned at this particular stand might be interesting for the other researchers aiming at emotion monitoring in human-systems interaction.**

## I. Introduction

THIS paper concerns challenges in automatic multimodal affect recognition. Although it seems that the domain is well established and there are many off-the-shelf solutions, the reliability, accuracy and granularity of emotion recognition is still a challenge. In 2013 a project was started at Gdansk University of Technology (GUT) to build an emotion monitor stand that uses existing technologies in order to extend human-systems interaction with emotion recognition and affective intervention. The concept of the stand assumed combining multiple modalities used in emotion recognition in order to improve the accuracy of affect classification. The considered input channels included the ones that are most frequently used in the emotion recognition: physiological signals (skin conductance, respiration, electromyography, EEG, heart rate, peripheral temperature) [1], video input for facial expression analysis [2], keyboard and mouse usage patterns [3] as well as textual inputs for sentiment analysis [4]. The hardware layer of the stand was constructed in 2013, and the software layer in 2014 and 2015, however, the latter still requires extension, including improvement of classification algorithms. The paper describes the concept and construction details of the Emotion Monitor stand at GUT. Selected experiments held at the stand are described that provide an insight into practical aspects of automatic emotion recognition. The experiments are diverse, from the ones that aimed at establishment of reliable measurement procedures of physiological signals, ones that aimed at classification algorithms training and others that were practical applications of the stand in systems design. Although not every experiment was successful, all of them contributed to the knowledge on practical aspects of multimodal emotion monitoring. Lessons learned on the way are the main theme of this paper and the research questions of the article might be formulated as follows: *how to monitor emotional states in Human-Computer Interaction with acceptable reliability, accuracy and granularity and what are the main challenges in automatic multimodal affect recognition?* The main purpose of the paper is to evaluate the usability of the stand as well as to express the main limitations of emotion recognition in human-computer interaction.

## II. Related work

Works that are mostly related to this research fall into two categories: research on applicability of emotion monitoring in the context of human-system interaction and studies on emotion recognition based on different input channels.

First group of related papers provides rationale for emotion recognition application in human-systems interaction. Software usability testing can be extended with observation of human emotions [5][6] and it is also possible to measure and optimize software development processes [7][8][9]. Based on the methods for usability evaluation, it would be possible to evaluate educational software and resources designed for e-learning [10][11][12]. Physiological parameters can be also used for optimization of other emotion recognition algorithms and in affect-aware games and other intelligent personalized systems [13].

There are numerous emotion recognition algorithms that differ on input information channels, output labels, affect models and classification methods. As literature on affective computing tools is broad and has already been summarized several times (eg. [14]), only example papers are referenced. The most frequently used emotion recognition methods that might be considered for emotion monitor stand include:

- facial expression analysis (requires video as an input channel, however expressions might be partially controlled by people, especially when they know they are being observed or recorded) [2][14][16];
- audio (voice) signal analysis in terms of modulation (this method is seldom used in human-computer interaction as the voice communication channel is rarely used) [2][16];

This work was supported by Polish-Norwegian Financial Mechanism Small Grant Scheme under the contract no Pol-Nor/209260/108/2015 and by DS Funds of ETI Faculty, Gdansk University of Technology.

- textual input analysis (sentiment analysis requires conversational system interface) [17];
- physiological signals - although very precise and cannot be controlled by most of the people, require specialized equipment [1][15];
- behavioral patterns analysis (keystroke dynamics and mouse usage patterns) combined with other modalities can improve the accuracy of affect recognition; moreover those are the most natural input channels in HCI [3].

The best recognition results are obtained when fusing information from diverse input channels and early and late fusion can be distinguished [18]. Early fusion methods combine features derived from separate input channels to create a common feature vector for classification [19]. Late fusion combines the classification results provided by separate classifiers for every input channel; however, this requires some mapping between emotion representation models used as classifier outputs [20]. The highest accuracies are obtained mainly for two-class classifiers and multimodal input channels (including physiological measurements).

## III. Emotion monitor concept

The emotion monitor stand objective is to conduct experiments on computer users affective states retrieval and analysis. The stand is equipped with computers, cameras and a set of biosensors, which allow to monitor user activities and record multiple user observation channels at the same time. The data are then processed further to extract features and classify emotional states from single or multimodal input channels. Schema of the emotion monitor stand is provided in Figure 1.

Investigator Area
Subject Area

Fig. 1 The concept of emotion monitor stand hardware configuration

The emotion monitor stand is divided into two separated areas: a subject area, where a user performs tasks that are under observation and an investigator area, where a researcher is able to monitor user's activities and track biometric parameters. During investigation, when different emotional states would be evoked on purpose, it would disturb experiments, when a subject would have a possibility to turn to the investigator personally, therefore the investigator and subject areas are separated.

The emotion monitor stand is equipped with the following devices: (1)biometric sensors set, including skin conductance, blood-volume pulse, respiration, temperature, electromyography and EEG sensors, (2) analytical device that allows to simultaneously sample multiple channels with high frequency, (3)front camera that records face and upper part of the subject's body, (4)side camera that records experiment execution, (5)computer 1, which allows the subject to perform tasks under investigation, (6)computer 2, which allows the investigator to monitor user activities and parameters.

Software layer of emotion monitor includes an application to store and track biometric data, tools for observation and recording of video images, keyboard and mouse usage tracker and user activity logger. Apart from the applications recording input channels, the main emotion monitor's application is the one that combines input channels and multiple classifiers in order to provide an affective state estimate. The result might be displayed with diverse visualization tools (general or dedicated for emotion representations).

## IV. Emotion monitor hardware layer construction

In 2013 an emotion monitor stand was constructed at Gdansk University of Technology as a dedicated stand in research laboratory room. The investigator's area and the subject's area are separated with a part-wall made out of furniture, which allows for visual, and partly acoustic separation. Photos of the subject's and the investigator's area are provided in Fig. 2 (left and right respectively).

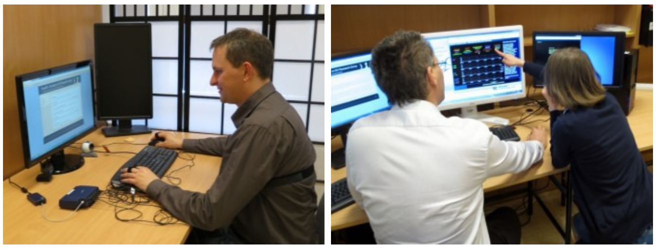

Fig. 2 Emotion monitor stand at GUT (left - the participant's area, right - the investigator's area)

The equipment of the stand was chosen based on capabilities and availability. Coder FlexComp Infiniti by Thought Technology, Canada was chosen as biosensors analytical device. The coder is a ten-channel multimodal device dedicated for real-time biofeedback, psychophysiology training and monitoring. It is connected with computer database via TT-USB device and allows to simultaneously record up to ten channels with sampling rate 2048 samples per second. The coder removes noise from all input channels and performs signal amplification and preliminary filtration that is adjusted to sensor type. EEG sensors, which are compatible with the coder, allow to perform impedance measurement, which allows to provide EEG signal of high quality. Other available devices had less input channels, lower sampling rates or did not allow to perform impedance measurement.

The biometric sensor set for the emotion monitor stand was designed to measure physiological parameters that are commonly used in affect recognition. and the choice was justified by literature review. Sensors are compatible with the FlexComp Infiniti coder and other coders produced by Thought Technology. Some of the sensors in the predefined set were doubled in order to try out multiple locations at the same time. Detailed list of sensor types includes: skin conductance, electromyography, respiration, temperature, electroencephalography and blood-volume pulse sensors.

Additionally three standard computer sets with two monitors each were provided for the stand. One computer is dedicated for biometric recording and emotion recognition and two monitors allow to display more parameters at the same time. The second computer is provided for a subject to perform tasks under investigation, additional monitor allows an investigator to track user's progress with the tasks. The third computer was added for the investigator-subject communication (investigator displays commands for a subject) – see a black monitor on the left photo in Figure 2.

The stand is normally equipped with three cameras: two in front of the subject and one side camera. The front cameras include one standard RBG camera of medium quality and additionally RGB-D camera with infrared depth sensor that allows for posture analysis independent of illumination for special applications.

## V. Emotion monitor software layer structure

There is a number of applications installed at the stand, however not all of them are used simultaneously. The applications might be divided into the following categories: (1) tools for input channels recoding and pre-processing; (2) applications for the data processing into feature vectors and classifiers' training; (3) software for classification and validation of the results (might be the same tools as above); (4) tools for emotional state visualization and interpretation.

The conceptual and actual diagram regarding software layer of the emotion monitor stand is provided in Fig. 3.

### *A. Data acquisition tools*

Thought Technology BioGraph Infiniti application was installed for gathering biometric data from the coder. The system was chosen due to compatibility with the coder, but also due to signal quality optimization features including verifying signal quality and adjusting sensor placement, integrated electrode impedance measurement as well as artifact rejection feature, both automatic and manual. Additionally, an optional Physiology Suite, which is specifically designed for monitoring and assessing physiological functions: recording biomeasurement sessions, reviewing recorded data for the purpose of artifact rejection, generating session reports and demonstrating the results, was installed.

Emotion monitor is also equipped with a set of applications for computer user behavioral observations: Mobii eye tracker, keystroke tracker and mouse tracker, Morae Recorder and Observer, and Logitech Video Capture.

As in some experiments there is a need for simultaneous recording of up to 6 camera images, the change of the software recording video is considered, as it allows to capture one camera image only (at one computer) and in the experiments with multiple cameras is not sufficient.

### *B. Training, classification and validation tools*

This part of the emotion monitor stand is still under

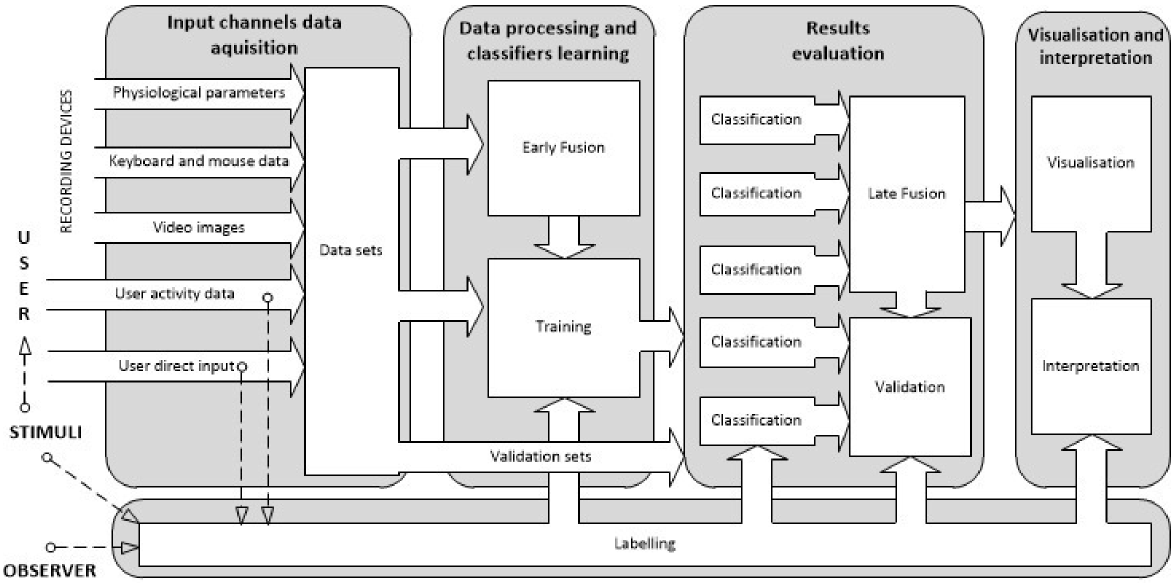

Fig. 3 Emotion monitor stand at GUT - the software layer

development, as there are several challenges in the automatic classification of computer users emotional states. Although the concept was to train classifiers off-line and then use them in real time, this would require more research, than was assumed. Therefore currently, during experiments only data acquisition is performed and the analysis and interpretation is performed afterwards. The analytical and training tools we use include the following: Morae Manager, Knime, Statistica, MatLab, SAS, Origin.

### *C. Visualization tools*

There is an emotional state visualizer that was prepared for the stand at GUT, however now it is not used, as the integration tool for real-time analysis and visualization is under development. Therefore apart from the dedicated tools we use a number of external tools for the data visualization, eg. Knime, Origin.

### *D. Early and late fusion*

The main concept of the stand was to perform the integration of emotional activation information from multiple input channels. One might consider early fusion, in which the data is combined to create common feature vectors. This approach has at least two important drawbacks: timing synchronization and temporary unavailability of input channels.

The first challenge we have encountered is timing synchronization. It seems simple with the timestamps provided by computers, however in practical acquisition of the affective activations the issue lies in the delay of the emotion expression for different channels, eg. heart rate change and skin conductance change last up to one/two seconds, facial expressions are delayed in comparison with the physiological signals. This is the result of the sympathetic and parasympathetic system activation and this is how it works. As a result it is hard to assign the same label to exactly the same period of time for different channels.

Another challenge is temporary unavailability of the input channels. All of the channels used are subject to temporal unavailability: for biosignals movement artifacts must be removed, as they interfere with informative peaks, face recognition is dependent on: face position and illumination conditions eg. if a user moves head a little bit, face recognition tool must follow the face (find it again), moreover keyboard and mouse are usually used interchangeably, with pauses. The common feature vectors are full of blank values, asynchronously for the input channels.

Late fusion that is based on the integration of the recognized emotional states from different classifiers suffers from diverse emotion representation models and lack of mapping between them. Facial expression analysis algorithms for emotion recognition use Ekman's Facial Coding System and provide six basic emotions as a result. The biosignals are best in recognition of the arousal dimension of emotional state, and not the valence (positive and negative experience might cause the same activation of the nervous system). There is a constant challenge of labeling, which will be depicted with the experiment in section VI.

## VI. Experiments in emotion monitoring

There were 5 experiments already held at the stand: (1) a study on reliability of physiological signals measurements in the HCI context, (2) experiment with picture stimuli, two experiments (3) and (4) with sound that provided the knowledge required for the optoelectronic system for autistic children, and finally (5) game experience monitoring.

As some of the experiments were already reported [21] [22][23][24], this section would summarize results of experiments (1), (3), (4) and (5) as well as provide more detailed description of experiment (2), which was not reported before. The descriptions would focus on revealing observations on usefulness of the emotion monitor stand.

### *A. Experiment 1. The challenge of biosignals acquisition in human-computer interaction*

After the stand was constructed at GUT in 2013, the first challenge was encountered in the sensitiveness of biometric sensors readings to movements. The typical locations of the sensors are finger tips or finger bases, which is inconvenient while using mouse and/or keyboard in human-computer interaction. Therefore, an experiment aiming at eliminating sensors from hands and finding alternative locations that are as good as typical finger placement was held. As the experiment was already reported in detail [21], only the major findings are summarized. The experiment allowed to draw some conclusions on human-computer interaction monitoring based on bio-measurements of muscle electric activity, respiration, temperature, pulse or skin conductance:

1. Emotion recognition in human-computer interaction should not use EMG measurements placed on trapesius muscle nor sensors located at finger tips (temperature, BVP sensor). Alternative locations of temperature and BVP sensor on earlobes could be accepted as a solution for human-computer interaction monitoring.

2. Skin conductance sensor location on forearm is perceived as less disturbing than location on fingers. Location on forearm is also less sensitive to mouse movements.

3. Respiration sensor are perceived as low disturbing and insensitive to movements, except from body movements.

4. For the signal recorded by all sensors artifacts connected with large movements (body movements) should be removed independently of their location on body.

In emotion recognition algorithms, which are based on biomeasurements, relative values should be provided rather than absolute values, as there are significant differences between individuals. Normalization or standardization procedure should be performed with personal average, instead of overall average calculated for all subjects.

Therefore baseline recording is important for experimental settings, as well as natural environments [21]. The experiment allowed to find a method for reliable acquisition of physiological signals in human-computer interaction.

### *B. Experiment 2. The challenge of labelling*

The concept of the experiment assumed registration of biometric parameters when evoking emotions on the basis of pictures. GAPED (Geneva Affective Picture Database) set was chosen, as the pictures in the set are labeled with the emotional activations in PAD (Pleasure Arousal Dominance) model. The experiment aimed at: acquisition of data for learning algorithms that cause emotions as well as determination whether the readings in alternative locations of sensors vary with emotions.

The pictures were grouped into 6 groups of similar emotional activations for: fear, sadness, anger, disgust and joy. The sixth group represented photos considered neutral for the reference. In each group 5 pictures were chosen and displayed one after another. Picture groups were separated with rest, when no picture was shown. Moreover, before the slide show of photos, a baseline was recorded. Necessity of the baseline recording results from the diversity of individual biometric readings.

The experiment succeeded in determining whether the readings in alternative locations of sensors vary with emotions, however failed in training classifiers for emotion recognition. The resulting recognition rate for the six emotional states never reached more than 30% independently of the classifier, training method and its parameters. Detailed analysis of the results for specific people revealed that pictures were not efficient stimuli to evoke emotions for part of them. There were a number of computer science students involved in the experiment, for whom even the drastic pictures from wars and hospitals were not enough to evoke reactions, as they are used to such views by intensively playing shooter games. For this group of people, the slide show of pictures that lasted for 20 minutes was simply boring and it was visible in physiological signals that headed towards relaxation state, independently of how drastic picture was shown.

Another interesting group of participants reacted to each and every picture independently of what was presented, even a photo of a blue mug or a box caused the reaction (visible with skin conductance fluctuation). This group of participants, which might be described as highly-reactive, also sometimes exhibited skin conductance raise before the picture was actually shown.

The minority of the participants exhibited the expected reactions: high for the drastic photos and low for more neutral ones.

The experiment revealed that choosing a stimuli is an important matter (obviously), but also that stimuli's label is not enough for labeling the data for emotion recognition. In the picture set there was one picture repeated twice in different contexts (in different picture groups) and the reaction to it depended mostly on the context, and not the actual photo (if any reaction was there). As a result we have tried alternative labeling methods, however they were found insufficient in this experiment.

However, the experiment brought to deeper understanding of the challenge of labeling with emotional states and those are the lessons learned:

1) There is a difference between the expression of emotion and the actual emotion eg. one might smile, although feeling embarrassed by the picture.

2) People exhibit more facial expressions when talking with others than in front of the computer screen (eg. typical surprise reaction of “jaw dropping” was never encountered). Micro-expressions must be recognized and interpreted instead.

3) Expectation of a stimuli results in pre-condition reaction (difficult to synchronize it with label).

4) There is no way of actually determine, what the emotional state of a person is (emotion has external expressions, however it is an internal phenomena, there is a two-factor theory of emotional reaction: both stimuli and the interpretation is required for the emotion to appear).

5) Some people do not exhibit facial expressions, for the others, the actual expression varies significantly.

6) When labeling pictures, sounds, videos or other stimuli with questionnaires one might obtain anticipated emotional state instead of the actual one.

7) People differ significantly in the ability to recognize and express their own emotional states.

8) Emotional reactions might be caused by some internal thoughts (some participants exhibited skin conductance fluctuations during baseline and rest recordings).

Although finished with no success, it was a valuable experiment, which revealed lots of research issues to work.

### *C. Experiments 3 and 4. Practical applications*

The other three experiments were practical applications of the stand. Experiments (3) and (4) were conducted to construct an optoelectronic system supporting behavioral therapy of autistic children [22][23]. The first experiment aimed at selection of physiological parameters which are closely correlated with person's emotional state. Measuring changes of those parameters and adequate data processing can show the emotion of investigated person. The experiment used a stimuli of 1 minute sound that started with 1kHz constant sound that was gradually silenced and finished with a shot sound. Only few parameters gave very strong change in measured signal after the shot sound: skin conductance, respiration and electromyography, however the individual reaction varied for subjects. The respiration rate and skin conductance changes were chosen to be monitored in the elaborated system. Another experiment (4) was conducted in order to evaluate the prototype of the optoelectronic system supporting behavioral therapy of autistic children. Recently, this system has been tested in one kindergarten for children with disabilities. Such support will be very useful and can significantly improve psychological treatment of those children [23].

## VII. Results and discussion

Apart from typical challenges in classification: feature selection, choosing classifier and its structure, proper training methods and validation, there are more challenges in automatic emotion recognition. The first one ins reliable data acquisition, as all input channels are subject to some noise and temporal unavailability. The main challenge seem still the labeling with emotional states. One might consider labeling with user reports, expert observations, user activity or stimuli labels, however all of the techniques could be questioned. Perhaps a combination of the two or three different labeling methods is a way, however the problem of blending in the case of constrictions remains. Another challenge is the fusion (early or late) of the emotional expressions estimate from different input channels and this field has gathered some researcher attention so far [19], however still much is to be revealed.

The author is aware of the fact that this study is not free of some limitations. First of all, the report on the experiment is subjective one, as the paper aimed at sharing lessons learned rather than reporting the actual experiments.

The question formulated at the beginning of the paper *how to monitor emotional states in Human-Computer Interaction with acceptable reliability, accuracy and granularity?* remains open and requires further research. However, the second question *what are the main challenges in automatic multimodal affect recognition?* , which was the main purpose of this study, was provided with some answers.

## VIII. Conclusion

Although there are some off-the-shelf solution for recognizing human affect (produced by Affectiva or Empathica) as well as many “smart” watches that track physiology, determining the actual emotional state of a human being is still a challenge, even for qualified psychologists. With all the complicated equipment and algorithms the only thing we could track is emotion’s external symptoms. Moreover the reliability and the accuracy of the provided estimate depends on many conditions: availability of the input channels, air conditions (temperature, humidity) and the context a human is in. Perhaps the internal phenomena of the emotion is what makes us really unpredictable, i.e. humans.

# Pawlak's flow graph extensions for video surveillance systems

Karol Lisowski*, Andrzej Czyżewski*
*Electronics, Telecommunications, and Informatics Faculty
Gdansk University of Technology, Narutowicza 11/12, PL80-233 Gdansk, Poland

***Abstract*—The idea of the Pawlak's flow graphs is applicable to many problems in various fields related to decision algorithms or data mining. The flow graphs can be used also in the video surveillance systems. Especially in distributed multi-camera systems which are problematic to be handled by human operators because of their limited perception. In such systems automated video analysis needs to be implemented. Important part of this analysis is tracking object within a single camera and between cameras' fields of vision. One of element needed to re-identify the single real object besides object's visual features and spatio-temporal dependencies between cameras is a behaviour model. The flow graph after some modifications, is a suitable data structure, which concept is based on the rough set theory, to contained as a behaviour model in it. Additionally, the flow graph can be used to predict the future movement of given object. In this paper a survey of authors research works related to employing flowgraphs in video surveillance systems is contained. The flow graph creation based on the paths of objects inside supervised area will presented. Moreover, a method of building a probability tree on the basis of the flow graph and a method for adapting the flowgraph to the changing topology of the camera network are also discussed.**

## I. Introduction

THE video surveillance systems have become common in public places and provided new possibilities (as well as challenges) in fields like security, crime prevention and automated video data processing. One of the main problems related to increasing number of cameras is that cameras' Fields of Vision (FOVs) do not overlap. In other words, there are locations which are not observed by any of the cameras. Thus the method for tracking object in a such adverse environment is needed. Therefore, this issue formed the basis of the authors' research work presented in this paper.

Tracking objects in a single camera is based on visual features of a moving object which differ from a background of a video image [1], [2]. Unfortunately such an approach is not suitable for the posed problem of re-identification of the same object in two different cameras. Therefore, some additional information related to statistical data analysis need to be obtained. There are two more types of premises (except of a comparison of visual features) which can be used to track objects more efficiently, that are:

- time of transition between given pair of the cameras
- probability that object will pass between a given pair of the cameras.

The first type of premise can be presented in the form of the weighted directed graph called topology graph. Edges of the topology graph determine physical possibility of transitions between cameras and describe time of these transitions. The description of transition time can be in form of:

- a single value (like average time of transition)
- a probability destiny function (e.g. Gaussian)
- a model (approximation) of time transition time (e.g. with Gaussian Mixture Model)

The second type of the premise (that is behaviour model) can be also described with a weighted directed graph but in this case it is also acyclic graph called flow graph. The idea of flow graphs was introduced by Pawlak and is based on the rough set theory [3], [4]. This paper is focused on a presentation of methods related to behaviour modelling with the Pawlak's flow graphs based on the data from video surveillance system. Utilization of the presented modified flow graph corresponds to tracking objects between cameras with non-overlapping fields of vision (FOVs). A general aim of this paper is presentation of the survey of the authors' works on the implementation of the Pawlak's flowgraph (as behaviour model) in the video surveillance systems. Certain paths of objects through observed area are more frequent than others and some transitions are more probable. The behaviour model can be considered as a container for knowledge about these patterns. In order to perform tracking object between cameras, three types of premises can be used to re-identify a single real object: visual features, time of transition and probability of choosing particular transition. The last premise is contained in the behaviour model (in the flow graph). The idea of Pawlak's flow graph is consistent with the rough set theory and Bayes' theorem. Description and definition of the flow graph can be found in the literature [5], [6], [7]. The flowgraph can be utilized in context of data mining and decision tree building [4]. Additionally, the flowgraph idea can be employed in processing of musical meta data [8]. Extensions and modifications of the flowgraph were also introduced [9], [10], [11].

The paper begins with a short presentation of the idea of flowgraphs with accordance to the rough set theory (see Sec. II). Next, in Sec. III modifications and extensions are introduced that were needed to apply, in order to use them with metadata obtained from the analysis of video data from surveillance system. Sec. IV presents an application of the extended flow graph in surveillance system and describes consecutive steps of authors' research work. The paper ends with summary and conclusion in Sec. V

## II. Pawlak's flow graphs and Rough Set Theory

In order to start a reflection on the flow graphs, some terms related to the rough set theory have to be presented according to literature [3]. Thus, a data set used in rough set theory is called an information system. The set of attributes denoted as $A$ must considered. Each attribute $a \in A$ may have values from a certain set $V_a$ (called the domain). If two disjoint subsets of attributes (called conditions $C$ and decisions $D$) are distinguished in the information system, then such a system becomes a decision system is denoted as:

$$S = (U, C, D),\ C \sqcup D \tag{1}$$

where $U$ is called the universe, $C$ is a set of condition attributes and $D$ is a set of decision attributes.

Based on the Pawlak publication [12] definition of flowgraph and their properties will be presented below. The flowgraphs are actually a kind of data structure suitable for containing a distribution of information flow and to present statistical features of objects from the mentioned universe $U$. Such an approach enables a new possibility of statistical data analysis belonging to intelligent methods.

A flow graph can be considered as a directed acyclic graph:

$$G = (N, E, \varphi) \tag{2}$$

where $N$ is a set of nodes, $E$ is a set of edges ($E \subseteq N \times N$) and $\varphi : E \to (R^+ \cup \{0\})$ is a flow function. Moreover, the idea of flow graph assumes the following notations and terminology:

- $(x, y)$ determines an edge with a node $x$ as an input and a node $y$ as an output, the edge $(x, y)$ must be contained in the set $E$;
- $I(x)$ is the set of all inputs of node $x$ and $O(x)$ is the set of all outputs of node $x$, while $x \in N$;
- also output and input of the whole flowgraph $G$ can be denoted as $I(G) = \{x \in N : I(x) = \emptyset\}$ and $O(G) = \{x \in N : O(x) = \emptyset\}$;
- input and output nodes are called external nodes and the rest of nodes are internal;
- $\varphi(x, y)$ is called throughflow from $x$ to $y$ which fulfils condition $\varphi(x, y) \neq 0$ for each edge $(x, y)$ in the set $E$.

Thus, for each node $x$ of a flow graph $G$, the inflow can be determined as:

$$\varphi_+(x) = \sum_{y \in I(x)} \varphi(y, x) \tag{3}$$

and the outflow can be defined as:

$$\varphi_-(x) = \sum_{y \in O(x)} \varphi(x, y) \tag{4}$$

In a similar way input and output of the whole flow graph can be formulated as:

$$\varphi_+(G) = \sum_{x \in I(G)} \varphi_-(x) \tag{5}$$

$$\varphi_-(G) = \sum_{x \in O(G)} \varphi_+(x) \tag{6}$$

Each internal node $x$ fulfil the condition:

$$\varphi_+(x) = \varphi_-(x) = \varphi(x) \tag{7}$$

where $\varphi(x)$ is called a throughflow of node $x$. For the whole flow graph $G$ the following formula is true:

$$\varphi_+(G) = \varphi_-(G) = \varphi(G) \tag{8}$$

where $\varphi(G)$ is a throughflow of the whole flow graph $G$. Hence, considering these assumptions all flows in the graph $G$ can be normalized with the value of $\varphi(G)$ as is presented in the formulae:

$$\sigma(x, y) = \frac{\varphi(x, y)}{\varphi(G)},\ \ 0 \leq \sigma(x, y) \leq 1 \tag{9}$$

$$\sigma(x) = \frac{\varphi(x)}{\varphi(G)},\ \ 0 \leq \sigma(x) \leq 1 \tag{10}$$

The value of $\sigma(x, y)$ is called the strength of edge $(x, y)$ and the value of $\sigma(x)$ is called the strength of node $x$.

Above defined normalized flows in the flowgraph allow for obtaining relative parameters assigned to the edges which are called certainty factor:

$$cer(x, y) = \frac{\sigma(x, y)}{\sigma(x)},\ \ \sigma(x) \neq 0 \tag{11}$$

and coverage factor:

$$cov(x, y) = \frac{\sigma(x, y)}{\sigma(y)},\ \ \sigma(y) \neq 0 \tag{12}$$

## III. Using flowgraph for behaviour modelling

In order to create behaviour model based on the flow graph a video surveillance system will be considered as in the previous paper [13]. Thus, a set of locations related to particular cameras is distributed on a certain area which can be described with the formula:

$$C = \{c_1, ..., c_N\} \tag{13}$$

where $c_i$ is camera with $i$ index and $N$ is a number of the cameras ($1 \leq i \leq N$). As it was mentioned a network of the cameras can be presented with the topology graph on which spatial dependencies between cameras are described (see Fig. 1)

Object which moved through the observed area creates a path which contains consecutive locations visited by the object. This path can be defined with the following formula:

$$p = \{(c_{id_1}, 1), ..., (c_{id_L}, L)\} \tag{14}$$

where $c_{id_1}$ and $c_{id_L}$ corresponds to camera which is visited by the object at the entrance to the observed area and at the exit from this area, respectively; numers from $id_1$ to $id_L$ define consecutive values of the index $i$ from Eq. 13. Thus, the set of paths can be described as presented by the following formula:

$$P = \{p1, ..., p_M\} \tag{15}$$

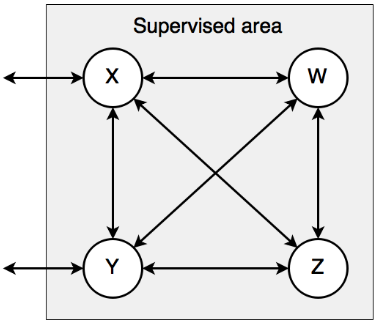

Fig. 1: The graph presenting topology of video surveillance system. According to Eq. 13: $C = \{w, x, y, z\}$

where $M$ is the number of paths in the set. Having the input data prepared in this way, next steps of creating the behaviour model can be carried out. However, in the beginning, the attributes and the domains must be reconsidered. Hence, the attribute used in the flow graph contains two parts:

- the index (number) that describes an order of this element in its path,
- the label of camera in which an object appeared.

For example, the attribute $X_1$ means that the given object was observed for the first time (on entrance to the observed area) in the camera 'X'. The consecutive domains are determined with the index mentioned above. The example flow graph created on the basis of the set of paths is presented in Fig. 2. Moreover, the certainty and coverage factors are also used in a specific way. In order to realize above, also parameters of the flowgraph need to be redefined as the following formulae show:

$$\begin{aligned} \sigma\left(x_i, y_{i+1}\right) &= \tfrac{\varphi(x_i, y_{i+1})}{\varphi(G)} \\ \sigma\left(x_i\right) &= \tfrac{\varphi(x_i)}{\varphi(G)} \\ cer\left(x_i, y_{i+1}\right) &= \tfrac{\sigma(x_i, y_{i+1})}{\sigma(x_i)} \\ cov\left(x_{j-1}, y_j\right) &= \tfrac{\sigma(x_{j-1}, y_j)}{\sigma(y_j)} \end{aligned} \tag{16}$$

where $\sigma(x_i, y_{i+1})$ defines the rate of objects passing from the camera $x$ in the step $i$ of the path to the camera $y$ in the next step $i + 1$ of the path, $\varphi(x_i, y_{i+1})$ determines the number of paths (in the set of path) which contain a transition from step $x_i$ to step $y_{i+1}$, the total number of paths taken into consideration while building the flow graph is denoted as $\varphi(G)$, and $\varphi(x_i)$ is the number of paths in the set of paths which contains the step (flow graph's node) $x_i$. Also the values of the certainty an coverage change their meanings. The certainty ($cer$) estimates the conditional probability that the object which left the camera $x$ in the step $i$ of its path will appear in the camera $y$ in the consecutive step $i + 1$, whereas the coverage ($cov$) determines estimation of the conditional probability that an object which appears in the camera $y$ in the step $j$ of the path was seen before, in the camera $x$ in the previous step $j - 1$ of the path. The certainty $cer$ is used to predict future movements of the object whereas the coverage $cov$ is useful in re-identification method. The $cov$ is utilized during the decision-making related to identification of the single object observed in two different cameras.

## IV. Flowgraphs in surveillance systems

The essential use case of the flow graph in the surveillance is related to prediction of object movements. The certainty factor estimates the probability of the future location that the object will visit, based on its previous route through the supervised area. Because of data concerning flows of objects through the observed locations, which is contained within the flow graph, probabilities of more than one location ahead can be predicted. As a result a probability tree is obtained. The formula which allows for creation of the probability tree (according to [14]) is shown in Eq. 17:

$$cer\left[x_{root}, \ldots, z_{end}\right] = \prod_{i=root}^{i=end} cer\left(x_i, x_{i+1}\right) \tag{17}$$

where the root of probability tree is denoted as $x_{root}$, the probability of the path from the vertex $x_{root}$ to $z_{end}$ is calculated as a product of probabilities of subsequent steps in the given path. An example probability tree created on the basis of the flow graph presented in Fig. 2 is shown in Fig. 3. The probability tree is created on the basis of the particular instance of the flow graph. It presents possible future transitions of the object observed in the certain camera in determined step of the object path.

Another important issue is the changing environment which is observed with cameras. It causes changes in the topology of the camera network. Some transitions may become physically impossible or new transitions appear. In such fluctuating conditions the created behaviour model may quickly become out of date and it will contain incorrect transition probability estimates. The flow graph is a quite slowly updating structure so a dedicated method for speed up adaptation to new conditions is needed. In order to solve this problem, an adaptation method employing some additional modifications, according to [15] is necessary:

- each path (obtained from video surveillance system) before adding to the set of paths and being used to build a recent behaviour model are weighted by so called importance factor;
- the importance factor is based on probability of the occurrence of the same path in the past;
- two instances of flowgraph are created: the first called $core\_$ and the second called $recent\_$
- measures of distance between two flow graphs also have to be introduced;
- values of two thresholds need to be determined: the first one called $learningThershold\_$ is created in order to enable making decision that flow graph $recent\_$ is a proper model of unchanging object behaviour, and the second one called $adaptiveThreshold\_$ is used to determine a moment in which adaptation method must be

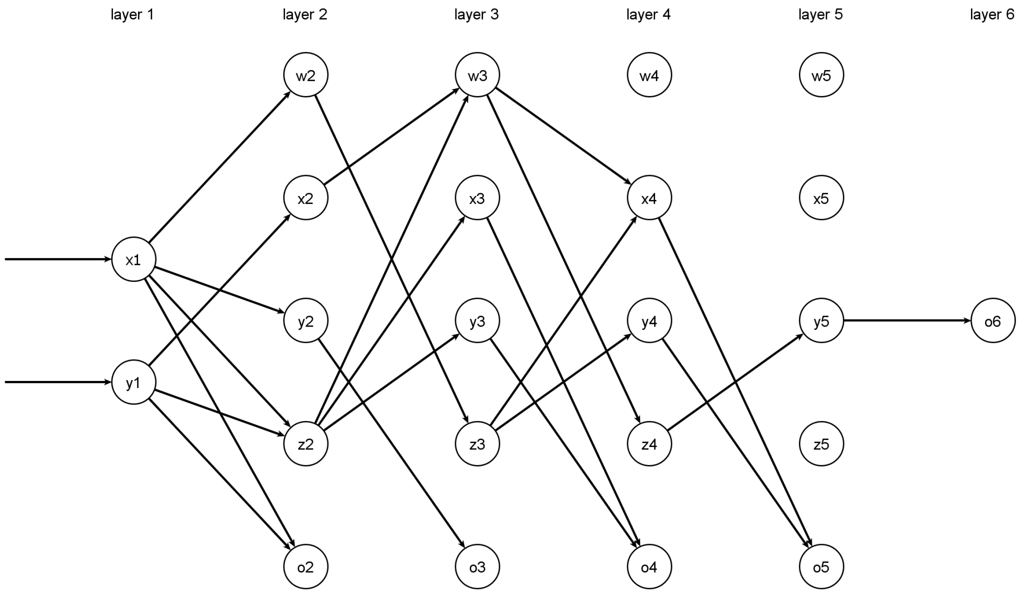

Fig. 2: The example flow graph obtained from the set of paths

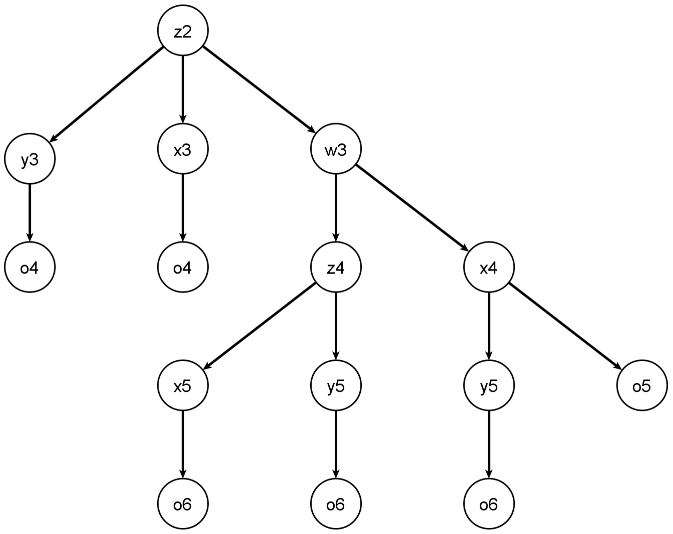

Fig. 3: Probability tree which begins in node $Z_2$ (what means that $x_{root} = Z_2$)

performed (when distance between $core\_$ and $recent\_$ is too large).

The adaptation method requires that some paths will be considered as more important ones than single paths. Moreover, a measure of importance of the path $imp$ needs to be introduced. In case of normal adding path to the flow graph, the importance factor $imp$ is equal to 1, but in the adaptation process $imp$ can be greater than 1. Hence, a weighting of each path must be performed and a weighted set of paths $w\hat{P}$ needs to be introduced, as follows:

$$\widehat{wP} = \{w\hat{p}_i\} \quad , \quad w\hat{p}_i = \langle \hat{p}_i, imp_i \rangle \qquad (18)$$

where $w\hat{p}_i$ is weighted path that contains path defined previously by Eq. 14 and $imp_i$ is importance factor of path $\hat{p}_i$.

The set of path $P$ is extended by probability of occurrence of a particular path in the past, upon fulfilling the condition:

$$Pr\left(\underline{Path} = p_i\right) = \frac{\|p_i\|}{\|P\|} \qquad (19)$$

where $\|p_i\|$ is number of instances of particular path in the set of paths $P$ and $\|P\|$ in number of all paths in set $P$.

The difference between two flowgraphs needs to be determined with distance metrics. The first metric is based on the average absolute deviation in certainty factor assigned to all edges of the flowgraph. This metric is called also conformity. In case that we have two flowgraphs denoted $A$ and $B$, it holds:

$$D = \frac{\sum\limits_{Edges_A} \left|cer_B\left(x,y\right) - cer_A\left(x,y\right)\right|}{\left\|Edges_A\right\|} \tag{20}$$

where $Edges_A$ is a set of edges in flowgraph $A$, $cer_A$ and $cer_B$ are certainty factors from flowgraph A and flowgraph B, respectively, $\|Edges\|$ is the number of edges in the flowgraph A.

The second metric utilizes probability distributions defined by Eq. 19. The metric is based on a coincidence index. Changes in the flowgraph are also related to changes in the probability distribution of paths $Pr\left(\underline{Path}\right)$. One of probability distributions must be determined as a reference (in this case it is $Pr_A$), whereas the second probability distribution is the modified one ($Pr_B$). The probability distribution $Pr_B$ comes from the flowgraph B that used more paths as input than the flowgraph A. The mentioned modification is implied as a possibility of appearance paths which were not present in the input set of the flowgraph A. In order to solve this problem a modification must be made of $Pr_B$. All instances of paths that are in probability distribution $Pr_A$ do not appear in probability distribution $Pr_B$ must be removed from the probability distribution $Pr_B$. Next, a renormalization of the probability distribution $Pr_B$ is made. The modified probability distribution $\hat{Pr}_B$ prepared in such a way can be used in the formula 21 as follows:

$$CI = \frac{\sum\limits_{\underline{Path}_A} \left[Pr_A\left(\underline{Path_A} = p_i\right) \cdot \hat{Pr}_B\left(\underline{Path_B} = p_i\right)\right]}{\left\|\underline{Path_A}\right\|} \tag{21}$$

where $\left\|\underline{Path_A}\right\|$ determines how many different instances of path is in the set of paths $P$ defined in Eq. 14.

The adaptation method operates in two phases. The first is creation of two new flow graphs ($core\_$ and $recent\_$) and adding paths to $recent\_$ in groups (of i.e. one hundred paths). After adding a group of paths, the distance between $core\_$ and $recent\_$ is calculated (using formula Eq. 20). If the distance is larger than $learningThershold\_$, then $recent\_$ is copied to the $core\_$ flowgraph and a next group of paths is added to the $recent\_$, otherwise the $core\_$ is considered as a proper behaviour model and the adaptation algorithm passes to the second phase. In this phase paths are still adding to the $recent\_$ in groups, but there is no copying of the $recent\_$ flowgraph to the $core\_$. After adding the group of paths the distance between the flow graph $core\_$ and the flow graph $recent\_$ is calculated (see Eq. 20) . If this distance is lower than $adaptiveThreshold\_$, the next group of paths is added to the $recent\_$ flowgraph, otherwise the importance weights (see Eq. 21) is calculated for the last group of paths and these paths are added to the $core\_$ flowgraph with appropriate weights. Next, consecutive groups of paths are added to the $recent\_$ flowgraph. The flowchart of this algorithm is presented in the Fig. 4.

In order to prove this concept, simulations were performed. The results of the simulations are presented in Fig. 5,

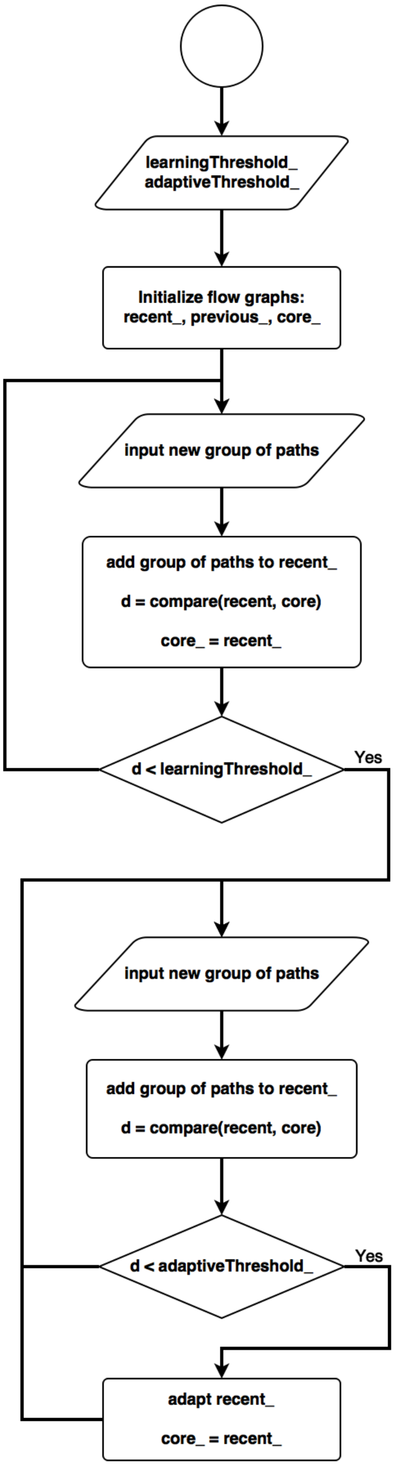

Fig. 4: Flowchart of the used adaptation algorithm

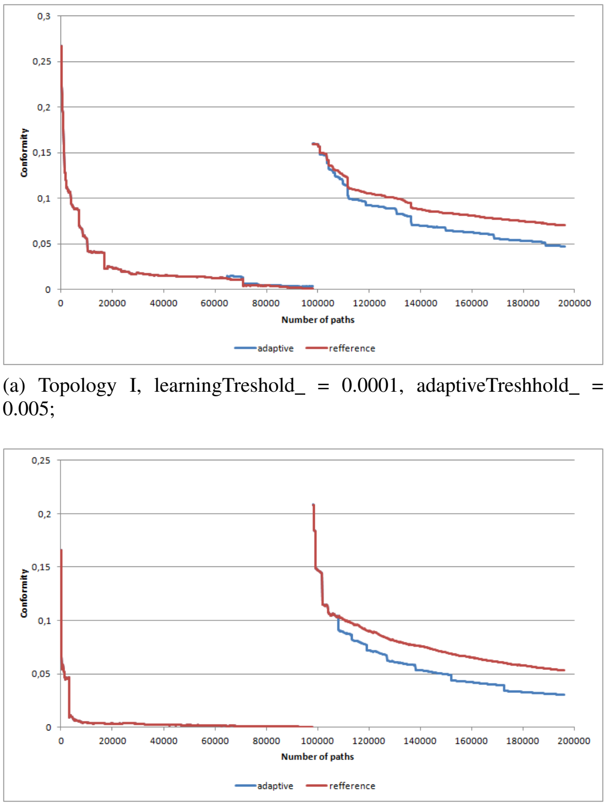
The simulation was carried out in the following way:

1) on the basis of real set of paths, which was quite small (about 1000 paths), a large set of path was generated (about 100 thousands paths),
2) the $real\_small\_$ flowgraph is built on the basis of this



(a) Topology I, learningTreshold_ = 0.0001, adaptiveTreshhold_ = 0.005;

(b) Topology II, learningTreshold_ = 0.0001, adaptiveTreshhold_ = 0.005;

Fig. 5: Result of preformed simulations for different topologies of video surveillance systems

small set of path,

3) building a flow graph enforced with adaptation method is performed with the large (generated) set of paths – adding paths in groups of 100,
4) the small set of path is modified in a way which simulates changing the topology of the cameras network,
5) the new version of $real_small\_$ flowgraph is built on the basis of this small modified set of path,
6) the second large set of paths is generated on the basis of this modified small set of paths,
7) adding the paths form the large set to the recent flowgraph occurs.

The charts from Fig. 5 present the distance (see Eq. 20) between the $real\_small\_$ flow graph and the $core\_$ flow graph (when adaptation method is in use). In order to show the difference, the $reference\_$ flow graph is added. This flow graph is built without any adaptation method. The drastic change in the center of the chart is related to the modification of the small set of the path (simulating change in the topology graph). In order to obtain real input data (a small set of object paths) the setup of 6 cameras, denoted as *Topology I*, was used. The *Topology II* was a group of 11 cameras. The $real\_small\_$ flow graph for both sets of camera was created basing on the analysis of 1,5 hour of video material.

## V. Conclusion and Future work

The flow graph is a suitable data structure to contain a behaviour model. It is prone to extensions, modifications and adaptation to various types of problems because of its transparency and simplicity. In case of video surveillance systems the flow graph is a container for knowledge concerning object behaviour which is easily to obtain and fast in use. The certainty and coverage factors can be clearly explained and easily applied to problems of object movement prediction (in correspondence to $cer$) or object re-identification (in correspondence to $cov$). Additionally, problem of changing conditions in video surveillance systems also can be also managed using the adaptation method presented above. This adaptation method allows for obtaining better conformity of the flow graph in case of modification of the topology of camera network. Moreover, the flow graph adapts faster to new conditions. The future works related to the flow graphs are concentrated on the application of them in tracking object in one camera in case when the object is obscured by another object or some other obstacles.

# Representing Parametric Concepts with Situation Theory

Roussanka Loukanova
Department of Mathematics, Stockholm University
Email: rloukanova@gmail.com

***Abstract*—We use higher-order, type-theoretic Situation Theory to model semantic concepts as situation-theoretic objects consisting of parametric information. Situation Theory contributes by representing concepts as classes of parametric objects, in a computational way. We use concepts that are often expressed by human language in taxonomy classifications, as a demonstration of the situation theoretic-approach to model parametric information in abstract concepts.**

## I. Introduction

THE IDEAS of Situation Theory were originally introduced by Barwise [1], and then by Barwise and Perry [2], for modeling information in nature. The work emerged from decades of efforts by varieties of model-theoretic approaches for adequate computational semantics of human language and cognitive science. In search for adequate semantics of human language, with his extensive work in mathematics, model-theory, and admissible sets, Jon Barwise soon realized that semantic objects for human language are special cases of objects in a more general theory of meaning and information. Since then, Situation Theory has been under development as a powerful, highly expressive theory of finely-grained information that is partial, underspecified, and situational. Semantics of languages is one of the prominent applications of Situation Theory, know as Situation Semantics.

Our intensive efforts on modeling semantic information and concepts are currently in several, concurrent directions, for intelligent applications to information and language processing. In nature, information typically is partial, parametric, and dependent on situations, in most of its components. For adequate modeling of semantic objects, we need to represent these natural features of information and languages. Applications to many contemporary technologies, which are related to data science, information, and language processing, require models of information and information processing. These models need to reflect information flow in nature and, in the same time, to be computational.

On the side of the mathematical foundations of Situation Theory, Aczel non-well-founded set theory, see Aczel [3], has proved to be the most suitable set theory for modeling classes of situation-theoretic objects that are proper classes, i.e., which are not sets in the classic Zermelo-Fraenkel set theory ZFC, while they are non-well-founded sets in Aczel set theory. Aczel non-well-founded set theory is an axiomatic system consisting of the ZFC axioms, except the Axiom of Foundation, which is replaced with Aczel Anti-Foundation Axiom (AFA), see also Rathjen [4]. Situation Theory, when based on Aczel non-well-founded sets, models circular information and self-reference, including for concepts. It can model potentially large classes of situation-theoretic objects, which theoretically are proper non-well-founded sets. What is significant, for practical, intelligent applications, is that situation-theoretic objects, even when properly non-well-founded by the AFA, have finite, not necessarily large representations, e.g., visualized as cyclic graphs. Large objects can be limited for practical applications, e.g., by restrictions from specific domains of applications.

Situation Theory has been under development as a theory of the inherently relational and situational nature of information, in general, not only of linguistic meanings, by diverging from the traditional possible-world theories of semantics with type-theoretic settings, in particular from Montague's IL (see Montague [5]). Detailed discussions and motivations of the situation-theoretic objects, such as situation types similar to the ones introduced in this article, are given in Barwise and Perry [2]. For an informal introduction to Situation Theory and Situation Semantics for human language, with examples and intuitions, see Devlin [6]. Note that the typed situation-theoretic objects that we use in this paper extend the ideas of situated objects in the early works on Situation Theory, and in addition, are strictly defined objects of mathematical structures. Formal introduction, in the lines of our work here, is given in Loukanova [7]–[10]. These works include examples from human language, while Loukanova [11], [12] provides syntax-semantics constructions of human language expressions, by using phrase-structure syntax, which is the precursor and theoretic backbone of parsers in currently prevailing computational syntax.

One of the distinguished applications of Situation Theory has been Situation Semantics for semantic representations of human language in computational grammars. Head-driven Phrase Structure Grammar (HPSG) is one of the first practical grammar frameworks, based on formal syntax of human language by using typed, linguistic feature-value structures, see Pollard and Sag [13], [14], and Sag et al. [15]. Originally, HPSG was introduced by the ideas of Situation Theory for distribution of partial information throughout grammatical representations, via typed feature-value structures. Various, partly specified feature-structures can be combined according to grammar principles and constraints, by unification and expending them with new information. From start, HPSG came with ambitions to use Situation Semantics for including

978-83-60810-66-8/$25.00©2015, IEEE

semantic representations in syntactic analyses. Current HPSG systems have been successfully realizing such semantic representations with a specialized language, Minimal Recursion Semantics (MRS), for handling scope ambiguities, see, e.g., Copestake et al. [16]. Loukanova [17] shows that the concept of minimal recursion in MRS has a functional formalization by the formal language of acyclic recursion introduced in Moschovakis [18]. By considering the relational character of the predicate symbols used in elementary predications in MRS, we see MRS as an implementation of a special case of a formal language for Situation Theory, in the lines of Loukanova [10], while more work on the relationship is necessary. The original Situation Semantics inspired other work in linguistics. E.g., it was used for semantic analysis of questions, see Ginzburg and Sag [19]. Lambalgen and Hamm [20] used concepts of Situation Semantics for semantics of tense and aspect, from cognitive perspective.

Situation Theory is an open area of theoretic development, with potentials for varieties of applications. While it has established classic applications to computational semantics, as briefly summarized above, both Situation Theory and Situation Semantics are largely open areas, in theory and applications. Currently, Situation Theory has new significance as a theory of heterogeneous information, along with the proliferation of interdisciplinary technologies and applications, especially in Artificial Intelligence and other areas that involve intelligent computation.

This paper is on a specific task of using situated information, with parametric objects, to represent hierarchically linked classes of parametric concepts. We employ situated types that support linking parametric objects with restrictions. We introduce primary restrictions over parametric objects as types associated with the argument roles of relations and types. These restrictions are called appropriateness conditions over argument roles. The argument roles (commonly known as argument slots) of relations and types can be filled up only by objects satisfying the respective appropriateness conditions.

The notational symbolism that we use to designate abstract objects of Situation Theory reminds of expressions of a formal language, but by these notations, we do not define a formal language and do not use any such formal language per se. I.e., Situation Theory is a higher-order, typed, mathematical structure. In this work, we use Situation Theory as a model theory of information, by a focus on specific abstract objects, without formal language. On the other side, a formal language for Situation Theory can provide many advantages. E.g., it is important to have a formal language for situation-theoretic analyses of human and artificial languages, via semantic representations by formal terms (which are usually called logic forms). Introducing a formal language for Situation Theory is the topic of other work, see Loukanova [10], [21], for development of formal languages of Situation Theory. In this work, our focus is on introducing semantic domains of situation-theoretic objects, i.e., complex types with parameters and complex, restricted sets of linked parameters. In the second part of the paper, we use situation-theoretic objects to represent parametric concepts, i.e., concepts as model-theoretic objects with rich informative structure, where information can be parametric.

*Note 1:* The situation-theoretic objects are often designated by multi-line expressions, i.e., spread over several lines, for lack of space in a single line, but also to visualize the structure of the objects. We have tried to follow traditional indentation as in programming, wherever possible, but primarily, we try to follow the convention that the arguments of a given relation or type are vertically aligned.

## II. A Brief Overview of Basic Situation-Theoretic Notions

This section introduces situation-theoretic notions and objects that are fundamental for representation of information and essential for the following sections of the paper. Informally, the informational pieces, called *infons*, are basic and complex objects that have structure carrying information about relations and objects filling the arguments of the relations, at time-space locations. Recursively, basic and complex infons are constructed by starting with primitive relations, argument roles, primitive individuals filling the argument roles of the relations, basic space-time locations, and positive or negative polarity. The polarity of an infon carries the information about whether or not the objects in the infon are in its relation.

### A. Primitive Individuals

A collection (typically, a set) $\mathcal{A}_{\text{IND}}$ is designated as the set of primitive *individuals* of Situation Theory:

$$\mathcal{A}_{\text{IND}} = \{a, b, c, \dots\} \tag{1}$$

The objects in $\mathcal{A}_{\text{IND}}$ are set-theoretic objects, not necessary atomic urelements, which are considered as primitives in Situation Theory. In various versions of Situation Theory, designated for specific applications, some of the individuals in $\mathcal{A}_{\text{IND}}$ may be parts of other individuals in $\mathcal{A}_{\text{IND}}$, and as such, can be in respective *part-of* relations.

### B. Space-time Locations

Situation Theory make a substantial use of a given class $\mathcal{A}_{\text{LOC}}$ of space-time points, periods, and regions units. Note that $\mathcal{A}_{\text{LOC}}$ can be a proper class, or a set, depending on the version of Situation Theory that one can select to use in applications.

$$\mathcal{A}_{\text{LOC}} = \{l, l_0, l_1, \dots\} \tag{2}$$

The collection $\mathcal{A}_{\text{LOC}}$ is endorsed with relations of time precedence $\prec$, time overlapping $\circ_t$, space overlapping $\circ_s$, space-time overlapping $\circ$, and space and time inclusions $\subseteq_t$, $\subseteq_s$, $\subseteq$. In some versions of Situation Theory, the space-tile locations can be given by complex objects, e.g., as pairs of two components, one for space locations (regions), and one for time points or periods.

### C. Primitive Relations

Significantly, Situation Theory has a collection (which can be a set in practical applications, or a proper class) $\mathcal{A}_{\text{REL}}$ of abstract, primitive objects that are the primitive, i.e., basic, relations: $\mathcal{A}_{\text{REL}} = \{r_0, r_1, \dots\}$ The elements of $\mathcal{A}_{\text{REL}}$ are abstract representatives of real or virtual relations. For example, some of them can be abstract representatives of real properties of objects and relations between objects, in reality, or in virtual models, which humans are attuned to distinguish perceptually in reality, or cognitively, i.e., conceptually.

In typical set-theoretic practice, relations between set-theoretic objects are represented as sets of ordered tuples of the objects being in the relevant relations. On the contrary, Situation Theory takes the relations in $\mathcal{A}_{\text{REL}}$ as primitive, first-class objects. I.e., the objects in $\mathcal{A}_{\text{REL}}$, are primitive objects that are not themselves sets of tuples of individuals being in those relations. Set-theoretically, the primitive relations in $\mathcal{A}_{\text{REL}}$, as well as the other primitive objects in Situation Theory, such as individuals, properties, relations, and types, can be taken as urelements of the meta-theoretic set theory. E.g.,

$$\mathcal{A}_{\text{REL}} = \{\, man, woman, dog, run, like, \dots \} \tag{3}$$

By introducing more complex situation-theoretic objects, it is possible to define the notion of the *extension* of a given relation $r$, in a given situation $s$ as the set of the tuples of objects being in the relation $r$ in $s$. For example, the extension of the relation $read$ in a given, specific situation $s$ and a space-time location $l$, is the set of all pairs $\langle a, b\rangle$ of objects, such that the primitive relation of reading holds between $a$ as the reader and $b$ as the object that is read, at the location $l$, in the situation $s$.

### D. Primitive Types

Situation Theory has a collection (a relatively small, finite set) of objects, which are called *primitive* or *basic* types, that represent our intuitions, cognitive concepts of types, and type classifications of objects in specific areas of applications:

$$B_{\text{TYPE}} = \{\text{IND}, \text{LOC}, \text{REL}, \text{TYPE}, \text{POL}, \text{PAR}, \tag{4a}$$
$$\text{ARoles}, \text{INFON}, \text{SIT}, \text{PROP}, \models\} \tag{4b}$$

where IND is the type of individuals; LOC: of space-time locations; REL: of relations (primitive and complex); TYPE: of types (primitive and complex); POL: of two polarity objects (e.g., represented by the natural numbers 0 and 1); PAR: of parameters; ARoles: of abstract argument roles (primitive and complex); INFON: of situation-theoretic objects that are basic or complex information units; SIT: of situations; PROP: of abstract objects that are propositions; $\models$ is a type called "supports". Some of these types will be explained later.

### E. Primitive Parameters — Indeterminates

Situation Theory has a collection (a set) of primitive parameters, for each of the basic types, e.g.:

$$\mathcal{P}_{\text{IND}} = \{\dot{a}, \dot{b}, \dot{c}, \dots\}, \qquad \mathcal{P}_{\text{LOC}} = \{\dot{l}_0, \dot{l}_1, \dots\}, \tag{5a}$$
$$\mathcal{P}_{\text{REL}} = \{\dot{r}_0, \dot{r}_1, \dots\}, \qquad \mathcal{P}_{\text{POL}} = \{\dot{i}_0, \dot{i}_1, \dots\}, \tag{5b}$$
$$\mathcal{P}_{\text{SIT}} = \{\dot{s}_0, \dot{s}_1, \dots\}, \qquad \dots \tag{5c}$$

We assume that, for every type $\theta$ : TYPE, there is potential availability of parameters of that type $\theta$, (6a).

$$\mathcal{P}_\theta \text{ is a class of parameters, for every } \theta : \text{TYPE} \tag{6a}$$
$$p \in \mathcal{P}_\theta \quad \text{iff} \quad p : \theta \text{ and } p : \text{PAR} \tag{6b}$$

Thus, theoretically, the classes of types and parameters can be proper classes, which are Aczel non-well founded sets, see Aczel [3]. Note that in applications, for many types $\theta$ : TYPE, it can be the case that $\mathcal{P}_\theta = \emptyset$. Practically, it would be useful, to add classes $\mathcal{P}_\theta$ not in advance, but depending on needs, and to add fresh, new parameters to them "on-the-go".

Sometimes, but not always, we use a notation originally introduced in Situation Theory, to denote parameters with dotted letters, as in (5a). Marking letters with dots is a visual distinction of parameters from other individuals and objects. However, we should stress that this paper is about modeling domains of Situation Theory, not about a formal language. Letters, characters, and expressions that we use are notational means of denoting objects in situational domains.

In this paper, we start with the idea of situation-theoretic parameters as representing very primitive concepts that are distinguished only by their types. Thus, $\mathcal{P}_{\text{IND}}$ is the class of the primitive concepts of individuals, e.g., $\dot{a}$, $\dot{b}$, etc., are concepts of individuals. $\mathcal{P}_{\text{LOC}}$ is the class of the primitive concepts of space-time locations, e.g., $\dot{l}_0$, $\dot{l}_1$, etc., are concepts of space-time locations. $\mathcal{P}_{\text{REL}}$ is the class of the primitive concepts of relations, where any element $r \in \mathcal{P}_{\text{REL}}$ is a concept of a relation. E.e., $blue$, as a unary relation, i.e., a property of objects, is the concept of an object being blue in color, in space-time. $give$ is the concept of a relation between three objects, one being an individual giving an object to another individual, which takes place in space-time. Typically, relations between objects and properties of objects happen in space-time. The class $\mathcal{P}_{\text{SIT}}$ consists of primitive parameters that represent abstract concepts of situations. We consider that the biological nervous systems, at least those of humans and other advanced living organisms, are attuned to recognize both abstract entities and specific instances of abstract entities. In particular, human brain has inner facilities to form and comprehend concepts for individuals, relations, space-time locations, and situations, as well as specific representatives, i.e., instantiations, of the abstract concepts.

*Notation 1:* For any given type $T$ (primitive or complex) and an object $\Theta$, we write $(T : \Theta)$ to designate the proposition that $\Theta$ is of type $T$, and $T : \Theta$ iff $\Theta$ is of type $T$. An alternative notation of can be used, i.e., $\Theta : T$, as in some type systems, such as the intensional logics of Montague and Gallin. We allow both notations depending on convenience, i.e., given a type $T$ (primitive or complex) and an object $\Theta$, we write

$$\begin{gathered}(T : \Theta) \quad \text{iff} \quad (\Theta : T)\\ \text{i.e., the proposition that } \Theta \text{ is of type } T\end{gathered} \tag{7a}$$
$$T : \Theta \quad \text{iff} \quad \Theta : T \quad \text{iff} \quad \Theta \text{ is of type } T \tag{7b}$$

The alternative notations in (7a)–(7b) can be used depending on the context, which makes clear the usage. Note that $(T : \Theta)$

and $(\Theta : T)$ in (7a) both designate the proposition that $\Theta$ is of type $T$, while the alternatives in (7b) designate the verified proposition, when factually $\Theta$ is of type $T$.

### F. Primitive Argument Roles

We assume a collection (a set) of primitive objects $\mathcal{BA}_{\text{ARoles}}$ designated as *primitive argument roles*, which is a sub-collection of the class of $complexargumentroles$:

$$\mathcal{BA}_{\text{ARoles}} = \{\rho_0, \dots, \rho_n, \dots\} \subset \mathcal{A}_{\text{ARoles}} \tag{8}$$

A set of argument roles is associated with each of the primitive relations, and each of the primitive types, by a function $\textsc{ArgR}$, with domain and range: $Dom(\textsc{ArgR}) = \mathcal{A}_{\text{REL}} \cup B_{\text{TYPE}}$, and $Range(\textsc{ArgR}) \subseteq \textsc{type} \times \mathcal{A}_{\text{ARoles}}$. Thus the argument roles of each type and each relation $X$ (basic or complex, recursively for the complex ones) are associated with corresponding types that restrict what objects can fill up the argument roles. I.e., every relation or type $X$, is associated with argument roles:

$$\textsc{ArgR}(X) = \{T_1 : arg_1, \dots, T_n : arg_n\}, \tag{9a}$$

$$\text{where } arg_i : \text{ARoles and } T_i : \textsc{type},\ i = 1, \dots, n, \text{ for some } n \geq 0 \tag{9b}$$

The types $T_i$ are called *appropriateness constraints* of the corresponding argument roles $arg_i$, $i = 1, \dots, n$, of the relation (type) $X$. Complex relations and types are associated with argument roles and corresponding appropriateness constraints, according to recursive definitions given in what follows, supplemented by examples.

In what follows, we assume that if an argument role $arg_i$ of a relation or type $X$, (9) is restricted by a type $T_i : arg_i$, this argument role can be filled up by a situation-theoretic object of type $T_i$, including by parameters, e.g., by using (6b).

### G. Basic Infons

Basic infons can be represented by specialized, marked tuples

$$\langle infon, \gamma, \theta, \tau, i \rangle \tag{10}$$

where $\gamma \in \mathcal{R}_{\text{REL}}$ is a relation (primitive or complex), $\textsc{loc} : \tau$, $\textsc{pol} : i$, and $\theta$ is a function, called the *argument-role filling of* $\gamma$, which fills up the argument roles $arg_1, \dots, arg_n$ $(n \geq 0)$ of $\gamma$ with objects $\xi_1, \dots, \xi_n$ of respective types $T_1, \dots, T_n$, i.e.:

$$\theta = \{\langle T_1 : arg_1, \xi_1 \rangle, \dots, \langle T_n : arg_n, \xi_n \rangle\} \tag{11}$$

for some situation-theoretic objects $\xi_1, \dots, \xi_n$ satisfying the corresponding appropriateness constraints of the argument roles of the relation $\gamma$.

*Notation 2:* The basic infons (10), as well as some of the complex ones are denoted by (12):

$$\ll \gamma, \theta, \tau, i \gg \tag{12}$$

*Notation 3:* When the types of the argument roles are agreed, i.e., understood by the context, the function filling the argument roles is denoted by (13).

$$\theta = \{\langle arg_1, \xi_1 \rangle, \dots, \langle arg_n, \xi_n \rangle\} \tag{13}$$

### H. Complex Infons

Complex infons for representation of conjunctive and disjunctive information are formed by the operators conjunction and disjunction. In some earlier versions of Situation Theory, the operators conjunction and disjunction in the infon constructions were taken to be primitive relations between infons, for which locations are irrelevant.

*Notation 4:* For sake of space, by assuming that the order of the argument roles is agreed to avoid confusion, we shall adopt the traditional linear notations of the basic infons, with or without the type constraints over the argument roles, as in (14a)–(14d).

$$\ll \gamma, T_1 : arg_1 : \xi_1, \dots, T_n : arg_n : \xi_n, \textsc{loc} : \tau; i \gg \tag{14a}$$

$$\ll \gamma, arg_1 : \xi_1, \dots, arg_n : \xi_n, \textsc{loc} : \tau; i \gg \tag{14b}$$

$$\ll \gamma, T_1 : \xi_1, \dots, T_n : \xi_n, \tau; i \gg \tag{14c}$$

$$\ll \gamma, \xi_1, \dots, \xi_n, \tau; i \gg \tag{14d}$$

We denote the class of all infons, basic or complex, by $\mathcal{I}_{\text{INFON}}$.

## III. Basic Semantic Concepts

In this section, we introduce the idea of representing basic semantic concepts as situation-theoretic objects with parametric components. We use prototypical examples of semantic relations and parametric information peaces.

*Example 3.1:* Assume that $read_2 \in \mathcal{A}_{\text{REL}}$, i.e., $read_2$ is a primitive situation-theoretic object of type $\textsc{rel}$, i.e., by (7b), $read_2 : \textsc{rel}$. Assume also that the relation $read_2$ has two argument roles as in (15):

$$\textsc{ArgR}(read_2) = \{\textsc{ind} : reader, \textsc{ind} : readed\} \text{ for } reader, readed \in \mathcal{A}_{\text{ARoles}} \tag{15}$$

Then, we have the following infons in (16a)–(16d).

$$\ll read_2, \textsc{ind} : reader : a, \textsc{ind} : readed : b, \textsc{loc} : l; 1 \gg \tag{16a}$$

$$\ll read_2, \textsc{ind} : reader : \dot{a}, \textsc{ind} : readed : \dot{b}, \textsc{loc} : \dot{l}; 1 \gg \tag{16b}$$

$$\ll read_2, \textsc{ind} : reader : a, \textsc{ind} : readed : \dot{b}, \textsc{loc} : \dot{l}; 1 \gg \tag{16c}$$

$$\ll read_2, a, b, l; \dot{p} \gg \tag{16d}$$

Note that we use the “misspelled” notation $readed$ for the semantic argument role of the relation $read_2$, which is to be filled by the object that is being read. I.e., $readed \in \mathcal{A}_{\text{ARoles}}$ is an abstract argument role denoted by this “misspelled” variant of the past participle of the verb “read”. This notation is by a trend in the early versions of Situation Semantics, by which, the argument role for the actor of an activity, usually denoted by a verb, is represented by using the suffix “er”, and the argument role for the object acted upon by using the suffix “ed” or “en”. Thus, some argument roles can have “misspelled” notations. How the argument roles are denoted is a matter of agreement settings. We have chosen here that trend, to avoid indexing the argument roles with natural numbers, i.e., $arg_1, \dots, arg_n$, which carries connotations that the argument roles have been linearly ordered, which is not always the case. We would like to stress that, in general, there is no intrinsic order over the argument roles of relations and types, except in specific cases and for notational needs.

In (16a)–(16d), $a, b \in \mathcal{A}_{\text{IND}}$ are individuals, $l \in \mathcal{A}_{\text{LOC}}$ is a location, while $\dot{a}, \dot{b} \in \mathcal{P}_{\text{IND}}$ are parameters for individuals, $\dot{l} \in \mathcal{P}_{\text{LOC}}$ is a location parameter, and $\dot{p} \in \mathcal{P}_{\text{POL}}$ is a parameter for either of the two polarities $\{0, 1\}$. E.g., the unknown individual, which fills up the argument role of the material that is being read, is represented by a semantic parameter $\dot{b}$ that is restricted to be of type IND, by the constraint over the argument role that $\dot{b}$ fills up, i.e., $\text{IND} : \mathit{readed} : \dot{b}$. This constraint allows $\dot{b}$ to be of both types IND and PAR, i.e., $\text{IND} : \dot{b}$ and $\text{PAR} : \dot{b}$, by using (6b). Similarly, for the constraints over $\dot{a}, \dot{l}, \dot{p}$.

We stress that the parameters are not variables in a formal language. In Situation Theory, parameters are first-class model-theoretic objects. In this paper, we use the parameters $\dot{a}$, $\dot{b}$ as representing the abstract concept of individuals that are 'unknown', and $\dot{l}$ represents a concept of a space-time location, without being any specifically determined location. The two specific individuals $a$, $b$, the location $l$, and the 'confirming' polarity 1, are instantiations of the corresponding concepts of two individuals, a location, and a polarity represented by parameters.

Next, we give examples for other parametric infons, by using a relation of reading, which is an alternative to the relation $read_2$ in (16a)–(16d), for having an extra argument role for an intended listener, which could have been denoted by $listener$. To avoid the connotation that the object filling up this argument role listens (which might not be the case), we denote it by $readee$.

*Example 3.2:* Now, we assume that $read \in \mathcal{A}_{\text{REL}}$, i.e., $read$ is a primitive situation-theoretic object of type REL, i.e., by (7b), $read : \text{REL}$. The significant difference is that, unlike in Examle 3.1, here the relation $read$ has the following three argument roles.

$$\begin{aligned} \text{ARGR}(\mathit{read}) = \{&\text{IND} : \mathit{reader}, \text{IND} : \mathit{readed}, \\ &\text{IND} : \mathit{readee}\} \end{aligned} \tag{17}$$
$$\text{for } \mathit{reader}, \mathit{readed}, \mathit{readee} \in \mathcal{A}_{\text{ARoles}}$$

Now we consider the infon (18a)–(18e).

$$\ll \mathit{read},\ \text{IND} : \mathit{reader} : a, \tag{18a}$$
$$\text{IND} : \mathit{readed} : \dot{b}, \tag{18b}$$
$$\text{IND} : \mathit{readee} : \dot{c}, \tag{18c}$$
$$\text{LOC} : \mathit{Loc} : \dot{l}; \tag{18d}$$
$$\text{POL} : \mathit{Pol} : 1 \gg \tag{18e}$$

The infon (18a)–(18c) represents the information that an individual $a$ reads the unknown or undetermined material $\dot{b}$ (i.e., $\dot{b}$ is a semantic parameter) to the unknown or undetermined $\dot{c}$ (i.e., $\dot{c}$ s a semantic parameter), at the unknown or undetermined location $\dot{l}$ (i.e., $\dot{l}$ is a location parameter). The informational piece (18a)–(18e) is about the relation $read$ between specific objects $a$, $\dot{b}$, $\dot{c}$, taking place at the specific location $\dot{l}$. The difference is that $a \in \mathcal{A}_{\text{IND}}$ is explicitly given as known, determinedly picked up from the set $\mathcal{A}_{\text{IND}}$. While $\dot{b} \in \mathcal{P}_{\text{IND}}$, $\dot{c} \in \mathcal{P}_{\text{IND}}$, and $\dot{l} \in \mathcal{P}_{\text{LOC}}$, are also specific, but are either unknown or simply left indeterminate, i.e., as parameters.

*Example 3.3:*

$$\ll \mathit{read},\ T_a : \mathit{reader} : a, \tag{19a}$$
$$T_b : \mathit{readed} : \dot{b}, \tag{19b}$$
$$T_c : \mathit{readee} : \dot{c}, \tag{19c}$$
$$\text{LOC} : \mathit{Loc} : \dot{l}; \tag{19d}$$
$$\text{POL} : \mathit{Pol} : \dot{p} \gg \tag{19e}$$

In (19a)–(19e), by $T_a$, $T_b$ and $T_c$, we represent sets of types that constrain the argument roles $reader$, $readed$, $readee$ of the relation $read$, by undetermined types.

By using a parameter for polarity, the infon (19a)–(19e) represents the parametric information that the specific object *$a$ either reads or does not read the undetermined $\dot{b}$ to the undetermined $\dot{c}$, at the undetermined location $\dot{l}$.* The undetermined polarity is represented by a semantic parameter $\dot{p}$ that is restricted to be of type POL, by the constraint over the argument role that $\dot{p}$ fills up, i.e., $\text{POL} : \mathit{Pol} : \dot{p}$. This constraint allows $\dot{p}$ to be of both types POL and PAR, i.e., $\text{POL} : \dot{p}$ and $\text{PAR} : \dot{p}$, by using (6b). Similarly, for the constraint over $\dot{l}$.

The importance of using the polarity parameter $\text{POL} : \dot{p}$, in this example, is that we do not have an explicit disjunction — we still have a piece of information by (19a)–(19e) about the relation of reading concerning $a$ as a possible reader.

The reason for which we have chosen examples with the relation of reading is not only to demonstrate the definitions, but also because it is denoted by a verb that syntactically can have either one, two, or three syntactic arguments. With the Examples 3.1–3.3, we make a point for a distinction between syntactic arguments of lexemes, in this case of the verb "read", and the corresponding semantic argument roles of the semantic relations denoted by those lexemes. Typically, a sentence like (20b) can be rendered into a term having a component infon similar to one of the infons in (16a)–(16d), which may be combined with additional infons depending on the noun phrases A and B. Thus, the verb "read", co-occurring with two syntactic arguments, would be treated as denoting a relation $read_2$ associated with two semantic argument roles (15). Similarly, the verb "read" in a sentence like (20a) can be rendered into a relation $read_1$ associated with one semantic argument role.

$$\text{A reads.} \tag{20a}$$
$$\text{A reads B.} \tag{20b}$$
$$\text{A reads B to C.} \tag{20c}$$

A sentence like (20c) can be rendered into a term with a component infon similar to the one in (18a)–(18e). In this way, when the verb "read" co-occurs with three syntactic arguments, it is rendered into a relation $read$, which is different from $read_1$ and $read_2$, by having three semantic argument roles (17). As a choice, one may keep up with this line of introducing different, variant relations, depending on the number of argument roles. This choice is deficient in representing that there is a common semantic relation of reading that may exhibit only some of its semantic argument roles in language expressions like (20a)–(20c).

Here we point that by using semantic parameters, we can render the verbal lexeme "read", occurring in the three kinds of sentences like (20a)–(20c), into the same relation $read$, associated with three semantic argument roles (17). For sentences like (20a), read would be rendered into the relation $read$, by filling up each of the argument roles $readed$ and $readee$ with undetermined parameters. The role $reader$ can be filled up by a specific individual $a$, or by a parameter $\dot{a}$ along with additional information depending on the NP A. In sentences like (20b), read would be rendered into the same relation $read$, by filling up the argument role $readee$ with an undetermined parameter, while the roles $reader$ and $readed$ can be filled by specific individuals, or by parameters along with additional information depending on NPs A and B. In this way, we have the same semantic relation $read$, which may exhibits only some of the semantic information associated with it, explicitly in syntactic expressions like (20a)–(20c). Information that is not expressed in (20a)–(20c) and is not available by context, is kept parametric and underspecified.

Thus, by the relation $read$ associated with semantic argument roles (17), we model a general, semantic concept of reading. Its argument roles can be filled up by parameters or specific individuals. Furthermore, the parameters can be additionally specified as we show in the second part of the paper. We used $read$ as a prototypical example of a class of similar basic semantic concepts.

## IV. Propositions

*Definition 1 (Proposition):* A proposition is a semantic, situation-theoretic object, represented set-theoretically in Aczel non-well-founded sets, by the tuple $\langle \text{PROP}, \mathbb{T}, \theta \rangle$, where $\mathbb{T} \in \mathcal{T}_{\text{TYPE}}$ is a type that is associated with a set of argument roles (21)

$$\text{ArgR}(\mathbb{T}) = \{T_1 : arg_1, \ldots, T_n : arg_n\} \tag{21}$$

and $\theta$ is a function, called the *argument-role filling* of the type $\mathbb{T}$, which fills up the argument roles $arg_1, \ldots, arg_n$ $(n \geq 0)$, of $\mathbb{T}$ with objects $\xi_1, \ldots, \xi_n$ of respective types $T_1, \ldots, T_n$, i.e.:

$$\theta = \{\langle T_1 : arg_1, \xi_1 \rangle, \ldots, \langle T_n : arg_n, \xi_n \rangle\} \tag{22}$$

for some situation-theoretic objects $\xi_1, \ldots, \xi_n$ satisfying the corresponding appropriateness constraints of the argument roles of the type $\mathbb{T}$, i.e.:

$$T_1 : \xi_1, \ldots, T_n : \xi_n \tag{23}$$

*Notation 5:* Typical notations are

$$\begin{aligned} \langle \text{PROP}, \mathbb{T}, \theta \rangle &\equiv \langle \mathbb{T}, \theta \rangle && \text{(24a)} \\ &\equiv (\mathbb{T} : \theta) && \text{(24b)} \\ &\equiv (\theta : \mathbb{T}) && \text{(24c)} \end{aligned}$$

The notations (24a) and (24b) resemble the application operators, where "$\mathbb{T}$ applies to the argument(s) $\theta$". The notational variants (24b) and (24c) are used alternatively depending on the context and the specific types $\mathbb{T}$. The notation (24c) follows the verbal expression "the proposition that the object(s) filling up the argument role(s) of $\mathbb{T}$ are of type $\mathbb{T}$".

*Definition 2 (Situated propositions):* Situated proposition, instantiated in a situation $s$, is any proposition (25):

$$\langle \text{PROP}, \models, \text{SIT} : s, \text{INFON} : \sigma \rangle, \tag{25}$$

where $s$ is a situation parameter $s \in \mathcal{P}_{\text{SIT}}$ i.e., $\text{SIT} : s$ and $\sigma$ is a basic or complex infon, i.e., $\sigma \in \mathcal{I}_{\text{INFON}}$.

The type $\models$ (pronounced "supports") has two argument roles, (26):

$$ArgR(\models) = \{\text{SIT} : arg_{\text{SIT}},\ \text{INFON} : arg_{\text{INFON}}\} \tag{26}$$

A proposition (25) is pronounced "the proposition that the situation $s$ supports the infon $\sigma$", or "the proposition that $\sigma$ holds in the situation $s$".

*Notation 6:*

$$\begin{aligned} \langle \text{PROP}, \models, \text{SIT} : s, \text{INFON} : \sigma \rangle &\equiv \langle \text{PROP}, \models, s, \sigma \rangle && \text{(27a)} \\ &\equiv \langle \models, s, \sigma \rangle && \text{(27b)} \\ &\equiv (s \models \sigma) && \text{(27c)} \end{aligned}$$

## V. Complex Types and Relations

Situation Theory has an abstraction operator, which resembles the $\lambda$-abstraction in functional $\lambda$-calculi, but is model-theoretic, informational abstraction. The informational abstraction is not a syntactic construction of a $\lambda$-expression in a formal language. It defines abstract complex relations and complex types, with abstract argument roles. These abstract situation-theoretic objects can be modeled with set-theoretic objects, by choosing appropriate set theory, e.g., a classic set-theory for more restricted applications, while choosing Aczel non-well-founded set theory, such as in Aczel [3], for more sophisticated applications.

### A. Complex Relations

*Definition 3 (Complex relations and argument roles):* Let $\sigma$ be a given infon, and $\{\xi_1, \ldots, \xi_n\}$ a set of parameters, i.e., primitive or complex objects of type PAR, $\text{PAR} : \xi_i$, for $i = 1, \ldots, n$ $(n \geq 0)$, which may occur in $\sigma$ (when some $\xi_i$ does not occur in $\sigma$, the abstraction over $\xi_i$ is vacuous, but it adds an additional argument role to the complex relation). Let, for each $i \in \{1, \ldots, n\}$, $T_i$ be the union of the constraints over the argument roles filled up by $\xi_i$. Then $\lambda\{\xi_1, \ldots, \xi_n\}\sigma$ is a *complex relation*, with abstract argument roles denoted by

$[\xi_1], \ldots, [\xi_n]$ and having $T_1, \ldots, T_n$ as *appropriateness (type) constraints*, respectively, i.e.:

$$\big[T_1 : [\xi_1], \ldots, T_n : [\xi_n] \mid \sigma\big] \in \mathcal{T}_{\text{REL}}, \quad \text{and} \tag{28a}$$

$$\begin{aligned} &\text{ARGR}(\big[T_1 : [\xi_1], \ldots, T_n : [\xi_n]) \mid \sigma\big] \\ &\quad = \{\langle[\xi_1], T_1\rangle, \ldots, \langle[\xi_n], T_n\rangle\} \\ &\quad \equiv \{T_1 : [\xi_1], \ldots, T_n : [\xi_n]\} \end{aligned} \tag{28b}$$

Instead of (28a), we shall primarily use the notation (29b), by suppressing the types of the argument roles when they are understood. The notation (29a) may be useful too.

$$\big[T_1 : [\xi_1], \ldots, T_n : [\xi_n] \mid \sigma\big] \tag{29a}$$

$$\equiv \{\lambda(\xi_1), \ldots, \lambda(\xi_n)\}\sigma \tag{29b}$$

$$\equiv \lambda\{\xi_1, \ldots, \xi_n\}\,\sigma \tag{29c}$$

Upon agreed order, which is a typical practice in mathematics and in computer science, the argument roles (usually called argument slots) and/or the types constraints can be skipped, and only the objects filling up the argument roles (slots) are listed.

### B. Complex Types

In this subsection, we define the abstract objects complex types. They are significant for what follows in this paper.

*Definition 4 (Complex types and argument roles):* Assume that

1) $\Theta$ is a given situation-theoretic proposition, and $\xi_1, \ldots, \xi_n$ are parameters, i.e., PAR : $\xi_i$, for $i = 1, \ldots, n$ ($n \geq 0$).
2) For each $i \in \{1, \ldots, n\}$, $T_i$ is the union of all the appropriateness constraints of all the argument roles of constituents of $\Theta$ that are filled up by $\xi_i$.

Note that $\Theta$ may have various, components (constituents), which are either types or relations, with arguments roles that are filled by $\xi_i$. In addition, a single constituent type, or a constituent relation, may have more than one argument role filled by $\xi_i$.

The result of the *abstraction over the parameters* $\xi_1, \ldots, \xi_n$ from the proposition $\Theta$ is a *complex type* (30a), with argument roles $[\xi_i]$ that are associated with *appropriateness (type) constraints*, respectively, $(T_i : [\xi_i])$, for $i = 1, \ldots, n$ ($n \geq 0$), i.e., (30b):

$$\big[T_1 : [\xi_1], \ldots, T_n : [\xi_n] \mid \Theta\big] \in \mathcal{T}_{\text{TYPE}}, \quad \text{and} \tag{30a}$$

$$\begin{aligned} &\text{ARGR}([T_1 : [\xi_1], \ldots, T_n : [\xi_n] \mid \Theta]) \\ &\quad = \{\langle[\xi_1], T_1\rangle, \ldots, \langle[\xi_n], T_n\rangle\} \\ &\quad = \{T_1 : [\xi_1], \ldots, T_n : [\xi_n]\} \end{aligned} \tag{30b}$$

Thus the abstraction over the parameters $\xi_1, \ldots, \xi_n$, from the proposition $\Theta$, results in complex, abstract argument roles $[\xi_1]$, …, $[\xi_n]$ of the complex type $\big[T_1 : [\xi_1], \ldots, T_n : [\xi_n] \mid \Theta\big]$. The abstraction creates argument roles along with appropriateness type constraints $T_1 : [\xi_1], \ldots, T_n : [\xi_n]$.

Note that, as in the complex relations, the parameters $\xi_i$, $i = 1, \ldots, n$, are primitive or complex objects of type PAR, PAR : $\xi_i$, for $i = 1, \ldots, n$ ($n \geq 0$), which may occur in $\Theta$. When some $\xi_i$ does not occur in $\Theta$, the abstraction over $T_i : \xi_i$ is vacuous, but it adds an argument role of the complex type (30a). In the cases when $n = 0$, the complex type has no argument roles.

*Notation 7:* A complex type $[T_1 : [\xi_1], \ldots, T_n : [\xi_n] \mid \Theta]$ is alternatively denoted by (31b), when the argument roles of the result of the abstraction operation are suppressed; and with (31c) when the corresponding type constraints over the complex roles are suppressed too.

$$[T_1 : [\xi_1], \ldots, T_n : [\xi_n] \mid \Theta] \tag{31a}$$

$$\equiv [T_1 : \xi_1, \ldots, T_n : \xi_n \mid \Theta] \tag{31b}$$

$$\equiv [\xi_1, \ldots, \xi_n \mid \Theta] \tag{31c}$$

$$\equiv \lambda\{\xi_1, \ldots, \xi_n\}\Theta \tag{31d}$$

Similarly to the complex relations in (29a)–(29c), complex types might sometimes be denoted by the $\lambda$-notation $\lambda\{\xi_1, \ldots, \xi_n\}\Theta$ in (31d). Whether a situation-theoretic object $[T_1 : \xi_1, \ldots, T_n : \xi_n \mid \vartheta]$, as an abstraction over the parameters PAR : $\xi_1$, …, PAR : $\xi_n$ in an object $\vartheta$, is a complex relation or complex type depends on whether $\vartheta$ is an infon or a proposition, not on what notation we use for it per se. Nevertheless, we shall primarily use the notations in (29b)–(29c) for relations, and (31a)–(31c) for types, in order to make clear distinction between (1) the abstract complex relations, which are abstractions over parameters from infons; and (2) the abstract complex types, which are abstractions over parameters from propositions.

## VI. Complex Concepts

In this section, we demonstrate how to use complex parametric types to model taxonomic concepts. The concepts can be at different level of abstraction over various parameters.

### A. A Sample Concept

Here we demonstrate the general ideas of concepts in taxonomic classifications, e.g., the class of *odd-toed, ungulate* entities as a subclass of *animate* entities. Then, we demonstrate how to instantiate the concept of an odd-toed, ungulate entity with a specific representative $a$ having a complex property, e.g., walking in a space-time location and sleeping in another space-time location.

$$T_{animate} \equiv \tag{32a}$$

$$\begin{aligned} &[\text{IND} : [x] \mid (\dot{s} \models \ll animate, \text{IND} : arg : x, \\ &\qquad\qquad \text{LOC} : \dot{l}; 1 \gg)] \end{aligned} \tag{32b}$$

The type $T_{otu}$ defined in (33a)-(33c) is the type of odd-toed ungulate individuals in some (parametric) situation $\dot{s}$ and location $\dot{l}$:

$$T_{otu} \equiv [T_{animate} : [x] \mid (\dot{s} \models \tag{33a}$$

$$\ll \textit{odd-toed}, T_{animate} : arg : x, \text{LOC} : \dot{l}; 1 \gg \land \tag{33b}$$

$$\ll ungulate, T_{animate} : arg : x, \text{LOC} : \dot{l}; 1 \gg)] \tag{33c}$$

### B. Instantiation of Concepts

The type (34a) is a two-argument type of a situation and a location, in which a specific odd-toed ungulate individual $a$ walks. Note that the type (34a) is defined only in case the proposition $(a : T_{otu})$ is true, i.e., $a : T_{otu}$, which is so in case $a$ of type $T_{otu}$.

$$[\text{SIT} : [\dot{s}_0], \text{LOC} : [\dot{l}_0] \mid (\dot{s}_0 \models \tag{34a}$$

$$\ll \mathit{walk}, T_{otu} : \mathit{walker} : a, \text{LOC} : \dot{l}_0; 1 \gg)] \tag{34b}$$

The type (35a)-(35d) is a three-argument type of situations $\dot{s}_0$ and locations $\dot{l}_0$, $\dot{l}_1$, such that, in the situation $\dot{s}_0$, the odd-toed ungulate individual $a$ walks through the location $\dot{l}_0$, and sleeps through the location $\dot{l}_1$, and where the locations $\dot{l}_0$ and $\dot{l}_1$ are not overlapping in time.

$$[\text{SIT} : [\dot{s}_0], \text{LOC} : [\dot{l}_0], \text{LOC} : [\dot{l}_1] \mid \tag{35a}$$

$$(\dot{s}_0 \models \ll \mathit{walk}, T_{otu} : \mathit{walker} : a, \text{LOC} : \dot{l}_0; 1 \gg \wedge \tag{35b}$$

$$\ll \mathit{sleep}, T_{otu} : \mathit{sleeper} : a, \text{LOC} : \dot{l}_1; 1 \gg) \wedge \tag{35c}$$

$$(\dot{l}_0 \not\circ_t \ \dot{l}_1)] \tag{35d}$$

The type (36a)-(36d) is a four-argument type of situations $\dot{s}_0$, $\dot{s}_1$ and locations $\dot{l}_0$, $\dot{l}_1$, such that, in the situation $\dot{s}_0$, the odd-toed ungulate individual $a$ walks through the location $\dot{l}_0$, and, in the situation $\dot{s}_1$, $a$ sleeps through the location $\dot{l}_1$, where the locations $\dot{l}_0$ and $\dot{l}_1$ are not time overlapping.

$$[\text{SIT} : [\dot{s}_0], \text{LOC} : [\dot{l}_0], \text{SIT} : [\dot{s}_1], \text{LOC} : [\dot{l}_1] \mid \tag{36a}$$

$$(\dot{s}_0 \models \ll \mathit{walk}, T_{otu} : \mathit{walker} : a, \text{LOC} : \dot{l}_0; 1 \gg) \wedge \tag{36b}$$

$$(\dot{s}_1 \models \ll \mathit{sleep}, T_{otu} : \mathit{sleeper} : a, \text{LOC} : \dot{l}_1; 1 \gg) \wedge \tag{36c}$$

$$(\dot{l}_0 \not\circ_t \ \dot{l}_1)] \tag{36d}$$

### C. Concept Subdivision

A conceptual class can be subdivided into subclasses by using subtypes. E.g., we demonstrate the technique, by the type $T_{nocturnal}$ in (37a) defined as a subtype of the type $T_{otu}$ defined in (33a)-(33c).

$$T_{nocturnal} \equiv [\text{IND} : [x] \mid \tag{37a}$$

$$(\dot{s} \models \ll \mathit{nocturnal}, \text{IND} : x, \text{LOC} : \dot{l}; 1 \gg)] \tag{37b}$$

Now, the type $T_{nocturnal\text{-}otu}$ in (38a)-(38f), has a single argument role $[\dot{a}]$:

$$T_{nocturnal\text{-}otu} = [\{T_{nocturnal}, T_{otu}\} : \dot{a} \mid \tag{38a}$$

$$(\dot{s}_2 \models \ll \mathit{healthy}, T_{nocturnal} : \mathit{arg} : \dot{a}, \tag{38b}$$

$$\text{LOC} : \dot{l}_2; 1 \gg) \wedge \tag{38c}$$

$$(\dot{s}_0 \models \ll \mathit{walk}, T_{otu} : \mathit{walker} : \dot{a}, \text{LOC} : \dot{l}_0; 1 \gg) \wedge \tag{38d}$$

$$(\dot{s}_1 \models \ll \mathit{sleep}, T_{otu} : \mathit{sleeper} : \dot{a}, \text{LOC} : \dot{l}_1; 1 \gg) \wedge \tag{38e}$$

$$(\dot{l}_0 \not\circ_t \ \dot{l}_1) \wedge (\dot{l}_0 \subset \dot{l}_2) \wedge (\dot{l}_1 \subset \dot{l}_2)] \tag{38f}$$

The type $T_{nocturnal\text{-}otu}$ in (38a)-(38f), that has a single argument role $[\dot{a}]$ with the argument constraint $\{T_{nocturnal}, T_{otu}\}$ for appropriate filling, i.e.:

$$\text{ARGR}(T_{nocturnal\text{-}otu}) = \{\, \{T_{nocturnal}, T_{otu}\} : [\dot{a}] \,\} \tag{39}$$

Now, while the types in Examples VI-A-VI-C share the parameters for a situation $s$ and a location $l$, we might consider them as related by them, as long as these types are used together, as if in a "package". In case these types are "separated", the parameters $s$ and $l$ can be anchored, i.e., instantiated, with unrelated objects of the respective types.

### D. Instances of Concepts in Conceptual Sub-divisions

Let $c_1$ be a parameter assignment for the type $T_{nocturnal\text{-}otu}$ in (38a)-(38f), such that:

$$c_1(\dot{s}_0) = s_0, \quad c_1(\dot{l}_0) = l_0, \tag{40a}$$

$$c_1(\dot{s}_1) = s_1, \quad c_1(\dot{l}_1) = l_1, \tag{40b}$$

$$c_1(\dot{s}_2) = s_2, \quad c_1(\dot{l}_2) = l_2. \tag{40c}$$

Then the following propositions have the same truth values:

$$(c_1(T_{nocturnal\text{-}otu}) : a) \text{ is true} \tag{41a}$$

$$\Longleftrightarrow$$

$$(c_1(T_{nocturnal}) : a) \wedge \tag{41b}$$

$$(c_1(T_{otu}) : a) \wedge \tag{41c}$$

$$(s_2 \models \ll \mathit{healthy}, T_{nocturnal} : \mathit{arg} : a, \tag{41d}$$

$$\text{LOC} : l_2; 1 \gg) \wedge$$

$$(s_0 \models \ll \mathit{walk}, T_{otu} : \mathit{walker} : a, \tag{41e}$$

$$\text{LOC} : l_0; 1 \gg) \wedge$$

$$(s_1 \models \ll \mathit{sleep}, T_{otu} : \mathit{sleeper} : a, \tag{41f}$$

$$\text{LOC} : l_1; 1 \gg) \wedge$$

$$(l_0 \not\circ_t \ l_1) \wedge (l_0 \subset l_2) \wedge (l_1 \subset l_2) \tag{41g}$$

In general, in order to model parametric assignments and cognitive concepts, including for semantics of natural language, and in systems of taxonomic information, we allow the sub-propositions $(c_1(T_{nocturnal}) : a)$ and $(c_1(T_{otu}) : a)$ may be true by "preserving" parametric information via assignment $c_1(\dot{s}) = \dot{s}$ and $c_1(\dot{l}) = \dot{l}$. Then, the following propositions are truth equivalent:

$$(c_1(T_{nocturnal}) : a) \iff (T_{nocturnal} : a) \tag{42a}$$

$$\iff (c_2(T_{nocturnal}) : a) \tag{42b}$$

In the above types, there is not explicit requirement that further update of information, by a new parameter assignment $c_2$, have to agree on the parameters $\dot{s}$ and $\dot{l}$ (which in certain cases may be desirable). Let $c_2$ be a parameter assignment for the type $T_{nocturnal}$ in (37a), such that:

$$c_2(\dot{s}) = s', \quad c_2(\dot{l}) = l'. \tag{43}$$

Then:

$$(c_2(T_{nocturnal}) : a) \quad \text{is true} \tag{44a}$$

$$\begin{aligned} \iff (s' \models \ll \mathit{nocturnal}, \text{IND} : \mathit{arg} : a, \\ \text{LOC} : l'; 1 \gg) \quad \text{is true} \end{aligned} \tag{44b}$$

$$\begin{aligned} \iff s' \models \ll \mathit{nocturnal}, \text{IND} : \mathit{arg} : a, \\ \text{LOC} : l'; 1 \gg \end{aligned} \tag{44c}$$

The parameter assignment $c_1$ may not agree with $c_2$, for example, in case $s \neq s'$ and $s \neq s'$. There is a need for explicitly expressing that $c_1$ should be a parameter assignment for the types $T_{nocturnal}$ in (37a), $T_{otu}$ in (33a)-(33c), and $T_{animate}$ in (32b), so that they agree on $\dot{s}$ and $\dot{l}$, as in (45):

$$c_1(\dot{s}) = s, \quad c_1(\dot{l}) = l, \tag{45}$$

The effect of (41a) is represented in (46a)–(46h):

$$(c_1(T_{nocturnal\text{-}otu}) : a) \text{ is true} \tag{46a}$$

$$\Longleftrightarrow$$

$$(s \models \ll nocturnal, \text{IND} : arg : a, \text{LOC} : l; 1 \gg) \wedge \tag{46b}$$

$$\begin{aligned}(s \models \ll odd\text{-}toed, T_{animate} : arg : a, \text{LOC} : l; 1 \gg \wedge \\ \ll ungulate, T_{animate} : arg : a, \text{LOC} : l; 1 \gg) \wedge\end{aligned} \tag{46c}$$

$$(s \models \ll animate, \text{IND} : arg : a, \text{LOC} : l; 1 \gg) \wedge \tag{46d}$$

$$(s_2 \models \ll healthy, T_{nocturnal} : arg : a, \text{LOC} : l_2; 1 \gg) \wedge \tag{46e}$$

$$(s_0 \models \ll walk, T_{otu} : walker : a, \text{LOC} : l_0; 1 \gg) \wedge \tag{46f}$$

$$(s_1 \models \ll sleep, T_{otu} : sleeper : a, \text{LOC} : l_1; 1 \gg) \wedge \tag{46g}$$

$$(l_0 \not\circ_t \; l_1) \wedge (l_0 \subset l_2) \wedge (l_1 \subset l_2) \tag{46h}$$

## VII. Linking Parameters in Informational Structures

The following examples are patterns of how to achieve effects of linking argument roles of relations and types and their filling. The results are complex informational structures, as in (41a)–(46h), that represent general, informational patterns.

### A. Complex, Interrelated Types

The type $T_{sitan}$ in (47a)-(47b) is a three-argument type, with argument roles for an individual, $\text{IND} : [\xi]$, a situation, $\text{SIT} : [\dot{s}']$, and a location, $\text{LOC} : [\dot{l}']$.

$$T_{sitan} = [\text{IND} : [\xi], \text{SIT} : [\dot{s}'], \text{LOC} : [\dot{l}'] \;\mid \tag{47a}$$

$$\begin{aligned}(\dot{s}' \models \ll animate, \text{IND} : arg : \xi, \\ \text{LOC} : \dot{l}'; 1 \gg)]\end{aligned} \tag{47b}$$

Thus, the type $T_{sitan}$ is a type having three argument roles: the argument $[\xi]$ that can be filled up by an animate individual; the argument $[\dot{s}']$ can be filled up only by a situation where the individual filling up the role $[\xi]$ is animate; and $[\dot{l}']$ can be filled up only by the corresponding location in that situation. E.g., as in the proposition (48b) that is constituent of the type $T_{sitotu}$ in (48a)-(48c).

The type $T_{sitotu}$ in (48a)-(48c) is a three-argument type, with argument roles for an individual, $\text{IND} : [x]$, a situation, $\text{SIT} : [\dot{s}]$, and a location, $\text{LOC} : [\dot{l}]$, and is a type of odd-toed ungulate individuals $x$ in a situation $\dot{s}$ and a location $\dot{l}$:

$$T_{sitotu} = [\text{IND} : [x], \text{SIT} : [\dot{s}], \text{LOC} : [\dot{l}] \;\mid \tag{48a}$$

$$(T_{sitan}, \text{IND} : [\xi] : x, \text{SIT} : [\dot{s}'] : \dot{s}, \text{LOC} : [\dot{l}'] : \dot{l}) \wedge \tag{48b}$$

$$\begin{aligned}(\dot{s} \models \ll odd\text{-}toed, \text{IND} : arg : x, \text{LOC} : \dot{l}; 1 \gg \wedge \\ \ll ungulate, T_{sitan} : arg : x, \text{LOC} : \dot{l}; 1 \gg)]\end{aligned} \tag{48c}$$

The constituent proposition $(T_{sitan}, \text{IND} : [\xi] : x, \text{SIT} : [\dot{s}'] : \dot{s}, \text{LOC} : [\dot{l}'] : \dot{l})$ in (48b) states that the objects $x$, $\dot{s}$, and $\dot{l}$ (filling correspondingly the argument-roles $[\xi]$, $[\dot{s}']$, and $[\dot{l}']$ of the type $T_{sitan}$) have to be of type $T_{sitan}$.

### B. Interrelated Generalizations

Now, we demonstrate the generalization of the type $T_{nocturnal}$ in (37a) to a situated type that has three arguments:

$$T_{sitnoct} = [\text{IND} : [\zeta], \text{SIT} : [\dot{s}''], \text{LOC} : [\dot{l}''] \;\mid \tag{49a}$$

$$(\dot{s}'' \models \ll nocturnal, \text{IND} : \zeta, \text{LOC} : \dot{l}''; 1 \gg)] \tag{49b}$$

The type $T_{sitnoctotu}$ in (50a)-(50e) is a three-argument type, with argument roles for an individual, $\text{IND} : [x]$, a situation, $\text{SIT} : [\dot{s}]$, and a location, $\text{LOC} : [\dot{l}]$, and is a type of odd-toed ungulate individuals $x$, that are nocturnal, in a situation $\dot{s}$ and a location $\dot{l}$.

As in (48a)-(48c), the constituent proposition $(T_{sitan}, \text{IND} : [\xi] : x, \text{SIT} : [\dot{s}'] : \dot{s}, \text{LOC} : [\dot{l}'] : \dot{l})$ in (50b) states that the object parameters $x$, $\dot{s}$, and $\dot{l}$ (filling correspondingly the argument-roles $[\xi]$, $[\dot{s}']$, and $[\dot{l}']$ of the type $T_{sitnoct}$) have to be of type $T_{sitnoct}$. Any objects respectively instantiating these parameters have to be of these types too. The constituent $(T_{sitnoct}, \text{IND} : [\zeta] : x, \text{SIT} : [\dot{s}''] : \dot{s}, \text{LOC} : [\dot{l}''] : \dot{l})$ in (50c) is a proposition, which stating that the same object parameters $x$, $\dot{s}$, and $\dot{l}$ (filling correspondingly the argument-roles $[\zeta]$, $[\dot{s}'']$, and $[\dot{l}''])$ have to be of type $T_{sitnoct}$, also.

$$T_{sitnoctotu} = [\text{IND} : [x], \text{SIT} : [\dot{s}], \text{LOC} : [\dot{l}] \;\mid \tag{50a}$$

$$(T_{sitan}, \text{IND} : [\xi] : x, \text{SIT} : [\dot{s}'] : \dot{s}, \text{LOC} : [\dot{l}'] : \dot{l}) \wedge \tag{50b}$$

$$\begin{aligned}(T_{sitnoct}, \text{IND} : [\zeta] : x, \text{SIT} : [\dot{s}''] : \dot{s}, \\ \text{LOC} : [\dot{l}''] : \dot{l}) \wedge\end{aligned} \tag{50c}$$

$$(\dot{s} \models \ll odd\text{-}toed, \text{IND} : arg : x, \text{LOC} : \dot{l}; 1 \gg \wedge \tag{50d}$$

$$\ll ungulate, T_{sitan} : arg : x, \text{LOC} : \dot{l}; 1 \gg)] \tag{50e}$$

Therefore, the truth conditions for the proposition (51a) are equivalent to those for the conjunction (51b)–(51d), where $a$, $s$, and $l$, are either specific objects or parameters, respectively for an individual, situation, and space-time location. I.e., the proposition (51a) stating that $a$, $s$, $l$ are of the type $T_{sitnoctotu}$ is true iff the conjunctive proposition (51b)–(51d) is true by instantiating the parameters $x$, $\dot{s}$, $\dot{l}$ with $a$, $s$, $l$, correspondingly:

$$(T_{sitnoctotu}, \text{IND} : [x] : a, \text{SIT} : [\dot{s}] : s, \text{LOC} : [\dot{l}] : l) \tag{51a}$$

$$\Longleftrightarrow$$

$$(T_{sitan}, \text{IND} : [\xi] : x, \text{SIT} : [\dot{s}'] : \dot{s}, \text{LOC} : [\dot{l}'] : \dot{l}) \wedge \tag{51b}$$

$$\begin{aligned}(T_{sit\text{-}nocturnal}, \text{IND} : [\zeta] : x, \text{SIT} : [\dot{s}''] : \dot{s}, \\ \text{LOC} : [\dot{l}''] : \dot{l}) \wedge\end{aligned} \tag{51c}$$

$$\begin{aligned}(\dot{s} \models \ll odd\text{-}toed, \text{IND} : arg : x, \text{LOC} : \dot{l}; 1 \gg \wedge \\ \ll ungulate, T_{sitan} : arg : x, \text{LOC} : \dot{l}; 1 \gg)\end{aligned} \tag{51d}$$

$$\text{is true for } c(x) = a, \; c(\dot{s}) = s, \; c(\dot{l}) = l, \tag{51e}$$

where $c$ is a function for parameter assignment, i.e., instantiating, the parameters $x$, $\dot{s}$, $\dot{l}$ with $a$, $s$, $l$, correspondingly. In what follows, we shall use simply the equality sign for direct parameter assignment, without using the assignment function *c*. The above information can be expressed all together in the following way:

$$\begin{aligned}&(T_{sitnoctotu}, \text{IND} : [x] : a,\ \text{SIT} : [\dot{s}] : s,\\ &\qquad \text{LOC} : [\dot{l}] : l\ )\end{aligned} \tag{52a}$$

$$\iff (p_1 \wedge p_2 \wedge p_3) \quad \text{is true} \tag{52b}$$

where

$$\begin{aligned}p_1 = \big(\big[[x], [\dot{s}], [\dot{l}]\ \mid \big(&T_{sitan},\ \text{IND} : [\xi] : x,\\ &\text{SIT} : [\dot{s}'] : \dot{s},\\ &\text{LOC} : [\dot{l}'] : \dot{l}\big)\big],\end{aligned} \tag{53a}$$

$$\text{IND} : [x] : a,\ \text{SIT} : [\dot{s}] : s,\ \text{LOC} : [\dot{l}] : l\big), \tag{53b}$$

$$\begin{aligned}p_2 = \big(\big[[x], [\dot{s}], [\dot{l}]\ \mid \big(&T_{sitnoct},\ \text{IND} : [\zeta] : x,\\ &\text{SIT} : [\dot{s}''] : \dot{s},\\ &\text{LOC} : [\dot{l}''] : \dot{l}\big)\big],\end{aligned} \tag{53c}$$

$$\text{IND} : [x] : a,\ \text{SIT} : [\dot{s}] : s,\ \text{LOC} : [\dot{l}] : l\ \big), \tag{53d}$$

$$\begin{aligned}p_3 = \big(\big[&[x], [\dot{s}], [\dot{l}]\ \mid\\ &\big(\dot{s} \models \ll \textit{odd-toed},\ \text{IND} : \textit{arg} : x,\\ &\qquad \text{LOC} : \dot{l}; 1 \gg \wedge\\ &\ll \textit{ungulate},\ T_{sitan} : \textit{arg} : x,\\ &\qquad \text{LOC} : \dot{l}; 1 \gg \big)\big],\end{aligned} \tag{53e}$$

$$\text{IND} : [x] : a,\ \text{SIT} : [\dot{s}] : s,\ \text{LOC} : [\dot{l}] : l\ \big) \tag{53f}$$

Now, instead of repeating the informational patterns in (52b)-(53f), for various specific types and properties, we can use sub-typing, by type and relation parameters, which can be instantiated as necessary.

$$(T_{sitnoctotu}, \text{IND} : [x] : a,\ \text{SIT} : [\dot{s}] : s,\ \text{LOC} : [\dot{l}] : l\ ) \tag{54a}$$

$$\iff (p_1 \wedge p_2 \wedge p_3) \tag{54b}$$

where

$$\begin{aligned}p_1 = \big(\big[&[x], [\dot{s}], [\dot{l}]\ \mid\\ &\big(T_1,\ \text{IND} : [\xi] : x,\ \text{SIT} : [\dot{s}'] : \dot{s},\\ &\qquad \text{LOC} : [\dot{l}'] : \dot{l}\ \big)\big],\\ &\text{IND} : [x] : a,\ \text{SIT} : [\dot{s}] : s,\ \text{LOC} : [\dot{l}] : l\ \big),\end{aligned} \tag{55a}$$

$$\begin{aligned}p_2 = \big(\big[&[x], [\dot{s}], [\dot{l}]\ \mid\\ &\big(T_2, \text{IND} : [\zeta] : x, \text{SIT} : [\dot{s}''] : \dot{s},\\ &\qquad\qquad \text{LOC} : [\dot{l}''] : \dot{l}\big)\big],\\ &\text{IND} : [x] : a, \text{SIT} : [\dot{s}] : s, \text{LOC} : [\dot{l}] : l\big),\end{aligned} \tag{55b}$$

$$\begin{aligned}p_3 = \big(\big[&[x], [\dot{s}], [\dot{l}]\ \mid\\ &\big(\dot{s} \models \ll r,\ \text{IND} : [x] : x,\\ &\qquad \text{LOC} : [l] : l; 1 \gg \big)\big],\\ &\text{IND} : [x] : a,\ \text{SIT} : [\dot{s}] : s,\ \text{LOC} : [\dot{l}] : l\ \big),\end{aligned} \tag{55c}$$

$$\begin{aligned}r = \big[[x], [\dot{l}]\ \mid &\ll r_u,\ \text{IND} : [x] : x,\\ &\qquad \text{LOC} : [l] : l; 1 \gg \wedge\\ &\ll r_t,\ \text{IND} : [x] : x,\ \text{LOC} : [l] : l; 1 \gg \big],\end{aligned} \tag{55d}$$

$$\begin{aligned}r_u = \big[&\text{IND} : [x],\ \text{LOC} : [\dot{l}] : \dot{l}\ \mid\\ &\ll u,\ T_1 : \textit{arg} : x,\ \text{LOC} : \dot{l}; 1 \gg \big],\end{aligned} \tag{55e}$$

$$\begin{aligned}r_t = \big[&\text{IND} : [x],\ \text{LOC} : [\dot{l}] : \dot{l}\ \mid\\ &\ll t,\ \text{IND} : \textit{arg} : x,\ \text{LOC} : \dot{l}; 1 \gg \big],\end{aligned} \tag{55f}$$

$$T_1 = T_{sitan},\ T_2 = T_{sitnoct},\ u = \textit{ungulate}, \tag{55g}$$

$$t = \textit{odd-toed}, \tag{55h}$$

$$a = a_0,\ s = s_0,\ l = l_0 \tag{55i}$$

Now, the parameter $t$ in (54b)–(55i) can be left underspecified, by dropping out the instantiation $t = \textit{odd-toed}$ in (55h). However, one may still need to restrict the possible instantiations of $t$. E.g., that can be done by replacing (55f) and (55h) with (56a)–(56b).

$$\begin{aligned}r_t = \Big[&\text{IND} : [x],\ \text{LOC} : [\dot{l}] : \dot{l}\ \mid\\ &\ll t_o,\ \text{IND} : \textit{arg} : x,\ \text{LOC} : \dot{l}; 1 \gg\ \vee\\ &\ll t_e,\ \text{IND} : \textit{arg} : x,\ \text{LOC} : \dot{l}; 1 \gg \Big],\end{aligned} \tag{56a}$$

$$t_o = \textit{odd-toed},\ t_e = \textit{even-toed} \tag{56b}$$

Another possibility to introduce alternative instantiations, i.e., alternative parameter assignments, is by using sets and *membership instantiations*:

$$\begin{aligned}p \in M,\ \text{for given } &T : \text{TYPE}, p \in \text{PAR}, p : T,\\ &\text{and a set } M \text{ of objects of type } T\end{aligned} \tag{57}$$

I.e., in (54b)–(55i), we can replace the assignment $t = \textit{odd-toed}$ in (55h) with (58).

$$t \in \{\ \textit{odd-toed}, t = \textit{even-toed}\ \} \tag{58}$$

The truth values of the proposition in (51a), i.e., in (52a) and (54a), can be determined, i.e. calculated, from (51b)–(51e), alternatively from (52b)–(53f), or (54b)–(55h). The informational structures in (52b)–(53f) and in (54b) reveal detailed informational compounds and how they are "linked" in general informational patterns. In particular, the informational structure of (54b) reveals:

1) The informational structures of the propositions $p_1$ and $p_2$ have the same pattern given in (59):

$$\big(T, \text{IND} : [\xi] : x, \text{SIT} : [\dot{s}'] : \dot{s}, \text{LOC} : [\dot{l}'] : \dot{l}\big) \tag{59}$$

Note that the distinctions between $\dot{s}'$ and $\dot{s}''$, and respectively, between $\dot{l}'$ and $\dot{l}''$, are inessential. The propositions $p_1$ and $p_2$ differ in the specific instantiation of the type parameter $T$ with $T_{sitan}$ and $T_{sitnoct}$, respectively.

2) $p_3$ is the general information pattern for a situated, propositional content, where $r$ is a relation parameter, which can be instantiated, i.e., anchored to by a parameter assignment, or equality like (55d), to any unary relation (without counting the location argument, which is specially designated). In this case it is instantiated by a complex conjunction infon. The parameter $r$ can be considered as a relation parameter $r$ with any number of arguments, $n \geq 0$:

$$\begin{aligned}\big(\dot{s} \models \ll r,\ &T_1 : \textit{arg}_1 : x_1,\ \ldots, T_1 : \textit{arg}_n : x_n,\\ &\text{LOC} : [l] : l; 1 \gg \big)\end{aligned} \tag{60}$$

## VIII. General Argument Structure in Complex Relations

The relation parameters $r_t$ and $r_u$ are instantiated to complex relations by (55f) and (55e) respectively, both of which have the same informational structure as $r_{2,R_2}$ in (61):

$$\begin{aligned} r_{2,R_2} = [&\textsc{ind} : [x],\ \textsc{loc} : [\dot{l}] : \dot{l} \ \mid \\ &\ll R_2,\ \textsc{ind} : \mathit{arg} : x,\ \textsc{loc} : \dot{l}; 1 \gg] \end{aligned} \tag{61}$$

The relation $r_{m,R_n}$, in (62), is the generalization of the two-argument, parametric relation $r_{2,R_2}$ in (61) to a parametric relation $r_{m,R_n}$ of several complex argument roles $[x_{j_1}]$, ..., $[x_{j_m}]$, $[\dot{l}]$, by abstraction over the location parameter $\dot{l}$, and a set of parameters, $T_{j_1} : x_{j_1}, \dots, T_{j_m} : x_{j_m}$, filling some of the argument roles of an $n$-argument relation parameter $R_n$:

$$\begin{aligned} r_{m,R_n} = \big[&T_{j_1} : [x_{j_1}],\ \dots,\ T_{j_m} : [x_{j_m}],\ \textsc{loc} : [\dot{l}] : \dot{l} \ \mid \\ &\ll R_n,\ T_1 : \mathit{arg}_1 : x_1,\ \dots, T_n : \mathit{arg}_n : x_n, \\ &\quad \textsc{loc} : \dot{l}; 1 \gg \big] \end{aligned} \tag{62}$$

## IX. Conclusions and Future Work

### A. Conclusions

The paper covers the topic of linking parametric information in taxonomic concepts that are constructed by using relations and types having complex argument roles. In general, the argument roles of complex relations and types are constrained by situational types. The argument roles can only be saturated by appropriate situational objects of the corresponding types. The objects that fill-up the complex argument roles in parametric objects can be parametric too. Constituents of information can be linked via recursively constructed, parametric components and instantiations.

We have shown how informational patterns can be productively re-used by different instantiations, with updated situational constituents, which can be specific or again parametric. The constraints over abstract argument roles are expressed recursively with complex types, via abstraction operator.

The presented situation-theoretic approach is primarily intended for modeling information that is typically partial, parametric, and depends on context and situations, as in concepts. In addition, in the contemporary explosion of technologies for large databases of uncertain information, we find that Situation Theory can be used for efficient representation of large collections of data and information streams. Information can be hierarchically organized according to informational types in classes and subclasses. Instead of repeating larger or smaller amounts of details, concepts represent parametric generalizations, which can be instantiated depending on needs and specific situations. Typically, parametric instantiations are dependent on situations. Situation-theoretic types, which are used in concepts with components that are parameters for situations, carry informational content that is "placed" in abstract, "unknown" situations.

### B. Future Developments

Future work, which is related to the topic of this paper, is linking parametric objects via complex restricted parameters, for representing underspecified cognitive concepts. Situation Theory with similar parametric objects has been used for semantics of attitude expressions and quantifier ambiguities (e.g., see Loukanova [11], [12], [22]).

A related topic, on which we work concurrently, is development of formal languages for Situation Theory, see Loukanova [10], [21]. Forthcoming work is on association of such formal languages with denotational and algorithmic semantics. The denotational structures of such formal languages are situation-theoretic domains, as in Loukanova [7]–[9], and in this paper. The varieties of formal languages depend on the areas of application, coverage of semantic concepts, and the situation-theoretic domains of objects. A formal language of Situation Theory can be useful for expressing general semantic concepts such as the ones introduced in this paper.

As we explained in Section I, Aczel non-well-founded set theory provides a theoretic limitation of the situation-theoretic objects, including situations, to objects that conform to Aczel Anti-Foundation Axiom (AFA). These objects can be large as non-well-founded sets, and can be circular, but they have finite representations, e.g., by finite graphs, which, in case of circular information, are circular graphs. Specific applications can have additional restrictions on the objects in their domain and still allow circular information, if needed. In typical applications, circularity is undesirable by leading to circular algorithms, which may not end. Excluding circular situation-theoretic objects from the domains is complicated at model-theoretic level. Using a formal language of Situation Theory, as in Loukanova [10], provides a useful tool by formulation of acyclicity constraints over formal terms denoting situation-theoretic objects.

A primary area of applications of Situation Theory is to computational semantics of languages. Typical approaches to computational semantics encounter problems due to progressive expansion of ambiguities, and multiple, unknown, or undetermined interpretations, which actually depend on partial, and underspecified semantic information. Situation-theoretic objects, as introduced in this paper, model informational content of concepts by using semantic parameters. which can be instantiated depending on context, situations, events, and other resources.

Among the target areas of applications of the presented approach are neuroscience of language and cognitive science, where cognitive concepts are essential. Of particular interests are situation-theoretic models of forming, developing, productivity, and efficiency of language and cognitive concepts and universals.

An open area of work is on formal languages of Situation Theory, e.g., as in Loukanova [10], [21], expanding them with syntax-semantics inferences, checks for consistency, and in addition, implementing them as computerized systems. Such practical implementations require work on developments of specialized algorithms, their classification with respect to complexity, developments of databases, and techniques for evaluations.

### C. Comparative Studies

Detailed comparative study of the technique introduced in this paper with other techniques for representation of concepts is an unexplored area. The technique introduced here shares ideas with work from fuzzy networks, see Yager [23]. Another direction of comparative study, by considering prospects for new developments, is with the approach of Rough Neural Computing (RNC), see Pal et al. [24]. Comparison with RNC would be of especial interest because RNC is a development of modeling neural networks for computations by using lexemes from human language. Similarly, situation-theoretic representations of concepts, as introduced here, have essential components consisting of semantic representations of lexical items and phrases from human language. Comparative studies may open possibilities for enhanced integration of approaches. We have a preliminary view that approaches that use fuzzy logic and fuzzy sets can benefit by further developments integrating Situation Theory and formal languages for it. This will enhance representation of fuzzy informational concepts and other informational units, by enriching them with content that is structured information, even if partly known and otherwise underspecified. On the other hand, Situation Theory and formal languages for it, may benefit by incorporation of fuzzy set theory and weighted parametric information, for practical applications.

A promising direction of developments is for relational databases with Situation Theory and semantic representations, by using formal languages of it. This is essential for domains such as health and medical sciences, where semantic information is typically partial, underspecified, and dependent on situations. E.g., situation-theoretic approach introduced here can contribute to enhanced databases systems introduced in Ślęzak et al. [25], and Sosnowski and Ślęzak [26].

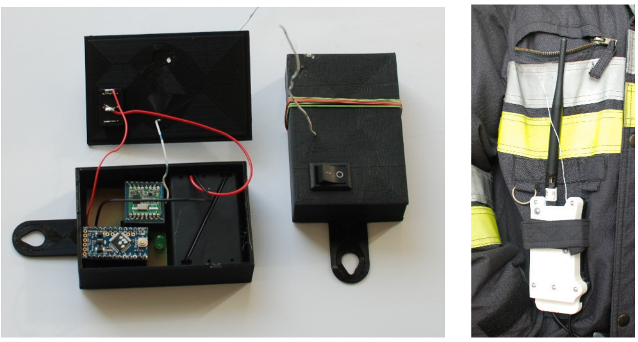
***Abstract*—This paper summarizes our approach and experimental evaluation of infrastructure-based Indoor Positioning System (IPS) designed to be used by First Responders. We are using 868 MHz single channel, power-efficient radio markers and RSSI (Receiver Signal Strength Indicator) fingerprinting. Artificial Neural Network translates vectors of RSSI constructed using mobile units into position. Special preprocessing needs to be applied to on-line signal to construct a vector for classification.**

## I. Introduction

Positioning system in GPS-denied environments (such as large buildings, tunnels etc.) can play crucial role in the Search and Rescue operations. Indoor Positioning Systems (IPSs) can improve not only safety of First Responders, e.g. Smoke Divers who have to search the building and safely withdraw having very limited oxygen supply, but also system like that could assist in decision making and risk management at rescue scene [1] by enhancing situation awareness of the Incident Commander. Yet, reliable information about deployment of resources (both humans and equipment) in the dynamical changing, decision-demanding environment is very challenging. This paper summarizes our approach for infrastructure-based indoor localization designed to be a part of risk management system for Incidents Commanders.

IPS can significantly optimize performance of fire brigade at incident scene in various aspects. Firstly, communication can be significantly enhanced as it was discussed in [4]—basing on interviews with experts and some on-field experiments the number of voice communication could be significantly reduced. Secondly, one of the most significant factor that is known to be source of accident (or near-miss incidents) at a fire scene is the lack of situational awareness[1]. Information about deployment of personnel is a key-factor at incident place. At the same time, it should be advised how to present the information. Amount of information generated at the scene can easily overwhelm [1] the Incident Commander.

Most reliable IPSs involve usage of infrastructure-based techniques, in which various transmitters (or beacons) are deployed in buildings beforehand. That enables us to position the receiver node carried by the subject. Different techniques can be used for such setup (see survey [2] for extensive summary). Following this survey, we have chosen to exploit radio Received Signal Strength Indicator (RSSI) fingerprinting, because of two main reasons: (1) relatively cheap and easy to deploy, and (2) accuracy can be easily tuned by adjusting number of anchor nodes.



(a) Anchor node (b) Receiver node

Fig. 1: Radio Nodes: anchor nodes are deployed at known locations around the building while Receiver node is carried by the First Responder.

RSSI fingerprinting is an empirical technique based on measuring the intensity (strength) of received signal at known positions. Those measurements form features (fingerprints) of signal attenuation of different radios influenced mostly by walls and steel constructions of the building. Positioning can be seen as a problem of classification of incoming signal in order to find “best-match” from known database.

In our setup we also have taken into consideration issues that are specific for search and rescue operation. Firstly,

The research was supported by the Polish National Centre for Research and Development (NCBiR)—Grant No. O ROB/0010/03/001 in the frame of Defence and Security Programmes and Projects: “Modern engineering tools for decision support for commanders of the State Fire Service of Poland during Fire&Rescue operations in the buildings”.

[1] *The National Fire Fighter Near Miss Reporting. Annual Report 2008.*

978-83-60810-66-8/$25.00©2015, IEEE

the algorithm needs to be fault-tolerant: damage of a single radio should not increase significantly the positioning error. Secondly, it is known that fire environment could alter signal propagation significantly [3].

The contributions of this paper are as follows:

- experimental evaluation of IPS based on RSSI fingerprinting and Artificial Neural Networks,
- discussion on hardware design of radio markers (anchor nodes).

## II. Related Work

Due to the growing demand for indoor positioning systems, wireless location is an important area of research in recent years. Many studies have been published concerning different types of localization techniques.

Both Personal Dead Reckoning (PDR) and Foot-mounted Pedestrian Navigation System use Inertial Measurement Units (IMUs) for path estimation. However, since the IMU position error accumulate during the procedure of walking, a lot of attention is paid to systems based on a pre-installed infrastructure. Nowadays, the most frequently used technology is based on radios, e.g.: pseudo-satellite transmitters, Radio Frequency Identification (RFID) markers and Ultra-Wideband (UWB) radars. This has many advantages, radio is not limited by the line-of-sight condition as radio signals can penetrate walls and diffract around objects [5].

Several methods have been proposed to estimate the location using sensor networks. Usually, the approach is based on reference nodes (beacons, anchor nodes), which positions are known. The position of the receiver is calculated from the information it receives from the beacons.

The position can be derived from distance estimates between the beacons and receiver node. Most radio receivers in a wireless system have the ability to measure the Radio Signal Strength Indicator (RSSI). This can be later translated to a distance by using a path loss model. Generally, the relation between RSSI and distance is determined by the following formula

$$\mathrm{RSSI}(d) = P - R - 10\alpha \log_{10} d, \tag{1}$$

where $P$ is the transmitted power, $\alpha$ is the path loss exponent which falls linearly and $R$ is a constant that depends on the conditions of the environment, $d$ is the distance from transmitting end [6].

Generally, three main methods are used for the problem of localization: trilateration, multilateration and fingerprinting. Trilateration and multilateration are based on the propagation model, conceptually simpler, but difficult to calculate in a complex environment—firstly distance needs to be estimated accurately, which involves usage of more expensive transceivers (e.g. UWB radio that uses ToF model[2]) and, secondly, environment (and its changes over time) modelling can be challenging. In contrast, fingerprinting is empirical method in which signal attenuation in the building are measured and, therefore neither the signal propagation model is not used nor the building plan does not to be known.

Trilateration technique uses properties of triangles to determine the location, therefore it usually requires at least three access points on the surface. While using this technique precise distance needs to be measured (which usually is not achievable using RSSI). Precise distance is measured using different physical techniques: Angle of Arrival (AoA) is a method that locates the user by measuring the angle of incoming signal, Time of Arrival (ToA) is a technique based on the Time of Flight (ToF). While using this method the clocks of all physical units must be precisely synchronized and clock drift compensated. All this makes the final system more complex.

Multilateration is a navigation technique based on measurement of the difference between the distances to two or more stations located at known locations that transmit a signal in the indicated times [7]. It differs from trilateration in that it does not use absolute measurement of Time of Flight, but its differences (TDoA, Time Difference of Arrival). Position is then estimated by the intersection of hyperboloids which are places consisting of points having equal TDoAs. In this case, the problem can be represented as an optimization problem and solved using, for example, the method of the least squares or gradient descent method.

Due to the fact that certain signals can be disturbed by presence of obstacles, some extensions (like, e.g., multiwalls model) to above-mentioned methods were introduced.

Fingerprinting is another method frequently used in indoor positioning. In this technique radio signal strength is measured at different locations beforehand. During the first (training or off-line) stage signal strength data is collected is the physical location (usually up to $50 \times 50\, m^2$) to the training/labelling database, or to a non-linear mapping. In the second (on-line) stage of the mobile unit measures RSSI and compares its value to values held in the database. In result location with similar matching is returned. The location of the fingerprint technique requires an adequate number of reference devices and stable environment before calibration, because the result is sensitive to environmental changes, such as moving objects in a building that may have an impact on the properties of the signal. Fingerprinting can obtain good performance, since the noise arising from all obstacles is already included in the map. Therefore, we do not have to add to it any additional model.

The widely used basic matching algorithm used in fingerprinting is the $k$-Nearest Neighbour ($k$-NN) [8]. In the on-line positioning step the $k$-NN algorithm is searching for $k$ neighbour closest (in the sense of the Euclidean distance) between classes of fingerprint database and the real-time RSSI values to determine the location. The Support Vector Regression (SVR) [9] as well as, Artificial Neural Network (ANN) are in widespread use as well [10], [11], [12], [13]. Comparison of different architectures of neural networks can be found in [12].

Moreover, there are attempts to combine such estimation with dead-reckoning navigation using foot-strapped inertial measurement units [14].

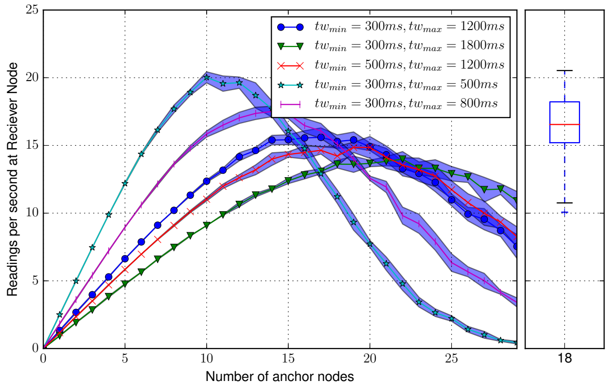

Fig. 2: Simulation of radio sampling vs density of radio displacement. On the right results for empirical data (for $tw_{min} = 300$ ms and $tw_{max} = 1200$ ms) is enclosed.

## III. Hardware setup

We use transceivers based on RFM22 Hope Microelectronics co. silicon with 17 cm coper wire antenna (half-wave long). RFM22 have ability to work in very different modes (modulation, frequency, transmit power). Additionally, our setup involves computations of neural network on mobile device (Odroid-U3), sending it via ZigBee 867 Mbps (2.4 GHz) and displaying actual positioning using Recon Jet head-mounted display[3].

The relatively low frequency (868 MHz) was chosen because of the high penetration ability of signal comparing to power consumption. Also, the noise from different devices operating in this particular frequency band is expected to be smaller (comparing to e.g. 2.4 Ghz). It is worth to note that higher penetration gives us possibility to build sparse node networks, which drastically lowers the cost of overall system. Another issue is signal attenuation in smoke and fire environment which is known issue (see [3]) but there is not enough comparable results to choose the best operating band for this purpose.

Two type of radio nodes was constructed: anchor node (see Fig. 1a) and receiver node (Fig. 1b). Anchors send periodically small portions of data including identifier and message number. Receiver Node is gathering those packages while establishing RSSI and reports it to processing unit.

Configuration of RFM22 was as follows: 868 MHz frequency transmission band, FSK modulation without Manchester encoding (error detection technique—disabled for shorter time of transmission) and +17 dBm mode (transmit power). During initial test we confirmed sufficient wall penetration and expected RSS loss.

Every anchor node operates on exactly the same frequency and, because of that, two radios which transmit their signal can drown each other. Two or more radios that are in mutual coverage area cannot transmit their data in the same time. Therefore, transmission synchronization needs to be performed to overcome problem of mutual jamming. Nevertheless, direct clock synchronization is very complicated in Wireless Sensor Networks (see [15] for overview of the problem), especially in indoor environment (where GPS-based synchronization is unavailable).

Straightforward, node-independent mutual jamming prevention technique based on randomized transmission was implemented. Node number $i$ transmits its mark which usually lasts for about 15 ms, and then radio goes into sleep mode for $T_i$ ms. Idle time is picked randomly after each transmission from the interval

$$tw_{min} < T_i < tw_{max}. \qquad (2)$$

This way, idle time is long enough to allow other radios to transmit their data and short enough to retransmit packet, if it was dropped while mobile is not moved far. Due to the high noise in RSSI estimation it is important to get as many readings as possible. The data is later preprocessed using moving window technique (see Section V-A).

Figure 2 shows simulation result for selected values of $tw_{min}$ and $tw_{max}$ with regard of the number of anchor nodes. Increased number of anchor nodes obviously lead to increased sampling rate at Receiver Node. This, however, can be done only to some extent, after which sampling rate is degrading (because of the collisions in transmission). Peeks at Fig. 2 indicates more or less "optimal setup". Having estimated number of nodes that can jam each other on deployed building interval of sleeping time should be adjusted using this simulation.

Sampling rate estimated from empirical data (which was $16.3 \pm 2.5$ rps) in our experiment is higher than expected (depicted by the box plot on the right-hand side of Fig. 2). In our experimental deployment (see Fig. 6) distant nodes are on the edge communication reach and, therefore, they have limited possibility to drown each other.

## IV. System Description

Overall system processing schema is illustrated in Fig. 3. Operation of IPS that is based on fingerprinting is divided into two phases: off-line and on-line. In the first fingerprints are collected and learning procedure is performed. In on-line phase, on the other hand, incoming signal is processed "on-the-fly" and algorithm outputs position.

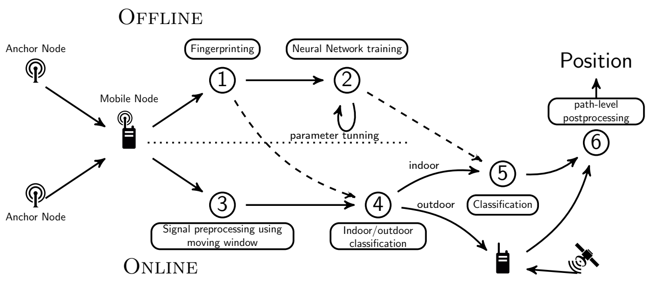

Fig. 3: Processing steps of the Localization Algorithm

At step ① fingerprints are collected (numbers in circles refers to Figure 3). Radio signal strength is recorded using

[3] http://www.reconinstruments.com/products/jet/

mobile device at predefined places (with known GPS position) and used to construct a feature vector (fingerprint) for particular point.

In the on-line situation at the beginning (③) RSSI signal needs to be preprocessed to create a test vector for ANN. Due to the fact that RSSI values from different radios did not arrive at the same time, sliding window technique is exploited—due to the small sampling rate fast movements of mobile unit can degrade precision of test vector formulation (windowing technique introduces lags). Later we remap entries of this vector to the interval $[0,1]$ in order to use the neural network at step ②.

Node ④ is used to resolve the method that will be used for positioning. It turns out that the simple thresholding of signals is inadequate, because some radios can be transmit with lower RSSI value outside than inside. However, it is true that the signal strength with decrease with the distance from the building. Indoor/outdoor detection is beyond the scope of this paper.

Classification (mapping RSSI to position) is performed at step ⑤. Just after it simple mapping to GPS coordinates is performed.

At the end ⑥ path needs to be post-processed (expected high RSSI noise introduces a lot of distortions on path). Kalman Filter is a good candidate for solving this problem, because of the motion model that can be expressed by it.

## V. Neural network-based fingerprinting

This section describes our framework for IPS based on Artificial Neural Network.

Most commonly used type of Artificial Neural Network (ANN) consists of several layers: the input layer is connected to layers of hidden units, which provide information to the output layer. For learning ANN the most commonly used method is the backpropagation algorithm. It tries to adjust weights of each neuron in order to reduce the error between the desired and calculated output. In this way, the neural network learns how to map input to output. The aim of the network is not only to restore the training input data but also to generalize the data to new situations (by interpolating capabilities). The number of input nodes and hidden layers depends on the design issue and depends on the number of base stations deployed in the environment.

### A. Input data preparation and training set construction

The data collection process involves marking of the reference points on the floor and making measurements for a 30–60 s. All points laid on the same plane. In this way at every point we received a number of recordings consisting of RSSI which comes from different radios. Therefore, we obtained a RSSI fingerprint log consisted of triplets

$$(i, \rho_i^{j,k}, P_j), \tag{3}$$

where $i = 1,\ldots,N$, denotes radio number, $P_j = (\text{latitude}, \text{longitude}, \text{elevation})$ is a position of $j$th fingerprint and $\rho_i^{j,k}$ is a $k$th RSSI value recorded at point $P_j$.

Since all radios may not be visible at once (due to interference and momentary jamming of radios), in order to obtain a vector of RSSI signals from all radios (which will be used as an input to network) we had to aggregate recordings at a given point. Therefore, as input corresponding to point $P_j$ and reading $k$ we took set

$$\left\{\operatorname{avg}\left(\{\rho^{j,k_l}\}_{l=1}^{K_j/2}\right) \mid M \text{ rand } \{k_l\}_{l=1}^{K_j/2} \subset \{1,\ldots,K_j\}\right\}, \tag{4}$$

i.e. we averaged random subsamples of recordings (by taking half of the recordings) for point $P_j$. In order to get rid of the noise we do it $M$ times. Therefore, $M$ can be interpreted as an aggregation (folding) parameter.

Let us define point signals in time $t$ from $N$ radios in $j$th point by the following

$$\rho^j(t) = [\rho_1^j(t), \ldots, \rho_N^j(t)]. \tag{5}$$

Such signals consist of RSSI recordings aggregated and averaged as above.

Due to issues described below, which are related to neural networks, we need to map GPS coordinates using affine scaling into interval $[0,1]$. Similarly, RSSI values from radio are converted into $[0,1]$.

### B. Network architecture

Neural Network that we use for IPS is depicted in Fig. 4. It consists of input layer constructed from RSSI vector for actual reading, output layer denotes position in three dimensional space (latitude, longitude and elevation) and the $L$ number of hidden layers. We have used sigmoid activation function, therefore units in input and output vectors need to be mapped by scaling into interval $[0,1]$.

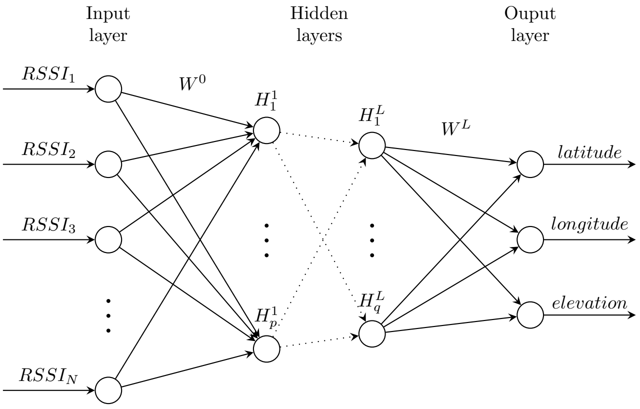

Fig. 4: Neural network setup.

The number of hidden layers and number of neurons at each layer should be tuned accordingly to specific task. Nevertheless, it is important to say that this particular architecture depends significantly on number of anchor nodes used for IPS system. It is hard to estimate time complexity of the learning algorithm. Estimation for the worst case scenario is

$$MNL\prod_{i=0}^{L}\#W^i, \tag{6}$$

where $\#W^i$ is the number of weights in layer $i$ and $L$ is the number of layers in the network. We see that it depends strictly on the size of the building, since additional reference nodes need to be added.

Learning takes quite long, depending on the permissible error. For example, for our problem with permissible error equal to 0.01 and folding parameter equal to 20 (which means that the number of samples grows by the factor of 20) it took between 4 and 10 h on a single core. The number of iterations was set to 10000. It is important to notice that quality of network classification depends on the number of iterations and goal set.

### C. On-line signal classification

Due to the possible interference and temporary signal deficiencies input data in on-line classification need to be preprocessed first. During the movement the mobile unit can receive readings from different anchors in different times (radio reading are sparse and unevenly sampled), therefore we used sliding window technique to receive feature vector at given time.

In order to impute missing values of signal strength we can use local linear approximation as follows

$$\begin{aligned}\rho(t+\Delta t) &= \rho(t) + \rho'(t)\Delta t + \mu \\ &= \rho(t) + \beta d'(t)\log_{10} d(t) + \mu, \end{aligned} \tag{7}$$

where $\beta$ is some constant and $\mu$ denotes higher order terms with small magnitude. Assuming that locally velocity of the subject is constant ($d'(t) = v_{\mathrm{loc}} = \mathrm{const}$) we use it to smooth the signal. The result is shown in Fig. 10 and was not so impressive as supposed. Therefore, we used linear regression.

Given fingerprints as in (3) we want to obtain input signal for the network as in (5).

Since at given time not all radios may be visible we define moving window $W$ of length $\tau$ for time series $s$ (till time $t$) as

$$W_\tau(s)(t) := [s(t-\tau), \dots, s(t)] \tag{8}$$

which will collect the signal strength in a short period.

To this end, we performed moving average on RSSI from the last two seconds. If there was no radio signal from a given radio in the given window, then we put 0. In short,

$$\hat{\rho}(t) := \big[\mathrm{MA}_k\big(W_\tau(\rho_1)(t)\big), \dots, \mathrm{MA}_k\big(W_\tau(\rho_N)(t)\big)\big], \tag{9}$$

where $\mathrm{MA}_k$ stands for moving average operator of length $k$. Signal prepared in this way can be used as an input to the neural network. For post-processing we used the Kalman filter. Therefore, path are smoother and better corresponds to reality.

### D. Network architecture tuning

We found out that standard heuristics, like taking two hidden layers with number of neurons in the second layer being half of that in the first layer (see [16] for more information) works quite fine. We used very large first layer since we need embed data in high dimension and obtain overfitting in order to discriminate it. Next layer is smaller but we get better generalization properties and avoid overfitting. Such architecture can be obtained when analysing in detail Fig. 7.

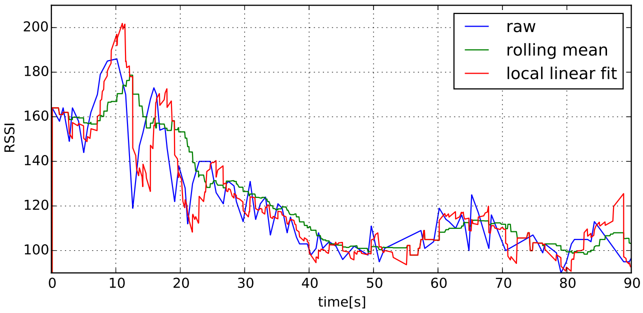

Fig. 5: RSSI (anchor number 4) while moving (only showing first 1.5 min of the recording). Rolling mean (moving average) have very good smoothing capabilities but it introduces certain lag while local linear regression seems to work on-line but does not lead to errors cancellation.

## VI. Experimental Section

We conducted experiment using 18 anchor nodes deploying them on the one floor of approximately 30 × 30 m building. Fig. 6 shows displacement of radios and fingerprints. Note that the data was collected only in selected rooms and passages. Additionally, the figure show bicubic interpolation of RSSI signal strength for 5th radio basing on fingerprint features.

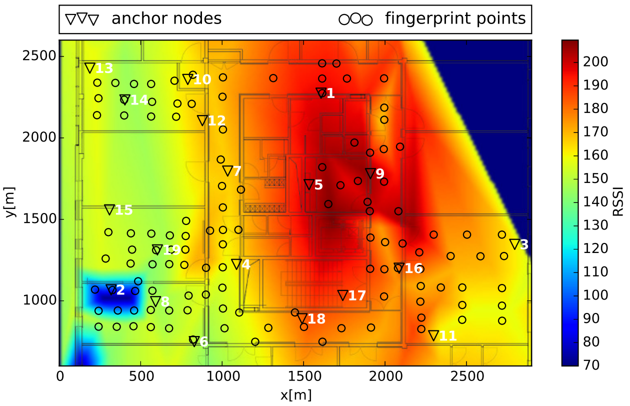

Fig. 6: Interpolated RSSI map for 5th radio. Blue colour in the right upper corner means that there were no data.

We performed collection at 119 points gathering 5991 records (samples) overall. Each position was recorder for about $18.1 \pm 4.2$ seconds which gives us $297.3 \pm 90.2$ records on average. Points were not distributed uniformly, but they were chosen in such a way that there were no large area without samples. Moreover, significant error was introduced while we manually collected GPS positions of reference points.

Two experiments were conducted: stationary position estimation and movement/path reconstruction. For training the neural networks we have used folding parameter $M = 20$. It may seem rather small, but that enables us to perform parameter sweeping through different network architectures in reasonable time (see Fig. 7).

### A. *Position in stationary points*

In the first experiment we tested position estimated at stationary points (without movement). Recorded fingerprints were divided into two separate sets in ratio 70/30. Points was chosen manually and are depicted in Fig. 6. Test sample was prepared according to Equation (4).

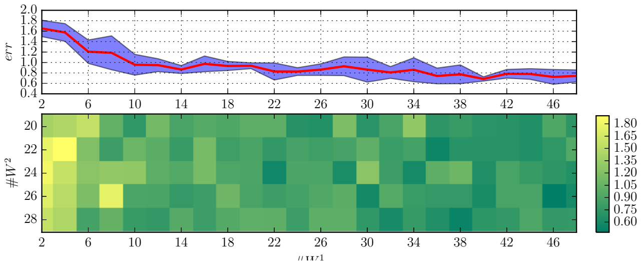

Fig. 7: Position estimation error using ANN with $\#W^1$ and $\#W^2$ neurons on the first and the second layer respectively (lower figure). Upper figure shows column-wise summed up results for $H^1$ layer.

As it can be seen, our heuristics works quite good. For example, when there is about 10–14 neurons in the first layer the average error falls below 0.5 m. Larger networks do not guarantee an improvement of the results (even though some of them were significantly better).

### B. *Paths*

Second experiment was focused on path reconstruction. We asked a subject to perform a walk-through the building with receiver node. Results are depicted in Fig. 8–10. True path was marked on figures using video camera recordings.

As it was already written, most of the errors in the motion is introduced by the low frequency of refreshing rate and, thus, there is the necessity to use of sliding windows.

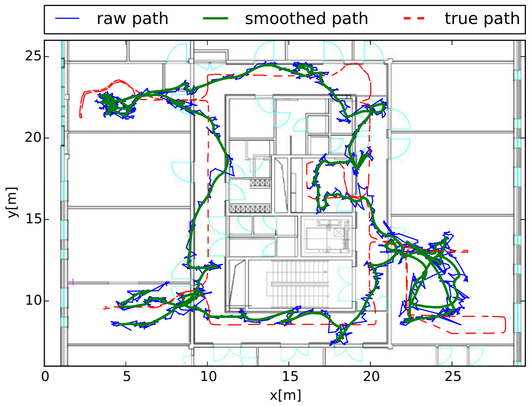

Fig. 8: Path for network with [18, 13, 21, 3] perceptrons in layers. Moving average size of $k = 5$ s.

The differences on the path are more apparent, where overfitting dominates interpolation ability of the network. For example, the path in the corridor, surrounded by a small amount of training points, is better suited than in other places.

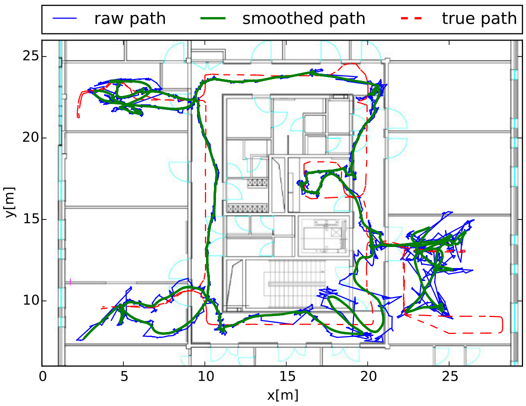

Fig. 9: Path for network with [3, 40, 26, 3] perceptrons in layers. Moving average size of $k = 5$ s.

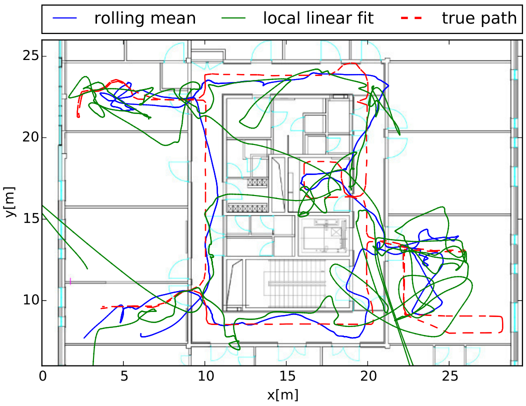

Fig. 10: RSSI smoothing comparison.

In smaller networks we can see that path is being pulled off (Fig. 9).

Another issue is the necessity of usage of sliding window technique—it introduces a certain lag into the feature vector construction. Simply speaking, different RSSIs are recorded at different places therefore we do not know signal strength precisely in time. The problem is illustrated on both previous mentioned figures at the path in lower-right room.

Our initial idea was to use forecasting on RSSI signal that can minimize lagging issues with standard rolling window techniques. Ability of forecast the signal strength lies on the assumption that RSSI is dependent on motion (acceleration and decelerations are not random), see Equation (7). Therefore, we tested the idea using local linear regression instead of rolling mean. Results are depicted in Fig. 10 and show clearly that this simple forecasting is not working due to the large impact of noise to path estimation. Nevertheless, the idea of compensating the signal sampling with motion prediction is worth pursuing in the future works.

### C. *Discussion*

Fingerprint coverage does not have to be dense (neural networks have very good interpolation capabilities), but we noticed a problem with the estimation of places “on edges,” where the paths are pulled towards more places with more dense fingerprint coverage. Some special case should be applied in order to overcome that.

It is worth noting that more anchor nodes not necessarily means better performance—sparse node deployment allow higher signal sampling rate and, therefore, allow better estimation of high-velocity motions. Observe, however, that we cannot assume that radios have different sampling, because we do not know whether the situation when radio sees only few neighbours will change in the future. During fire some wall may broke down and opens new way for the signal.

We also noticed a negative correlation between the velocity of movement of the subject and location accuracy. This is obviously due to the fact that we get only a few samples of RSSIs for a given position. In result the path can oscillate around the correct location.

Moreover, it can be observed that iron oxygen cylinder carried by the firefighters can distort the signal very badly. For example, there were situations where orientation (rotation along the axis) lead to tremendous improvement of the position.

*Abstract*—**The paper presents the results of research related to the efficiency of the so called rule quality measures which are used to evaluate the quality of rules at each stage of the rule induction. The stages of rule growing and pruning were considered along with the issue of conflicts resolution which may occur during the classification. The work is the continuation of research on the efficiency of quality measures employed in sequential covering rule induction algorithm. In this paper we analyse only these quality measures (9 measures) which had been recognised as effective based on previously conducted research.**

## I. Introduction

THE SEQUENTIAL covering rule induction algorithms can be used both for classification and descriptive purposes [1, 2, 3, 4, 5, 6, 7]. The main principle of the sequential covering rule induction algorithms is unchanged, despite the development of increasingly sophisticated versions of such algorithms. It involves the induction of rules in two phases: growing phase and pruning phase. In the growing phase, the elementary conditions occurring in the rule premise are specified. In the pruning phase, some of these conditions are removed. In comparison with other induction methods, rule sets obtained by the covering algorithms are characterised by good classification as well as descriptive capabilities. Taking into consideration only the classification abilities, better results can be often obtained using other methods, for example neural-fuzzy networks [8, 9] support vector machines [10], or ensemble of classifiers [11]. Models obtained in this way, however, are characterised by much less interpretability than classification (decision) rules. In the case of rule learning for descriptive purposes, the algorithms for induction of rules satisfying certain minimum quality criteria are most commonly used [12, 13, 14]. Induction of all rules that satisfy the given quality criteria leads to the induction of a very large number of rules which then must be limited by the filtering algorithms using so-called rule interestingness measures [15, 16, 17]. If the primary objective is to describe data, it is possible to use modified covering algorithms (so-called rule-based subgroup discovery [18, 13, 19]). These algorithms aim at the induction of statistically significant rules which cover regions in the feature space of as small union as possible. Rule sets generated in this way are characterised by worse classification abilities than in the standard covering algorithms. If the analysis objective is to create a classification system that uses an interpretable data model, application of sequential covering rule induction algorithms is the most sensible solution. The quality of the rule set obtained by the covering algorithm depends on the quality measure [20, 1, 21, 22, 23, 24, 25, 26] used in the growing and pruning phases. The used quality measure is one of the factors affecting the classification accuracy, the number of rules induced and their other characteristics (e.g. the statistical significance).

The objective of the paper is to present the results of research related to the efficiency of using the combinations of different measures at each stage of the rule induction. The sequential covering approach and the top-down method were applied as the basic induction algorithm. In this approach one can distinguish the stages of the rule growing and pruning. In these stages it is possible to use different optimisation criteria which control the rule creation process. These criteria are commonly called rule quality measures or search heuristics. Different quality measures can also be used at the stage of classification conflicts resolution - this way the mechanism of weighted voting gets modified. The paper features an analysis of the combination of 9 measures which were recognised as effective (this choice will be explained further in the paper). The analysis was conducted based on 34 data sets. In addition, the paper contains some supplementary information about the applied quality measures.

## II. Related Works

Measures used for the rule evaluation are divided into two categories [16]: objective and subjective measures. Most of the objective measures are defined on the basis of the contingency

This work was supported by Polish National Centre for Research and Development (NCBiR) grant PBS2/B9/20/2013 in frame of Applied Research Programmes.

table that characterises the quality of a rule in the context of a fixed (usually training or validation) data set [27, 23]. The task of the subjective measures is to evaluate the rules according to subjective user's preferences. The subjective measures evaluate such features of rules as: unexpectedness, surprisingness, novelty, utility or actionability [16]. The method of measuring these features depends on the application domain and the purpose of analysis. Our range of interest includes objective rule quality measures, also known as evaluation or search heuristics [22, 28, 29]. At present, in the literature over 50 objective measures can be found [20, 22, 15, 23, 28, 24, 26, 29]. A lot of measures used for evaluation of decision (classification) rules have wider significance - they function also as rule interestingness (attractiveness) measures [15, 30, 16, 17, 31]. Interestingness measures are used for evaluation of already induced rules, both decision and association. In the next part of the paper we will use the common term quality measures. The quality measure applied in decision rule induction is significant for the quality of an output set of rules. This is confirmed by empirical research [32, 20, 21, 23, 25, 26].

In [22, 23] Fürnkranz and Janssen conducted an analysis of the efficiency of measures which contain one or several parameters. These authors present a methodology to adapt the values of parameters contained in quality measures to the specifics of the analysed data set. In addition, they demonstrate that, as the parameters change, certain measures begin to behave similarly to others (such an analysis was conducted for m-estimates and Klösgen measures). In our articles [26, 33], in turn, we are analysing the measures which do not contain parameters and we demonstrate their efficiency on a data set similar to the one quoted in Fürnkranz's work. However, we use an algorithm which generates the rule set instead of a rule list. This results in the necessity to use the mechanism for classification conflicts resolution, i.e. there is another place (apart from rule growing and pruning) where a rule quality measure can be applied. This way it is possible to achieve better accuracy of the classification, particularly higher specificity and sensitivity of the classifier [33].

There are also works that deal with the decision rule length. In the paper [34] the analysis of relationships between length and the coverage of the decision rule is described. Relationships are considered as the influence of the length on the rule coverage and also as the reversed: the influence of the rule coverage on its length. In the other paper [35] a Dominance Based Rough Set Approach generated rules, and their length, determines the relevance of attributes, what becomes a criterion for a feature selection. There was also an attempt to characterise rule induction as a process specified by domain ontology [36], describing all data mining algorithms.

## III. Rule Induction

Let us assume that a finite set $Tr$ of examples is given. Each training example is described by a set $A \cup \{d\}$ of features, i.e. $a : Tr \to Va$ for each $a \in A \cup \{d\}$. The set $Va$ is called the range of the attribute $a$. Elements of $A$ are called conditional attributes, the variable $d$ is called a decision attribute, and its value is identified with the assignment of an example to a specific concept (decision class). Conditional attributes can be of symbolic (discrete-valued) or of numeric (real-valued) type. The decision attribute is of symbolic type. Each example $x$ belonging to the $Tr$ set can be written as a vector $x = (x_1, x_2, \ldots, x_{|A|}, y)$, where $a_i(x) = x_i$ for each $i \in \{1, 2, \ldots, |A|\}$ and $y = d(x)$. The conditional expression of the following form is called a decision rule:

$$IF\ w_1\ AND\ w_2\ AND\ \ldots\ AND\ w_k\ THEN\ d = v$$

An example satisfying all elementary conditions $w_i$ is assigned to the concept indicated in the rule conclusion. Construction of elementary conditions $w_i$ may be various and depends on a rule induction algorithm. Any elementary condition is most often the expression of the one of the two following forms: $w_i \equiv a_i\ op\ Z_i$, where $a_i$ is the name of the conditional attribute, $op$ is one of the relation operators $\{=, \leq, \geq, >, <\}$, $Z_i$ is the element of the range of the attribute or just $w_i \equiv a_i \in Z_i$ where $Z_i$ is a interval in the range $Va_i$: $Z_i \subset Va_i$. The positive examples are those belonging to the decision class pointed in the rule conclusion. The negative examples are the remaining ones.

Let $p$ denote the number of positive examples covered by the rule ($P$ stands for all positive examples in the training set), and let $n$ denote the number of negative examples covering the rule ($N$ stands for all negative examples). On the basis of this notation a contingency table for the rule can be built (Table I).

TABLE I
The contingency table for the rule covering $p$ positive and $n$ negative examples.

| | | |
|---|---|---|
| $p$ | $n$ | $p + n$ |
| $P - p$ | $N - n$ | $P + N - p - n$ |
| $P$ | $N$ | $P + N$ |

The aim of majority of rule induction algorithms is to find the minimal set of classification rules which cover and correctly predict decision classes of a given set of examples and which additionally are characterised by high values of $p$ and low values of $n$. Finding the optimal solution for such a problem is a computationally expensive task, therefore most of the rule induction algorithms use some heuristics. One of the most common approaches, used also in our implementation, is the sequential covering (known also as separate-and-conquer) strategy [4, 6].

To put it briefly, this strategy consists in learning a rule which covers some part of training examples. Next, the examples covered by the learnt rule are removed from the training set and the rule learning process starts recursively for the remaining examples.

Our implementation of the rule induction algorithm also works in the separate and conquer fashion. The outcome of the algorithm is a set of rules describing each decision class of a training set. The process of induction of a single rule consists of two phases: growing and pruning. In the growing

            uncoveredPositives)
            bestQuality := $-\infty$
            bestCondition := $\emptyset$
            foreach c in conditions do
                evaluate the quality of rule with c condition added
                to its antecedent
                quality := Evaluate(rule c, ruleQualityMeasure)
                if quality > bestQuality then
                    bestQuality := quality
                    bestCondition := c
                end
            end
            add selected elementary condition to the antecedent of
            the rule
            rule := rule $\cup$ bestCondition
            covered := Covered(rule, examples)
        while until (stop criterion);
        rule pruning phase
        Prune(rule, ruleQualityMeasure)
        covered := Covered(rule, examples)
        uncoveredPositives := uncoveredPositives $\setminus$ covered
        ruleSet := ruleSet $\cup$ rule
    end
end
return ruleSet
```

**Algorithm 1:** The algorithm of rule induction

phase, the elementary conditions are added one by one to the premise of the rule. In the case of nominal attributes, the elementary condition can take the form of $(a = v)$, and for the numerical attributes it can take one of two forms: $(a < v)$ or $(a \geq v)$. For the numerical attributes the value v is the arithmetic mean between two successive values from the range of attribute $a$. The set of all the possible elementary conditions which might be added to the rule is created on the basis of examples currently covered by the rule. It means that the domains of the attributes are narrowed to the values which are taken by the examples covered by the currently formed rule. Moreover, the elementary condition is tested only if its addition to the rule causes that such a refined rule covers at least one positive example not covered by rules generated so far. The refinement that has the highest value of the specified rule quality measure among all refinements possible in a single step is selected as the final one. If several refinements obtain the same value of the rule quality measure, the refinement covering more uncovered positive examples is chosen.

During the induction of rules it should be taken into account that some attribute values of individual examples are not always known. In the literature, several propositions of strategies for handling unknown values of the attributes in rule learning algorithms can be found [37]. In our implementation it is assumed that the elementary condition always returns truth value false for the unknown value of the attribute. It means that if the example has unknown values, it can be covered only by the rule which does not contain attributes with unknown values for this example.

The process of rule growing is terminated if the rule is accurate (i.e. it covers none of the negative examples) or if the addition of the next conditions to the rule no longer increases its precision (which may take place if examples with identical attributes values but different decisions exist in the training set). After the rule growing phase, the rule is pruned. The rule pruning algorithm uses a hill-climbing strategy. At each iteration, it deletes the elementary condition without which the rule has the highest improvement in the value of quality measure. After each removal, the value of rule quality measure is recalculated on the entire set of training examples and the deletion of conditions is repeated until it does not cause decrease in the current value of quality measure. The pruned rule is added to the final set of rules, and then the process of rule induction starts again for the rest of the uncovered positive examples.

The assumed heuristic of rule building therefore focuses on induction of rules characterised by high values of specified quality measure and thus constitutes a generic framework for studying behaviour of various quality measures.

## IV. Rule Quality Measures

Quality measures strongly associated with decision rules evaluation are collected in surveys [27, 21, 23, 28, 29].

The papers [27, 21] focus mainly on studying measures influence' on conflicts resolution during classification. Janssen and Fürnkranz [23] present research on parametrised quality measures and the procedure of data driven selection of their parameters. Papers by Yao and Zhong [29] and Lavrac, Flach, and Zupan [28] focus on defining quality measures in the language of probability. Interestingly enough, the mentioned authors' considerations concern disjoint sets of measures.

Our choice of nine decision rule quality measures is provided in Table II. The selection is a result of a previous experiments — in already quoted works [26, 33], about 30 measures were analysed with respect to their efficiency. To check the efficiency, the measures were used in the rule induction algorithm - the same measure was used at each induction stage and during the resolution of classification conflicts. Then the classification abilities of the obtained rule classifier were checked. The classification abilities were analysed from the point of view of overall classification accuracy and balanced accuracy. In the case of two decision classes and the discrete classifier, this measure is equivalent to the AUC criterion [38]. In the case of a bigger number of classes, the balanced accuracy informs about the average accuracy of each decision class. This measure is suitable to verify the classifier which works on unbalanced data. Additionally, the number of rules was analysed with respect to the interpretability of the obtained rule sets. Without going deeper in the measure selection methodology, which is presented for example in [33], 9 evaluation measures were selected. These measures achieved good results, at least from the point of view of one of the three above mentioned criteria - statistically they performed better than other measures in the majority of data sets.

TABLE II
THE LIST OF SELECTED OBJECTIVE RULE QUALITY MEASURES.

$$\begin{aligned}
\mathbf{g} &= \frac{p}{p+n+2}\\
\mathbf{wLap} &= \frac{(p+1)(P+N)}{(p+n+2)P}\\
\mathbf{LS} &= \frac{pN}{nP}\\
\mathbf{Rss} &= \frac{p}{P}-\frac{n}{N}\\
\mathbf{MS} &= \frac{p}{n+P}\\
\mathbf{C1} &= Coleman\cdot\frac{2+Cohen}{3}\\
\mathbf{C2} &= Coleman\cdot 0.5\left(1+\frac{p}{P}\right)\\
\mathbf{corr} &= \frac{pN-Pn}{\sqrt{PN(p+n)(P-p+N-n)}}\\
\mathbf{s} &= \frac{p}{p+n}-\frac{P-p}{P-p+N-n}
\end{aligned}$$

$$\begin{aligned}
Cohen &= \frac{(P+N)(\frac{p}{p+n})-P}{\frac{P+N}{2}\frac{p+n+P}{p+n}-P}\\
Coleman &= \frac{(P+N)\frac{p}{p+n}-P}{N}
\end{aligned}$$

Now, we will focus on a brief discussion of the measures and presentation of their properties. The $g-measure$ ($g$ = 2) was proposed by Fürnkranz and Flach [22] and is a simplified version of the Laplace estimate. The $g-measure$ ($g$ = 2) assumes that a rule covering only one positive example is assigned true precision equal to 0.33. Many experiments (e.g. in papers [39, 23]) indicate that the precision of a rule evaluated on a training set is too optimistic. This especially concerns rules covering a small number of positive examples. If a rule covers large number of positive examples, the correction introduced by the number 2 has less and less meaning.

The $Weighted\ Laplace$ ($wLap$) measure is derived from decision tree induction algorithms and it is the Laplace estimate multiplied by $(P+N)/P$. So it takes into account the distribution of examples between the current positive class ($P$) and the remaining classes ($N$).

The $Logical\ sufficiency$ ($LS$) measure is applied to association rule evaluation as well as to decision rule induction [29]. It belongs to the group of measures which emphasise precision of rules during their evaluation and pay less attention to the number of examples covered by the evaluated rule.

The RSS measure is a measure equivalent, in terms of the generated rule order, to the well-known weighted relative accuracy (WRA) measure used by Lavrac, Flach, and Zupan [28], both in rule induction and subgroup discovery. However, RSS and WRA have different ranges of values. The use of RSS for classification conflicts resolving leads to better results than the use of the WRA measure.

The $MutualSupport$ ($MS$) measure is, in context of decision rule evaluation, presented in the paper by Yao and Zhong [29]. Let us assume that a rule of the form $\varphi \rightarrow \psi$ is given. MS measures the strength of dependencies not only between $\varphi \rightarrow \psi$, but also between $\varphi \leftarrow \psi$. It follows that we can consider it as a measure evaluating the strength of the double implication $\varphi \leftrightarrow \psi$. Therefore, the measure prefers rules characterised by high coverage.

The $Correlation$ ($Corr$) measure computes the correlation coefficient between the predicted and the target labels. It was applied to classification rule induction algorithms as well as to subgroup discovery and evaluation of association rules [15, 23, 40].

The $s-Bayesian\ confirmation$ ($s$) measure has been proposed by Christensen [41] and Joyce [42] as a confirmation measure. The first component of the measure evaluates the rule precision and the second is responsible for decrease in the quality of rules that cover small number of positive examples. Its application in evaluation of decision rules obtained by the rough set theory was considered in papers [43, 30].

Measures C1 and C2 have been proposed by Bruha [27, 21]. The measures are a combination of two quality measures known as the Coleman and Cohen (see Table II) measures. Bruha noticed that the Coleman measure prefers rules with high precision and small coverage, while the Cohen measure prefers rules with high coverage. Hence, C1 and C2 join the assessment made by the Coleman and Cohen measures

## V. Experiments and Results

In this paper, the performance of the rule-based classifier is evaluated by the two criteria: overall classification ( $Acc$ ) accuracy and balanced accuracy ( $BAcc$ ). The overall accuracy is the ratio of the number of correctly classified examples to the number of all examples. This is one of the most common criteria for assessing a classifier. However, in the case of unbalanced distribution of examples between decision classes, higher value of overall accuracy is often achieved at the cost of low accuracy of minority classes, therefore in such a case the balanced accuracy is more appropriate. It calculates the classification accuracy of each decision class and then takes an average over all classes. In the case of 2-class problems, balanced accuracy is equivalent to Area Under the ROC Curve (AUC) criterion [38]. One can meet with the interpretation that balanced accuracy calculated for a number of classes is a generalization of AUC for multi-class problems [44].

The used rule induction algorithm generates an unordered set of rules, therefore during the classification of examples it may happen that the test example is covered by rules pointing at different decision classes. In that case, a strategy

TABLE III
CHARACTERISTICS OF DATA SETS USED IN EMPIRICAL STUDIES.

for resolving such conflicts has to be chosen. The most popular one is known as the voting scheme and consists in assigning a numeric value called the confidence degree to each rule. Confidence degrees of the rules covering the test example are summed up for each decision class and then the class with a maximal confidence degree is picked. In this paper the voting scheme is also used during classification. Initially, we assumed that the confidence degree of each rule is equal to its value of some quality measure used during the rule induction. If the test example is not covered by any of the rules, it is treated as wrongly classified.

All presented results stand for average values obtained based on the analysis of 34 data sets from the UCI Repository [45]. The analysis of each set was conducted with the use of the stratified 10-fold cross validation strategy. Comparisons were made on the same partitions of the data sets. The characteristics of these sets are presented in Table III. As it can be seen, the sets with different characteristics were selected for the analysis, particularly in relation to the number of decision classes, the distribution of examples between the classes and types of the attributes. The following abbreviations mean: *cl.* – number of classes, *obj.* – number of objects, *maj. class* – a majority class fraction in %, *nom.* – a number nominal attributes.

Tables IV and V contain the results of the classification of rule based classifiers which were obtained in such a way that the same quality measure was used at each stage of the rule induction and during the resolution of classification conflicts.

TABLE IV
RESULTS OF THE MEASURES COMPARISON ON 34 DATA SETS.

| measure | rules | $Acc[\%]$ | $BAcc[\%]$ |

| s | 51 | 15 | 86 | 2.6 | 0.96 | 0.34 |

It can be seen that the C2 measure leads, on average, to the highest overall classification accuracy, wLap to the highest balanced accuracy, and RSS to the smallest number of rules but with significantly worse classification qualities (in the paper [33] it was proven that this worsening is statistically relevant). What is more, the Corr measure can be a reasonable compromise between the number of generated rules and their classification abilities. A more detailed analysis of the measures efficiency can be found in [26, 33]. Table V presents yet unpublished results which characterise the rule sets generated by means of particular measures. Here we can find the following interesting regularities:

- the highest values of $Acc$ and $BAcc$ take (with a few exceptions) the measures leading to induction of more rules, the average precision of the rule (denoted as $AvgPrec$) obtained by such measures is greater than 0.95, the average coverage (denoted as $AvgCov$) is not greater than 0.36; if the induction of rules aims at classification, it is appropriate to use measures attaching the utmost importance to the rule precision;
- in the classifiers obtained based on measures leading

to the induction of a smaller number of more general rules (the average precision of induced rules is not higher than 0.96, the average coverage is not less than 0.34), there is a large number of classification conflicts (Classification conflicts); a large number of these conflicts is resolved incorrectly, which explains the lower quality of the classifiers;

- the larger the rule coverage, the greater the number of positive examples covered by them uniquely;
- the rule average precision and rule average coverage are correlated with the number of induced rules;
- the average number of elementary conditions (Elementary conditions) contained in the rule premises is correlated with the number of induced rules and their average coverage.

The experiments show that the rules generated by means of measures which lead to the induction of a large number of precise rules (precision $> 0.95$) contain fewer elementary conditions than the rules obtained with the use of measures which promote more general rules. This means that the ranges of elementary conditions, set by means of MS and RSS measures, are wide. This, in turn, implies that each individually considered condition covers a large number of examples, including negative ones. In order to have more detailed rules with "wide" elementary conditions, it is necessary to place more conditions in the rule premise. The measures which are oriented towards the induction of precise rules (wLap, C1, C2) make conditions with narrower ranges, thus the number of conditions in the rule premise is smaller.

The first experiment to check whether it is sensible to use the combination of measures aimed at selecting a measure to resolve classification conflicts. The experiment was conducted in such a way that for the set measure (the same at the stages of growing and pruning) applied in the rule induction, the measure for resolving classification conflicts was changed. The results are presented in Table VI.

The first column of this table denotes the quality measure used in the rule induction. The second column denotes the quality criterion of a final classification phase. The following nine columns correspond to nine quality measures used during the voting in the classification. Each of these nine values is an average rank of a specific classifier (ranks for the classifiers should be read by rows) — the lower is the value of the ranking, the better are the results achieved by the measure (value equal to 1 would mean that the measure was always first in the ranking). Experiments were performed on 34 mentioned datasets in a stratified 10 fold cross validation model. A Friedman test with the significance level $\alpha = 0.05$ does not show statistical differences only for the $s$ measure and the criterion $Acc$ . If post–hoc analysis is performed and the critical distance is calculated it occurs that most of measures behave in a similar way: there are no significant differences between classification accuracy between different measures application. However, it is worth to notice that for the $Acc$ criterion $C2$ measure is the right choice and for the $BAcc$ criterion the $wLap$ is the right choice. $C2$ measure (according to $Acc$ criterion) is the best in 5 of 9 cases (measures) and is always in the best three places. $wLap$ measure (according to $BAcc$ criterion) is four time the best one and not worse than third in other cases. Additionally, an averaging row is also included in the bottom of the table. Emphasised averaged values confirm the above conclusions.

The influence of application of C2 measure during classification instead of a measure used in the rule induction is presented on the left side of the Table VII. The first column points the measure used in a rule induction, second column points the measure used during the classification and the third column means the $Acc$ of a classification. Additional column remarks the p-value of the Wilcoxon test, which null hypothesis is that there is no statistical significant difference between the algorithm which uses the same measure during classification and during the rule induction and the algorithm which uses the C2 measure during classification. Analogical summary for the wLap measure applied in the classification with the $BAcc$ classification quality criterion is presented on the right side of the Table VII.

As it can be observed in the most of cases the final classification quality is improved as the result of application a specified rule quality measure. In the case of a C2 measure this result is rather expected as this measure is strictly dedicated for the classification conflict resolution purposes [27, 21]. wLap measure also improves classification results and the statistical significance of this improvement is very high in the most of cases. This is a new and important observation.

Having the selected rule quality measures for two criteria of classification quality ( $Acc$ and $BAcc$ ) we performed experiments on application of different rule quality measures during the rule growing and pruning phase. This time rankings were calculated on the basis of 81 experiments (nine measures for the growing and nine for the pruning). Results are presented on Fig. 1.

TABLE VIII
COMPARISON OF RESULTS OF THE COMBINATION OF QUALITY MEASURES FOR THE $Acc$ .

| Growing/Pruning/ Classification | Acc | Rules | Wilcoxon |
|---|---|---|---|
| 1. C2-C2-C2 | 82.3 | 127 | 1 - 2 (+)<br>1 - 3 (+)<br>1 - 4 (+) |

| 1. wLap-wLap-C2 | 81.8 | 156 | 1 - 2 (+)<br>1 - 3 (+)<br>1 - 4 (+) |
| 2. wLap-RSS-C2 | 78.3 | 30 | 3 - 2 (+)<br>2 - 4 (-) |
| 3. RSS-wLap-C2 | 79.4 | 37 | 3 - 4 (+) |
| 4. RSS-RSS-RSS | 78.2 | 34 | |

It features a matrix which reflects the ranking of the given combination of measures. As it was already mentioned, 81 combinations of measures were checked. For the $Acc$ criterion, the conflicts resolving measure was always the C2 measure, while for $BAcc$ - the wLap measure. The matrices show that it is not possible to draw straightforward conclusions from such a general comparison. It is interesting that the values presented in antidiagonal (X-X - showing the case when the same measure is used in both phases of the rule induction) are very close to the lowest values in row X and column X. A more detailed analysis was conducted for the C2 and wLap measures (as the best due to their classification abilities) as well as Corr and RSS (as the best due to the number of generated rules). In Tables VIII and IX an analysis of the combination of these measures was conducted for the $Acc$ (Table VIII) and $BAcc$ (Table IX) criteria. The first column of both tables includes the combination of measures, while the second one - the $Acc$ ( $BAcc$ ) value obtained by the given combination. Finally, the third column features the achieved number of rules. The fourth column contains the results of the paired comparison of particular combinations (the Wilcoxon test was used; p-value=0.1) of four models. X-Y (+) means that the combination X is statistically better than Y. The (-) symbol means that there is no such a difference.

Let us assume that the precise measure (C2, wLap) is marked P, while the general measure (Corr, RSS) - C. Additionally, the P-C inscription means that in the phase of the rule growing the precise measure was used, while in the

rule pruning - the general one. Both tables demonstrate the following dependencies:

- the P-C combination, when compared with P-P, leads to a significantly worse quality of the classifier and to a decreasing number of rules,
- the C-P combination, when compared with C-C, leads to a significant increase of the classification quality with, simultaneously, a small increase in the number of rules,
- it is not significant for the number of determined rules whether we use the C-P or P-C sequence, however it is recommended to use C-P for classification abilities as it allows to significantly raise these classification abilities (with respect to C-C).

Moreover, the C2-C2-C2 sequence allowed to achieve the highest classification accuracy. No other combination allowed to statistically improve the $Acc$ value. On the other hand, the C2-C2-wLap combination leads to significantly higher $BAcc$ values, than the wLap-wLap-wLap combination.

## VI. CONCLUSIONS

When real problems are solved (analysed), the measure is usually selected with respect to the data set specifics. The automatic method for the measures selection is based on internal cross-validation. Our earlier works allowed to limit the number of measures which are considered by the automatic method [33], which significantly speeds up the calculations. The results of this work extend the knowledge about the combinations of measures which should be tested first in the automatic method. Our results can also be useful for the user for whom the maximisation of the classification accuracy is not the most important criterion, while it is more important to have proper balancing of the model complexity (number of rules) with its classification abilities.

Currently the RapidRuleInduction plug-in is prepared for the RapidMiner environment. The plug-in will contain the possibilities to induce the rules by means of combining different quality measures - similarly to the plug-in we developed for the R environment [46].

*Abstract*—**In this paper, we define a new practical technology-driven Resource Constrained Scheduling Problem (t-RCPSP). We propose three approaches, applying constructive heuristics to tackle effectively the practical application of RCPSP. In the RCPSP formulation, the constraints are defined to design the tasks in the spaces constructed by non- and renewable resources, without violating the precedence relationships and technologies in real world problem that exists in Plastic and Rubber Processing company. The difficulty of t-RCPSP is NP-hard and we proposed three constructive specialized methods: duration based heuristics (DBH), locally optimal resource usage PEC and NEH heuristic adaptation. The paper presents results of computational experiments that show the effectiveness of the proposed approaches.**

## I. Introduction

The automated computer-aided scheduling in real world application has a tremendous impact on the enterprise. Production schedule building process by human needs a lot of time (long hours), what increases costs and strongly depends on the human condition (costly mistakes). Moreover, the automated scheduling process requires less time (only seconds), is faultless and can be run anytime, e.g. to reschedule in the case of break-down production. In most cases, schedule generated by computer is more efficient than schedule built by the human.

In this paper, an automated scheduling problem practical application in Plastic and Rubber Processing Industry is investigated. Mainly, there is a set of injection molding machines, specialized devices, set of (sub)products and ingredients. Such renewable (e.g. machines, devices) and non-renewable (product's ingredients) resources should be assigned to client requests (tasks) to get near optimal usage in the production process. The major element of automated scheduling system is schedule builder. If solution is to be useful in practice, schedule builder should give the (sub)optimal production schedule in reasonable time: less than 1 minute is acceptable.

It is widely known that the automated computer-aided scheduling in real world application may reduce human work. However, our specific domain requirements make complicated application of classical algorithms. We propose three types of RCPSP solving methods: duration based heuristics (DBH) based on the greedy algorithm, classical NEH adaptation and method (PEC locally optimal resources usage driven.

The proposed technology-driven t-RCPSP can be generalized to RCPSP, which in literature is presented as NP-hard [1] and there are no exact algorithms to solve it in reasonable computation time. Some researches recommend heuristics [7][8]Error: Reference source not foundError: Reference source not found as fast and quite effective RCPSP solving tools.

To get schedule near optimal some metaheuristic approaches are recommended, e.g. Simulated Annealing [2], Tabu Search [12][15], Genetic Algorithms [18][22], Evolutionary Algorithms [5]Error: Reference source not found (hybrids EA [21]). Also, some swarm intelligence methods can be successfully applied to RCPSP, like Ant Colony Optimisation [4][9][10][11], hybrid ACO [13], Particle Swarm Optimization [23] or Bee Colony Algorithms [25].

The rest of the paper is organized as follows. Section 2 presents general RCPSP problem statement and specific domain requirements; technology-driven t-RCPSP model is proposed. Section 3 describes details of three proposed heuristics. Experiments of developed methods in a given dataset are presented in section 4. Finally, section 5 presents summary of gained results and gives some possible further research directions.

## II. Problem statement

In this section, the main elements of classical RCPSP are presented. In a real world problem, such RCPSP model can be useless. The main reason is that, in practical application, to realize the client's request machines and devices can use several configurations of ingredients that may cause entirely different task duration. Thus, problem that we met in MP2 company enforced us to extend RCPSP by several elements. Proposed technology-driven RCPSP (*t-RCPSP*) model in details is presented below.

### *A. Short description of technology-driven RCPSP*

In classical RCPSP Error: Reference source not found each task is described by duration, start and finish time. Tasks are non-preemptive, which means that preemption is not allowed. Each task can be lined to other one in timeline. We use discrete time measure - timeslots.

978-83-60810-66-8/$25.00©2015, IEEE

In the presented t-RCPSP application (schema is presented on Figure 1), we need to run several tasks, which are non-preemptive. Each task has its execution deadline and duration time that depends on used resources. To apply task and produce required product(s) some resources are used: machines, devices, materials and subproducts.

Resources are renewable (machines and devices) and non-renewable: materials (such plastic, paints and other ingredients) and subproducts. As some products are composed of other products, there is relation start-finish between tasks that produce needed subproducts of the given task. Some resources (machines and devices) are dedicated, what means that can be assigned only one activity at a given time [6].

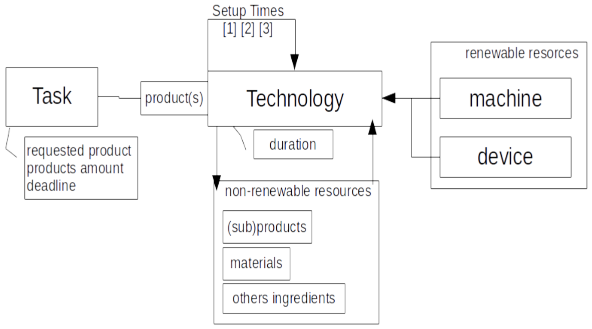

Fig 1. Schema of t-RCPSP

In t-RCPSP specific set of constraints that should be satisfied is defined. The feasible schedule satisfies all constraints defined as follows:

C1. Each task is applied only on one proper machine using specialized device,
C2. Each machine and device can be used only once in selected timeslot,
C3. Each device can cooperate with machine in various way, using other configuration of ingredients,
C4. Each task requires a given amount of ingredients: materials and subproducts,
C5. The task that produces subproducts must be finished before task requiring it,
C6. Each task has defined deadline and number of products,
C7. Each task has assigned duration time that depends on number of required products and used machine and device,
C8. There are 4 types of machine setup times that depend on two adjacent tasks:

- no operation – if two tasks produce the same products,
- start (15 timeslots duration) two tasks produce the same products and machine has been stopped,
- rinse (30 timeslots) two tasks use the same device and machine but provide other products,
- full refitting (120 timeslots) to clean machine and change device.

All devices are specialized to provide a given type of products using the machine, materials or/and subproducts. The device can be applied only to selected machines, and its effectiveness is connected with machine and configuration of ingredients. The main goal of t-RCPSP is to generate feasible schedule (according to C1-C8 constraints) to minimize its duration – makespan, calculated as the difference between first task start and end of the last task in the final schedule. The minor criteria is to reduce the average latency of schedule execution given as the difference between each task end time and its defined deadline.

This problem is NP-hard [1][3][6] and overconstrained. There are no effective algorithms therefore we propose use some heuristics to solve it in acceptable time. The extra constraint required by MP2 company is time limit, i.e. solving method execution cannot exceed 1 minute of CPU computational time of reference machine.

### *B. t-RSPSP - formulation*

The feasible schedule ($S$) consists $j=1,..,J$ tasks and each task is defined as a tuple:

$$J{:}=<\{request\_products\ [amounts]\ldots\},\ sj,\ dtj,\ ddj> \tag{1}$$

where $ddj$ defines task execution deadline, $sj$ means timeslot to start task in the discrete time period; However $dtj$ value strongly depends on used resources: machine, device and materials. To link such aspects model we defined technology $t=1,..,T$ as follows:

$$T{:}=<M,\ D,\ \{resources\ I\ [amount]\},\ \{products\ P\ amount\},\ dtt> \tag{2}$$

where $dtt$ value determines the task execution time using given set of resources. To apply technology to produce products ($P$) it uses renewable resource ($m=1,..,M$ machines and $d=1,..,D$ devices) and some product ingredients ($I$) as non-renewable resources: $MA=1,..,i$ materials and other resources $R=1,..,r$, including subproducts.

Various technologies can produce the same product using other resources and give other execution time. Such technology definition as an abstract layer makes possible to link the same resources in another way. Set of technologies describes the effectiveness of model and makes optimization simpler. The primary optimization goals are defined as follows:

$$min\ MAKESPAN(S) = max\ (sj+ddj) - min(sj) \tag{3}$$

Such formula gives information about the total schedule $S$ execution time, calculated as the differences between the last task's finish and start of the first task. It should be minimized to make schedule execution possible shorter. Another measure that gives quality of given schedule $S$ is the average latency defined as follows:

$$min\ AVG\_LATENCY(S) = \tag{4}$$

$$\frac{1}{k}\sum_{1..k}\left\{\begin{matrix} 0\, if\; sj+dtj<ddj \\ else\; ddj-sj+dtj \end{matrix}\right\}$$

Such measure gives the averaged value of how late each task is due to its defined deadline. It should be minimized to finish each task before its deadline and possible to avoid the delay (and potential financial penalties).

## III. Proposed methods

Each of three proposed methods: NEH adaptation, duration based heuristic (DBH) and resource optimal usage PEC are based on some observations and motivations. Moreover, methods differ not only in implementation but they also use various parameters. Proposed heuristics use sorting deadline criteria of tasks. We defined three basic criteria: ascending (tasks with earlier deadline have priority), descending (the opposite situation) and random order. We decided to implement the random task order to get reference to the other two. In this section, details of proposed methods are presented.

### *A. Duration based heuristic – DBH*

The main motivation of DBH is to build the shortest schedule using adaptation of classical greedy algorithm based on rule heuristics [19]. The DBH pseudocode is presented on Pseudocode 1. DBH heuristic works on all unassigned tasks and proposes first possible timeslot and uses the shortest technology to execute it.

The DBH heuristic asks model for set of tasks that can be preformed in selected timeslot (line 6). List of tasks is sorted by criteria (randomly, ascending or descending deadlines) to get one task (line 9). Then the technology with the shortest execution time is given to apply in given timeslot (line 10). If all model constraints are satisfied task is assigned in the schedule (line 11) and removed from list of unassigned tasks (line 12). If there no tasks that can run, the model takes next timeslot (line 13).

### *B. Local optimal resource usage heuristic – PEC*

In DBH heuristic technology is selected that gives the shortest time of task realization. Such strategy is optimal locally because doesn't take into consideration optimal renewable resource usage. In PEC heuristic (see Pseudocode 2) such aspect is included as some local search method. As DBH only assigns the first task, PEC heuristic tries to assign the larger number of tasks in given timeslot (line 11-17). All analyzed tasks are unassigned for schedule (line 19-23). Only the best task sequence for given timeslot is selected and all included tasks are assigned to final schedule (line 26-29).

To reduce the PEC computation complexity some limits are introduced – the *size* PEC parameter defines number of tasks that are analyzed in one sequence. As *size* parameter equals to 1 PEC heuristic works as DBH, the greater value needs much more CPU working time but returns production schedule more efficient.

The PEC heuristic is a type of compromise between semi-blind greedy DBH and brute force method that analyzes all possible permutations to get the (local) optimal schedule. The *size* parameter gives a range of above compromise to get possible better schedule than build by DBH.

### *C. NEH2 as NEH heuristic adaptation*

Results of experiments with PEC and DBH heuristic showed that tasks sequence for effectiveness of algorithms have big impact on the final schedule. Such observation encourage us to find algorithm which can optimize this aspect. The classical NEH (Nawaz, Enscore, Ham) [14] algorithm is considered as one of the most effective method of minimizing the makespan for Permutation Flowshop Scheduling Problem. The main goal in original NEH is to find the optimal sequence of operations to get more optimal

Pseudocode 1. DBH pseudocode

```
    procedure DurationBasedHeuristic ( SORT_CRITERIA )

1    UT = Tasks               // unsigned tasks
2    TS = 0;                  // timestamp
3    RUT_TS = {}              // sequence of ready to run unassigned tasks
4    do
5     assigned=false
6     RUT_TS = getApplicableTasks (UT, TS)
7     if ( |RUT_TS| > 0 )
8       RUT_TS:= SORT( RUT_TS, SORT_CRITERIA );
9       Task = RUT.getFirstTask();
10      Tech = getShortestDurationApplicableTechnology( Task, TS )
11      assigned = schedule.assign (Task, Tech, TS)
12    if (assigned==true) UT = UT / Task
13    else TS++
14   while ( |UT|>1 )
```

schedule. As evaluation can be applied makespan or other schedule measure. In this paper model RCPSP some NEH modification must be implemented.

The basic version of NEH heuristic builds schedule partially to find optimal sequence of tasks adding next task to partial schedule, finally composing the whole schedule. In our approach NEH is considered rather as metaheuristics that proposes sequence of tasks that make schedule optimal (see Pseudocode 3). The other algorithm schedules task to build partial schedule – we decided to use the classical greedy algorithm. The best task sequence is marked as base task sequence (line 16), that is extended by next tasks probing all positions in the task sequence. Let's analyze the NEH working illustration. Having task A and task B, NEH executes *greedyAlgorithm* to find optimal tasks sequence (AB or BA). Let's assume that BA is optimal, to extend sequence BA adding new task C the *greedyAlgorithm* probes sequences: CBA, BCA and BAC and so on.

The basic NEH procedure is too time-consuming to apply in real world application. The next step of NEH implementation was to optimize its computational complexity. The most expensive operation is *GreedyAlgorithm* and this factor should be reduced. We observed that *GreedyAlgorithm* builds each time the whole schedule which is a huge extravagance. The next step was to use partially build schedule and reverse task sequence build strategy.

PSEUDOCODE 3. NEH2 PSEUDOCODE

```
     procedure NEH2 (SORT_CRITERIA)

1    UT = Tasks          // unsigned tasks
2    BestTS = <>         // best sequence according to MAKESPAN
3    CurrentTS = <>      // current (candidate) tasks sequence
4    BaseTS = <>         // base task sequence
5
6    UT = SORT( UT, SORT_CRITERIA )
7    BestTS = CurrentTS = UT.getFirstTask()
8    for each Task from UT
9     CurrentTS = BaseTS
10    for each position i=|CurrentTS| insertion Task into CurrentTS
11              for each position CurrentTS to i
12                    rTask = CurrentTS.removeTask(i)
13                    ReTasks.addTask(rTask)
14             end for
15             value = GreedyAlgorithm(CurrentTS, ReTasks, Task)
16      if (value < bestValue or i==|CurrentTS|)
17        bestValue = value
18        BestTS = CurrentTS + Task + ReTasks
19      end if
20    BaseTS = BestTS
21   end for
```

For example, in basic NEH for three task (A, B and C, let assume that BA sequence is an optimal) the analyzed sequences are: CBA, BCA and BAC. In reverse order in NEH2 we build BA schedule as base, then BAC. In next sequence BCA from schedule is removed task A, then inserted C and A. In basic NEH to examine three task sequence 9 task is scheduled, in reduced version (NEH2, see Pseudocode 4) only 6 tasks is (re)scheduled.

The main modification of NEH2 heuristic is to remove from the initial sequence and reschedule only tasks that are next inserted (see line 11-14). To evaluate the partial schedule is build by *GreedyAlgorithm* (line 15) to examine the sequence of tasks.

The NEH2 computation complexity reduction makes possible practical application of heuristic in simpler cases. Such NEH2 heuristic has been examined. Results of test are presented in the next section.

## IV. EXPERIMENTS AND RESULTS

The t-RCPSP model is specialized to MP2 company requirements. All proposed methods in verification procedure need an empirical data. We analyzed real data and prepared dataset that is complete for the domain: various number of tasks, machines, devices and technologies. Such dataset allows us to do research and compare results of proposed methods.

All experiments are implemented in standard C/C++. Machine for test was equipped with Intel Core2 Duo 2.53 GHz, 4GB RAM and Windows7 OS. For each experiment, only one Core was used.

### A. *Experiments' set-up and dataset*

Prepared dataset MP2dataset[1] consists of seven various types of configurations – summary of dataset is presented in Table1. There are three types of simple settings (10_3x3_10, 50_10x20_40 and 75_10x20_40) that involve small number

TABLE I.

| Legend: tasks _ machines x devices _ technologies | | | | |

[1] MP2dataset is published in http://imopse.ii.pwr.edu.pl/

of tasks (respectively 10 or 50) and small number of devices, less than 20. Two configurations have medium difficulty (100_30x30_100 and 200_30x30_100) where number of tasks is larger (100 or 200) and there is increased number of possible technologies to 100. Additionally, the configuration 300_30x100_500 is difficult because of large number of tasks and extremely a lot of technologies (500) and devices (100). The last configuration consists of 500 tasks, which is the most difficult for methods testing.

To get dataset more general, for each configuration 100 instances were generated. The data generator constructs instances randomly according to the specific domain requirements and configuration. Analyzing the real data we assumed some additional dataset parameters: task deadline *ddt* in <10,50> defined in discrete timeslots, the maximal number of generated products by technology is 5. Each technology can produce no more that 2 types of products and use no more than 4 types of materials. Each product can be generated by 2 or more technologies. The longest technology duration not exceeds 10 timeslots.

### B. *Experiments results*

The main goal of provided experiments was to investigate how presented methods are effective in solving t-RCPSP. The method's results are described by makespan and averaged latency of all tasks in given schedule. The other comparative aspect was computational CPU time needed by methods to obtain results. All methods were investigated using MP2dataset and results were averaged to compare to others (see Table II). Research consists all examined methods DBH, NEH2 and PEC using one main parameter, sorting criteria: by task deadline ascending, descending and random. The PEC uses extra parameter: *size* of task list.

Experiments results presented in Table II give information that all developed heuristics are useful in solving t-RCPSP. In 4/7 cases the minimal makespan provided DBH, however NEH2 in such cases gives slightly worse results and in 3/5

cases returns solutions that compete with others. The NEH2 in more complicated cases (300 and 500 tasks) execution time exceeded 1 minutes CPU time and results are not taken into consideration. PEC only in one case returns the best solution (75 tasks, PEC(3) asc). Increasing the PEC *size* parameter value in most cases reduces makespan, e.g. comparing results of PEC(3) and PEC(4) using descending task deadline order. To summary results of all methods for all instances: DBH dsc needs average 319,97 timeslots to execute all 700 instances, DBH asc needs 324,06 timeslots and PEC(5) dsc has the third place: 328,9 timeslots. The longest averaged makespan schedule (equals to 337 timeslots) achieved PEC(3) heuristic with ascending task order. Analysis of the results presented into Table II can draw the conclusion that descending sorting criteria of tasks gives better results in the minimization of schedule makespan. Random tasks order makes solution the worst in all investigated cases. All methods are deterministic, the averaged results are computed on 100 instances of each configuration. In case of random tasks order, results for each instances are repeated 10 times and then averaged.

Results presented in Table III describe how generated schedules are late using as measure the average latency of all tasks in the schedule. The gained results proved our intuition that the best results give ascending sorting criteria of tasks – task with the shorter deadline is taken into consideration earlier. All methods showed that are effective, but it is rather impossible to point the best one. In 2/7 cases DBH gives the best solution, PEC in 4/7 cases (using *size* parameter equals to 3, 4 or 5). Results gained by NEH2 are not qualitative. Moreover, NEH2 in one case returns the best solution (100 tasks configuration). Comparing the averaged latency for 700 instances (whole MP2dataset) the best method gives 7,28 latency (DBH asc), the second one 7,73 (PEC(5) asc) and third one 7,91 (PEC(4) asc). The worst averaged latency achieved PEC(3) dsc: 21,23.

Comparing methods' working time (see Table IV) it is worth mentioning that methods are fast and effective. The provided MP2dataset of 700 instances gives an opportunity to compare methods results and recommend them to real-world applications. Increasing size of the problem, methods are practical as computational time not exceeds 10 seconds. Such short computational time makes possible to run several methods to get set of schedules and give a human operator a real choice.

The computation complexity of presented heuristics is $O(k^2)$ for DBH and $O(size!k^2)$ for PEC. The NEH2 complexity is larger because core of NEH2 is $O(k^2)$ but in each step uses *greedyAlgorithm* that is $O(k)$, what gives finally NEH2 $O(k^3)$. The result is that the computational time of NEH2 increases so dramatically that needed time is unacceptable in construction process of schedules that consist of more that 200 tasks. In such cases other methods are more effective and less demanding for CPU working time.

## V. Summary

Standard RCPSP, in presented work, was extended by technologies to solve practical problem in Plastic and Rubber Processing Industry – we defined t-RCPSP. Such model makes possible, in simply and intuitive way, a formalization of real-world problem. Each technology links non-renewable and renewable resources, uses various types of ingredients in production. Technologies that produce the same products may use resources in different way, more or less effectively. It can case be other production time consumption, too. The technology-driven RCPSP model gives a lot of possibilities to build effective heuristics. We proposed three of them: NEH2 adaptation, locally optimal resource usage PEC and duration driven heuristic DBH. Analyzing a real production schedule instances we implemented a data generator to get the MP2dataset (published in Internet) that includes 700 instances in 7 basic problem configurations to empirically prove efficiency of proposed methods. Results of experiments showed that proposed methods can be used as effective tool for scheduling in production company. Moreover, the next step was done: all presented methods were developed as automated scheduling module in MP2 company computer system.

### A. Further research

As the practical aspect of further research is the definition of more domain-based measures of final schedule and used technologies. In presented paper, only the makespan and latency are analyzed as the measure. However, in practice such technology can be more energy consuming, may need more labor (including human work) or can be less effective as a scrap measure is considered. The existence of several measures of schedule leads to the situation when multiobjective optimisation should be considered.

Investigating the comparison of presented methods we can see some possible directions of further work. The most promising is using metaheuristics (such as Evolutionary Algorithms or Tabu Search) to build schedule near optimal in cost/time criterion. Metaheuristics usage needs more computational time than simple heuristic – but our experience (e.g. Error: Reference source not foundError: Reference source not found) shows that results are (sub)optimal. Additionally, metaheuristics are using evaluation function (as the superposition of several schedule measures) can provide schedule dedicated to given user. Especially Tabu Search [12][15][16][20] application to RCPSP is very strong trend in literature.

***Abstract*—In this paper novel project scheduling difficulty estimations are proposed for Multi-Skill Resource-Constrained Project Scheduling Problem (MS–RCPSP). The main goal of introducing the complexity estimations is an attempt of estimation the project complexity before launching the optimization process. What is more, the dataset instance generator is also presented as a tool to create new instances for extending the research area. Furthermore, the dataset proposed in previous works is extended by new instances, described thoroughly and released as a benchmark dataset. The dataset instances are also scheduled using simple heuristic and greedy algorithm in duration- and cost- oriented optimization modes. Finally, a brief summary of investigated methods and potential further research directions is presented.**

***Index Terms*—scheduling, RCPSP, dataset, benchmark, heuristics, indicator**

## I. Introduction

Resource-Constrained Project Scheduling Problem stands as one of the most important and the most investigated [9], [10] kind of known types of scheduling problems. It is because of its practical nature and the need to find good ways for resolving it not only for scientific, but also industry purposes. Its goal is to find the best schedule for the project, by assigning scarce resource to defined tasks. The quality of the schedule is mostly defined as its duration, cost or some combinations of those indicators.

As MS–RCPSP is the extension of classical RCPSP, it makes the problem NP–hard [2]. Hence, there is no way to find a method that would be able to find the optimal solution in polynomial, reasonable time. Therefore, one of the main approach to solve RCPSP and its potential extensions is to use soft computing methods, especially metaheuristics [19].

To make the problem definition more practical in industrial point of view, we introduced the skill domain. Tasks require some specified skill to be performed by resources owning some subset of skills defined in the project. Therefore, not every resource is able to perform every task in the project. It makes the problem more constrained but on the other hand – more realistic. RCPSP extended by skills domain is called Multi–Skill RCPSP (MS–RCPSP).

The goal of the paper is to present several indicators for the difficulty of the project to be scheduled. The difficulty could be understood as a measure how much the solution space is constrained – how hard is to build feasible and good enough schedule. The secondary objective is to share the dataset and propose it as a benchmark for other researchers, to build a common platform for evaluating methods solving MS–RCPSP.

The rest of the paper is organised as follows. Section II presents some approaches in solving MS–RCPSP using some of the mentioned metaheuristics. Then section III describes the problem statement. Then Section IV presents complexity estimations we proposed for MS–RCPSP. Section V describes the way how new instances are generated. Furthermore in the Section VI the dataset has been presented and then its instances have been used in experiments in Sec. VII while the last Section VIII describes approaches we have recently investigated and proposes ways for further research.

## II. Related work

NP–hard [2], combinatorial nature of MS–RCPSP is one of the reasons of common use of metaheuristic–based approaches in solving the problem. Nevertheless, some constraint programming methods or simpler heuristics are also used to solve this kind of problems [20].

However, there is still lack of papers regarding multi–objective Multi–Skill extension of RCPSP. Some approaches solving MS–RCPSP in project duration domain [1], [16] or project cost domain [12] could be found. On the other hand, there are methods solving classical RCPSP extended by cost domain, but without skills considerations. Such research has been presented in [15], [6], [4], [13] and [24]. Hence, we have decided to combine those two elements: multi–objective optimization and multi–skill domain for project scheduling problem.

Although classical RCPSP is deeply investigated and numerous approaches could be easily compared using PSPLIB instances, it is very hard to find multi–objective MS–RCPSP methods working on datasets that could be regarded as a benchmark. Some papers describe instances artificially generated ([5], [16]), while some others propose methods of PSPLIB dataset adaptation ([1], [3], [7], [12]). We analysed some published benchmark datasets, but they were usually unsuitable for our approach as they do not cover multi-objective nature of the problem, even multi–skill domain has been developed ([23]). The other unsuitable example is a benchmark for Multi–Mode RCPSP (MM-RCPSP) published in [21], but it does not involve skills constraints and make the main focus on multi–mode characteristics. Hence, the need of definition new dataset has arisen.

978-83-60810-66-8/$25.00©2015, IEEE

Some difficulty estimations for any project scheduling problems could be found in [11] or [13]. However those proposed difficulty estimations based mostly on tasks, precedence relations between them and resource properties. There is a lack of difficulty estimations that would be dedicated for MS–RCPSP, involving skills domain.

Among many papers regarding the resource – constrained project scheduling problems and its extensions, we found that we had something in common with the approach presented in [13]. Despite some similarities, there are some crucial elements that make our approach, defined in detail in [14], different. We regard both of them as worth of investigating. Tab. I presents the comparison – similarities and differences in four main areas we decided to point out.

Based on the information in the Tab. I, some common elements between our approach and the one presented in [13] in all of the mentioned areas can be found. Firstly, investigated problems are similar in a way that both of them regard multi–objective optimization in Multi–Skill Resource–Constrained Project Scheduling Problem (MS–RCPSP). Both problems are additionally defined by some resource, precedence and skills constraints. However those constraints differ in details (i.e. distinguishing skill types).

There are also some similarities regarding the dataset published. First of all, both of the datasets are published in the Internet, so anyone has an access to dataset instances and can use them to investigate own optimization methods in MS–RCPSP. What is more, the number of dataset instances is the same. However, the strategy of building the dataset was different. We used information about number of different skill types and number of precedence relations. Not only the most common indicators, like number of tasks or number of resources, what can be found in [13]. Based on those additional indicators we tried to build as most balanced dataset as possible. Therefore, we tried to adjust the number of resources, skills and precedence relations in a way to make our complexity indicators similar for 100 and 200-tasks project instances as well.

## III. Problem statement

The goal of the MS–RCPSP is to order given set of tasks and assign resources to them in a way to provide feasible and as good solution as possible. The quality of the solution could be measured in its duration, cost or any other measure defined according to business requirements.

In MS–RCPSP the set of tasks ($J$) is given, while every task has to be performed during the project execution. Each task is described by its start ($S_j$) and finish dates ($F_j$), duration ($d_j$) and skill required by it to be performed. What is more, tasks can be related between themselves by precedence relations. It means some tasks (successors) cannot start before some other would be finished (predecessors). It makes the solution space for given instance more constrained, as there are fewer possibilities to put the tasks in given period. Predecessors of given task $j$ are defined as $P_j$ while overall number of predecessors in a project is $p$.

Furthermore, the set of resources ($K$) is also given. Every resource $k$ is described by its salary ($s_k$) and skills covered ($Q^k$). Therefore, a subset of tasks than can be performed by $k$ resource could be obtained and is denoted as $J^k$.

Skill required by task to be performed determines which resource can be assigned to it. Every skill type could appear in a project in various familiarity levels, denoted as an integer value from 0 to 4. Resources with skill type required by given task but on the lower than required level cannot be assigned to such task. The number of all skills (including different familiarity levels) is denoted as $q$, while the number of skill types in the project is denoted as $\bar{q}$

What is more, any resource cannot be assigned to more than one task in the overlapping period. If such a situation occurs, **conflict** is detected and has to be resolved, to get valid, feasible solution. It is made by shifting some of conflicting tasks in time–line in a way to make it start just after another conflicted task would be finished. The decision which of conflicted tasks should be taken to be shifted is made by checking which has been previously added to the project definition, because we do not distinguish various levels of task priority. Each task is equally important to be scheduled in the project.

Any project schedule ($PS$) has to be conflicts–free and has to satisfy the precedence constraints between tasks. If it satisfied those both kind of constraints, we would call it as a **feasible** schedule. Only feasible ones can be regarded as finite solutions. What is more, every infeasible solution could be made feasible. However, making schedule feasible could make its duration longer.

### A. Calendar restrictions

Due to use Microsoft Project as a base for our dataset, we needed to obtain some calendar restrictions that are strictly related to used software.

First of all, standard calendar in Microsoft Project is designed to handle projects in real–life, where classical five–days week of work is used. It was also a requirement asked by the VolvoIT enterprise that we cooperate in the research field of project scheduling. However, weekends are taken into account. If resource is assigned to task that cannot be finished before weekend, it will be finished after the weekend. The task duration is bigger but number of man–hours (or man–days) required for given task does not change. Therefore various project duration measures can be obtained. One can be made based on the overall duration of project – between its start and finish dates, including weekends where tasks are not performed but influence on other tasks' start dates and the project finish. Other approach could be to ignore any festivals and weekends and regard seven days week of work. Until now we prefer the first approach as it is more practical.

Furthermore, the localization issue has to be taken into account when considering calendar restrictions. Depending on the localization settings, some changes in the calendar could appear, regarding some national or cultural–related festivals. In example, there would be other free days in China than in Poland, where different festivals are taken place.

TABLE I
SIMILARITIES AND DIFFERENCES BETWEEN IMOPSE [14] APPROACH AND THE APPROACH PRESENTED IN [13]

| Area | Similarities | Differences |
|---|---|---|
| Problem definition | Multi-skill<br>Multi-objective<br>Resource-constrained<br>Precedence relations<br>Skills<br>Minimal one resource required by given task to be performed<br>Repair operator → enlarging project duration | Resource load - 'dedication' measure<br>No skill levels<br>Task can be assigned to more than one resource<br>No conflict, different rule of repair operator<br>Approach more academic than practical |
| Dataset | Same number of instances: 36<br>Published in the Internet | Instances distinguished only by number of tasks and number of resources<br>Constant vs. varied number of skill types in a dataset instance |
| Generator | Published in the Internet as a benchmark<br>Developed in the JAVA programming language | No graphical user interface<br>Output format not connected with MS Project |
| Methodology | Time vs. cost tradeoff<br>Focus on multiobjective, Pareto–based optimization | Complexity estimators vs. hypervolume, attainment |

Linking above constraints with potential dynamic date of project start – the date, when the first task is assigned to resource in the timeline – there is a risk that the same project with the same task–to–resource assignments (schedule) can be finished in various dates, depending on the day of start. Project instances start at various dates, except the ones with D* suffix that have been prepared strictly for given enterprise and were required to be start all at the same day. It has been set to 12th April of 2012.

To avoid those calendar restrictions .def format has been introduced. It is described in detail in Subsec. VI-A.

### B. Evaluation function

The goal of MS–RCPSP is to find the best (as quick or / and as cheap as possible) final project schedule. Hence, we could present it as bi–objective optimization problem. Because of totally different domains of duration and cost, we cannot simply aggregate those two objectives. Therefore, the normalization process is performed, to get the value scope between 0 and 1. It allows us to aggregate those two objectives and combine them into one evaluation function.

We have also preserved the possibility to choose which objective is more important in given optimization process. It is made by setting weights both for the duration ($\omega_\tau$) and cost aspect. The sum of both weights sum to 1 and the scope of values is from 0 to 1. It means that setting the weight of duration aspect to one automatically sets the weight of cost to 0 and vice versa. Naturally that weight can be set by float value. Specifically, both weights could be set to 0.5. In that case, both objectives would be equally important in the optimization process. We proposed three baseline weight configurations: duration optimization (DO, $\omega_\tau = 1$), balanced optimization (BO, $\omega_\tau = 0.5$) and cost optimization (CO, $\omega_\tau = 0$) [14].

An important remark is that those objectives are in opposition to each other. It means that setting weights to make the optimization process more cost–oriented could cause getting cheaper project schedule, but with the risk that final schedule would be longer. Analogously, shorter project schedule could be obtained with spending more money on it.

Evaluation function is formulated as follows:

$$\min f(PS) = \omega_\tau f_\tau(PS) + (1 - \omega_\tau) f_c(PS) \tag{1}$$

where: $w_\tau$ – weight of duration component, $f_\tau(PS)$ – duration evaluation component, $f_c(PS)$ – cost evaluation component. Both components are non–negative values, while $w_\tau \in [0; 1]$.

The time component $f_\tau(PS)$ is calculated as follows:

$$f_\tau(PS) = \frac{\tau}{\tau_{max}} \tag{2}$$

Where: $\tau_{max}$ – maximal (pessimistic) possible duration of the schedule $PS$, computed as the sum of all tasks' duration [14]. It occurs when all tasks are performed serially in project: one–by–one. No matter, how many and how flexible resources are.

The cost component $f_c(PS)$ is defined as follows:

$$f_c(PS) = \frac{\sum_{i=1}^{J} c_j - c_{min}}{c_{max} - c_{min}} \tag{3}$$

where: $c_{min}$ – minimal schedule cost – a total cost of all tasks assigned to the cheapest resource, $c_{max}$ – maximal schedule cost – a total cost of all tasks assigned to the most expensive resource [14]. Note: $c_{max}$ and $c_{min}$ do not involve skill constraints. It means that $c_{min}$ value could be reached also for non–feasible solution. Analogously to $c_{max}$.

### C. Solution space size

Given number of tasks and number of resources, we can estimate the solution space size (SS), as:

$$SS(n, m) = n! * m^n \tag{4}$$

Where $n$ is a number of tasks and $m$ is a number of resources [14]. However, that estimation also takes into account non–feasible solutions, because skill–constraints are not satisfied. To give an example, let's assume $n = 10$ and $m = 5$ – without any precedence relations we get $SS(10, 5) = 3.54 * 10^{13}$ combinations. It is worth mentioning that each task can be placed only once in the schedule, but resources could be assigned more often. An extreme situation occurs if the same one resource would be assigned to perform each task.

Large solution space size makes impossible checking each of the combinations manually. However, space includes also non–feasible solutions that do not satisfy defined conditions. Moreover, above example is a simplification and in real world problems we meet a higher number tasks (about $n = 100$) and resources ($m = 20$) – it gives $SS(100, 20) = 1.19 * 10^{288}$ of all solutions.

## IV. Complexity estimations

As a result of cooperation with VolvoIT Department in Wroclaw [18], [20], [19], we defined following elements [14]:

- requirements and constraints dedicated to the industry,
- project scheduling difficulty indicators.

Project difficulty indicators have been verified and approved by experienced project manager in the enterprise.

The main goal of investigating such estimations was to compare how the project elements (tasks, resources, precedence relations, skills) characteristics could influence on the optimization process based on the quality of obtained result (project schedule duration or performance cost) or optimization processing time.

Proposed difficulty estimations are described below. All estimations are normalised before being taken to compute the overall complexity measure.

### A. affiliation ($\lambda$)

States, how much tasks are related between them. The bigger value means the tasks are more related. The project complexity is bigger, because the scheduling flexibility is restricted (more tasks are related to others, so they cannot be scheduled flexibly). It is computed as follows:

$$\lambda = \frac{p}{n} \tag{5}$$

Where $p$ – number of precedence relations, $n$ – number of tasks.

### B. load ($\nu$)

Reflects, how much resources are loaded by tasks. The bigger value means, the more tasks are assigned to one resource (the project complexity is bigger, because the solution space is bigger). It is computed as follows:

$$\nu = \frac{n}{m} \tag{6}$$

Where $m$ – number of resources.

### C. time difference ($\Phi_T$)

Describes how tasks are varied by their duration. The bigger value means tasks are more varied. That makes scheduling more difficult, because tasks' order influences on overall duration time. It is computed as follows:

$$\Phi_T = \frac{\sigma_d}{d_{max} - d_{min}} \tag{7}$$

Where: $\sigma_d$ – standard deviation of tasks' duration in schedule, $d_{max}$ – maximal task duration in schedule, $d_{min}$ – minimal task duration in schedule.

### D. cost difference ($\Phi_C$)

Indicates how tasks are varied by their performance cost. The interpretation is similar to the time difference ($\Phi_T$). It is computed as follows:

$$\Phi_C = \frac{\sigma_C}{c_{max} - c_{min}} \tag{8}$$

Where: $\sigma_C$ – standard deviation of tasks' cost in schedule, $c_{max}$ – maximal task cost in schedule, $c_{min}$ – minimal task cost in schedule.

### E. variety ($\mu$)

Reflects how resources are varied by their skills. The bigger value means the project is more difficult to be scheduled because tasks are more dedicated to resources (no other can be assigned to the specified task). It is computed as follows:

$$\mu = \frac{q}{m} \tag{9}$$

Where: $q$ – number of different skills existing in the project. Important: each level of the same skill name is regarded as a new skill.

### F. universality ($\beta$)

States the average number of resource skills. The bigger value means it is easier to schedule a project because resources are more universal. It is computed as follows:

$$\beta = \frac{\sum_{i=1}^{m} Q^i}{m} \tag{10}$$

Where: $Q^i$ – number of skills owned by $i$ resource.

### G. adjustment ($\pi$)

Shows how many resources available to be assigned in the project are capable of performing tasks that are needed to be performed. Ergo – how many resources can deal with each task. The bigger value means it is more difficult to schedule a project because resources are strictly adjusted to the tasks by their skills covered, and skills needed. It is computed as follows:

$$\pi = \frac{\sum_{i=0}^{Q} \Delta(q_i) * \sigma(\Delta(q))}{max(\Delta(q_1), \Delta(q_2), ..., \Delta(q_q)) * q} \tag{11}$$

Where:

$$\Delta(q_i) = \frac{|Q^i - TQ(i)|}{min(RQ(i), TQ(i))} \tag{12}$$

Where: $RQ(i)$ – number of resources covering skill $i$ (normalized by number of all resources ($m$) in the project). $TQ(i)$ – number of tasks, that require skill $i$ to be performed (normalized by number of all tasks ($n$) in the project).

### *H. Flexibility ($\theta$)*

The flexibility $\theta$ of the instance $PS$ has been estimated as the sum of a number of potential assignments of tasks to a given resource divided by number of resources ($n$). It can be stated as follows:

$$\theta = \frac{\sum_{k=1}^{n} \bar{J}^k}{m} \tag{13}$$

Where $\bar{J}^k$ is the number of tasks that can be performed by resource $k$, while $m$ is the number of resources in a project.

Having discussed the usage of those estimations' legitimacy, each measure has been subjectively weighted and confirmed by an experienced project manager (to determine their priority in overall project's difficulty measure). Having those weights set up, the project's (*PF*) difficulty measure function could be defined as follows:

$$diff(PF) = 8\lambda(PF) + 9\nu(PF) + 3\Phi_\tau(PF) + \\ +3\Phi_C(PF) + 6\mu(PF) - 4\beta(PF) + 7\pi(PF) + 5\theta(PF) \tag{14}$$

The bigger the value $diff(PF)$ is, the more difficult to schedule the project is. Universality measure has been taken with a negative value. It is because the bigger the universality value is, the project is easier to schedule as resources are more skill–flexible and can be assigned to more different tasks, relaxing more skill constraints.

Depending on project manager preferences, weights assigned to given estimations could be changed, what would influence on the overall $diff(PF)$ measure.

## V. Instances generator

The main goal of implementing the dataset instance generator is to provide other researchers the possibility to investigate their methods not only on proposed dataset instances, but also on some other that would be created individually by given researcher. Dataset instance generator has been prepared for MS–RCPSP but it can be easily adjusted to handle classical RCPSP instances like PSPLIB [8]. It has been implemented in JAVA programming language, using MPXJ[1] library for processing project files from MS Project. It can create project definition not only in .mpp (XML) format, but also the simpler (.def) one. The more detailed description of .def format is available in Subsec. VI-A. Instances have been created based on the real–life project instances got from international entreprise (Volvo IT).

Instances generator is an element of resources developed in our **Intelligent Multi–Objective Project Scheduling Environment**[2] platform. Besides instances generator, the platform contains solution validator (see Subsec. VI-B), instances we generated and used to verify our approaches and the best found solutions for those instances in three above–mentioned optimization modes: DO, BO, CO. Every solution is saved in ready–to–use in MS Project .xml format, containing all tasks, resources, skills, precedence relations and obtained schedule.

The general process of generation new instances could be split into main steps:

1) Read and validate parameter values provided by the end user
2) Define resources,
3) Define skills and assign them to resources,
4) Define tasks and precedence relations,
5) Assign resources if necessary,
6) Save project.

In the further parts of this section, following steps would be described in detail. The pseudocode of the generator has been presented in Alg. 1

**Algorithm 1** Generator pseudocode

```
 1: $pool \leftarrow \emptyset$
 2: #generate_resources
 3: for $r \in K$ do
 4:     #generate_resource
 5:     $set\_standard\_salary(minSt, maxSt)$
 6:     #set_skills($r_i$)
 7:     $q \leftarrow setNumSkills(min, max)$
 8:     for $j = 0; j < q$ do
 9:         $set\_skill\_type\_from\_range(minST, maxST, q_j)$
10:         $set\_skill\_level\_from\_range(minSL, maxSL, q_j)$
11:         if $skill\_not\_exists(q_j, pool)$ then
12:             $pool \leftarrow pool.add(q_j)$
13:         $r \leftarrow addSkill(q_j)$
14: #generate_tasks
15: for $t \in J$ do
16:     $t \leftarrow set\_duration(minDuration, maxDuration)$
17:     $t \leftarrow set\_skill(pool)$
18: #generate_relations
19: for $i \in P$ do
20:     $relSource \leftarrow rand(T)$
21:     $relDest \leftarrow rand(relSource, T, min, max)$
22:     $relSource \leftarrow addPredecessor(relSource)$
23: if $make\_assignments$ then
24:     #assign_resources [initial schedule builder]
25:     for $n \in J$ do
26:         $R \leftarrow capable\_resources(n)$
27:         $r' \leftarrow rand(R)$
28:         $assign(n, r')$
29: $save\_result$
```

### *A. Resources*

The number of resources that would be generated is provided as a parameter for the proposed tool. For every generated resource its standard rate salary is set as a random between the minimal and maximal value (see Alg. 1, line: 5) set by the end–user in the configuration of the generator.

### *B. Skills*

Analogously to resource definition, the number of different skill types is set by the end–user during the configuration. We

[1] http://mpxj.sourceforge.net

[2] http://imopse.ii.pwr.edu.pl

declared 4 levels of the skill familiarity for given resource. However, the end–user is also obliged to define how many types of skills could be covered with given resource. It is desired that number of skill types owned by resource would be no greater than the number of skill types existing in the project. Number of skill types is set randomly from the minimal and maximal value (set by end–user). However, during recent dataset instances generation, we decided to make the number of skill types for every resource as a constant – minimal ($min$) and maximal ($max$) number of skill types have been set as the same value – line 7.

During skill generation process for given resource, a skill type is selected from given range of types (line: 9) while skill level is also selected from given scope (line: 10). We decided to make four levels of skills as it covered the requirements presented by project manager from the enterprise. If selected skill is not available in skills pool, it is both assigned to the resource and added to the skills pool (line 13). It provides that skills required by any tasks to be performed would be selected from the pool of skills that are owned by at least one resource (line 17).

### C. Tasks

Having resources, and skills covered by them defined, tasks could be obtained. The number of tasks is set by the end–user. What it more user also sets the duration scope of the task (line: 16). Those are the bounds within the task duration would be randomly set (line: 16). For the sake of generation project instances for our research, we made an assumption that task duration would be the number between 8 and 40 hours. It reflects to the range between 1 and 5 days of any task's duration. The skill required by any task is selected from the pool of available skills in given project instance (line: 17).

### D. Precedence relations

One of the last steps during generation process is to define the precedence relations. End–user defines the number of those relations. S/he is also responsible for defining the general scope of relations. It means, the bigger relations scope set, the bigger distance between tasks is allowed in building the precedence relations diagram (line: 21). In other words, setting small relation scope could cause that resulted schedule would contain precedence relations between tasks that have been defined one by one or with slight distance (like task first and third). However, if the relation scope would be set to a bigger value, there could be relations in the final schedule between some tasks defined in the beginning and the end of the generation process (e.g. precedence relation between the first and the last task defined).

The bigger the distance between source and destination task is, the more complex the project instance critical path is. As a consequence, duration–based optimization would potentially be more difficult for such project instance.

### E. Assign resource

Finally, the initial schedule could be built by assigning resources to given tasks, preserving precedence and skill constraints (lines: 26–28). Produced schedule would always be feasible. The way how resources are assigned to tasks is set randomly. Hence, if there is more than one resource that can be assigned to given task, then generator could assign this task in different ways in different executions of generation process. Schedule is generated using the Serial Generation Scheme [9], what provides that generated schedule would be always feasible.

### F. Save project to file

The last step in the process of generation an instance is to save (line: 29) the resulted project. If user sets the output file type to *xml* (*mpp*), then generator produces the result in the format that could be easily loaded in Microsoft Project tool. If user selects *def* output format or does not select any, then the result would be saved in more compact format that could be read by any text editor. If *assign resources* option has been ticked, then tasks can have resources assigned. However it regards only generating output only in xml (mpp) format. The name of produced file relates to the name proposed by the end–user in given text field in the configuration screen.

## VI. Dataset summary

Due to evaluate not only the project schedule duration, but also the cost of the schedule including skills domain, we cannot use the standard PSPLIB benchmark dataset [8] in our research; that does not contain any information about the task performance cost. What is more, PSPLIB dataset instances do not reflect the MS–RCPSP. Hence, we prepared the dataset, containing 36 project instances, which have been artificially created, in a base of real–world instances, got from the Volvo IT Department in Wroclaw.

The dataset summary has been presented in the Table II. There are two groups of created project instances: one contains 100 tasks and the second – 200 tasks as typical ones performed in given international enterprise. Within each group, project instances are varied by number of available resources and the precedence relationship complexity. Number of resources for instances from both groups were chosen in a way to preserve constant average resource load and average task relations ratio for given instances. The skill variety has been set up to 9 or 15 different skill types for each project instance while any resource can dispose of exactly six different skill types. Because of the different resources and relations number, the scheduling complexity for each project is varied.

This dataset stands as an extension of dataset presented in [18], [19], [20], and that is the reason some instances are named with suffix *Dx*. This suffix refers to dataset instances that have been previously created and presented in those papers. Because of the extension the dataset, the need of introducing more clear namesystem has arisen. Suffix has been added to refer previously created files, keeping the naming convention applied after dataset extension.

### A. Project definition format (.def)

Because of changing the research's approach to be more generic, we decided to focus more on the dataset instances

TABLE II
COMPLEXITY INDICATORS AND DIFFICULTY MEASURE FOR IMOPSE DATASET INSTANCES. PROJECT INSTANCES REGARDED AS THE MOST DIFFICULT TO BE SCHEDULED ARE WRITTEN **BOLD**, WHILE THOSE ONES, WHO ARE INDICATED AS THE EASIEST TO SCHEDULE ARE WRITTEN *ITALIC*.

| Dataset instance | Features | | | | Indicators | | | | | | | | Difficulty |

stored in *.def* format that is easier to maintain and use by researchers. Hence we adopted instances created for MS Project to more generic form.

It led to remove the summary tasks that are specific for MS Project *.mpp* format. Summary tasks are used to group atomic tasks into more complex (i.e. task called 'development' could be split to some atomic tasks: database structures creation, development of business logic and development of user interface). However, MS Project allows to use summary tasks as predecessors for others. Therefore we multiplied precedence relations by copying them from predecessor's summary task to all of tasks included by this summary one. As a result new *Dx* instances have been created. Furthermore, some tasks, represented as summary ones, have been removed from the project. To be consistent with previous works, we keep names of those files the same. Those files are provided with additional description explaining the difference in number of tasks and precedence relations between file name and file content.

Adjusted dataset instances with *Dx* suffix have smaller number of tasks. Number of precedence relations is significantly bigger in all *Dx* instances. Roughly describing, it is more than twice precedence relations as in former instances, while number of tasks has been decreased in all instances in about 20% (about 20 tasks for instances with 100 tasks and 40 for instances with 200 tasks).

We have also presented in Tab. II the values of proposed complexity estimations. Finally, the overall complexity measure, as an aggregation value of complexity estimations components has been presented. Based on the overall complexity value, the most complex projects in scheduling point of view has been highlighted by bold. The overall complexity measure has been computed according to the Eq. 14. Changing weights of complexity estimations components would affect the final complexity value for each dataset instance. Hence, the complexity of each project could be different depending on priorities set by project manager.

In our approach all universality estimations values are equal to 1. It is because we made an assumption that every resource

has the same number of different skills and this is also the maximal number of potential skills covered by resource, used in normalization. If we decided to make the number of skills covered by resource various, depending to given resource, then the universality estimation values would not be always equal to 1.0.

### B. iMOPSE Solution Validator

We released also an additional tool to validate generated solutions in case of preserving all constraints defined in MS–RCPSP. Such validator is available on the iMOPSE project website[3]. Validator checks whether all tasks have any resource assigned (assignments validation), final schedule is conflict–free (conflicts validation), any task having predecessors is set to be started after all its predecessors would be finished (precedence relations validation) and whether any task has resource assigned that is capable of performing it (skill validation).

Validator shows not only the validation results but also the quality the validated solution – its duration measured in hours and cost measured in some currency units. If some validation rules are broken, they are shown to end–user.

Validator is compatible with .def project definition format. For further information how to use the validator, please refer to documents related with the tool – User's Manual or Case study – available on iMOPSE Platform.

## VII. EXPERIMENTS AND RESULTS

The main goal of conducted experiments was to link and compare both (*.mpp* [14] and *.def* based) approaches, considering the impact of calendar restrictions.

We decided to use simple duration– and cost– oriented heuristic [20], greedy algorithm and compare them with ACO and HAntCO approaches described in [14]. Furthermore, greedy algorithm and simple heuristics have been used to schedule .def dataset instances.

However, proposed heuristic and greedy approaches for cost optimization turned out to become the same method. Therefore, presented results are divided into main two parts regarding optimization modes: duration optimization ($\omega_\tau = 1$) and cost optimization ($\omega_\tau = 0$). Each of those main part is also divided for three parts in cost optimization (heuristic, ACO, HAntCO) and four parts in duration optimization (heuristic, greedy, ACO, HAntCO).

Table III presents the obtained results for both optimization modes using both proposed methods (simple heuristic and greedy algorithm). It also contains results obtained by ACO and HAntCO approaches described in detail in [14]. This

[3] http://imopse.ii.pwr.edu.pl

table presents optimization results for dataset instances with calendar restrictions (*.mpp*).

Greedy algorithm is a method that works iteratively. In every step of greedy scheduling, one task is added to the schedule. The decision, which task to which resource should be assigned in given algorithm step is made based on the current partial schedule. In other words: in a given step, currently best task–to–resource assignment option is chosen and the next step is performed until all tasks would be scheduled. Classical greedy algorithm assumes possibility to analyse not only current state of the partial schedule, but also to investigate several further steps. In that approach combinations of several tasks are analysed and the best one, containing given number of tasks–to–resource assignments is selected and added to the partial schedule. However, in our approach we discuss only current schedule state, omitting the analysis of several assignments. Therefore, number of steps of proposed greedy algorithms would be always equal to the number of tasks in a project.

For duration oriented optimization mode, greedy algorithm analyses which task should be added to make the partial schedule the shortest. For cost-oriented optimization mode, the criteria of selecting tasks bases on the cost of the assignment given task to given resource. For every task, various resources are analysed to be assigned, and the cheaper one is chosen.

In cost-oriented optimization mode, both greedy algorithm and simple heuristic (Resource Salary based [20]) works according to the same schema, described above. However, for the duration–oriented optimization, heuristic and the greedy algorithm differs in details. In the greedy algorithm task is assigned to given resource and then added to the partial schedule then conflicts are fixed and finally the project duration is computed. In simple heuristic (Successors List Size based [20]) firstly the resource that would be the earliest free (not assigned to any task) is selected. Then task is assigned to this found task while its start time is set just after then end of the last of tasks previously assigned to given resource. It allows to build feasible schedule without the necessity of fixing conflicts as the method is the resource conflict–free.

Taking into account results gathered in the Tab. III we can conclude that for duration optimization method, the HAntCO outclassed other methods, provided the best results in 28 of 36 cases (78%). ACO turned out to be the best method for 6 cases (16%), while greedy gave best results in 3 of 36 cases (8%) and heuristic was the most suitable in 2 of 36 cases (6%).

For cost optimization method, simple heuristic gives the best result for almost all of dataset instances (34/36, 94%). However, for remaining two instances heuristic also provided solution with the smallest cost, but the schedule duration was bigger than for other method (HAntCO). For most of the instances (32/36, 89%) HAnt-CO provided the same, best result than obtained from heuristic. ACO–approach provided the same, best results in 18/36 (50%) cases. The most interesting fact for cost optimization is that ACO provided best results mostly for dataset instances containing 100 tasks - 17/18 cases (94%) and only once for dataset instances containing 200 tasks (6%).

In the Tab. IV we compiled the summary of obtained best results for classical optimization methods - heuristics and greedy algorithm for instances not regarding calendar restrictions (*.def*). It can be also found in the iMOPSE website. As we are oriented to use *.def* format in further research, obtained project schedules are measured by hours rather than days as it has been so far, in *.mpp* format. Obtained results stand as a benchmark for further research when using .def format. On the other hand, Tab. III is still regarded as a benchmark for methods working on *.mpp* format.

TABLE IV
SUMMARY OF BEST OBTAINED RESULTS FOR DATASET INSTANCES NOT REGARDING CALENDAR CONSTRAINTS (*.def*).

| Dataset instance | Heuristic CO | | Heuristic DO | | Greedy CO | |
|---|---|---|---|---|---|---|
| | Hours | Cost | Hours | Cost | Hours | Cost |

Results obtained in the Tab. IV show that SLS [20] heuristic provides better results in DO mode in all of 36 dataset instances. It clearly shows that SLS heuristic is definitely better optimization method than greedy algorithm in this problem.

However the project definitions are compatible to each other between *.def* and *.mpp* formats, there are some small differences in cost result in CO, using the same method. It is because of the adjustment made when transferring *.mpp* to *.def* format. For the sake of simplicity, task's duration in .def has been rounded up to the integer values. It lead to the differences, because cost of performing project is a sum of each task's performance cost. While task's performance cost is computed as a multiplication of task duration and assigned resource's salary. As a result of rounding up, cost of each task has increased slightly, even though the same resource is assigned to it. Therefore the overall cost is slightly bigger for solutions obtained for *.def* files.

## VIII. Conclusions and further work

In this paper some novel difficulty indicators for instances of Multi–Skill Resource–Constrained Project Scheduling Problem have been presented. Furthermore the extended dataset has been presented and suggested as a benchmark for this problem, as no other benchmark dataset can be found that satisfies proposed constraints. Furthermore, those instances have been scheduled using greedy algorithm, to provide an initial platform for comparing results obtained by various researchers.

Proposed complexity estimations stand some first step in project scheduling data analysis. Guessing the project complexity could be helpful in parameters' tuning for various optimization methods. As more complex / difficult to schedule project is, the optimization process would potentially last longer for the same parameter configuration than for other instances. Hence, the decision maker could decide to change the parameters, e.g. by decrease number of method iterations. We managed to make those observations sure in our EA–based approach, where building schedule for the project with suffix D2 generally lasts longer than for the project with suffix D1.

The goal of presenting the dataset instance generator is to allow and encourage other researchers to focus on the problem and possible solutions and methods we propose. We still believe there is a lot to investigate and research. What is more, the dataset instance format we propose is very common in many industries, as the MS Project is a common standard.

We are also on the point of investigating approaches concentrated to different multi–objectiveness handling methods. Most of them we analyse are based on Pareto–front (like NSGA-II [22], [17] or other methods). One of the goals is to find a way how to provide a set of non–dominated results to the project manager, to delegate the matter of making decision which of those proposed solutions is the best, according to the specificity of the company it regards. E.g. in some industries the aim is to finish the project as soon as possible while in some others the most important is to perform it in the cheapest way. Still we would like to give the choice from a pool of some solutions.

*Abstract*—**The goal of this paper is to describe the approach for automatic identifying human organs from a medical CT images and discuss results of its comparison to different classification methods. The main premise of this approach is the use of data sets together with the relevant domain knowledge. We test our approach on multiple CT images of chest organs (trachea, lungs, bronchus) and demonstrate usefulness and effectiveness of the resulting classifications. The presented approach can be used to assist in solving more complex medical problems. Keywords: CT images, concept approximation, classifiers, decision trees, medical object recognition, object classification, domain knowledge, organs identifying, medical system**

## I. Introduction

A DESIGN of human–machine interface is the most important aspect of computer aided interpretation of medical image exams. Assists include decision support, reminder and navigation techniques to help avoid diagnosis errors, content-based data mining capabilities, and access to reference libraries. Human–machine systems should take advantage of computer capabilities to increase physicians interpretation capabilities [1].

An automatic identification of medical objects visualized by Computed Tomography (CT) imagery (e.g., organs, blood vessels, bones, etc.), without any doubt, could be useful, to support solving many complex medical problems using computer tools. Our approach is based on a two-level classifier. On the lower level, our approach uses a classical classifier based on a decision tree that is calculated on the basis of the local discretization (see, *e.g.*, [2], [3]). This classifier is constructed and based on the features extracted from images using methods known from literature (see [4], [5] for more details). At a higher level of our two-level classifier, a collection of advisers works that is able to verify actions performed earlier by the lower-level classifier. This is possible by using domain knowledge injected to advisers. Each of the adviser is constructed as a simple algorithm based on a logical formula, that on input receives selected information extracted from a tested image and a decision returned by the lower-level classifier, and the output returns confirmation or negation for the suggestion generated by the lower-level classifier. It consists in the fact, that in a situation where the decision taken by the lower-level classifier, is clearly incompatible with domain knowledge, the adviser suggests to refrain from taking a decision. Thanks to this, increases the accuracy of such the two-level classifier, with a slight decrease in its coverage. To illustrate the method and to verify the effectiveness of presented classifiers, we have performed several experiments with the data sets obtained from Second Department of Internal Medicine, Collegium Medicum, Jagiellonian University, Krakow, Poland.

In the Section II, we describe the problem of medical image understanding. Second section present conception of design a system for automatic medical objects classification. Finally, we present the complete structure of two-level classifier, results of the comparison to other classification methods performed on medical data sets for the automatic classification of chest organs (see Section IV).

## II. Medical image understanding

A process of radiological interpretation generally includes the understanding of medical image content resulting in recognition of possible pathology symptoms, most often called detection, and assessment of comprehensive image information in a context of current clinical case-knowledge. It involves image-based detection of disease, defining disease extent, determining etiology of the disease process, assisting in designing of the clinical management plans for the patient, based on imaging findings, and following response to the therapy [6].

The other area of application of the automatic image understanding technique is deep and requires a detailed analysis of particularly difficult images, especially in case of doubts and difficulties in deciding on final diagnosis. A very important difference between all traditional methods of automatic image processing (or recognition) and the new paradigm for image understanding is that there is one directional scheme of the data flow in the traditional methods; there are two-directional interactions between signals (features) extracted from the image analysis and expectations resulting from the knowledge

This work was partially supported by the Polish National Science Centre grant DEC-2013/09/B/ST6/01568 and by the Centre for Innovation and Transfer of Natural Sciences and Engineering Knowledge of University of Rzeszów, Poland.

978-83-60810-66-8/$25.00©2015, IEEE

of image contents, as given by experts (physicians). The results of all analyses of medical image characteristics and objects visible in them, generated by computers, allow the physician to base his/her reasoning on much more reliable and quantifiable premises than just a visual assessment of that image, improving both the effectiveness of his/her activities, and the feeling of reliability and security. Finally, the increasing acceptance of techniques for the automatic recognition and classification of biological objects distinguished in medical images can help the doctor make the right diagnostic decisions, although these techniques sometimes require the doctor to be able to critically assess the automatically suggested categories, as every recognition technique carries some level of error, while nothing excuses the doctor's personal responsibility for his/her decisions [7].

Medical image analysis is one of the areas of computer vision where domain knowledge plays a very important role, because localized pixel information obtained from CT images is often ambiguous and unreliable [8]. The history of knowledge-based medical image analysis is older than the history of practical usage of CT imaging. One of the early studies in knowledge based medical image analysis was done by Harlow and Eisenbeisc [9] on radiographic image segmentation, when CT imaging was not yet available in hospitals. They proposed a top-down control system using a trees structured model description containing knowledge about locations and spatial relations of parts/organs of the human body. In his thesis work, Selfridge [10] discussed image understanding systems in general and divided the causes of difficulties into problems of model selection, segmentation techniques, and parameter setting [8].

We conclude that the automatic detection of organs is the first step to understand medical images and it is necessary to begin the process of proper medical diagnosis support. To understand the CT image correctly, a computer should detect and recognize all medical objects located on the image by using domain knowledge. The knowledge about objects located in the medical image, allows the correct identification of areas related to various medical problems. To understand medical image correctly, a computer should detect and recognize quite correctly all medical objects located on the image by using domain knowledge (extremely challenging task even for a man).

## III. Conception of design a system for automatic medical objects classification

### A. A general description

In order to understand the medical images, it is important to create a tool for understanding the interior of the human body on different levels of abstraction and tracking of interaction between the observed medical objects. The main issues to be addressed include problems with the quality of the medical image data, problems with domain knowledge descriptions and problems with modeling and exploration of the human body, which is very complex. The system should include the assumptions, such that the system should support work of doctors (not replace), expert always decide, system should allow for future sharing of knowledge and should naturally communicate in order to exchange knowledge (speech).

### B. "Low-Level" features (LLF)

There is no "*ideal set of features*" which characterize the object. Features are selected individually depending on the recognized objects. In the computer analysis of the images, extracted features from the image, can be assigned to one of the categories, such as non-transformed structural characteristics (*e.g.*moments, power, amplitude information, energy, etc.),transformed structural characteristics (*e.g.*frequency and amplitude spectra, subspace transformation methods, etc.), structural descriptions (formal languages and their grammars, parsing techniques, and string matching techniques) and graph descriptors (*e.g.*attributed graphs, relational graphs, and semantic networks) described in detail in [4] and [5]. In this publication we call these features as Low-Level Features (LLF). In total, for the purposes of the experiments we define 18 LLF features (see Table I).

TABLE I
"Low-Level" Features

| **Name** | **Description** |
|---|---|
| **DT** | Distance to the first image in the series (mm) |
| **SIZE** | Object size |
| **WIDTH** | Object width |
| **HEIGHT** | Object heihgt |
| **DFL** | The distance from the object to the left edge of the image |
| **DFT** | The distance from the object to the top edge of the image |
| **R1** | Size of the object located in the region R1 |
| **R2** | Size of the object located in the region R2 |
| **R3** | Size of the object located in the region R3 |
| **R4** | Size of the object located in the region R4 |
| **R5** | Size of the object located in the region R5 |
| **R6** | Size of the object located in the region R6 |
| **R7** | Size of the object located in the region R7 |
| **R8** | Size of the object located in the region R8 |
| **R9** | Size of the object located in the region R9 |
| **CIRCUIT** | Object circuit |
| **TFACTOR** | Object thickness factor |
| **SFACTOR** | Object shape factor |

### C. "Domain Knowledge" Features (DKF)

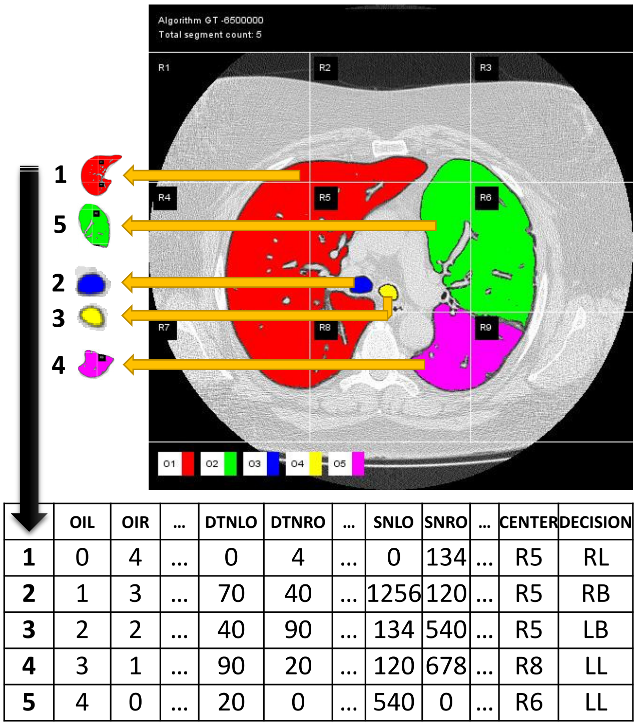
To understand the image, it is also necessary to define the additional features that will define the acquired domain knowledge from experts. We call these features Domain Knowledge Features (DKF). DKF can be assigned to one of the categories, such as:

- features used to describe domain knowledge about the number of objects that surround an analyzed object,
- features used to describe domain knowledge about the distance from analyzed object to surrounding objects,
- features used to describe domain knowledge about the size of objects that surround an analyzed object,
- features used to describe domain knowledge about position of an object.

In total, for the purposes of the experiments we define 13 DKF features (see Table II).

TABLE II
"DOMAIN KNOWLEDGE" FEATURES

| Name | Description |
|---|---|
| **CENTER** | Center of the object region (*e.g.*R1, R2 ...) |
| **OIL** | The number of objects on the right side |
| **OIR** | The number of objects on the left side |
| **OIA** | The number of objects above |
| **OIB** | The number of objects below |
| **DTNLO** | Distance to the nearest object on the left side |
| **DTNRO** | Distance to the nearest object on the right side |
| **DTNAO** | Distance to the nearest object above |
| **DTNBO** | Distance to the nearest object below |
| **SNLO** | The size of the nearest object on the left side |
| **SNRO** | The size of the nearest object on the right side |
| **SNAO** | The size of the nearest object above |
| **SNBO** | The size of the nearest object below |



| | OIL | OIR | ... | DTNLO | DTNRO | ... | SNLO | SNRO | ... | CENTER | DECISION |
|---|---|---|---|---|---|---|---|---|---|---|---|
| **1** | 0 | 4 | ... | 0 | 4 | ... | 0 | 134 | ... | R5 | RL |
| **2** | 1 | 3 | ... | 70 | 40 | ... | 1256 | 120 | ... | R5 | RB |
| **3** | 2 | 2 | ... | 40 | 90 | ... | 134 | 540 | ... | R5 | LB |
| **4** | 3 | 1 | ... | 90 | 20 | ... | 120 | 678 | ... | R8 | LL |
| **5** | 4 | 0 | ... | 20 | 0 | ... | 540 | 0 | ... | R6 | LL |

Fig. 1. Examples of "domain knowledge" features extraction

## D. Medical data

Our experiments were carried out on the data obtained from the clinical hospital Jagiellonian University Medical College in Kraków (the patients were diagnosed with asthma). The entire data set counted 26 patients (19 woman, 7 man). The average age of patients was 58.12 years (st.dev. 6.78 years, age range from 47 to 70 years). In all patients, volumetric CT torso scans were performed at both full inspiration and expiration with using 16-channel multi-detector CT scanner Toshiba (manufacturer's model name: Aquilion). The acquired data were reconstructed using a kernel (FC86) with 1 mm increments. Images were stored in the Digital Imaging and Communications in Medicine (DICOM) format. For each patient was taken 300 to 400 images (full inspiration) with a resolution of 512x512 pixels. The total size of the data set for the experiment count 9655 CT images.

From all images we select every fifth image (20% of all images, 5mm increments) to pre-processing. As a result of the segmentation process, we acquired 7491 objects for experiments. For all the objects we set LLF and DKF features, further all objects are classified by an expert to one of the 7 classes (chest organs) presented in the Table III.

TABLE III
OBJECT CLASSES

| Class | Object | Number |
|---|---|---|
| **TR** | Trachea | 671 (8,96%) |
| **RL** | Right lunge | 1621 (21,64%) |
| **LL** | Left lunge | 1616 (21,57%) |
| **RB** | Right main bronchi | 190 (2,54%) |
| **LB** | Left main bronchi | 211 (2,82%) |
| **LL+RL** | Object by gluing the left and right lungs | 55 (0,73%) |
| **OT** | Other objects | 3127 (41,74%) |

The entire data set was divided 20 times randomly into two sets - a set with training data and a set with test data (around 70% of the data getting into a training set - 18 patients, other (around 30%) into test set - 8 patients). All the experiments we conducted on these datasets.

# IV. EXPERIMENT RESULTS

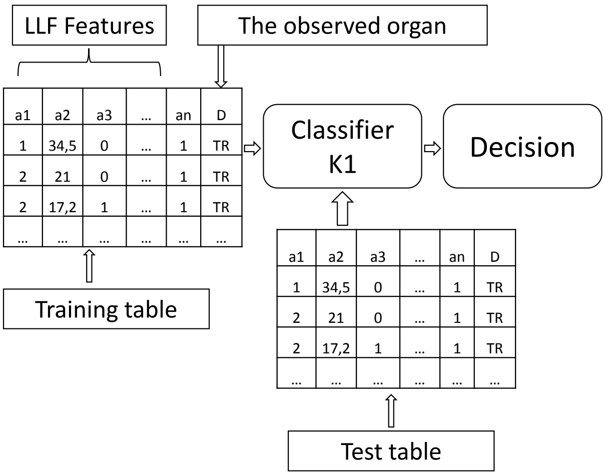
To verify the effectiveness of classification we prepare four methods. With using training data we built a classifier, which has been tested on test data. We designed a classifier to the automatic classification of chest organs. In method four we have implemented the two-level classifier in the IMPLA (Image Processing Laboratory), which is a continuation of the RSES-lib library (forming the kernel of the RSES system [11]), in the field of image processing. The IMPLA has developed recently in Interdisciplinary Centre for Computational Modelling, University of Rzeszów, Poland.

## A. Method 1

Method 1 is a method based on the decision tree with local discretization (LLF features, the quality of a given cut is computed as a number of objects pairs discerned by this cut and belonging to different decision classes, see, *e.g.*, [2], [3]). The method gave good results. Diagram of this method presented on Figure 2.

## B. Method 2

The second method was similar to the method 1 and based on the decision tree with local discretization. This method has used both LLF and DKF features.



| a1 | a2 | a3 | … | an | D |
|---|---|---|---|---|---|
| 1 | 34,5 | 0 | … | 1 | TR |
| 2 | 21 | 0 | … | 1 | TR |
| 2 | 17,2 | 1 | … | 1 | TR |
| … | … | … | … | … | … |

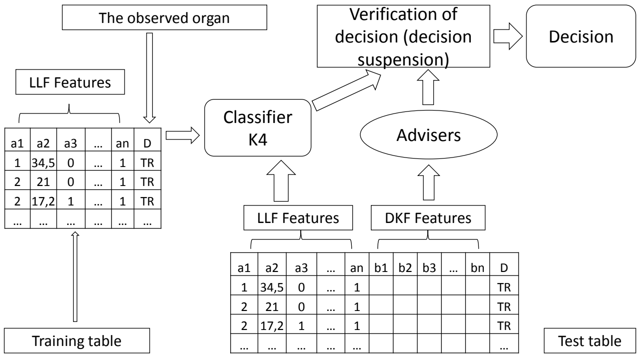
| a1 | a2 | a3 | … | an | D |
|---|---|---|---|---|---|
| 1 | 34,5 | 0 | … | 1 | TR |
| 2 | 21 | 0 | … | 1 | TR |
| 2 | 17,2 | 1 | … | 1 | TR |
| … | … | … | … | … | … |

Fig. 2. Diagram of method 1: The decision tree with local discretization

### C. Method 3

Method 3 was similar to the method 1 and based on the decision tree with local discretization. This method has used only DKF features.

### D. Method 4



| a1 | a2 | a3 | … | an | D |
|---|---|---|---|---|---|
| 1 | 34,5 | 0 | … | 1 | TR |
| 2 | 21 | 0 | … | 1 | TR |
| 2 | 17,2 | 1 | … | 1 | TR |
| … | … | … | … | … | … |

| a1 | a2 | a3 | … | an | b1 | b2 | b3 | … | bn | D |
|---|---|---|---|---|---|---|---|---|---|---|
| 1 | 34,5 | 0 | … | 1 | | | | | | TR |
| 2 | 21 | 0 | … | 1 | | | | | | TR |
| 2 | 17,2 | 1 | … | 1 | | | | | | TR |
| … | … | … | … | … | | | | | | … |

Fig. 3. Diagram of method 4: Two-level Classifier with ”advisers”

Method 4 is a method based on two-level classifier with ”advisors” (Figure 3). In this approach classification decision is dependent on suggestions of domain knowledge advisers. DKA suggest decisions based on domain knowledge *e.g.*”*Left lung is located on the right side of medical image*”, ”*Object located on the left side of medical image is probably not a left lunge*”. We prepare 15 DKA for all chest organs. Advisers are divided into two groups:

- YES advisers - Advisers to advise on YES *e.g.*”*yes, this is probably the left lung*” (6 DKA),
- NO advisers - Advisers to advise on NO *e.g.*”*no, this is probably not the left lung*” (9 DKA).

Verification was followed on the basis of the DKF features *e.g.*if object center is located in region R3, R6 or R9 then YES adviser for right lunge take *false* decision. Advisers suggest what should be a decision (YES advisers) or suggested what should not be a decision (NO advisers). If any of the advisors suggested otherwise than the classifier (in some sense, the low-level classifier), decision was suspended (see [12]). All the decisions taken by the DKA pause the classifier decision where decisions are different. This is the direct reason for the decline coverage of the analyzed objects. By using domain knowledge we have obtained an improvement in the automatic classification of each chest organ. We presented the results of the experiments in the Table IV.

TABLE IV
COMPARISON OF THE RESULTS TRAIN&TEST (METHODS 1,2,3 AND 4)

| | **Method 1** | | **Method 2** | |
|---|---|---|---|---|
| Object | Acc | St.Dev. | Acc | St.Dev. |
| **TR** | **94,00%** | 3,61% | 93,97% | 4,99% |
| **RL** | **97,31%** | 0,98% | 97,56% | 0,83% |
| **LL** | **97,64%** | 0,92% | 97,56% | 1,11% |
| **RB** | **78,55%** | 6,04% | 78,12% | 4,97% |
| **LB** | **76,77%** | 6,00% | 75,74% | 8,80% |
| **LL+RL** | **87,95%** | 24,01% | 86,82% | 23,94% |
| **OT** | **94,73%** | 1,76% | 94,76% | 1,23% |

| | **Method 3** | | **Method 4** | | |
|---|---|---|---|---|---|
| Object | Acc | St.Dev. | Acc | St.Dev. | Coverage |
| **TR** | 79,61% | 6,45% | **99,90%** | 1,02% | 94,58% |
| **RL** | 81,66% | 2,89% | **98,32%** | 0,61% | 99,27% |
| **LL** | 80,73% | 3,96% | **98,44%** | 0,50% | 98,82% |
| **RB** | 60,77% | 11,65% | **88,19%** | 4,06% | 85,52% |
| **LB** | 49,33% | 7,63% | **85,04%** | 5,06% | 88,76% |
| **LL+RL** | 22,38% | 23,03% | **97,92%** | 3,50% | 94,09% |
| **OT** | 75,12% | 2,07% | **96,40%** | 1,27% | 97,57% |

### E. Comparison of classifiers by different paradigms

In Table V we give the results of experiments in applying different classification methods to our data. Those methods were developed in the following systems well known from literature: WEKA [13] and RSES [11]), and our Method 1 and 4. The coverage of all WEKA tested methods was equal 1.0 (every object was classified, without DKA). DKA approach can be used in the future in all presented WEKA methods. We used the various settings for C4.5 (WEKA) and k-NN (WEKA) methods. In Table V we presented the results of the best our approach. Tested methods gives different results depending on the class of decision.

Experimental results showed that the presented method of automatic classification of each chest organ gives good results and the results are comparable with results from other systems.

## V. CONCLUSIONS AND FURTHER WORKS

The results of experiments performed on medical data sets indicate that the presented approach seems to be promising. The use of domain knowledge significantly improved the quality of the medical object identification. The next steps will focus on the use of time dependencies between medical images (object tracking in time) and the addition of a classifier resolving conflicts between advisers.

TABLE V
COMPARISON RESULTS OF ALTERNATIVE CLASSIFICATION SYSTEMS

| Class | Result | Method 1 | Method 4 | C4.5 (WEKA) | k-NN (WEKA) | NaiveBayes (WEKA) | SVM (WEKA) | RandomForest (WEKA) |
|---|---|---|---|---|---|---|---|---|

***Abstract*—Spatial information describes the relative spatial position of an object in a video. Such information may aid several video analysis tasks such as object, scene, event and activity recognition. This paper studies the effect of spatial information on video activity recognition. The paper firstly performs activity recognition on KTH and Weizmann videos using Hidden Markov Model and k-Nearest Neighbour classifiers trained on Histogram Of Oriented Optical Flows feature. Histogram of Oriented Optical Flows feature is based on optical flow vectors and ignores any spatial information present in a video. Further, in this paper, a new feature set, referred to as Regional Motion Vectors is proposed. This feature like Histogram of Oriented Optical Flow is derived from optical flow vectors; however, unlike Histogram of Oriented Optical Flows preserves any spatial information in a video. Activity recognition was again performed using the two classifiers, this time trained on Regional Motion Vectors feature. Results show that when Regional Motion Vectors is used as the feature set on the KTH dataset, there is a significant improvement in the performance of k-Nearest Neighbour. When Regional Motion Vector is used on the Weizmann dataset, performances of the k-Nearest Neighbour improves significantly for some of the cases and for the other cases, the performance is comparable to when oriented optical flows is used as a feature set. Slight improvement is achieved by Hidden Markov Model on both the datasets. As Histogram of Oriented Optical Flows ignores spatial information and Regional Motion Vectors preserves it, the increase in the performance of the classifiers on using Reginal Motion Vectors instead of Histogram of Oriented Optical Flows illustrates the importance of spatial information in video activity recognition.**

## I. Introduction

SPATIAL information describes the physical position of an object and its spatial relationship to other objects. It plays a crucial role in video activity recognition and may be very useful in differentiating between static and mobile activities. Mobile activities are activities where a person performing the activity moves along the field of view and static activities are activities where the person performing the activity remains at one place. Spatial information provides the position of a person and thus considering spatial information while activity recognition is expected to aid differentiation between static and mobile activities.

The importance of spatial information has also been studied by a group of researcher in Amsterdam [1]. According to them, the spatial extent of an object depends on the object to be classified itself. Spatial extent captures contextual information and for some objects the spatial extent is the whole scene whereas for some the extent is to a specific rigid boundary. For identifying functionalities such as walking or jumping, the more the context, the better it is. For identifying objects such as a car, a plane or a bus, the context is the object only.

In video activity recognition literature spatial information is often captured by various local space-time features as defined in [2], [3], [4], [5], [6], [7], [8], [9], [10], [11] and [12]. These local space-time features capture frame-wise spatial information by first detecting interest points with either interest point detectors (Harris detector, Hessian detectors, edge detector, corner detectors) or various sampling methods (dense sampling [13] or motion adaptive sampling [14]) for each frame, then spatio-temporal regions are defined around all the detected points in each frame and finally the spatio-temporal regions are described using one of the local space-time features. Other attempts to capture spatial information is contextual bag of words (CBOW) [15] and BOW with spatial pyramid [16]. Both [15] and [16] are extensions of the bag of words(BOW) feature set. BOW is a frequency based feature set which was initially used for text classification where it represents the occurrence of words in a text document. It has now been adapted in computer vision where it represents a video by counting the occurrence of a visual word in the video. Thus, BOW is a frequency based descriptor and it ignores any spatial relationship between the visual words. The extensions [15] and [16] were proposed to incorporate the missing spatial relationship explicitly in BOW.

Following the local space-time approaches this paper proposes a new feature set to preserve spatial information in activity recognition data. The new feature set, referred to as regional motion vectors (RMV), is based on optical flow vectors. Evaluation of the new set on KTH videos shows significant improvement in classification accuracy when compared with histogram of oriented optical flows (HOOF), an existing optical flow based feature set which does not preserve spatial information. The new feature set has also been assessed on the Weizmann dataset.

The next section (Section II) explains the proposed methodology, followed by the similar work section (Section III), the experimental setup section (Section IV), the results section (Section V), the conclusion (Section VI) section and finally the future works section (Section VII).

## II. Proposed Methodology

In this paper a new feature set based on optical flow vectors has been proposed. The new feature set is derived such that it preserves the spatial information present in a video. RMV was

978-83-60810-66-8/$25.00©2015, IEEE

derived by dividing a frame $f$ of resolution $n \times m$ into sub-regions using a grid of resolution $r \times s$, adding the magnitude of the optical flow vectors in each sub-region, and normalising the sum of RMVs to unity. Thus the overall relative motion $\psi$ of a sub-region $SR_{(a,b)}$ in a frame was computed as shown in Equation 1

$$\psi(SR_{(a,b)}) = \sum_{i=(a-1)r+1}^{ar} \sum_{j=(b-1)s+1}^{bs} |OFV(i,j)|/N, \quad (1)$$

where,
$a \in \{1, 2, \cdots, n_r\}$,
$b \in \{1, 2, \cdots, m_s\}$,
$n_r = \lfloor \frac{n}{r} \rfloor$,
$m_s = \lfloor \frac{m}{s} \rfloor$,
$OFV(i,j)$: Optical Flow Vector of the $i^{th}$ row and $j^{th}$ column,
$SR_{(a,b)}$: a sub-region $SR_{(a,b)}$,
$N$: normalisation constant.

Equation 1 was applied to all the sub-regions in a frame, thus producing a column vector $\Psi_t$ as shown in Equation 2:

$$\Psi_t = \{\psi(SR_{(a,b)})\}, a \in \{1, 2, \cdots, n_r\}, b \in \{1, 2, \cdots, m_s\}, \quad (2)$$

where,
$\psi(SR_{(a,b)})$: the motion of sub-region $SR_{(a,b)}$.

All such $\Psi_t$ were concatenated to form the RMV feature set (Equation 3):

$$RMV = \{\Psi_1, \Psi_2, \cdots, \Psi_T\}. \quad (3)$$

In this method, spatial information was preserved in the videos by dividing a frame into several sub-regions $SR_{(a,b)}$, $a \in \{1, 2, \cdots, n_r\}$ and $b \in \{1, 2, \cdots, m_s\}$. As the sub-regions were spatially correlated, any information extracted from these regions inherited the spatial relationship from the regions. Thus, the spatial information was not lost.

The next section (Section III) describes some of the existing features that are similar to the feature proposed in this paper.

## III. Similar work

Histogram of oriented optical flow (HOOF) proposed by Chaudhary et al. in [4] is a widely used feature set for video activity recognition. It is similar to RMV because both of them are calculated from raw optical flow vectors; however, unlike RMV, HOOF does not divide a frame into sub-regions. To extract HOOF, firstly optical flow vectors are calculated using either Horn-Schunck or Lucas-Kanade algorithm, then the flow vectors are binned into ninety angular bins, ranging from $-180°$ to $+180°$, according to their orientation and finally, the magnitude of the vectors in each of the bins is summed. Thus, while HOOF is a measure of motion in some specified directions (defined by the angular bin range) in each frame, RMV is a relative measure of motion of each sub-region in a frame. Also, while any spatial correlation among the flow vectors is lost in HOOF due to the binning strategy which ignores the spatial positioning of the flow vectors, RMV preserves such correlation by dividing a frame into several spatially correlated sub-regions.

Another feature set for representing a video which is very similar to the feature set proposed in this paper is the feature proposed by Janez Pers et al. in [11]. Similar to RMV proposed here, derivation of their representation also included dividing a frame of a video into various sub-regions. However, after the division, they calculated HOOF in each of the sub-regions unlike ours where only the relative motion of each of the sub-regions was calculated. Further, they converted the calculated HOOFs into a sequence of symbols and their final representation of a video was a sequence of symbols, the final representation of our method was a sequence of relative motions of various sub-regions in each frame of a video. Perz et al. proposed a frequency based representation of videos whereas this paper proposes a motion based representation of videos.

Raw optical flow vectors have also been used to derive space time appearance (STA) descriptor proposed in [17]. The computation of STA descriptors in [17] commenced by detecting interest regions in a video and then, the detected regions were divided into sub-regions. Dense optical flow vectors were calculated using the Farneback and TV-L1 optical flow algorithms and grid histograms representing the distribution of the optical flow vectors were computed in each sub-region. Grid histograms were concatenated to form the grid vectors and a weighted average of the grid vectors formed the order one STA (STA1) descriptors. Order two STA (STA2) descriptors were then obtained by combining the grid histograms to form component vectors and then binning the component vectors into k2 bins. The final feature was obtained by concatenating the STA2 descriptors into a vector. The only similarities between STA and RMV are the division of interest regions into sub-regions and use of optical flow vectors. While STA is again a frequency based approach which represents the distribution of optical flow vectors upto two orders, RMV does not represent any such distribution and only measures the motion of sub-regions in a frame.

While the features proposed in [11] and [17] preserve spatial information, HOOF in [4] does not preserve any spatial information. As the main aim of the proposed method was to preserve the spatial information in video data to aid activity recognition, the effectiveness of the proposed method has been studied by comparing its performance only with HOOF. HOOF is a feature set derived from optical flow vectors without any spatial information and the proposed method (RMV) is a feature set again derived from optical flow vectors but with spatial information. Thus, a comparison between the two methods is expected to illustrate the effectiveness of the proposed method as well as the importance of spatial information in video activity recognition.

The next section (Section IV) describes the experimental setup for comparing both the methods.

## IV. EXPERIMENTAL SETUP

RMV and HOOF were tested on videos from the KTH dataset [18] and the Weizmann dataset [19].

The KTH dataset is a video dataset consisting of six different human actions, namely boxing, hand-waving, hand-clapping, jogging, running and walking. These six actions were performed by twenty five subjects under four different scenarios: outdoors, outdoors with varying scale, outdoors with subjects wearing a variety of clothes and indoors. All the videos were taken over homogenous backgrounds with a static camera and a frame rate of twenty five frames per second. For this study, each video of this dataset was further divided into four sub-videos, and therefore, with twenty five people, six actions, four scenarios and four sub-videos, there are in total 2400 sub-videos in the dataset. Out of these, 120 sub-videos of each action were selected randomly, thus providing a total of 720 sub-videos for experimentation.

The Weizmann dataset [19] contains nine people performing ten different actions: gallop, jump, walk, run, gallop sideways, bend, one hand waving, jumping jack,two hand waving, jumping in place and skip. The actions were recorded at a resolution of 180 × 144.

For both the datasets in this study, the optical flow vectors for deriving HOOF were obtained using the Lucas-Kanade algorithm [20]. The optical flow vectors were then sorted into ninety angular bins, each $4^\circ$ wide, collectively covering the full angular range from $-180^\circ$ to $180^\circ$. The magnitudes of the optical flow vectors in each bin were added to produce a ninety dimensional optical flow vector (or histogram) for each frame. Thus for a $T$ frame sequence, we get a $90 \times T$ dimensional matrix referred to as HOOF. Principle component analysis was then used to reduce the data dimension to five, eight, twelve and sixteen.

For deriving regional motion vectors (RMV) feature set, the Lucas-Kanande algorithm was used to compute frame-wise optical flow vectors where each vector again had two dimensions - the magnitude and direction. Then, for the KTH dataset, instead of the angular bins, each frame was divided into sub-regions $SR_{(a,b)}$, $a \in \{1, 2, \cdots, n_r\}$ and $b \in \{1, 2, \cdots, m_s\}$ by using a patch of resolution $r = 10$ by $s = 20$. As the resolution of each frame was $n = 120$ by $m = 160$, so, each frame was divided into $(120/10) * (160/20) = 96$ regions. The vectors in each of these regions were grouped into one bin and their magnitudes were added. Vector sum of these vectors could also have been considered. However, as there was no significant difference, only the results obtained using magnitude have been listed. The value of $r$ and $s$ (size of the patch) could also have been varied. However, the size of the patch was chosen such that the number of bins was near to ninety - the number of bins in HOOF. To summarize, RMV produced a $96 \times 1$ dimensional column vector for each frame, and for a sequence of $T$ frames, a $96 \times T$ dimensional matrix. This matrix was known as regional motion vectors (RMV). Principle component analysis was again used to reduce the data dimension to five, eight, twelve and sixteen.

Similarly, RMV features for the Weizmann action videos were obtained by dividing each frame into sub-regions instead of angular bins. Again, a patch was used for the purpose, however, with a different resolution. The resolution of the patch used was $r = 18$ by $s = 16$ and since, the resolution of the frames were $n = 180$ by $m = 144$, $90 \times 1$ dimensional column vector was produced for each frame. For a sequence of $T$ frames, $90 \times T$ dimensional RMV matrix was produced. The dimension of the matrix was reduced to five, eight, twelve and sixteen using principal component analysis.

Once HOOF and RMV features were extracted, they were used with k-nearest neighbour (kNN) and hidden Markov model (HMM) classifiers. An unclassified pattern is assigned to the class of its nearest neighbour. The similarity between two *points* in the multi-dimensional space was defined either via their Euclidean distance ($EUC$) or by a neighbourhood counting similarity metric ($NCM$) [21]. These two measures can be extended directly to patterns, i.e. *sequences of points*. (When computing the Euclidean distance between sequences of unequal length, we truncate the longer sequence so that its length matches the shorter sequence.) Alternatively, $EUC$ and $NCM$ can be used as the underlying point-to-point similarity measures in dynamic time warping ($DTW$) [22], longest common subsequence ($LCS$) [23] or all common subsequences ($ACS$) [24] measures of similarity between sequences. Thus, eight measures of similarity were evaluated between sequences: $EUC$, $NCM$, $DTW + EUC$, $DTW + NCM$, $LCS + EUC$, $LCS + NCM$, $ACS + EUC$ and $ACS + NCM$. The performances of these measures were evaluated because some of these measures are widely used and are known to handle variation in time series data well. The kNN classifier along with the similarity measures were coded from scratch.

HMM was used with three Gaussian and six states and $EUC$ was the default similarity measure for this model. HMM was implemented using the Kevin Murphy toolbox [25] for HMM.

The classification regime was ten fold cross validation. The dataset was arranged such that the test set contained one video from each action category and the remaining videos from those categories were used as the training set. The following section (Section V) lists the performance of the two classifiers.

## V. RESULTS

This section lists the performance of all the classifiers using HOOF and RMV feature set on KTH and Weizmann videos. In this study HOOF is the optical flow feature set which lacks spatial information, i.e. any spatial relationship in the videos is lost when HOOF is extracted. On the contrary, when RMV feature is extracted, spatial correlations in the videos are also preserved. Thus, it is expected that a comparison of the performances of several classifiers(HMM and kNN in this study) using HOOF and RMV will illustrate the importance of considering spatial information during video activity recognition.

In this section, first the performance of the classifiers on the KTH dataset is listed, followed by the performance of the classifiers on the Weizmann dataset.

### *A. Performance of HMM and kNN on KTH dataset*

Table I presents the performance of kNN and HMM on the KTH dataset. In the table the first column represents the feature set used (RMV or HOOF) for activity recognition, the second column lists the classifiers used. It can be noted that several similarity measures ($EUC$, $NCM$, $DTW + EUC$, $DTW + NCM$, $LCS + EUC$, $LCS + NCM$, $ACS + EUC$ and $ACS + NCM$) have been explicitly specified with kNN in the second column. The measures indicate the method used with kNN to calculate similarity between two sequences while recognising activities. HMM was used with only $EUC$ distance measure and hence the measure has not been specified explicitly. The following columns three to six list the performance of both the classifiers on varying dimension of HOOF and RMV data. The varying dimensions have been indicated in the header as 5 PCs, 8 PCs, 12 PCs and 16 PCs. Here, PC stands for principle components and 5, 8, 12 and 16 stands for the number of principle components selected.

TABLE I. THE PERFORMANCE OF HMM & KNN WITH VARIOUS SIMILARITY MEASURES ON KTH DATASET USING BOTH THE HOOF AND THE RMV FEATURES. IN THE COLUMN HEADINGS, PC STANDS FOR PRINCIPLE COMPONENTS.

| Feature set | Classifiers | $5PCs$ | $8PCs$ | $12PCs$ | $16PCs$ |
|---|---|---|---|---|---|
| HOOF | HMM | 59 | 63 | 68 | 68 |
| | kNN + EUC | 59 | 64 | 67 | 66 |
| | kNN + NCM | 19 | 17 | 16 | 16 |
| | kNN + (DTW + EUC) | 60 | 67 | 70 | 72 |
| | kNN + (DTW + NCM) | 21 | 22 | 24 | 25 |
| | kNN + (LCS + EUC) | 26 | 25 | 25 | 24 |
| | kNN + (LCS + NCM) | 23 | 26 | 25 | 23 |
| | kNN + (ACS + EUC) | 22 | 21 | 21 | 21 |
| | kNN + (ACS + NCM) | 21 | 21 | 22 | 19 |
| RMV | HMM | 61 | 67 | 72 | 71 |
| | kNN + EUC | 86 | 88 | 89 | 90 |
| | kNN + NCM | 70 | 56 | 50 | 43 |
| | kNN + (DTW + EUC) | 77 | 77 | 78 | 79 |
| | kNN + (DTW + NCM) | 33 | 38 | 45 | 50 |
| | kNN + (LCS + EUC) | 34 | 38 | 33 | 16 |
| | kNN + (LCS + NCM) | 34 | 37 | 40 | 46 |
| | kNN + (ACS + EUC) | 33 | 35 | 33 | 33 |
| | kNN + (ACS + NCM) | 33 | 34 | 33 | 33 |

Following Table I, the performance of HMM and kNN on varying dimensional HOOF has been compared with their performance of varying dimensional RMV. The comparisons have been represented graphically in Figures 1, 2, 3 and 4. In the figures, classifiers are listed on the x-axis and the classification accuracy (activity recognition rate) achieved by them is listed on the y-axis.

Figure 1 compares the performance of HMM and kNN classifiers using five dimensional HOOF with their performance using five dimensional RMV data. It can be observed that performance of both HMM and KNN improves when RMV is used instead of HOOF. For HMM the improvement is marginal from $59\%$ when HOOF is used to $61\%$ when RMV is used. Significant improvement is noticed in cases where kNN was used with $EUC$ and $NCM$ similarity measures. In case of kNN with $EUC$ the change was from $59\%$ to $86\%$ and in case of kNN with $NCM$ it was from $18\%$ to $70\%$. The improvement in accuracy when RMV is used instead of HOOF indicates the importance of preserving spatial information in video data.

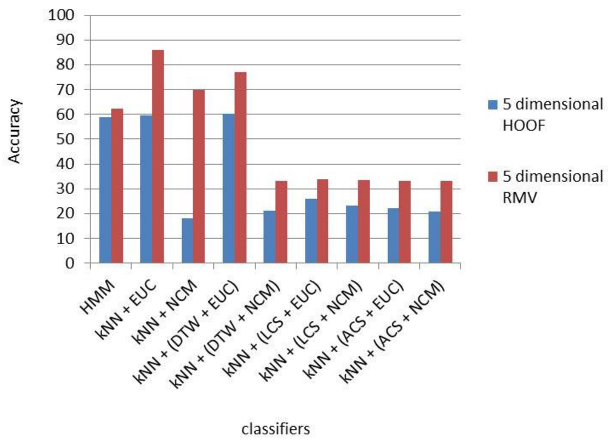

Fig. 1. Comparison of the performances of different classifiers on five dimensional HOOF and RMV data.

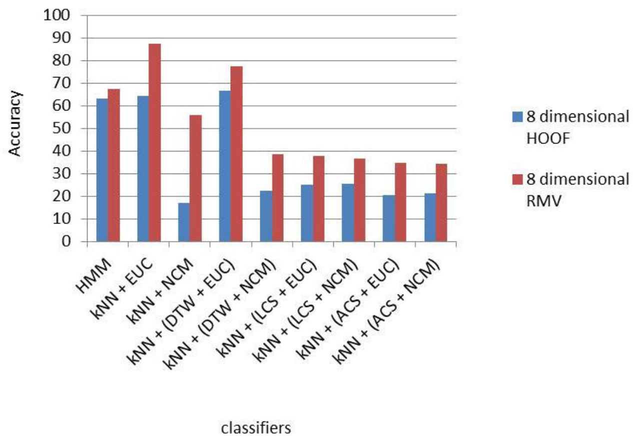

Fig. 2. Comparison of the performances of different classifiers on eight dimensional HOOF and RMV data.

Figure 2 presents a comparison similar to Figure 1. How-

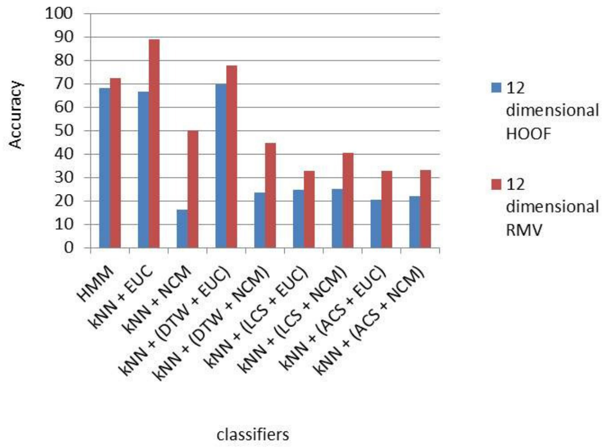

Fig. 3. Comparison of the performances of different classifiers on twelve dimensional HOOF and RMV data.

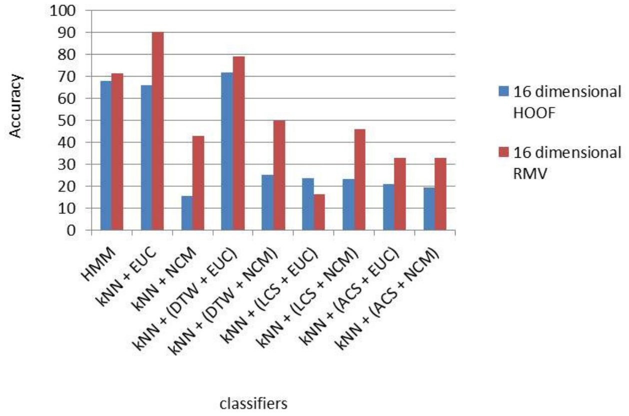

Fig. 4. Comparison of the performances of different classifiers on sixteen dimensional HOOF and RMV data.

ever, instead of five dimensional HOOF and RMV data, eight dimensional HOOF and RMV was used. It is observed that again an improvement in classification accuracy is achieved when RMV is used instead of HOOF. When RMV is used with kNN for activity recognition $EUC$ and $NCM$ similarity measures perform significantly better than when HOOF is used with kNN. $kNN + EUC$ achieved an accuracy of $64\%$ when HOOF is used (spatial information in videos is ignored) and it achieves an accuracy of $88\%$ when RMV is used (spatial information in KTH videos is considered). The accuracy obtained by $kNN + NCM$ in absence of spatial information (HOOF feature set is used) is $17\%$ and in presence of spatial information (RMV feature is used) is $56\%$. The results thus again show the importance of considering such spatial information.

Trend similar to Figure 1 and Figure 2 is also noted in Figure 3 and Figure 4, illustrating the importance of considering spatial information in videos.

It is also noted that in Figures 1, 2, 3 and 4 kNN with $DTW + EUC$ performs well consistently. When HOOF is used the accuracies are $60\%$, $67\%$, $70\%$ and $72\%$ for five, eight, twelve and sixteen dimensional HOOF data and when RMV is used the accuracies are $77\%$, $77\%$, $78\%$ and $79\%$ again for five, eight, twelve and sixteen dimensional data. Thus, for $DTW + EUC$ the accuracies are relatively stable through varying dimensional data. This was expected because $DTW$ is designed in such a way that it calculates a similarity score between two given sequences by matching each element of one sequence with every element of the other sequence. Such a matching facilitates comparing sequences having different number of frames which is very common in video data. Varying number of frames introduce a different type of variation which also hinders activity recognition. As $DTW$ handles such variation, its performance is relatively steady and superior to other similarity measures (for example when the data is five dimensional data, $DTW + EUC$ with kNN gives an accuracy of $60\%$ which is higher than other measures such as $NCM$ (18%), $LCS + EUC$ (26%), $LCS + NCM$ (23%), $ACS + EUC$ (22%) and $ACS + NCM$(21%).) during activity recognition.

However, it is also observed that although $DTW + EUC$ outperformed all the measures but $DTW + NCM$ performed poorly. This can be attributed to the different underlying *point to point similarity measure* that has been used with $DTW$. When the performance of $EUC$ and $NCM$ alone is compared, it is observed that when HOOF is used $EUC$ performs significantly better than $NCM$ with an accuracy of $59\%$ (accuracy obtained using $NCM$ is $18\%$). A possible explanation for such a performance of $NCM$ is its ability to work better on correlated data than uncorrelated data. This explanation is supported by the improvement in $NCM$'s performance when RMV, where the data is spatially correlated is used instead of HOOF, where the data is uncorrelated. The accuracy obtained by $NCM$ when RMV is used is $70\%$ and when HOOF is used is $18\%$. The behaviour of $NCM$ on correlated and uncorrelated data extends to $DTW$ when these two measures are used as the underlying point to point measure with $DTW$. Thus, $DTW + EUC$ performs superior to $DTW + NCM$. This behaviour of $NCM$ also supports considering spatial relationships and preserving spatial information during video activity recognition.

The next subsection lists and reviews the performance of kNN and HMM on Weizmann videos in the presence and absence of spatial information. Again, presence of spatial information is ensured by using RMV as the feature set and absence of the information is ensured by using HOOF.

### B. Performance of kNN and HMM on Weizmann dataset

In this subsection table II shows the performance of kNN and HMM using HOOF and RMV features. Similar to table I, column one shows the feature set being used, column 2 lists the classifiers and the rest of the columns (3-6) lists the obtained classification accuracy with varying dimensional HOOF and RMV.

Following the table are figures 5, 6, 7 and 8 which compare the performances of the classifiers while using five, eight, twelve and sixteen dimensional HOOF and RMV respectively.

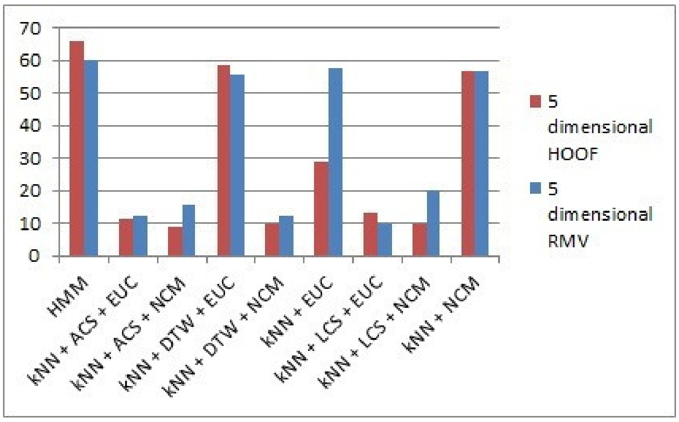

Fig. 5. Comparison of the performances of different classifiers on Weizmann dataset using five dimensional HOOF and RMV.

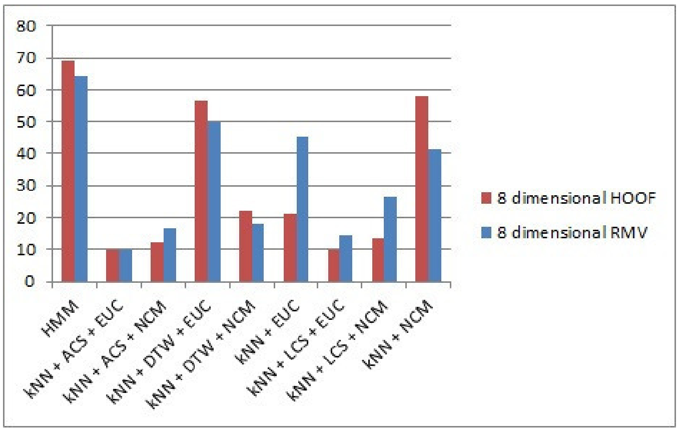

Fig. 6. Comparison of the performances of different classifiers on Weizmann dataset using eight dimensional HOOF and RMV.

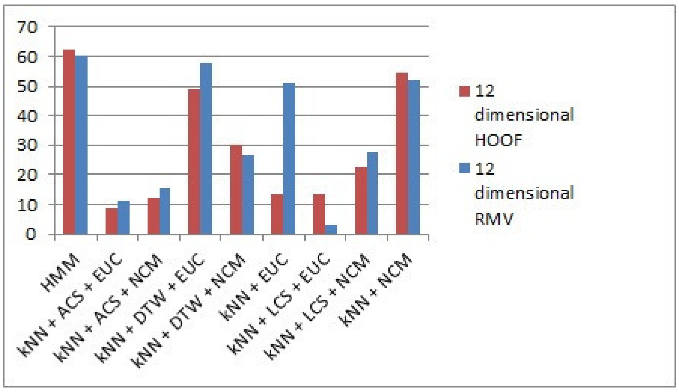

Fig. 7. Comparison of the performances of different classifiers on Weizmann dataset using twelve dimensional HOOF and RMV.

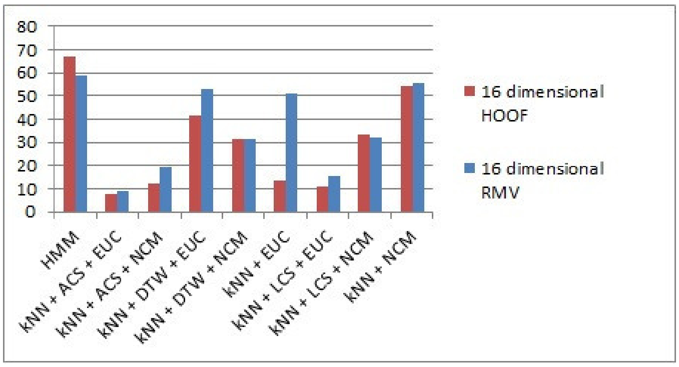

Fig. 8. Comparison of the performances of different classifiers on Weizmann dataset using sixteen dimensional HOOF and RMV.

TABLE II. THE PERFORMANCE OF HMM & KNN WITH VARIOUS SIMILARITY MEASURES ON WEIZMANN DATASET USING BOTH THE HOOF AND THE RMV FEATURES. IN THE COLUMN HEADINGS, PC STANDS FOR PRINCIPLE COMPONENTS.

| Feature set | Classifiers | $5PCs$ | $8PCs$ | $12PCs$ | $16PCs$ |
|---|---|---|---|---|---|
| HOOF | HMM | 66 | 69 | 62 | 67 |
| | kNN + EUC | 29 | 21 | 13 | 13 |
| | kNN + NCM | 57 | 58 | 54 | 54 |
| | kNN + (DTW + EUC) | 59 | 57 | 49 | 41 |
| | kNN + (DTW + NCM) | 10 | 22 | 30 | 31 |
| | kNN + (LCS + EUC) | 13 | 10 | 13 | 11 |
| | kNN + (LCS + NCM) | 10 | 13 | 22 | 33 |
| | kNN + (ACS + EUC) | 11 | 10 | 9 | 8 |
| | kNN + (ACS + NCM) | 9 | 12 | 12 | 12 |
| RMV | HMM | 60 | 64 | 60 | 59 |
| | kNN + EUC | 58 | 46 | 51 | 51 |
| | kNN + NCM | 57 | 41 | 52 | 56 |
| | kNN + (DTW + EUC) | 56 | 50 | 58 | 53 |
| | kNN + (DTW + NCM) | 12 | 18 | 27 | 31 |
| | kNN + (LCS + EUC) | 10 | 14 | 3 | 16 |
| | kNN + (LCS + NCM) | 20 | 27 | 28 | 32 |
| | kNN + (ACS + EUC) | 12 | 10 | 11 | 9 |
| | kNN + (ACS + NCM) | 16 | 17 | 16 | 19 |

From the figures, it can be seen that on several occasions, the performance of kNN increases when RMV is used instead of HOOF. An example is the improvement in classification accuracy from 29 to 58 for kNN+EUC when 5PC RMV is used instead of 5PC HOOF. Another example is the performance of kNN + (DTW+EUC) using 12 dimensional features. When 12 dimensional HOOF is used, the classification accuracy is 49, and when 12 dimensional RMV is used, the classification accuracy is 58. However, for some cases, the performance of the classifiers are either comparable or remains the same. For example,the highest classification accuracy obtained using kNN+(DTW+EUC) and 5 dimensional HOOF feature set is 59. However, when 5 dimensional RMV is used for the same case, the accuracy is 56. Then the performance of kNN + NCM on 5 dimensional HOOF is 57 which remains unchanged when 5 dimensional RMV is used.

Therefore, from the above results it can be observed that there is a significant improvement in the performance of the classifiers when RMV is used instead of HOOF on the KTH dataset. However, no such significant performance difference was noted for the classifiers when tested on Weizmann dataset using RMV and HOOF features. This can be attributed to the lack of direction information in the RMV feature set. Incorporating direction information in the feature set ensures that the direction (left to right or right to left) of mobile actions (jog, run, skip, walk) does not affect the classification / recognition results. As there are less number of mobile actions in the KTH dataset than the Weizmann dataset, lack of this information does not affect the overall performance of the classifiers on the KTH dataset. However, a closer look at the confusion matrix of the KTH dataset reveals that most of the misclassification is among the mobile activities, which in case of RMV can be attributed to the absence of direction information in the RMV feature set.

The competitive and sometimes better performance of all the classifiers on the Weizmann dataset does not reduce the significance of the proposed feature set. On the contrary, it shows the potential of the feature by performing well (on KTH dataset) and at par (on Weizmann dataset), even after the lack of direction information. This shows that beside direction, spatial relationships also play an important role in action classification and, thus, features preserving such spatial relationships are required.

Finally, it can be observed that the dimension of the data has been varied from five to sixteen. Data higher than sixteen dimension was not considered because the performance of the classifiers for most of the cases attains stability after eight dimensional HOOF and RMV data. Further, the computation time of kNN increases with increasing dimension and hence considering very high dimensional data is undesirable. Last but not the least, training HMM on such high dimensional data is not only time consuming but requires large number of training samples. As huge number of data may not always be available, data with dimension higher than sixteen is not considered.

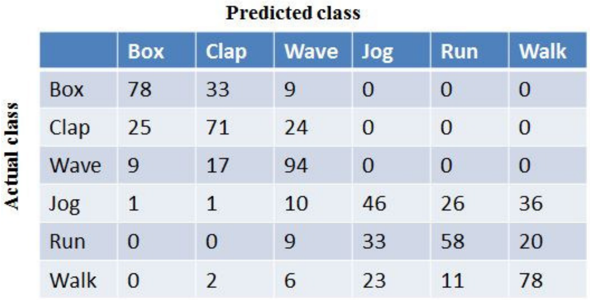
## VI. Conclusion

The main aim of this paper was to study the effects of spatial information in video data analysis. For this, the paper focussed on video activity recognition and videos from the KTH and Weizmann datasets, which are activity datasets, were selected for this purpose. Recognition was performed using two classifiers - kNN and HMM, trained firstly on HOOF and then on RMV features. HOOF is an optical flow based feature set which ignores any spatial information and therefore applying any classifier on such a feature set illustrates a scenario where spatial information has been ignored (absence of spatial information). RMV on the contrary is an optical flow based feature set where spatial information is preserved. Thus, any spatial relationships among objects in a video or object and background in a video is present in the feature set. A comparison of the performances of the classifiers with HOOF and RMV illustrated the effect of the presence and absence of spatial information on video activity recognition. Results show significant improvement in the performance of kNN classifier on KTH dataset, when spatial information is preserved. For example, kNN with EUC achieved an accuracy of 59% when trained with five dimensional HOOF data. This accuracy improved to 86% when five dimensional RMV data was used to train the kNN.

On the Weizmann dataset, when RMV is used in place of HOOF, the performance of the classifiers in some cases shows significant improvement. For example, while using kNN with EUC distance, the accuracy increases from 29% to 58% (when RMV is used instead of HOOF). Another example is when kNN is used with DTW+EUC, the accuracy increases from 49% to 58% when 12 dimensional RMV is used instead of 12 dimensional HOOF. For other cases, the performance of the classifiers are comparable. For example, the performance of kNN + NCM remains the same, at 57%, irrespective of the feature used.

## VII. Future work

Although the performance of kNN on using RMV, either increased or was comparable, improvement in the performance of HMM however was not very high. On the KTH dataset, with HOOF as the feature set, HMM achieved an recognition rate of 59% and with RMV feature set it obtained a recognition rate of 61%. Therefore, there is a scope of improving the performance of HMM further. Figures 9 and 10 shows the confusion matrices created by HMM when HOOF and RMV features are used respectively on the KTH dataset.



Predicted class

Actual class

Fig. 10. Confusion matrix showing the performance of HMM when RMV feature is used for activity recognition.

The matrices reveal the following flaws while performing activity recognition:

- The classifier discriminates very well between static (boxing, clapping, waving) and mobile (jogging, walking and running) activities, less well between different static activities, and quite poorly between different mobile activities. Static activities in a video refer to activities where a subject is standing at one constant position. Mobile activities refer to activities where a subject is moving along the field of view throughout the video. Thus, while boxing, clapping and waving in the KTH dataset are static activities, jogging, running and walking are mobile activities.

- The pace of mobile activities increases naturally from walking to jogging to running. Intuitively, one would expect that walking is misclassified as jogging more frequently than it is misclassified as running, and, likewise, running is misclassified as jogging more frequently than it is misclassified as walking. However, this is not reflected in the confusion matrix which was obtained using RMV.

Future attempts to improve the performance of HMM can concentrate on solving these flaws.

Some other possible future works are as follows:

- RMV ignores direction of the flow vectors. For activity recognition direction is one of the important factors. Future attempts will try to incorporate direction into RMV.
- In RMV spatial information was incorporated by dividing a frame into sub-regions which are spatially correlated to each other. This division was done using a grid of resolution $r \times s$. The values of $r$ and $s$ were chosen as 10 and 20 respectively for the KTH dataset and as 18 and 16 respectively for the Weizmann dataset. However, these are not constant values and can be varied, i.e. a grid of different resolution can be chosen for the same dataset. Also, the values of $r$ and $s$ varies from one dataset to another. Future research can concentrate on studying the effect of varying $r$ and $s$ on a dataset and also on coming up with a more principled approach of selecting the values of $r$ and $s$.
- Next, converting any feature set to their BOW representation and then using them with SVM for activity recognition is the state of the art in the activity recognition field. Thus, in future, RMV can also be converted it to its BOW representation and used with SVM to further assess its potentiality in video activity recognition. Further, the performance of RMV in its BOW form can be compared with the performance of HOOF in its BOW format. As RMV captures spatial information, spatial information is also added to its BOW representation. Similarly, as HOOF does not capture spatial information, its BOW form does not inherit any such information. A comparison between the BOW of RMV and BOW of HOOF will further illustrate the importance of spatial information.
- Finally, BOW itself lacks any spatial information and previously attempts have been made to incorporate spatial information in BOW. Some of these works include spatial pyramid [16] and CBOW [15]. A comparison of RMV in its BOW form with these works ([16] and [15]) on activity data may be another interesting research direction.

***Abstract*—We present diverGene – a novel, diversity-aware population selection operator for genetic algorithm – to be used especially for particularly complex and multi-criteria optimisation problems. Genetic algorithm is one of the most known evolutionary algorithms for solving hard optimisation problems. Many attempts have been made to improve its convergence rate and quality of the result. In this paper we propose a novel extension of the selection operator that makes it possible to control the level of diversity in the population. We discuss its theoretical background, including its computational hardness and propose an efficient way of computing it. The approach is implemented and tested on three hard optimisation problems: Knapsack Problem, Travelling Salesman Problem and a relatively new Travelling Thief Problem that might be viewed as the composition of the latter two. We report experimental results that seem to indicate that the novel approach has a potential to improve the quality of the results for some hard optimisation problems.**

## I. Introduction

In this paper we present `diverGene` – a novel, diversity-aware population selection operator for genetic algorithm. The idea is based on the concept of the *dispersion* of the solutions modelled by means of pair-wise dissimilarity between the solutions.

The proposed operator seems to be especially useful for particularly complex optimisation problems of multi-criteria nature, where the solution space should be intensively explored due to the potential variety and mutual non-similarity of potential good solutions to the problem.

### A. Genetic Algorithm

The *genetic algorithm* [1] is a heuristic for finding satisfactory solutions to problems, using a process inspired by the natural selection. It does not guarantee to find the optimal solution and is intended to be used mainly in cases when finding the optimal solution directly would be too computationally expensive to be practical (more formally for NP-hard optimisation problems). In such cases search heuristics are often used to find a solution that is usually not the best possible one, but is still useful.

The process starts by randomly creating a set of feasible solutions to the problem. This set of solutions is called *population* and each solution in the population is called *an individual*, in reference to the biological origins of the algorithm. The initial state of the population is called *the initial (first) generation*. During the course of the algorithm execution, the subsequent generations are created, each one based on its immediate predecessor. While the solutions encoded in the initial generation are completely random, the quality of solutions in each subsequent generation should gradually get better, in an evolutionary fashion.

*1) Selection:* The process of selection is responsible for the decision on *which* individuals from the current generation should be used when creating the next generation (or, in other words, how many children should an individual have - if any). This step is essential to the process. Properly defined selection causes the best individuals to reproduce more intensively, resulting in a general increase of the solution quality in the population. On the other hand a selection that is *too* strong may lead to some problems - if the algorithm were to always simplistically select only a small subset of the very best solutions, there would be a high likelihood of losing the diversity and getting stuck in a local maximum. The problem is traditionally solved by introducing an element of randomness - the better the solution the greater the possibility it will be selected as a parent. As a consequence, other solutions also have a chance of being selected, while the overall solution quality generally increases.

*2) Mutation Operator:* The process of selection results in the increase of the *overall* solution quality in a population by generally eliminating weak solutions and reproducing stronger ones, but by itself it doesn't improve the quality of individual solutions. It's the mutation operator that enables the algorithm to explore other (possibly better) solutions. During the mutation stage there is a small chance of individual elements of a solution being randomly changed, resulting in a solution that is similar to one previously selected, but slightly different. Sometimes the changes are beneficial, but perhaps even more

This work is partially supported by Polish Ministry of Science and Higher Education grant N N519 578038.

978-83-60810-66-8/$25.00©2015, IEEE

often they make the solution weaker. During the subsequent selection stages the stronger solutions are more likely to be chosen than the weaker ones. As a consequence individuals with harmful mutations will eventually be eliminated, while individuals with beneficial mutations will become the parents for multiple newly created individuals, some of which will in turn be mutated, bringing the possibility of further improvements. The mutation operator corresponds to the concept of *random local search* in the solution space.

*3) Cross-over Operator:* Cross-over stage brings a possibility of two different solutions being combined. This allows for new individuals that include good parts of multiple previously known solutions. Without the cross-over stage there would be no sharing of good "ideas" within the population.

### B. Motivation

As discussed in the "Selection" section above, too much focus on promoting only the best solutions in the current population during the selection stage (at the expense of alternative candidate solutions) may result in inadequate exploration of the space of possible solutions, or, equivalently in getting stuck in a local optimum.

On the other hand too little focus on choosing good result will result in a weak evolutionary pressure and population not getting better over time. The balance is traditionally achieved by giving better quality solutions a greater probability of being selected, but allowing other solutions to also be occasionally selected by random chance. While this method allows for some additional diversity it does not guarantee it.

In this paper, we investigate whether controlling the level of diversity within a population at the expense of a slight drop in the overall population quality would have a positive effect on the overall performance of the algorithm. In particualr we want to explore the effect of this aproach on problems containing multiple interdependent sub-problems, using the Travelling Thief Problem [8] as an example. It seems that increased population diversity would especially improve the performance of the genetic algorithm for such compound hard optimisation problems.

### C. Contributions

The contributions of this paper are the following:

- we propose `diverGene` – a novel *diversity-aware* selection operator that makes it possible to control the balance between the exploration and exploatation of the solution space. The selection is based on both fitness and diversity among its members.
- we report development of a flexible software framework for testing the operator with various settings.
- we report experimental results on three hard optimisation problems: the Knapsack problem, the Travelling Salesman Problem and the Travelling Thief Problem (the last one being particularly noteworthy since it is composed of two interdependent sub-problems). The experiments concern the impact of the operator in various settings on the quality of the solutions.

### D. Contents

We make a brief overview of the related works in Section II.

We give some theoretical background concerning the concept of diversity and, in particular, modeling it by means of *dispersion* in Section III. In this section we also present diverGene, our diversity-aware selection operator, and explain that exact computation of our operator is a hard computational optimisation problem itself by linking it to a known NP-hard optimisation problem.

Because of this, in Section IV, we explain how our selection operator can be efficiently computed with a known poly-time approximation algorithm.

Section V contains the specifications of the used benchmark optimisation problems and describes the some technical representation and implementation details.

In Section VI we report experimental results that are discussed in Section VII. We conclude in Section VIII.

## II. Related Work

Genetic algorithm belongs to the class of evolutionary algorithms. First mentions of algorithm based on the mechanics of biological evolution dates back to the half of the previous century, but it became popular through the work of John Holland [1].

The concept of Diversity plays an important role in complex systems [2]. In particular, the diversity of population in biology is an important mechanism that supports better exploration of the environment. Therefore, the concept of diversity-awareness of population in biology is an inspiration for the domain of genetic algorithms to avoid a premature convergence (exploatation).

The Max-Sum Facility Dispersion Problem, that inspired our choice of a specific approach to diversify the population was studied in many papers in the domain of Operational Research. An example of such work is [3] that also discusses its computational hardness and efficient approximation algorithms for this problem. The connection of this problem to Web search result diversification with a new, parameterised objective function that takes into account a balance between the total value and pair-wise dispersion is discussed in [4] which also inspired our approach presented in this paper. Similar approach to diversification was proposed in the problem of semantic entity summarisation in [6] where another nature-inspired approach is applied to optimise the diversification problem itself. The study of the influence of the properties of the pair-wise dissimilarity function on the approximation factor in Facility Dispersion Problem is recently studied in [7].

The Travelling Thief Problem was introduced in [8] as a benchmark for testing heuristic algorithms on a problem that better resembles real life problems, that are often way more complex than well known “academic” benchmark problems like TSP or Knapsack. By its definition, the Travelling Thief Problem, is a kind of combination of the Knapsack Problem and TSP Problem.

## III. diverGene: Diversity-aware Selection Operator

In this section we introduce diverGene – a modified selection operator that makes it possible to control the desired level of diversity in the population in genetic algorithm. In the classical genetic algorithm, the selection operator is based mainly on the fitness function of an individual. Our diversity-aware selection operator takes the fitness score into account, but additionally aims at guaranteeing some level of the diversity of solutions in the selected population.

More precisely, *diversity-aware selection* can be viewed as an optimisation problem itself and can be defined as to select a sub-population $S$ of cardinality $k$ out of the whole current population that maximizes the following parameterised objective function:

$$f_d(S) = (1-\alpha)\sum_{p\in S} f(p) + \alpha \sum_{p,q\in S} dissimilarity(p,q) \quad (1)$$

Where $S$ is the selected, diverse sub-population and $\alpha$ is a parameter controlling the balance between the total $fitness$ (the $f()$ function) of the selected individuals and pair-wise $dissimilarity$ between them. $dissimilarity$ is a function returning a numerical value showing how different two individuals are. It's exact definition depends on the problem under consideration.

### A. A Link to Max-Sum Facility Dispersion Problem

Now we are going to explain that maximising the objective function 1 used in the definition of our population diversity operator at the beginning of Section III is equivalent to some well-known optimisation problem that is NP-hard but for which there exists a fast approximation algorithm. Due to this we use this approximation algorithm for efficiently compute the population diversity operator.

More precisely, the diversity selection operator described in Equation 1 is inspired by the Facility Dispersion Problem [3] and its recent applications in Web Search Diversification Problem [4].

In Facility Dispersion Problem, the input consists of a complete, undirected graph $G(V,E)$, an edge-weight function $d : V^2 \rightarrow R^+ \cup \{0\}$ that represents *pairwise distance* between the vertices and a positive natural number $k \leq |V|$. The task is to select a $k$-element subset $S \subseteq V$ that maximises the objective function $dispersion(S)$ that represents the notion of *dispersion* of the elements of the selected set $S$.

Facility Dispersion Problem was studied in operational research for modeling the problem of selecting a set of mutually-distant (dispersed) locations for $k$ obnoxious facilities like nuclear plants, ammunition dumps, etc.

In the most common variant of this problem, called Max-Sum Dispersion Problem, the $dispersion$ function to be maximised is defined as the total pair-wise distance between the selected locations (to be maximised):

$$dispersion(S) = \sum_{\{u,v\}\subseteq S} d(u,v) \quad (2)$$

The Max Sum Dispersion problem is NP-hard even if the distance function $d$ is a metric, but in such case there exists a polynomial-time algorithm of approximation factor of 2 that was presented in [3].

Recently, the Max-Sum Facility Dispersion problem has new applications in the *Web Search Result Diversification Problem* where the selected items represent documents (or pieces of information) to be returned by the search system and $d$ models the pairwise *dissimilarity* between the documents.

Given a set $V$ of documents to be potentially relevant to a user query, a number $p \in N^+, k < |V|$, a *document relevance* function $w : V \rightarrow R^+$ and pairwise *document dissimilarity* function $d : V^2 \rightarrow R^+ \cup \{0\}$, the task is to select a subset $S \subseteq V$ that maximises the value of a properly defined *diversity-aware relevance function*. In [4] the following parameterised, bi-criteria objective function (to be maximised) is proposed as the diversity-aware relevance function:

$$f_{div-sum}(\lambda, S) = (k-1)\sum_{v\in S} w(v) + 2\lambda \sum_{\{u,v\}\subseteq S} d(u,v) \quad (3)$$

where $\lambda \in R^+ \cup \{0\}$ is a parameter that controls the diversity/relevance-balance.

In the same work it is observed that a proper modification of $d$ to $d'$ (Equation 4) makes the described problem of maximising $f_{div-sum}(\lambda, S)$ equivalent to maximising $\sum_{\{u,v\}\subseteq S} d'_\lambda(u,v)$, where:

$$d'_\lambda(u,v) = w(u) + w(v) + 2\lambda d(u,v) \quad (4)$$

Thus, it makes the *result diversification* problem described above equivalent to the Max Sum Dispersion problem for $d'_\lambda$.

Now, it is not hard to see that the problem of maximising our dispersion-aware fitness function $f$ (for any value of $\alpha$) defined in Equation 1 is equivalent to the problem of maximising the objective function in Equation 3 for appropriate selection of the value of $\lambda$, thus the problems are equivalent.

To sum up, as the consequence, the problem of maximising the diversity-aware population fitness function defined in Equation 1 is NP-hard, as being equivalent to Max-Sum Dispersion Problem, but any approximation algorithm used for Max-Sum Dispersion can be used to optimise our problem.

Due to this, in the experiments reported in this paper we use the 2-factor greedy approximation algorithm for Max-Sum Facility Dispersion problem described in [3] to efficiently solve our problem. This is described in Section IV.

## IV. Dissimilarity selection

Our efficient implementation of diversity-aware selection operator is based on the algorithm mentioned at the end of the previous section. This approximation algorithm for finding subsets (in which weights of edges between those vertices are maximised) of vertices in a graph, can easily be adapted for choosing a subset of individuals in a population that are most different from each other. One just needs to think of individuals as vertices and the level of dissimilarity between two individuals as the weight value on edges between the vertices representing them.

In our case we wanted to take into account both dissimilarity and fitness of the two individuals, as can be seen in the function defined in Equation 1. We utilised the link to the previously studied problems of Max-Sum Facility Dispersion and Web search diversification described in the previous section to define a $dissimilarity\_fitness$ function that combines dissimilarity between two individuals and their respective fitness values:

$$df(u, v) = fitness(u) + fitness(v) + 2\lambda dissimilarity(u, v)$$

We used the function to calculate values of edges between the individuals on the graph.

More precisely, the algorithm that we utilize to choose a $k$-element subset of individuals from the previous population to control its guaranteed level of diversity works in the following way:

1) Create a list with all possible pairs of individuals in a population.
2) Choose the pair with the highest $dissimilarity\_fitness$ score.
3) Remove all pairs containing one of the individuals from the chosen pair.

Repeat steps 2–3 $k/2$ times, where $k$ is the desired size of the selected population. If $k$ is odd, add an arbitrary final individual to the selected sub-population. This greedy algorithm guarantees the approximation factor of 2 to the solution of such defined optimisation problem [3].

### A. *Combining two types of selection*

We create the new population of size $N$ by combining the results of two kinds of selection - classical *roulette selection* and our own *dissimilarity selection* described in Section IV. First we select $k$ individuals using dissimilarity selection and then achieve the desired population size $N$ by selecting the remaining $N - k$ of the individuals using standard roulette selection. The result for small values of $k$ can be viewed as classic selection enriched by a small pool of individuals retained for their uniqueness (in combination with their fitness, since $dissimilarity\_selection$ takes both into account).

## V. Experimental Implementation

We used the Python programming language to create a flexible framework to test our novel diversity-aware operator on various optimisation problems.

In this Section we report experiments performed on two classic optimisation problems - Knapsack Problem and Travelling Salesman Problem. We also report additional series of experiments concerning the combination of the latter two – the Travelling Thief Problem. The framework is designed so that in the continuation work, the plugins with support for other optimisation problems can be easily added to it.

### A. *Knapsack Problem*

The Knapsack Problem is one of the a classic NP-hard optimization problems. In this problem, there are $n$ items. Each item has a value ($p_i \in Q^+$) and a weight ($w_i \in Q^+$). The capacity ($W \in Q+$) of the knapsack is limited.

The items should be picked so that their total value is maximized while their total weight does not exceed the knapsack capacity:

$$f(\bar{x}) = \sum_{i=1}^{n} p_i x_i, while \sum_{i=1}^{n} w_i x_i \leq W$$

where $\bar{x} = (x_1, x_2, \ldots, x_n)$ and $x_i \in \{0, 1\}$ indicates whether the item is picked ($x_i = 1$) or not ($x_i = 0$).

*1) Representing the Knapsack Problem in GA Framework:* A solution is represented as a set of items in a knapsack. The most natural representation of any solution as a chromosome is in the form of a characteristic vector of the given subset of the items.

The mutation operator "flips" bits at random positions of the corresponding characteristic vector. Each position has an equal probability of being flipped (in our experiments the probability always equals $p_{km} = 0.01$). If the item was previously in the set it will be removed, otherwise it will be added to the set.

The cross-over operator exchanges the state between random items between two solutions. Each position has an equal probability of being exchanged (in our experiments the probability always equals $p_{kc} = 0.05$).

Both operators may result in a solution that exceeds the allowed capacity. In such case we fix the solution by removing random items from the set until the capacity is abided by.

The dissimilarity score is calculated by counting the number of items present in one solution but not present in the other (the *Hamming distance*).

*2) Knapsack Dataset:* The dataset for Knapsack problem was generated purposely for our experiments. Each instance contains 32 items with different values and weights (both ranging between 1 and 500). The knapsack capacity is set to 500.

### B. *Travelling Salesman Problem*

The Travelling Salesman Problem (TSP) is also a classic NP-hard optimization problem. In this paper, we consider a 2-dimensional euclidean variant. In this variant of TSP, there are $n$ cities ($c$) with their coordinates ($cx$ and $cy$). A salesman must visit each city exactly once and minimize the total length of the complete tour. The aim is to find a permutaion of the set containing all cities which minimizes the following equation:

$$f(\bar{c}) = \sum_{i=1}^{n-1} d(c_i, c_{i+1}) + d(c_n, c_1)$$

where $\bar{c} = (c_1, c_2, \ldots, c_n)$ represents the tour and $d(A, B)$ is a distance between the cities $A$ and $B$:

$$d(A, B) = \sqrt{(Ax - Bx)^2 + (Ay - By)^2}$$

*1) Representing TSP in GA Framework:* The *ordered crossover* and *reverse sequence mutation* operators were used for TSP. The ordered crossover operator, presented by Goldberg in [5], is a two-point crossover. Given two random crossover points parent chromosomes are split into three parts. Child chromosome inherits the left and right parts from the first parent, and the middle part from the second one. The elemetns in the right and left parts are removed and rotated to avoid the duplication of elements [5].

In the reverse sequence mutation operator the sequence of elements between two randomly chosen positions is reversed.

The dissimilarity operator takes into consideration the number of different elements on the same positions in both chromosomes and compares it to the total number of elements. For each position, the values from both individuals are compared. If they differ, the counter is incremented. After analyzing the whole chromosomes the counter value is divided by the size of a chromosome (number of all cities in the instance).

*2) TSP Dataset:* The dataset for TSP experiments was taken from the TSPLIB library [9] containing sample instances for TSP. Berlin52 set was chosen [9] for the experiments. This set provides coordinates of 52 locations. The optimal solution to this problem is known, and it has the value of 7542.

### C. Travelling Thief Problem

The *Travelling Thief Problem* is an optimisation problem related to the Knapsack Problem and the Travelling Salesman Problem (both described above). It was created to better model real-life problems, often more complex than the well-known benchmark NP-hard problems.

The Travelling Thief Problem consists of two interdependent sub-problems. The sub-problems can not be solved individually, because the solution to one sub-problem strongly influences the quality of the solution of the second sub-problem. To achieve satisfactory results one needs to solve both sub-problems at the same time, finding the best *combination* of solutions. This resembles the challenge often occurring in the case of solving complex real-life problems with multiple, often mutually contradictory, constraints.

We decided to include the Travelling Thief Problem in our experiments as it seems a natural next step of our work since it can be viewed as a specific *composition* of the two problems described above: the Knapsack Problem and TSP. Thus, the two components of the specification introduce a multi-criteria structure. Additional complexity of this problem is introduced by modeling the varying *speed*, that depends on the current contents of the knapsack, that influences the total cost of the solution, as explained below in this Section. Such a complex, multi-criteria optimisation specification seems to be a very natural domain of application for our diversity-aware population control approach as it enforces exploring multpile, mutually dissimilar alternatives for the solution.

There are several variants of the TTP problem. The one implemented by us, known as $TTP_1$, is most likely the most popular one. There are $n$ cities (represented by a distance matrix) and $m$ items (each having its own value, weight and set of cities in which it can be found). A thief has to visit each city exactly once, picking some items located in those cities and putting them in their knapsack (which has a maximum weight capacity $W$). Thief's speed depends on the weight of the knapsack:

$$V_C = V_{max} - W_C \frac{V_{max} - V_{min}}{W}$$

$V_C$ represents the current speed, $W_C$ represents the current weight of the knapsack and $W$ represents the knapsack's maximum weight capacity. $V_{max}$ and $V_{min}$ are parameters describing the thief's maximum and minimum speed, respectively. The natural interpretation is as follows: the heavier the knapsack, the slower the thief. The speed is important, because the objective function that is to be maximized depends not only on the value of the picked items, but also on the total time of the travel, as the thief has to pay for the time when the knapsack is being used:

$$G(x, z) = g(z) - R \cdot t(x, z)$$

Where $g$ is the sum of values of all items in the knapsack, $R$ is the knapsack payment fee (rent) for the time unit and $t$ is the function calculating the time of the travel for the given solution. This means the thief needs to maximise their profit - the value of the stolen items reduced by the knapsack fee.

A solution consists of a tour $x$ and item picking plan $z$ (recording the information concerning which items should be picked in which city - if it is picked at all). The $G$ function strongly interconnects them, so they can not be optimised separately.

*1) Representing TTP in GA Framework:* TTP representation in GA framework is a union of previously described Knapsack and TSP representations. The dissimilarity value is calculated by counting the number of different picks - the items picked in the different cities at different times.

*2) TTP Dataset:* We used the dataset for TTP experiments taken from the webpage of the optimisation group of the University of Adelaide [10]. The data provided on this site was used as a benchmark set for competitions in 2014 and 2015. More precisely, the `Berlin52_n51_bounded-strongly-corr_01` dataset was chosen [10]. This set provides coordinates of 52 locations and 51 items, one in each city. The optimum solution to this instance is not provided by the creators of the dataset nor yet known, to the best knowledge of the authors.

## VI. Experimental Results

In the experiments we measured the influence of the dissimilarity operator on the best solution of the objective function $f(S)$ for diffrent population sizes. The tests where performed in three groups for each problem:

1) The best solution of $f(S)$ as a function of $k$ for 10, 25, 50 and 100 individuals in population with $\alpha$ set to 0.35 (Fig. 1, 2 & 3)

2) The best solution of $f(S)$ as a function of $\alpha$ for 10, 25, 50, 100 and 150 individuals in population with $k$ set to 20% of population (Fig. 4, 5 & 6)
3) The best solution of $f(S)$ as a function of population size with $\alpha$ set to 0.35 and $k$ set to 20% of population (Fig. 7, 8 & 9)

Each test was run 10 times and the median of all the 10 results was computed and reported.

### A. Computational Platform

Since the computations involved in our experiments were quite extensive it was more natural to perform them on a specialised computational platform. Due to this, all calculations were performed on the online data science platform Sense [11]. Sense is a recently launched (released March 18, 2015) cloud platform for data science and big data analytics built by Sense, Inc. company. It provides an interface to multiple scripted analytic tools like Python, Node.js, SQL and many more, and allows to launch a new engine with dedicated CPU and RAM for every created job. It also makes sharing data, scripts and jobs and colaborating on the same project easy.

## VII. Discussion of the Results

### A. The Best Solution of $f(S)$ as a Function of $k$

For the Knapsack problem some improvements in quality of solutions can be observed only for small populations (Fig. 1). For 10 and 25 individuals using the diversity-aware selection operator increased the value of the best solution by 12-15%. For bigger populations (50 and 100 individuals), though, the positive changes are almost unnoticeable. A critical value of $k$ can be also observed for all populations. Exceeding $k = 0.7N$, where $N$ is the population size, causes a dramatic decrease of the best solution value. This could be interpreted as too much exploatation at the expense of exploration for this relatively easy[1] problem would deteriorate the performance.

More significant positive impact of diversity operator on the quality of solution can be observed for TSP (Fig. 2). For all population sizes the results were improved by 30-35% when 15-35% of individuals were selected using the diversity-aware selection operator. The best solution decrease starts earlier than in the Knapsack problem but is not so rapid as in the case of Knapsack - in the worst case the percentage decrease between the best value of the objective function without and with diversity-aware selection operator is about 8% while in the Knapsack problem it is between 30-40%.

In the TTP experiments (Fig. 3) even stronger positive impact of our diversity operator on the solution quality can be observed. It reaches up to 40-45%. Importantly and interestingly, the peak representing the best solutions is shift towards the case when more individuals are being selected using our diversity-aware selection operator (about 70-75%). After reaching $k = 1N$ the collected results are the same or slightly worse then for computations without diversity-aware selection operator. That seems to indicate that for this, particularly hard and complex, optimisation problem the population diversity can only improve the performance of the algorithm while it almost *never* makes the quality worse.

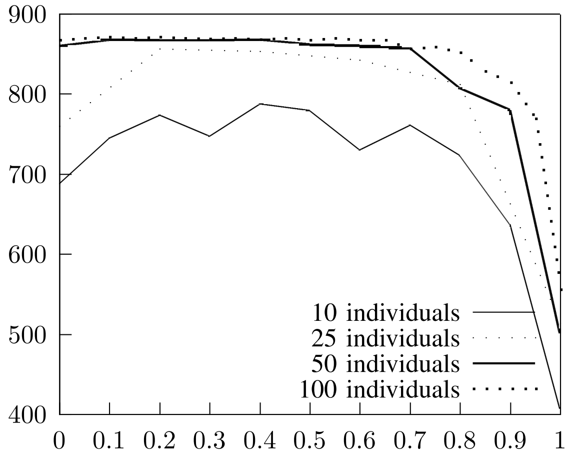

Fig. 1. $f(S)$ as a function of $k$ for Knapsack problem.

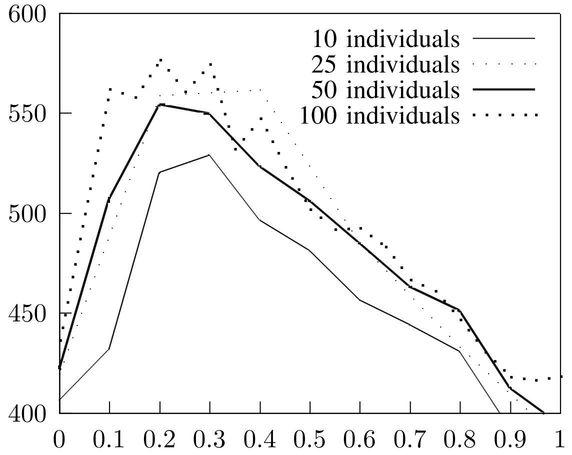

Fig. 2. $f(S)$ as a function of $k$ for TSP.

### B. The Best Solution of $f(S)$ as a Function of $\alpha$

Experiments performed for the Knapsack problem (Fig. 4) show that changes of $\alpha$ parameter have a positive impact on the best solution value only for the smallest tested population composed of 10 individuals (28% increase for $\alpha = 0.15$). For bigger populations adding $dissimilarity$ to $f(S)$ has no or only negative impact on the results.
For our current experimental settings, the TSP (Fig. 5) and TTP (Fig. 6) tests show no clear dependence between the results and changes of $\alpha$. This is an interesting signal that seems to be counter-intuitive (compared to the results concerning the dependence on the value of $k$ presented above) and should be

[1] Remind that Knapsack is a relatively "easy" computational problem among the NP-hard problems as there exists a pseudo-polynomial dynamic programming algorithm for it, what excludes it from the class of, so called, strongly NP-hard problems

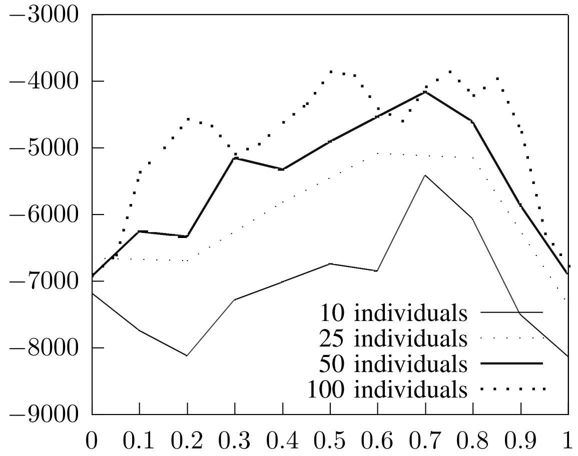

Fig. 3. $f(S)$ as a function of $k$ for TTP.

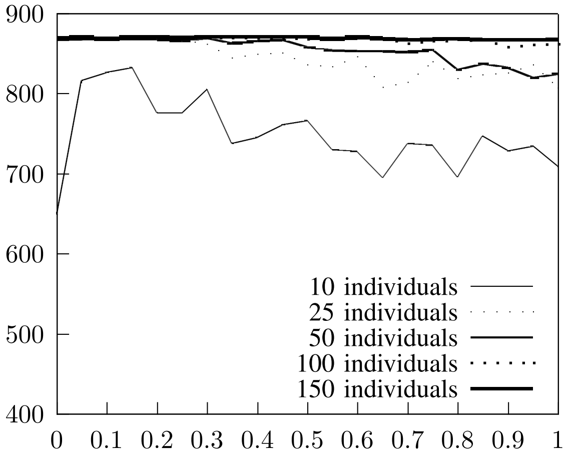

Fig. 4. $f(S)$ as a function of $\alpha$ for Knapsack problem.

further examined in the continuation work.

### C. The Best Solution of $f(S)$ as a Function of Population Size

Analysis of the last group of tests confirms the results observed in the first series of experiments (concerning the dependence of the solution quality on $k$). Namely, improvements in Knapsack problem solution (Fig. 7) are visible only for small populations and there is no change for bigger populations. For TSP (Fig. 8) a positive impact can be observed for all tested population sizes (10-200 individuals). The best solutions are equally improved throughout all the tested populations.

TTP results (Fig. 8) show, that for smaller populations there is a small postitve or even in some cases a negative impact on the objective function value. For bigger populations a positive impact is visible. It increases slightly with population size.

Most importantly, the reported experimental results clearly indicate that introducing diversity to the solution population can noticeably increase the quality of the solutions.

## VIII. Conclusions and Future Work

The experiments reported in this paper clearly indicate that controlling the population diversity in genetic algorithm in the way we proposed in this paper by using `diverGene` is a promising technique. In particular, picking a part of population using the diversity-aware selection operator can significantly improve results of the objective function $f(S)$ for the variant of the TSP problem that we studied and, even more significantly, for the TTP problem. There is also an interesting observation, that seems to be natural and intuitive, that the more complex and harder the optimisation problem the more improvement can be achieved by applying our diversity-aware selection operator.

More tests should be performed for the studied problems, including examining other implementations of dissimilarity operator and other settings.

Another interesting direction could be to study the convergence rate as the function of the population diversity.

It is a bit surprising that we did not observe much dependence of the quality of the solution on the value of the $\alpha$ parameter. This should be further investigated in the future work.

It would be also interesting to introduce the self-adaptation mechanism to our approach. More precisely, to make the algorithm itself dynamically controlling the values of the diversity-aware operator parameters (e.g. $k$ and $\alpha$) to better control the exploration/exploatation balance.

***Abstract*—In the field of data analysis, the use of metrics is a classical way to assess pairwise similarity. Unfortunately the popular distances are often inoperative because of the noise, the multidimensionality and the heterogeneous nature of data. These drawbacks lead us to propose a similarity index based on fuzzy set theory. Each object of the dataset is described with the vector of its fuzzy attributes. Thanks to aggregation operators, the object is fuzzified by using the fuzzy attributes. Thus each object becomes a fuzzy subset within the dataset. The similarity of a reference object compared to another one is assessed through the membership function of the fuzzified reference object and an aggregation method using OWA operator.**

## I. Introduction

ASSESSING the similarity between samples is a key of success in data analysis process. Many methods rely on similarity indices. Most of clustering ones uses pairwise comparisons when aggregating or separating samples [11], [12]. In the framework of case-based reasoning, solving problem needs for searching similar cases and assessing their similarities [10]. Recommender systems also deal with similarity between objects [18]. Thus the search for pairwise similarity indices remains an active field of research [2], [14]. The choice of similarity measures depends on the representation of objects we compare [5] [6]. In this paper, we restrict the scope of this study to the comparison of vector data.

When data is described with multidimensional vectors, the use of metrics remains the classical way to assess pairwise similarity [19], [6]. Unfortunately, database objects could have qualitative features making difficult to obtain standardized quantitative vectors of attributes from the objects. Thus the popular distances (Euclidean distance, Mahalanobis distance, Minkowski metric, Cosine distance, Correlation distance,... ) become often inoperative. Moreover noise or vagueness can corrupt data and the curse of dimensionality is also an obstacle in processing queries in high-dimensional space [3]. These drawbacks lead us to propose a similarity index which is not based on a distance function or a metric in the data space.

To overcome these difficulties, the fuzzy set theory gives a framework to design similarity indices [17], [20]. In this paper, the dataset forms the context for our pairwise comparisons between objects.

Each object $X_i$ of the dataset is fuzzified. Let $\tilde{X}_i$ be the fuzzy set obtained from the crisp object $X_i$, $\tilde{X}_i$ is the fuzzy version of $X_i$. The membership degree of the crisp object $X_j$ to the fuzzy set $\tilde{X}_i$ is considered as the similarity value from $X_j$ to the reference object $X_i$. Therefore the similarity indices we propose are only fuzzy membership functions. Note that such similarity indices based on membership functions do not necessarily define symmetric relations.

The challenge using our approach becomes to obtain a fuzzification of an object $X_i$ within the dataset [13]. To achieve this goal, the attributes of the object $X_i$ are considered as fuzzy numbers or fuzzy quantities. Then each crisp object $X_j$ is described with a vector of membership degrees relative to the fuzzy attributes of $X_i$. Thanks to fuzzy logic operators, we aggregate these membership degrees to obtain the aggregated membership value of $X_j$ to the fuzzy set $\tilde{X}_i$. The critical issue of this approach is the aggregation method we use. This communication proposes to adapt OWA operators [16] to define our aggregation method.

The paper is organized as follows.

In The sections 2 and 3 we present our approach for the fuzzification of the attributes. The section 4 exposes the methodology we use to evaluate the sensibility and specificity of each attributes. After the fuzzification of the data, we present in the section 5 the aggregation procedure used to build a new similirity index using an Ordered Weighted Aggregation operator. Before concluding, we present in the section 6 a comparison of our new pairwise similarity indice with the popular metrics.

## II. Domain of fuzzification

Let $E$ be a set of $n$ objects defined by:

$$E = \{X_i \ / \ 1 \leq i \leq n\} \tag{1}$$

where $X_i$ are the $n$ objects of $E$.

Each object is described by a vector of $p$ attributes. The object $X$ is represented by the $p$-tuple $(x_{ik})$ with $1 \leq k \leq p$ where $x_{ik}$ is the value of the $k$-th attribute of the object $X_i$. These $p$ attributes are either quantitative or qualitative. If the $k$-th attribute is quantitative, then its values lie within an interval $[a_k, b_k]$ of $\Re$. If the $k$-th attribute is qualitative, then its values are within a set $\{v_1, v_2, v_3, ...v_l\}$ of $l$ values. In both cases, we call $D_k$ the set we use to define the $k$-th attribute.

The domain of definition $D$ of $E$ is defined by:

978-83-60810-66-8/$25.00©2015, IEEE

$$D = \prod_{1 \leq k \leq p} D_k \tag{2}$$

Then we have: $E \subset D$ with: $\#E = n$. In the following each object becomes a fuzzy subset of $E$ relatively to its attributes. Thus $E$ is called domain of fuzzification.

## III. Fuzzification of the attributes

This section is devoted to the fuzzification of an object $X_i$ within the dataset $E$. Although the fuzzification of an attribute is itself beyond the scope of this document, we firstly describe the way we used to fuzzify each attribute value of the object $X_i$. Thus we obtain $k$ fuzzy attributes for $X_i$. Then we merge these fuzzy attributes to build the fuzzy object $\tilde{X}_i$ defined in $E$.

Let $X_i$ be an arbitrary reference object of the data set $E$. Let $x_{ik}$ be the value of the $k$-th attribute of $X_i$. The values of attributes are often imprecise and the meaning could be vague. Therefore it is convenient to represent such imprecise or vague values by fuzzy sets. Thus $x_{ik}$ is represented by a fuzzy subset of $D_k$. The membership function $m_k^i$ of this fuzzy subset is defined by:

$$\begin{array}{llll} m_k^i \colon & D_k & \longrightarrow & [0,1] \\ & x & \longmapsto & m_k^i(x) \end{array} \tag{3}$$

In this paper, these fuzzy sets are normalized with $m_k^i(x_{ik}) \leq 1$.

In this paper, we propose a simple and empirical approach of the data fuzzification. Each numeric value is represented by a conventional trapezoidal membership function defined by $(a, b, c, d)$ with (cf. fig. 1):

$$m_k^i(x) = \begin{cases} 0 & \text{if } x < a_i \\ \frac{x - a_i}{b_i - a_i} & \text{if } a_i \leq x < b_i \\ 1 & \text{if } b_i \leq x < c_i \\ \frac{d_i - x}{d_i - c_i} & \text{if } c_i \leq x < d_i \\ 0 & \text{if } d_i \leq x \end{cases} \tag{4}$$

Let $\overline{x}_k$ and $\sigma_k$ be respectively the mean and the standard deviation of the $k$-th attribute within $D_k$. If $dev_k^i$ is the deviation between $x_{ik}$ and $\overline{x}_k$ (i.e. $dev_k^i = |x_{ik} - \overline{x}_k|$), an empirical study leads us to propose:

$$\begin{cases} a_i = x_{ik} - \sigma_k - 0.5\, dev_k^i \\ b_i = x_{ik} - 0.5\, \sigma_k - 0.1\, dev_k^i \\ c_i = x_{ik} + 0.5\, \sigma_k + 0.1\, dev_k^i \\ d_i = x_{ik} + \sigma_k + 0.5\, dev_k^i \end{cases} \tag{5}$$

If the $k$-th attribute is qualitative, $x_{ik}$ is fuzzified using a degree of membership for each possible value of the attribute. Then $m_k^i$ is defined by $l$ values $(m_k^i(v_1), m_k^i(v_2), ...m_k^i(v_l))$ within $D_k$.

This paper proposes to use $m_k^i$ to fuzzify the object $X_i$ within $E$ in respect with its $k$-th attribute. The membership function of the object $X_i$ is defined by:

$$\begin{array}{llll} \mu_k^i \colon & E & \longrightarrow & [0,1] \\ & X_j & \longmapsto & \mu_k^i(X_j) = m_k^i(x_{jk}) = \mu_{jk}^i \end{array} \tag{6}$$

with $1 \leq j \leq n$ and $1 \leq k \leq p$.

If the value of $x_{ik}$ is not set, then we propose to define $\mu_k^i$ by simply $\mu_k^i(X_j) = \frac{1}{2}$ in order to ensure the robustness of the proposed approach.

At this stage of the communication, several points should be noted. Each object $X_i$ gives rise to $p$ fuzzy subsets of $E$.

Each subset is associated with an attribute. These fuzzy subsets are defined with reference to the object $X_i$. They are normalized because $\mu_{jk}^i \leq 1$.

We propose to consider the membership degrees $\mu_{jk}^i$ (with $X_j \in E$) as similarity values from $X_j$ to the reference $X_i$ with respect to the $k$-th attribute. If $\mu_{jk}^i = 1$, then $X_j$ and $X_i$ are considered as similar with respect to the $k$-th attribute. In contrast, if $\mu_{jk}^i = 0$, then $X_j$ and $X_i$ are considered as dissimilar with respect to the attribute. The more $\mu_{jk}^i$ is close to 1, the larger the similarity from $X_j$ to $X_i$ for the $k$-th attribute. Thus the membership function $\mu_{ik}$ (with $1 \leq k \leq p$) is considered as a similarity index to $X_i$ with respect to its attribute $x_{ik}$.

We can see in "fig. 1" that $x_{j_3k}$ is considered as similar to $x_{ik}$ but $x_{j_1k}$ is not comparable to $x_{ik}$. This similarity value is asymmetric. In "fig. 2" $x_{j_4k}$ is not comparable to $x_{ik}$ : $\mu_k^i(x_{j_4k}) = 0$ but $\mu_k^{j_4}(x_{ik}) > 0$.

The membership functions $\mu_{ik}$ give $p$ indices of similarity to $X_i$ within the set $E$. Let us define two characteristics of these indices that we call the sensibility and the specificity to the similarity with $X$.

Let $sens_{ik}$ be the mean of $\mu_{jk}^i$ when $X_j \in E$:

$$sens_{ik} = \frac{1}{n} \sum_{X_j \in E} \mu_{jk}^i \tag{7}$$

The value $sens_{ik}$ lies between 0 and 1. It assesses an average similarity between the reference object $X_i$ and the whole dataset $E$ in respect with the $k$-th attribute.

If $sens_{ik}$ is close to 1, then the $n$ similarity values $\mu_{jk}^i$ are also rather close to 1. Then the $n$ objects $X_j$ of $E$ are rather similar to $X_i$. In this case, the values $\mu_{jk}^i$ are sensitive indicators of the similarity to $X_i$. Since these values are rather equal to 1 or close to 1, then the value $\mu_{jk}^i$ becomes highly symptomatic of a dissimilarity (non-similarity) with $X_i$ when the indicator of similarity $\mu_{jk}^i$ is close to 0. Thus the $k$-th attribute is considered as an attribute sensitive to the similarity with $X_i$.

$\sigma_k + 0.5\ dev^{j_4}{}_k$
$x_{ik}$
$x_{j_4k}$
$x_{jk}$

Fig. 2. Asymmetric similarity values.

In contrast, if $sens_{ik}$ is close to 0, the $n$ similarity values $\mu^i_{jk}$ are also rather close to 0. Then the $n$ objects $X_j$ are rather dissimilar (non-similar) to $X_i$. In this case, the values $\mu^i_{jk}$ are specific indicators of the similarity to $X_i$. Since these values are rather equal to 0 or close to 0, then the value $\mu^i_{jk}$ becomes highly symptomatic of a similarity to $X_i$ when the indicator of similarity $\mu^i_{jk}$ is close to 1. Thus the $k$-th attribute is considered as an attribute specific of the similarity with $X_i$.

When we consider the $k$-th attribute, $sens_{ik}$ is a coefficient of the sensibility of this attribute to the similarity with $X_i$ and 1-$sens_{ik}$ is a coefficient of the specificity of the attribute for the similarity with $X_i$. These two coefficients characterize the $k$-th attribute with reference to the object $X_i$ within $E$.

Let us consider an example (see Table I) to explain these coefficients. The dataset $E$ has six objects $X_1$, $X_2$, $X_3$, $X_4$, $X_5$ and $X_6$. Each object is described with four attributes. The reference object is $X_1$. The four attribute values of $X_1$ are fuzzified. The four membership functions $\mu^1_1$, $\mu^1_2$, $\mu^1_3$ and $\mu^1_4$ indicate the degrees of similarity to $X_1$. In this example, the sensitivities of the four attributes are respectively 0.767, 0.400, 0.583 and 0.680. The 1st attribute is the most sensitive one. Only $X_6$ has 1st attribute value dissimilar from the one of $X_1$. Thus the 1st attribute reveals the dissimilarity with $X_1$. The specificities of the four attributes are respectively 0.233, 0.600, 0.417 and 0.320. The 2nd attribute is the most specific one. Only $X_2$ has 2nd attribute value similar to the one of $X_1$. Thus the 2nd attribute reveals the similarity with $X_1$.

TABLE I

Sensitivity and Specificity of the Attributes in Respect with the Reference Object $X_1$: Example of 6 Objects with 4 Fuzzy Attributes, $\mu_k$ are the Degrees of Membership to $X_1$ Relative to the $k$-th Attribute with $1 \leq k \leq 4$

| Objects | Fuzzy attributes | | | |
|---|---|---|---|---|
| | $\mu^1_1$ | $\mu^1_2$ | $\mu^1_3$ | $\mu^1_4$ |

| $X_6$ | 0 | 0.1 | 0.7 | 0.2 |
| sensitivity | 0.767 | 0.400 | 0.583 | 0.680 |
| specificity | 0.233 | 0.600 | 0.417 | 0.320 |

## IV. Aggregation with OWA Operators

Let us consider the reference object $X_i$ in $E$. The fuzzy subset defined by the membership function $\mu^i_{jk}$ depends on the value $x_{ik}$ of the $k$-th attribute of $X_i$. We propose to aggregate these $p$ fuzzy subsets taking into account all the attributes. The goal is to fuzzify the reference object $X_i$ within $E$ defining a new membership function $\mu^i$ fusing the functions $\mu^i_k$.

The aggregation operators give a classical way to merge the fuzzy subsets in $E$. Let $aggreg$ be an aggregation operator. The function $\mu^i$ is defined by:

$$\begin{array}{llll} \mu^i: & E & \longrightarrow & [0,1] \\ & Y & \longmapsto & \mu^i(X_j) = \underset{1\le k\le p}{aggreg}(\mu^i_k(X_j)) \end{array} \tag{8}$$

The aggregation operators are well studied in literature [7], [8]. The minimum is the reference operator to obtain a conjunction and the maximum is the one for a disjunction. The operators used in this paper are a tradeoff between the conjunction (AND) and the disjunction (OR).

If the similarity index $\mu^i_k$ is very sensitive ($sens_{ik}$ close to 1), then the similarity index $\mu^i_k$ should contribute to $\mu^i$ using a conjunction operator. Indeed, a conjunction seems desirable because significant information is obtained when $\mu^i_k$ is close to 0. In contrast, if the similarity index $\mu^i_k$ is very specific ($sens_{ik}$ close to 0), a disjunction operator seems preferable because significant information is obtained when $\mu^i_k$ is close to 1.

In this paper, the tradeoff between conjunction and disjunction is defined using an Ordered Weighted Aggregation (OWA operators proposed by R. Yager [16]).

Let us describe the function $\mu^i$ obtained when using such an OWA operator.

For an object $X_j$ in $E$, the membership degrees $\mu^i_k(X_j)$ are ordered by decreasing order. We obtain :

$$\mu^i_{(1)}(X_j) \ge \mu^i_{(2)}(X_j) \ge \mu^i_{(3)}(X_j) \ge ... \ge \mu^i_{(p)}(X_j)$$

The aggregation is defined by:

$$\mu^i(X_j) = \sum_{1\le k\le p} w_k \times \mu^i_{(k)}(X_j) \tag{9}$$

We denote $W$ the weighting vector :

$$W = [w_1, w_2, \dots, w_p] \tag{10}$$

with $\sum_{1\le k\le p}(w_k) = 1$ and $w_k \in [0,1]$

The weights are not associated with attributes but with their ordered positions. The challenge is to determine the weights.

The conjunction operator (i.e. the minimum) is obtained if :

$$W_* = [0, 0, \dots, 1] \tag{11}$$

The disjunction operator (i.e. the maximum) is obtained if :

$$W^* = [1, 0, \dots, 0] \tag{12}$$

The ordinary average is recovered if :

$$\bar{W} = \left[\frac{1}{p}, \frac{1}{p}, \dots, \frac{1}{p}\right] \tag{13}$$

Pérez and Lamata [15] discuss the weights determination by means of linear functions that we use in this paper.

To emphasize the conjunction, we propose to use decreasing weights $w_{min}$ defined by using the linear orders of Borda [4] where :

$$w_{min}(k) = \frac{2k}{p(p+1)} \tag{14}$$

where $1 \le k \le p$.

To emphasize the disjunction, we propose to use increasing weights $w_{max}$ defined by increasing linear orders with:

$$w_{max}(k) = \frac{2(p+1-k)}{p(p+1)} \tag{15}$$

where $1 \le k \le p$.

Then we have:

$$w_{min}(k) + w_{max}(k) = \frac{2}{p} \tag{16}$$

For example, if $p = 4$ $\begin{cases} W_{min} = \left[\frac{2}{20}, \frac{4}{20}, \frac{6}{20}, \frac{8}{20}\right] \\ W_{max} = \left[\frac{8}{20}, \frac{6}{20}, \frac{4}{20}, \frac{2}{20}\right] \end{cases}$ (17)

The membership function $\mu^i_k$ is a similarity index with $X_i$ in respect with the $k$-th attribute. $sens_{ik}$ describes the sensitivity of the index. In this paper, $sens_{ik}$ is considered as the ANDness of the attribute and 1-$sens_{ik}$ defines the specificity i.e. the ORness of the attribute. Then the weights of OWA operator we use are defined by:

$$w_k = C\left(\ (sens_{(ik)})w_{min}(k) + (1 - sens_{(ik)})w_{max}(k)\ \right) \tag{18}$$

where $C$ is the coefficient for obtaining $\sum_{1\le k\le p}(w_k) = 1$.

The membership degrees $\mu^i(X_j)$ with $X_j \in E$ are obtained through these weights. Such an OWA operator in $E$ permits us to define a similarity index $sim_i$ from the reference $X_i$ to the other objects $X_j$ of $E$ by:

$$sim(X_i, X_j) = \mu^i(X_j) \tag{19}$$

Note that the similarity index we propose is not necessarily symmetrical (cf. fig:fuzzy2). In fact $sim(X_i, X_j)$ is not always equal to $sim(X_j, X_i)$.

## V. Comparison with popular metrics

The way we describe to design pairwise similarity between multidimensional data leads us to propose a new pairwise similarity index based on fuzzy logic operators. This section is devoted to the assessment of the new similarity index we propose. First we define a criterion to compare the similarity indices. Second we apply this criterion for comparing our new pairwise similarity index with more classical indices based on the popular metrics.

### A. Assessment of a similarity index

Such a pairwise similarity indices are often used in the context of data clustering [9]. In this paper, we take the problem upside down using the clusters for assessing the similarity indices. The clusters define a partition of $E$, we call $C_{X_i}$ the cluster to which the object $X_i$ belongs and we call $sim$ a similarity index between two objects of $E$.

Let us consider all pairs of objects $(X_i, X_j)$ within the sample data $E$. If the two objects $X_i$ and $X_j$ belong to the same cluster, then an optimal similarity index from $X_i$ to $X_j$ should be equal to one (i.e. $X_i$ and $X_j$ are similar). On the contrary, if the two objects $X_i$ and $X_j$ belong to two different clusters, then an optimal similarity index from $X_i$ to $X_j$ should be equal to zero (i.e. $X_i$ and $X_j$ are dissimilar). Thus we define the intra-cluster similarity of $sim$ with:

$$intra(sim) = \frac{1}{n_1} \sum_{C_{X_i}=C_{X_j}} sim(X_i, X_j) \tag{20}$$

where $n_1$ is the number of couples $(X, Y)$ where $X$ and $Y$ belong to the same cluster. The inter-cluster similarity is defined with:

$$inter(sim) = \frac{1}{n_2} \sum_{C_{X_i} \neq C_{X_j}} sim(X_i, X_j) \tag{21}$$

where $n_2$ is the number of couples $(X_i, X_j)$ where $X_i$ and $X_j$ belong to two different clusters.

The similarity index $sim$ is optimal for the clusters when $intra(sim) = 1$ and $inter(sim) = 0$. Therefore we define a criterion to evaluate $sim$ with:

$$crit(sim) = intra(sim) - inter(sim) \tag{22}$$

The value $crit(sim)$ lies always between -1 and 1.

The higher $crit(sim)$, the more optimal $sim$ with respect to the clusters.

We propose to use this criterion to assess our new pairwise similarity index.

### B. Applications

This paper proposes a new way to evaluate the similarity between multidimensional vector data. The most classical way consists in using the popular metrics when data are quantitative. In this paper we consider Euclidean distance, Manhattan distance, Chebyshev distance, Canberra distance and Mahalanobis distance (see Table II). In fact, these distances are dissimilarity indices that we transform into similarity indices with:

$$simil(X, Y) = 1 - \frac{dist(X, Y)}{\max\limits_{A,B \in E} dist(A, B)} \tag{23}$$

where $dist$ is the distance that we use.

Then we have five similarity indices we call $Euclidean$, $Manhattan$, $Chebyshev$, $Canberra$, and $Mahalanobis$ which are based on their three respective popular metrics.

We compare these similarity indices based on distances with two indices we propose based on the aggregation operators of membership functions. The first one is called $simOWA$ that is the index which is described in this paper. It is based on OWA operators. The second one replaces the OWA operator with the arithmetic mean of the membership functions. This second one is called $Arithmetic$.

The similarity indices are computed using the databases from *Machine Learning Repository of UCI* [1].

In this paper we propose to use six numerical multivariate clustering databases that are $iris$, $wine$, $ecoli$, $glass$, $seeds$ and $haberman$. The number of attributes lies between 3 and 15. The number of objects lies between 100 and 500. The number of clusters lies between 3 and 10. $iris$ is the classical database that has 150 iris plants with 4 attributes and three clusters. The $wine$ recognition database has 178 objects with 13 attributes and three clusters. $ecoli$ is the database of sites of protein localization, it has 336 objects with 7 attributes and eight clusters. The $glass$ identification database has 214 objects with 9 attributes and seven clusters. The $seeds$ database of wheat varieties has 210 objects with 7 attributes and three clusters. $Haberman$'s survival database has 306 objects with 3 attributes and two clusters.

The results obtained are in Table III. We can see that the similarity indices proposed in this paper (SimOWA and Arithmetic) are better than the others in 5 cases and ranked second for one of them ($glass$ Database). In 5 cases of 6, the similarity indice based on the OWA operator gives us better results than the one based on the arithmetic mean.

## VI. Conclusion

The approach we propose has a significant advantage, it allows us to deal with imperfection that is a general case with real data. In medicine and biology, data is often imprecise mainly due to the inherent variability of biological data. In physics, data is also imperfect and it is usual to assign a value from a sensor with the accuracy of the measurement. Qualitative data is also imprecise or vague. Thus the use of the fuzzy set theory is relevant in this context of imperfect data.

In this paper we propose a simple method of fuzzification for imperfect multidimensional data. With this fuzzification we define a new similarity indice that will allow us in future works to identify the main features of the dataset and build a robust classification. We can also use this approach to compare a new object with the existing data, for example by finding the nearest objects.

***Abstract*—Machine learning has received increased interest by both the scientific community and the industry. Most of the machine learning algorithms rely on certain distance metrics that can only be applied to numeric data. This becomes a problem in complex datasets that contain heterogeneous data consisted of numeric and nominal (i.e. categorical) features. Thus the need of transformation from nominal to numeric data. Weight of evidence (WoE) is one of the parameters that can be used for transformation of the nominal features to numeric. In this paper we describe a method that uses WoE to transform the features. Although the applicability of this method is researched to some extent, in this paper we extend its applicability for multi-class problems, which is a novelty. We compared it with the method that generates dummy features. We test both methods on binary and multi-class classification problems with different machine learning algorithms. Our experiments show that the WoE based transformation generates smaller number of features compared to the technique based on generation of dummy features while also improving the classification accuracy, reducing memory complexity and shortening the execution time. Be that as it may, we also point out some of its weaknesses and make some recommendations when to use the method based on dummy features generation instead.**

***Keywords*—Weight of Evidence, WoE, dummy features, data transformation, nominal features, categorical features, heterogeneous data**

## I. Introduction

CLASSIFICATION is one of the most researched problems in the data mining community. The data mining process is consisted of business and data understanding, data preparation, modeling, evaluation and deployment [1]. One of the crucial parts of this process is the data preparation which has a very large influence over the success or failure of the classification. Data preparation is not a trivial task and is dependent on the nature of the data. There are many problems that need to be addressed during the data preparation such as the existence of outliers, errors, noise, missing values etc. It is important that the data is processed and transformed correctly so that the problems that exist in the raw data are eliminated or their influence reduced as much as possible. For this we use different data transformation methods.

Depending on the data type of the features different transformations are suitable. Some of the most common methods for data transformation are well described in [2] and [3]. Transforming numeric data, be it continuous or discrete, can be done in a variety of ways. Then again, transformations of nominal and categorical data are not as extensively researched. This issue is also highlighted in [4]. A very common way for transformation of nominal features is by generating dummy features (i.e. varables). It is characterized by simplicity, independence of the data domain, and ease of implementation. Authors in [5, 3, 6] recommend to generate dummy features when there is no mapping of nominal to numeric data. After the data transformation the distance between the dummy features of the instances can be calculated in different ways, as described in [7]: Euclidean distance, Hamming distance, Jaccard distance, Levenshtein distance, etc. In this paper we treat binary dummy features as numeric features, and the distances are calculated intrinsically in the learning algorithm.

Another similarity measure for nominal features is proposed in [8]. It gives greater weight to uncommon feature value matches in similarity computations and makes no assumptions about the underlying distributions of the feature values. Application of this measure in an unsupervised setting to define the similarity metric between pairs of objects is proposed in [9].

The term frequency-inverse document frequency (TF-IDF), as described in [10] and [11], is often used in text mining problems as a numerical statistic which estimates the importance of a word to a document in a collection of documents. In a similar manner this weight can be used to transform arbitrary nominal values into numerical just as it assigns weight to words in text mining and information retrieval. This approach is mentioned in [12], but using TF-IDF as nominal data transformation technique during the preprocessing phase has not be widely researched.

The weight of evidence parameter, originally defined in [13], can be used for estimating the evidence in support of a hypothesis. Additionally it can be used for transformation of nominal data. Its applicability with examples is also discussed in [14] and [2]. There are some computational limitations of this method and we have addressed them in [15], so it can be used even when the preconditions are not met. In [16] we present an application of this transformation for calculation of the information value of features, which is consequently applied for feature selection.

One of the most serious drawbacks of this method is that it is applicable only to binary classification problems. In this paper we are providing theoretical foundations in order to extend the applicability of the WoE method to multi-class

978-83-60810-66-8/$25.00©2015, IEEE

problems. In order to evaluate its advantages, limitations and drawbacks we are comparing it against the technique that generates dummy features. The reason are using this technique as benchmark is because it is most widely adopted in both literature and practice. With this in mind, we have tested both methods on binary and multi-class classification problems and we have trained Support Vector Machines (SVMs) with different types of kernels and a feed forward back-propagation neural network. Finally, we summarize the findings of our research and discuss the applicability of the proposed extension of the weight of evidence parameter and give some recommendations of when to use it.

## II. Transformation with generation of dummy features

This section describes in more detail the method for transformation of nominal into numeric features based on generation of dummy features. By using this technique $n$ new dummy features are generated from a nominal feature that has $n$ different values, when $n > 2$. When $n = 2$ only one dummy feature is generated. Equation (1) gives the total number of generated dummy features where $v_i$ is the number of different values of the $i$-th nominal features. Each of the generated features can have a value of 0 or 1, depending on the occurrence of a particular value of the original feature. This approach has been published for the first time in [17] and was mainly used in regression analysis. Also, [18] covers many aspects related to regression analysis with dummy variables. Over time, this technique has been added to many software packages as a common stage before applying various machine-learning algorithms. When the number of nominal features and the number of different values they can have is small, this transformation leads to good performance of the algorithms. The problems arise when there are a lot of nominal features that can have many different values. These kinds of situations lead to rapid increase of the number of generated dummy features, which in turn, slows down machine-learning algorithms. In fact, the memory requirements or time complexity of algorithms can expand to that degree that they cannot be executed in a reasonable time on the computers that we have today. This issue can be partially addressed by discarding some of the generated features based on their predictive power. By doing that, some potentially useful information in the discarded features is consciously thrown away.

$$z_{dummy} = \sum_{i=0}^{n} v_i \tag{1}$$

## III. Weight of evidence

Decision making is mostly based on estimating the probability that one event might occur. The complexity of decision making varies from trivial decisions to some complex ones that require more involved processing of data from multiple sources. The outcome of this probabilistic decision making depends on facts that might even have inter dependencies [19]. For each decision we need to weight the influence of the facts that contribute to it. This provides us means of mapping the risk associated with a given choice or fact on a linear scale.

The concept of numerically weighting evidence was first introduced in [13] and is a result of the work performed by Alan Turing and I.J. Good during World War II. It is a statistical quantitative method for evaluating the facts (evidence) in support of a hypothesis. The weighting is performed with the parameter Weight of Evidence (WoE)[2]. It is a great tool for estimating the relative risk based on the available data. In this section we describe the mathematical background of WoE when used for binary classification problems, originally described in [15] and subsequently in [20].

Equation (2) defines the weight of evidence (WoE) of the $i$-th value of the feature $A$, where $N_i^A$ is the number of data points (i.e. instances) that were labeled as negative, and $P_i^A$ is the number of data points that were labeled as positive for the $i$-th value of the feature $A$. $SN$ is the total number of negatively labeled data points, $PN$ is the total number of positively labeled data points in the training set, and $n^A$ is the number of different values for the feature $A$.

$$WoE_i^A = ln\left(\frac{\frac{N_i^A}{SN}}{\frac{P_i^A}{SP}}\right) = ln\left(\frac{N_i^A}{P_i^A}\right) - ln\left(\frac{SN}{SP}\right) \tag{2}$$

Values of $SN$ and $SP$ can be calculated with (3) and (4), respectively:

$$SN = \sum_{i=1}^{n^A} N_i^A \tag{3}$$

$$SP = \sum_{i=1}^{n^A} P_i^A \tag{4}$$

WoE, as illustrated in the second part of (2), has two components: a variable component and a constant component. These numbers are independent of the machine learning algorithm that is going to be applied in the data mining process. They are calculated in the preprocessing phase. The variable component is calculated based on the data points that have a particular value of feature $A$ and the constant component is based on the whole sample (the training data set). In real-time systems, these values should be calculated at regular tyme intervals based on the dynamic of the new data input. There are various statistics that can be monitored so we can determine the need of updating the WoE parameters.

Equation (2) implies that the values for $N_i^A$ and $P_i^A$ have to be different than zero, and given that they represent counts, these constraints transform to $N_i^A > 0$ and $P_i^A > 0$. However, these preconditions are not always met in real datasets thus imposing limited applicability of the WoE parameter. The following section reviews the adjustments of the WoE technique that overcome these preconditions as they were proposed in [15].

## IV. Calculation of Weight of evidence for binary problems when preconditions are not met

As mentioned in the definition of WoE, in order to calculate WoE, we must satisfy the constraints $P_i^A > 0$ and $N_i^A > 0$.

These conditions must be met for any value of the feature so that the WoE can be computed. To be able to compute WoE for all values of the nominal feature that needs to be transformed, we need to make some adjustments in the way WoE is calculated for the cases where the preconditions are not met. The different types of unsatisfied preconditions as proposed in [15] are listed below.

Case 1: *The number of positively labeled data points is zero ($P_i^A = 0$) and the number of negatively labeled data points is zero ($N_i^A = 0$).* This is a trivial case when there are no data points (i.e. instances) with the $i$-th value of the feature $A$, even though this value is valid for this feature. In such case we assume that $WoE_i^A$ is zero, meaning that this particular value of the feature $A$ will have no impact on any transformations nor will change the calculation of some other parameters that are dependent on WoE. In fact, this value could be even deleted from the possible set of values for the current attribute. However, because it does not have effect on anything, it could be retained in the set of possible values in case some data points from the data sets have the $i$-th value of variable $A$, as well as for future analysis.

Case 2: *The number of positively labeled data points is zero ($P_i^A = 0$) and the number of negatively labeled data points is greater than zero ($N_i^A > 0$).* There are no positively labeled data points, and only negatively labeled data points with the $i$-th value of the feature $A$. In order to apply (2), we propose to use the value $P_i^A = 1$ for the positively labeled data points. At the same time, we propose to add the appropriate number of negatively labeled data points, so the overall ratio of the added positively and negatively labeled data points will be equal to the ratio of positively and negatively labeled data points in the whole data set ($SN/SP$). In the following equations let us denote the artificially added positive data points (in this case only one) with $\delta p_i^A = 1$ and with $\delta n_i^A$ denotes the added negative data points. These artificial "additions" of data points does not involve actual additions of instances in any data set, rather it only alters the number of counted data points of particular type for the purpose of the calculations. If instead of one "added" data point ($\delta p_i^A = 1$) we were to add more, then we would need to add more negatively labeled data points $\delta n_i^A$ compared to what we are adding now. This, in turn, may pose a problem because the artificial data points may become greater than the actual data points that are negatively labeled. Equations (5) and (6) define how the number of added data points will be calculated, as well as, the proposed estimate of WoE with (10).

$$\frac{\delta p_i^A}{\delta n_i^A} = \frac{SP}{SN} \tag{5}$$

After applying $\delta p_i^A = 1$ in (5), we can calculate $\delta n_i^A$ with (6):

$$\delta n_i^A = \frac{SN}{SP} \tag{6}$$

Now $P_i^A$ and $N_i^A$ that were defined in section III can be modified to include the artificially added data points:

$$\Delta P_i^A = P_i^A + \delta p_i^A = 1 \tag{7}$$

$$\Delta N_i^A = N_i^A + \delta n_i^A = N_i^A + \frac{SN}{SP} \tag{8}$$

Then, instead of calculating WoE with (2) using $N_i^A$ and $P_i^A$, we can calculate it with their modified values $\Delta N_i^A$ and $\Delta P_i^A$, defined in the two previous equations:

$$WoE_i^A = ln\left(\frac{\Delta N_i^A}{\Delta P_i^A}\right) - ln\left(\frac{SN}{SP}\right) \tag{9}$$

And if we apply (7) and (8) in (9), finally we get the proposed estimate of WoE for this case of unsatisfied preconditions:

$$WoE_i^A = ln\left(\frac{N_i^A \times SP + SN}{SN}\right) \tag{10}$$

Case 3: *The number of negatively labeled data points is zero ($N_i^A = 0$) and the number of positively labeled data points is greater than zero ($P_i^A > 0$).* There are only positively labeled data points with the $i$-th value of the variable $A$. We propose to add one data point that is labeled as negative, so we can use $N_i^A = 1$ when applying (2), and to add the appropriate number of positively labeled data points, so the overall ratio of the added positively and negatively labeled data points will be equal to the ratio of positively and negatively labeled data points in the whole data set ($SN/SP$). As in the previous case, these artificial "additions" of data points are virtual because the instances in the data sets are left intact, rather we only alter the number of counted data points of a particular type. As for why we are using only one artificial "addition" the same observation as in Case 2 stands. In this case the number of artificially added negative data points is one ($\delta n_i^A = 1$), so (5) can be transformed as (11):

$$\delta p_i^A = \frac{SP}{SN} \tag{11}$$

Now $P_i^A$ and $N_i^A$ that were defined in section III can be modified to include the artificially added data points:

$$\Delta P_i^A = P_i^A + \delta p_i^A = P_i^A + \frac{SP}{SN} \tag{12}$$

$$\Delta N_i^A = N_i^A + \delta n_i^A = 1 \tag{13}$$

Finally, for this case of unsatisfied preconditions, instead of calculating WoE with (2) using $N_i^A$ and $P_i^A$, we can calculate it with their modified values $\Delta N_i^A$ and $\Delta P_i^A$, defined in the two previous equations:

$$WoE_i^A = ln\left(\frac{SP}{P_i^A \times SN + SP}\right) \tag{14}$$

In this section we reviewed the enhancement [15] for estimation of WoE for cases in which the it can not be calculated by using the original (2). With this approach we add some data points so that the number of positive and negative labeled data points is always positive. This has a very small influence on the data and does not change the overall distribution of the dataset. There are several benefits from using the proposed method for WoE estimation:

- It would be computable for all features and all values in the data set, meaning that WoE could be used to transform the nominal features into numeric.
- The computed WoE could be used for binning of some values of the features.
- Information value of all features could be computed, and later it could be used for feature selection.
- Many classification algorithms have preference of numeric over nominal features, and sometimes the distance between different data points cannot be estimated if the values of the features are nominal. After we calculate the WoE values, the data points can be compared in terms of WoE.

The proposed transformation could degrade the performance of the classification model when significant noise is present. The estimated risk in such cases could defer from the real risk. Noisy data, however, poses a serious problem in the data mining in general and should be addressed before performing any kind of data transformation and using some machine learning algorithm.

## V. One-vs-all generalization for multi-class problems of the weight of evidence parameter

One of the most constraining properties of the Weight of evidence parameter is that it is computable only for binary classification problems. On the other hand, many real data mining and machine learning applications require classification into more than two classes. In order for the WoE parameter to be applicable for such cases, the algorithm for its calculation needs to be modified accordingly. One way to achieve this is by representing the multi-class classification problem as a set of binary problems. After that, we can calculate the WoE values separately for each of the binary subproblems. In [21] and [22] is applied a similar approach, known as one-vs-all or one-vs-rest, for generalization of many machine-learning algorithms that natively support only two classes (e.g. SVMs). By applying the one-vs-all technique we can also generalize the WoE transformation for multi-class problems. We have followed this idea originally in [23], but without substantial formal definition nor significant empirical evidence. Here we explore the idea of one-vs-all generalization of the WoE transformation in more depth.

Algorithm 1 is repeated for each of the $m$ classes. With this algorithm from a dataset with $k$ nominal features and $m$ classes we generate $z_{woe}$ new numeric features, as defined with (15).

**Algorithm 1** One-vs-all generalization for multi-class problems of the Weight of evidence parameter

```
for $i = 1 \to m$ do
    Temporary label with $TempClass^1$ all instances that were originally labeled with $Class^i$).
    Temporary label with $TempClass^2$ all instances that were originally labeled with some class different than $Class^i$).
    Calculate the WoE parameters for all instances and all their nominal features using the temporary labels ($TempClass^1$ and $TempClass^2$).
    Transform all $k$ nominal features using the calculated WoE parameters in the previous step. This produces $k$ new numeric features.
    Add the $k$ generated numeric features to the transformed dataset.
    Remove the temporary labels of all instances and revert them to their original labels (classes).
end for
```

$$z_{woe} = \begin{cases} m \times n, & m > 2 \\ n, & m = 2 \end{cases} \tag{15}$$

The same algorithm can be applied for transformation of the numeric attributes in the original dataset into another numeric features as well. However, given the fact that there are plenty of algorithms for transformation of numeric features, we are not focusing on that kind of application of the WoE transformation.

## VI. Results

In this section we present the experiments that we conducted using the proposed method for data transformation. The first four subsections describe the performance metric and the cross-validation process that we used across all subsequent tests, how and when we performed feature selection and how we evaluated the performance. The following subsections describe how we have applied the weight of evidence transformation on the nominal features in some of the datasets obtained from the UCI Repository of Machine Learning Databases [24].

### A. Performance metric

The choice of performance metric to evaluate any transformation is very important. Several research papers indicate the fact that in some cases for a given dataset, the learning method that obtains the best model according to a given measure, is not the best method if a different measure is used. In [25] is shown that Naive Bayes and pruned decision trees are very similar in predictive accuracy. Later on, applying the same algorithms, in [26] the same authors show that Naive Bayes is significantly better than pruned decision trees in terms of AUC ROC. As it is said in [27] the different results cannot be explained by slightly different implementations or variants of machine learning algorithms, but on the fact that the two measures (accuracy and AUC ROC) evaluate different things. The predictive accuracy is perhaps the most popular metric for classification problems and many researchers have been publishing papers that show the performance of various algorithms, techniques and transformations in terms of predictive accuracy on the same datasets that we also use in this paper. Another property of accuracy is that it can be calculated for multi-class problems in the same way as it is calculated for binary problems, while other metrics does not natively support multi-class problems. Because of these reasons we have also decided to compare our results in terms of predictive accuracy.

Additionally, we wanted to compare the execution times of both transformations so we can have insight of that aspect too. We have implemented all algorithms in Matlab and all tests have been performed on Windows 7 Professional SP1 64 bit running on a virtual Intel Xeon X5680 at 3.33 Ghz with 8 GB RAM. We have used the built-in implementations of FFNN and SVMs in Matlab. All listed execution times consist of the data transformation, the training of the machine learning algorithm and making the predictions.

### B. Cross-validation

Some of the available datasets in the research community are consisted of training, validation and testing subset. However more often they are consisted of only one set that should be used for training, validation and testing, so the task of splitting the original dataset is left to the data analysts and researchers. The most common practice when evaluating performance in such cases is to perform cross-validation. There are few alternatives of how can cross-validation be performed and each of them has advantages and disadvantages. Stratified 10-fold cross-validation in [28] is recommended as the best model selection method, as it tends to provide less biased estimation of the accuracy. Following this recommendation we have decided to perform $k$-fold cross-validation while using different values for $k$: 2, 4, 6, 8 and 10. Usually the cross-validation is performed after the data is preprocessed. This means that all data cleaning, data transformations, and removal of outliers have to be performed, and then different subsets from the processed datasets are selected as training, validation and testing. This approach is suitable when the data transformations depend only on the actual values of features that should be transformed. Such transformations techniques are all mathematical functions that can be applied on numerical features or generation of dummy features from nominal features.

However, if the data transformations additionally depend on the relationship between the instances in the training set this approach is not suitable. Such relationship is present in the Weight of Evidence transformation because the transformed values depend on the set of values of the features that are being transformed and the set of values of all other instances in the dataset, as it is evident in (2). To review, the transformed value depends on the number of instances labeled with a particular class, and the number of instances that have a particular value of the original feature and are labeled with a particular class. These counts can vary for different subsets of the original dataset, thus a different transformed values can be obtained for the same original value. Ideally, if the dataset is large enough and if the distribution of values of the nominal features is nearly uniform, then the transformed values for different subsets of the dataset would not vary much. However, such conditions do not occur in real datasets, hence the need of to modify the cross-validation process. Algorithm 2 describes how the k-fold cross-validation is performed with repeated transformation of nominal features. By applying this algorithm for cross-validation, only the information that is present in the current set of training folds is used for data transformation.

**Algorithm 2** K-fold cross-validation with repeated transformation of nominal features

```
Randomly shufle the dataset
Randomly assign $Fold_i$ $(i = 1 \to k)$ to each instance in the shuffled dataset
for $i = 1 \to k$ do
    Assign all instances belonging to $Fold_i$ to $TestSet_i$.
    Assign all instances not belonging to $Fold_i$ to $TrainingSet_i$.
    Calculate $WoE_i$ parameters for all nominal features in $TrainingSet_i$.
    Transform all values of all nominal features in $TrainingSet_i$ using the transformation values $WoE_i$, thus obtaining $TransformedTrainingSet_i$.
    Transform all values of all nominal features in $TestSet_i$ using the transformation values $WoE_i$, thus obtaining $TransformedTestSet_i$.
    Train $Model_i$ using $TransformedTrainingSet_i$.
    Validate $Model_i$ using $TransformedTestSet_i$, thus obtaining $Results_i$.
end for
Aggregate $Results_i (i = 1 \to k)$
```

### C. Feature selection

In the machine learning literature there are a lot of published papers and books about various feature selection techniques, both for nominal and numeric features. Such paper is [29], where the most popular algorithms are described and illustrated with examples. This work focuses on data transformation techniques and therefore we have performed some basic feature selection, and have not tested more advanced methods. First thing that is performed for all datasets that we have worked on, all single-value features were removed. Also if such features were generated with one of the applied data transformation techniques they were also removed. This is because these features have no information value i.e. their entropy is zero, therefore having no predictive power regardless of which machine learning algorithm would later be applied.

In the case when some nominal feature has many different values and the dummy variables generation technique is used, a lot of dummy features would be generated. This can pose a serious problem for many machine learning algorithms because they would demand enormous amount of computer power, even to the extent that they would not be usable. To overcome this problem we have used a simple feature selection that restricts the number of dummy features that can be generated. Namely, only for the values of the nominal features that occur in more than 5% of the instances a dummy feature is generated, while for all other less frequently occurring values we generate only one common dummy feature. Choosing the value of 5% as a threshold provided good balance between retaining a small number of features while not loosing too much information. This simple algorithm is very effective in helping prevent the generation of vast amount of dummy features. Of course, a more intelligent feature selection can be applied but we did not want to defocus from the main topic of the paper.

### D. Performance evaluation

After applying the proposed transformation we have transformed all nominal features in the datasets into numeric and then we have trained few machine learning algorithms. In order to have basis for comparison, we have also generated dummy features from all nominal features in the original datasets and afterwards we have trained the same machine learning algorithms. To decrease the impact of randomness while making the splits of the data into cross-validation folds we have repeated the whole process multiple times and then we have aggregated the results. The following subsections describe each of the datasets, the performed data transformations and the performance in more detail. The performance is analyzed in terms of accuracy and execution time.

### E. The Annealing dataset

The annealing dataset was obtained from the UCI Repository of Machine Learning Databases [24] and it contains data for a classification problem. More particularly, it contains 798 instances described with 6 numeric and 32 nominal features. All instances are labeled with one of the 5 possible classes. Only the nominal features of the dataset were subject to transformation, while the numeric features were not transformed in any way.

First, we have generated dummy features for all different values of all nominal features in the original dataset. Note that for nominal features that have only 2 different values we do not generate dummy features rather we only convert their values to 0s and 1s, because these features are already dummy features with differently encoded values. By doing that we have generated 64 dummy features. From them 7 had the same value for all instances in the training and test sets, therefore they were removed. Finally, together with the original 6 numeric features the dataset 1 is comprised of 63 numeric features.

Then we have applied the proposed WoE transformation thus obtaining $32 \times 5 = 160$ new numeric features, as defined with (15). From them 40 had the same value for all instances in the training and test sets, meaning that there is no information value in them, therefore they were removed. Finally, together with the original 6 numeric features the dataset 2 is comprised of 126 numeric features.

Both datasets were tested using a feed forward back propagation neural network (FFNN), and SVM with a linear, quadratic, polynomial and RBF kernel. The training and test partitions of the datasets were obtained using k-fold cross validation and 2, 4, 6, 8 and 10 were used as $k$ values. An important thing to mention is that a same value of the original feature can be transformed into different values. This situation arises from the nature of the WoE values - they depend not only on the original values but also on the distribution of the other values of the same feature in the training dataset. This in turn require the WoE transformation to be performed for each training fold separately. In fact for k-fold cross validation the WoE transformation would be performed $k$ times, once for each training fold combination. Because the instances that belong to the folds are chosen randomly, the performance can vary and may not be consistent. Therefore, the whole process was repeated 10 times for each value of $k$. At the end we have calculated the average, minimum, maximum and standard deviation of the accuracies and the execution times for each algorithm and each transformation type using the data from the 10 repetitions.

Table I shows the accuracies for different values of $k$ of the 10 repetitions when a FFNN was trained with both datasets. We can see that for all values of $k$ the WoE transformed dataset produced better average accuracy. Next, table II shows the execution times when a FFNN was trained with both datasets. We can see that both transformations together with the training and test phase needed were completed in similar time, even though the WoE transformed dataset had about twice more features.

The next algorithm we trained was SVM with linear kernel. Tables III and IV show the results of this algorithm using both datasets. For it we can note that both the accuracy and execution time are similar to each other for both transformations, but are much better than the FFNN.

After that, we have trained a SVM with RBF (i.e. Radial Basis Function) kernel. Tables V and VI show the results of this algorithm using both datasets. For this algorithm we can note that both the accuracy and the execution time are similar to each other for both transformations, are significantly better than the FFNN and worse than the SVM with linear kernel.

The following algorithm that we have trained was a SVM with Polynomial kernel. Tables VII and VIII show the results of this algorithm using both datasets. For this algorithm we can note that the accuracy is slightly better when dummy transfomation is used and execution time is slightly better when WoE transformation is used. Overall the performance is similar to the SVM with linear kernel and to the performance of SVM with Quadratic kernel, which are shown with tables IX and X.

Tables XI and XII show the results of a SVM with MLP (i.e. multilayer perceptron) kernel using both datasets. For this algorithm we can note that the accuracy is slightly better when dummy transfomation is used and execution time is slightly better when WoE transformation is used. Overall the performance is similar to the SVM with RBF kernel.

Finally, we can conclude that for this particular dataset both transformations lead to similar performance in terms of accuracy and execution time when various machine learning algorithms are applied. We want to point out again the fact that the dataset has 1000 instances that are non-uniformly distributed into 5 classes. As a consequence the execution of the transformations is very fast and therefore they are very similar. Additionally the number of different values of the nominal features is very small therefore the advantages of the WoE transformation can not be exploited. For datasets like this one, where the number of instances, the number of nominal features and the number of different values are fairly small, both transformations provide similar results. However, in such cases we recommend applying the dummy transformation because it is easier to implement and it is a lot simpler to interpret and understand.

### *F. The PAKDD 2010 dataset*

The 14th Pacific-Asia Knowledge Discovery and Data Mining conference (PAKDD 2010) together with NeuroTech Ltd. and the Center for Informatics of the Federal University of Pernambuco (Brazil) co-organized a data mining competition [30]. This credit risk assessment problem comes from the private label credit card operation of a major retail chain. The company has been operating its private label card for over 10 years and has applied two different methods for risk assessment with the application's acceptance rate varying from 50% to 75% within this period. Each accepted application turns the applicant into a client and gives him/her the access to credit for purchasing on the retail chain to be billed 10 to 40 days after the purchase, on a monthly basis on a fixed month day. After his/her credit acceptance, a client would take some time to make their first purchase and receive their first bill. During the first year of using the card, the set of monthly bills and payment behavior is collected and used for credit risk assessment. If the client had any monthly defaults (delays longer than the agreed payment periods) he is labeled as bad, otherwise as good client. The goal is to exploit the information that was available when the applicant applied for credit and try to predict whether he would be a good or bad client. To achieve this we have used the training data consisting of various kinds of information for the applicants like age, profession, sex, marital status, monthly income etc. and the label (good/bad) to build prediction models.

For the purpose of the competition there are three available datasets, but the labels (i.e. target class) of only one of them are made publicly available. This dataset is named as Modeling and has 50000 instances, distributed as 26% vs. 74% per class. The dataset is real and collected manually during a long time period therefore some of the instances have missing, invalid or inconsistent data, some of the columns have no information value or have the same values for all instances etc. We have addressed these issues by removing some of the instances and the columns. Additionally, we have generated few nominal features that capture interactions between the original features: sex, marital status, age group, profession etc. After this stage of data cleaning and preparation we ended up with a dataset with 11 numeric and 24 nominal features and a total of about 42000 instances that were similarly distributed in respect to the target class.

First, we have generated dummy features for all different values of all nominal features in the original dataset. Note that for nominal features that have only 2 different values we do not generate dummy features rather we only convert their values to 0s and 1s, because these features are already dummy features with differently encoded values. By doing that we have obtained around 4630 dummy features. Obviously a dataset with such high number of features makes it difficult to train models on it. That is why we have performed a simple feature selection as described in subsection VI-C, which resulted in a dataset with about 140 dummy features. Finally, together with the original 11 numeric features the dataset 1 is comprised of about 150 numeric features. The exact number of features varies depending on the random split during the cross-validation.

Then we have applied the proposed WoE transformation and we generated for each nominal features one numeric feature which resulted in 24 new numeric features, as defined with (15). Together with the original 11 numeric features the dataset 2 is comprised of 35 numeric features.

Both datasets were tested using a feed forward back propagation neural network, and SVM with a linear, quadratic, polynomial and RBF kernel. The training and test partitions of the datasets were obtained using k-fold cross validation and 2, 4, 6, 8 and 10 were used as $k$ values. The whole process was repeated 10 times for each value of $k$, so the influence of randomness during the cross-validations can be neglected. The official performance metric of the competition is area under the receiver operating curve (AUC ROC) [26], but due to the reasons discussed in subsection VI-A, we have decided to compare the results in terms of accuracy. The first results were not very useful because the accuracy of the classifiers built from both datasets was in the most cases around 74%. Additionally in many cases the machine learning algorithms could not converge, meaning we could not compare the both transformations. The WoE transformed dataset usually provided better accuracy, but the overall results were insufficient to make firm conclusions. The fact that the accuracy was similar to the percentage of the more common class and the confusion matrices undoubtedly showed that the unbalanced dataset introduces serious problems for all machine learning algorithms. The algorithms trained on the dummy transformed dataset converged twice less often than the ones trained on the WoE transformed dataset, and in the rare cases when they both converged the WoE transformation almost always provided better results.

In order to make better comparisons of the transformations, it was obvious that a balanced dataset would be more suitable. While we can artificially generate more instances of the less common class, the most common way to balance a dataset is by "throwing away" some of the instances labeled with the more common class. When data is balanced, accuracy rates tend to decline [31]. If we balance the dataset by reducing the training set size, then this can lead to the degeneracy of the model because we are neglecting potentially useful training instances. Nevertheless, we have opted for this option because it was easier to implement the shrinking, but mostly because this way we can train algorithms much faster because of the smaller training sets. By doing this we have obtained a balanced dataset with around 22000 instances and afterwards we have performed all tests described in the previous paragraph. Important to mention here is that by repeating the whole tests 10 times we were able to select different subsets of instances of the more common class for each repetition, thus mitigating the issues of thrown-away information to some extent.

From all algorithms that were tested only the FFNN converged for all values of $k$ and all repetitions. The achieved results are shown in tables XIII and XIV. We can conclude that when FFNN was trained the WoE transformation produced 6% to 9% better accuracy in 10% to 40% more time than the dummy transformation.

After the training was performed for the SVM with RBF kernel we noticed that convergence could not be acheived when $k$ is 4, 6, 8 and 10 when the dummy transformed dataset is used. Similary, when the WoE transformed dataset was used the SVM converged when $k$ was 2 and in six of the repetitions when $k$ was 4. The results that we were able to collect are listed in tables XV and XVI. The results for SVM with MLP kernel were so similar that the averages look exactly the same despite the fact that the individual values were different. This can be seen in tables XVII and XVIII. From them we can conclude that when SVM with RBF or MLP kernel was trained the WoE transformation produced about 2% better accuracy about three times faster than the dummy transformation and additionally the SVMs were able to converge more often. Compared to the the FFNN, the SVMs produced about 20% better accuracy for $k = 2$ but were significantly slower - about 6 times.

The other SVMs with linear, polynomial and quadratic kernel could not converge for none of the repetitions and different $k$ values. We realize that these issues might be addressed by parameter tuning, but we cannot concentrate on this issue at the moment because it is not the focus point of this paper.

## VII. Conclusion

In this study we have proposed a data transformation method based on the weight of evidence parameter. This technique is applicable in binary and multivariate supervised learning problems particularly for the nominal and categorical features. We have tested this technique on two real datasets. To verify our results, we have also generated dummy features from all nominal features in the same datasets and afterwards we have trained the same machine learning algorithms (i.e. feed forward neural networks and support vector machines with different kernels).

The analysis of the results show that in datasets in which the number of instances, the number of nominal features and the number of different values are fairly small, both transformations provide similar results in terms of predictive performance and execution time. For this reason in such cases we recommend applying the dummy transformation, because is easier to implement and it is a lot simpler to interpret and understand. However, it was the opposite case when we applied both transformations to a significantly larger dataset (with more than 10000 instances) that has more nominal features and they have more different values. Very often machine learning algorithms could not be trained on the dummy transformed dataset because of the memory complexity or because convergence could not be achieved. On the same dataset, but transformed with WoE, the same algorithms achieved convergence and produced significantly better results both in terms of predictive performance and execution time.

The presented method can be used without prior knowledge of the nature of the datasets. In our future work, we plan to compare the WoE transformation with other techniques for data transformations for nominal features. Also we will train a larger set of classifiers and will apply these transformations on other datasets as well. Additionally when we train the classifiers we also need to investigate the effect of parameter tuning, for instance when training SVMs. Our goal is to make firm and well-explained conclusions of which transformation is most suitable for what kinds of datasets, so researchers and practitioners can make apply these transformations more confidently without having to try out all possible combinations before deciding which one is most suitable.

***Abstract*—Nowadays, companies collect data at an increasingly high rate to the extent that traditional implementation of algorithms cannot cope with it in reasonable time. On the other hand, analysis of the available data is a key to the business success. In a Big Data setting tasks like feature selection, finding discretization thresholds of continuous data, building decision threes, etc are especially difficult. In this paper we discuss how a parallel implementation of the algorithm for computing the information gain can address these issues. Our approach is based on writing Pig Latin scripts that are compiled into MapReduce jobs which then can be executed on Hadoop clusters. In order to implement the algorithm first we define a framework for developing arbitrary algorithms and then we apply it for the task at hand. With intent to analyze the impact of the parallelization, we have processed the FedCSIS AAIA'14 dataset with the proposed implementation of the information gain. During the experiments we evaluate the speedup of the parallelization compared to a one-node cluster. We also analyze how to optimally determine the number of map and reduce tasks for a given cluster. To demonstrate the portability of the implementation we present results using an on-premises and Amazon AWS clusters. Finally, we illustrate the scalability of the implementation by evaluating it on a replicated version of the same dataset which is 80 times larger than the original.**

***Keywords*—*Hadoop, MapReduce, information gain, parallelization, feature ranking***

## I. Introduction

THE volume of data that needs to be processed has increased significantly in recent years. Most of the organizations in the world base their decisions on the data they collect and they need large volumes of data to be processed in as little time as possible. Over the years many ideas have been developed for solving the Big Data challenge. Increasing the processing power is the logical way to go but this has proven to be effective up to a certain point. After that the hardware scaling is not yet effective enough. The idea of distributing the computation has become popular in recent years since the publications of Google's approaches for MapReduce [1] in 2004 and the concept of Big Table [2] in 2006. Other companies have followed similar paths introducing open-source solutions. One such system is Apache Hadoop that contains a set of algorithms for distributed processing, storage of large datasets on computer clusters, scheduling etc. It is a framework that is employed by industry leaders like Yahoo, Facebook, Ebay, Adobe, etc [3].

Machine learning algorithms such as decision trees [4], neural networks [5], Naive Bayes [6, 7] and many others can automatically analyze data and make conclusions, predictions or even find patterns that otherwise cannot be detected. The main drawback of these algorithms is the degrading performance in presence of redundant and irrelevant features. Other algorithms such as Support Vector Machines are able to cope with this problem to some extent, however, this ability increases the computational time so much that the algorithm doesn't give result in reasonable time. This has already been confirmed in the literature [8, 9, 10]. One way to resolve this is to perform feature selection [11, 9, 12], defined as the task of selection of feature subsets that describe the hypothesis at least as well as the original set. In [13] the most widely used methods for feature selection are introduced.

The rest of this paper is organized as follows. First, in section II we review the most recent approaches to parallelization of various algorithms. Afterwards in section III we describe the definition and applications of information gain. Next, in section IV we present we describe the services in the Hadoop ecosystem and then we present a framework for parallelization of algorithms. Thereupon, in section V we apply it for parallel and distributed computation of information gain based on MapReduce. Next, in section VI we present the experimental setup and the obtained results. Finally, in section VII we discuss the contribution of our work and our plans for further research.

## II. Related work

This section describes some of the most recent work on parallelizing different algorithms with MapReduce. The general approaches and limitations of different data mining algorithms when applied to massive datasets are described in [14]. Here some common data mining problems are explained from a Big Data perspective, but a MapReduce implementation is given only for some common problems like matrix manipulation and joins between tables.

A good overview of the parallel programming paradigms and frameworks in the Big Data era is presented in [15]. Here the authors describe the MapReduce paradigm, but more importantly introduce the frameworks that are built on top of it like: Pig Latin for processing data flows, Hive for non-real time querying of partitioned tables, and Spark and Twister for iterative parallel algorithms.

The authors in [16] address the problem of efficient feature evaluation for logistic regression on very large data sets. Here they present a new forward feature selection heuristic

978-83-60810-66-8/$25.00©2015, IEEE

that ranks features by their estimated effect on the resulting model's performance. They test the method on already available datasets from UCI, but also generate artificial datasets for which they know the logistic regression coefficients. They use that to evaluate the selected features.

By using the MapReduce paradigm in [17] a data intensive parallel feature selection method is proposed. In each map node, a method is used to calculate the mutual information and combinatory contribution degree is used to determine the number of selected features.

In [18] an implementation based on the MapReduce programming model of Naive Bayes is proposed. During the map phase all counts needed for calculating the conditional probabilities are emitted, and during the reduce phase they are aggregated.

A parallel implementation of the SVM algorithm for scalable spam filtering using MapReduce is proposed in [19]. By distributing, processing and optimizing the subsets of the training data across multiple participating nodes, the distributed SVM reduces the training time significantly. Merging of the results is actually a union of the individually computed support vectors. The cost of the parallelization is that because not all training data is available on all nodes, the performance can degrade. However, if the data is properly distributed on the nodes in regards to stratification per class, this problem can be mitigated.

A method for reducing the dataset to a small but representative subset is proposed in [20]. The idea is to use the representative subset for faster machine learning because the dataset size will be significantly reduces. The speedup is being calculated against a cluster with one node. However, if the dataset is too large, or the computation takes a lot of time the authors suggest to use more than one for estimating the speedup. By doing this one can calculate the speed of the current configuration versus the cluster with some smaller number of nodes.

In [21] an approach based on MapReduce for distributed column subset selection is proposed. In this approach each node has access to a random subset of features. This approach has a limitation that the datataset has to be manually splitted and the MapReduce jobs need to be written on lower level. The reason for this is that HBase segments the data horizontally by rows, so either the dataset needs to be transposed or to manually start different jobs and not to rely on a higher level language like Pig Latin or Hive.

Authors in [22] propose a wrapper approach for parallel feature selection. Here features are added to the selected set if after their addition, the performance of the classifier does not degrade. Then in a second phase from the subset obtained in the previous step, features are removed if their discarding does not degrade the classifier performance.

Apache Mahout [23] is an environment for quickly creating scalable performant machine learning applications based on MapReduce. Even though there are plenty of algorithms available in it, at the time of this writing, only two algorithms related to feature selection and dimensionality reduction in Mahout are available: Singular Value Decomposition (SVD) and Stochastic SVD.

## III. Information gain and its applications

Information gain is a synonym for KullbackLeibler divergence and has variety of applications. Very often it is used for ranking individual features as described in [24, 25]. The research discussed in [26] shows how information gain can be used for feature selection in text categorization problems. Authors in [27] propose using the information gain for discretization of continuous valued features into discrete intervals. In like manner, in [28] information gain is analyzed as an unsupervised method for discretization of continuous features. Likewise, in [29] it is applied for improving decision tree performance by prior discretization of continuous-valued attributes. In fact these papers have inspired many other researchers to propose various other applications based on the information gain and entropy. In [30] the information gain in conjunction with methods based on particle filters is used for exploration, mapping, and localization. Another application of information entropy for extending the rough set based notion of a reduct is proposed in [31]. There it is applied for calculation of minimal subsets of features keeping information about decision labels at a reasonable level.

In the remaining of this section when describing the information gain we use the notation we have also used in [32]. In order to calculate the information gain, first the entropy $H(X)$ of the dataset should be calculated. Let $X$ denote a set of training examples, and each of them $x_i$ is in the form $(x_i^1, x_i^2, ..., x_i^k, y_i)$. Let each column (i.e. feature) be a discrete random variable that takes on values from set $V^j, j = 1..k$. Let the set of possible labels (i.e. classes) is $L$, such as $y_i \in L$. Then the entropy of the dataset $X$ can be calculated with equation (1), where $p(l)$ is the probability of instance $x_i$ to be labeled as $l$ (i.e $y_i = l$) and is defined with equation (2).

$$H(X) = -\sum_{l \in L} p(l) \log p(l) \tag{1}$$

$$p(l) = \frac{|\{x_i \in X | y_i = y\}|}{|X|} \tag{2}$$

The information gain of the $j$-th feature of the dataset $X$ can be calculated with equation (3), where first part in the sum is the probability of the instance $x_i$ to have value $v$ of the $j$-th feature. The second part in the sum in equation (3) denotes the entropy of the subset of instances of $X$ that have the value $v$ of the $j$-th feature.

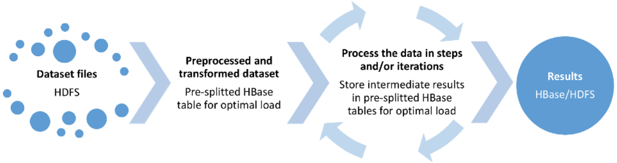
$$IG(X, j) = H(X) - \sum_{v \in V^j} \frac{\left|\left\{x_i \in X | x_i^j = v\right\}\right|}{|X|} H(\left\{x_i \in X | x_i^j = v\right\}) \tag{3}$$

As shown by equations (1),(2) and (3), calculation of information gain of all features boils down to counting the number of instances per feature, value and class. After we compute these counts, we can calculate the probabilities and consequently calculate the information gain. In section V we propose parallel implementation for calculating the information gain of each feature $j$ in the dataset $X$.

## IV. Framework for parallelization

Parallelization of algorithms introduces a handful of potential software bugs of usually related to race conditions, communication and synchronization between the different subtasks. Owing to that, writing parallel computer programs is more challenging than writing sequential ones. In Hadoop most of those challenges are already addressed by various mechanisms and services, so when it is used as a platform for implementation of algorithms, the programmer does not have to put much effort for solving those kinds of issues. Before explaining the details we want to point out that the proposed framework uses the principle of data-parallelism. Having that in mind, the same principles could be used in a regular SQL environment. Nevertheless, while many of the limitations and benefits of SQL vs NoSQL are much argued in the research community, the scalability properties of NoSQL databases are undisputed.

Given that understanding of the Hadoop ecosystem is essential for understanding our parallelization framework, first in the next subsection IV-A we review its services. Then in the following subsections we describe the several phases of the proposed framework. We have applied similar logic in [32], but the solution was not a generic one and was custom for the task at hand. On Fig. 1 is shown a general overview of the data flow during these phases. For data partitioning we propose using HBase tables which are pre-splitted for optimal data distribution, where as for parallel processing and writing MapReduce jobs we suggest using Pig Latin with appropriate user-defined functions.



Dataset files
HDFS
Preprocessed and transformed dataset
Pre-splitted HBase table for optimal load
Process the data in steps and/or iterations
Store intermediate results in pre-splitted HBase tables for optimal load

### A. Hadoop

The MapReduce [1, 33] paradigm is essential to the distributed computation and storage that Hadoop achieves. It consists of two phases: map and reduce. The first phase, map, splits the data into subsets. The reduce phase, aggregates the result from the output that the map phase produces. Procedures that can be performed in the map phase are: filtering, sorting, projecting and reading the data. The map phase returns an intermediate result consisted of keys and values. The reduce procedures use this data and perform aggregation. Hadoop delegates the data from the map phase to the reduce procedures. The MapReduce simplicity makes it very efficient for large-scale implementations on thousands of nodes.

Hadoop with its different services provides all the logistics and monitoring for the processes like scheduling, distribution, communication and data transfer, and also provides redundancy and fault tolerance. Many services or subsystems exist in Hadoop, but the most notable are: YARN (MapReduce2), HDFS and HBase [34][35].

YARN (Yet Another Resource Negotiator) [36] takes care of job scheduling, monitoring and resource management. Two separate daemons are responsible for these tasks: a global ResourceManager and per-application ApplicationMaster. The ResourceManager deploys resources among all the applications and the per-application ApplicationMaster negotiates for resources with the ResourceManager and works with the NodeManager to execute tasks and perform monitoring. YARN does the resource allocation and the distribution of MapReduce jobs to the apropriate nodes.

Hadoop Distributed File System (HDFS) [37] provides scalable, fault-tolerant, distributed storage system that works closely with MapReduce. It was designed to span large clusters of commodity servers. An HDFS cluster is consisted of a NameNode and DataNodes. The NameNode is responsible for the cluster metadata and DataNodes are responsible for data storage. The data is usually split into large blocks (typically 128 megabytes), independently replicated across multiple DataNodes.

HBase is an open source, non-relational, distributed database modeled after Google's BigTable. It runs on top of HDFS (Hadoop Distributed Filesystem), providing BigTable-like capabilities for Hadoop [38, 39, 40]. HBase is a NoSQL (Not Only SQL) database in which the tables are designed by analyzing usage patterns. This allows simplicity of design, horizontal scaling, and finer availability control. The data structures in NoSQL databases, such as HBase, allow faster executions of some operations than the execution of similar operations in relational databases. This mostly depends on the problem that must be solved. Tables in HBase can be used as the input and output for MapReduce jobs run in Hadoop. According to Eric Brewers CAP theorem, HBase is a CP type system (i.e. Consistent and Partition tolerant) [41].

The MapReduce programming model is very popular due to its simplicity. The extreme simplicity of MapReduce leads to much low-level coding that needs to be done for some operations that are much simpler when using relational databases. This increases development time, introduces bugs and may obstruct optimizations [42]. A group at Yahoo motivated by these repeatable tasks on daily basis, has developed a scripting language called Pig Latin. Pig is a high-level dataflow system that is a compromise between SQL and MapReduce. Pig offers constructs for data manipulation similar to SQL, which can be integrated in an explicit dataflow. Pig programs are compiled into sequences of MapReduce jobs, and executed in the Hadoop MapReduce environment [43].

### B. Loading data into HDFS

This is the first and most simple phase. This phase should be performed once or multiple times, depending on how the dataset is structured. The most common formats for datasets are:

- CSV (comma separated values). This format is usually used to store dense datasets.
- ARFF (Attribute-Relation File Format). Also used to store dense datasets.
- EAV (Entity Attribute Value). Used to store sparse matrices that have a lot of zeros and some non-zero

elements.

If the dataset is only one file then it will be copied from the Linux File System to HDFS using a simple command. This means that for such cases during this step we cannot have parallelism. However if the dataset is dispersed into multiple files, then all of them can be copied simultaneously to HDFS. Be that as it may, this step usually is very fast compared to the following steps for machine learning, so its parallelization may not be necessary at all.

### *C. Facilitating data parallelism with HBase*

After the previous step IV-B is finished the dataset files reside on HDFS. As it is extensively described in [37], each file in HDFS is replicated across several nodes for reliability. A typical file in HDFS is gigabytes to terabytes in size, splitted in blocks of 128 MB by default. If the files are too small than that could degrade the performance of the system and limit the level of parallelism. Map tasks usually process a block of input at a time. If the file is very small and there are a lot of them, then each map task processes very little input, and there are a lot more map tasks, each of which imposes extra bookkeeping overhead. Ideally the dataset will be one large file dispersed on multiple blocks on HDFS so when loaded, transformed and stored into HBase, greater parallelism can be achieved. Be that as it may, datasets are not always so large that HDFS can distribute them on all nodes and get optimal parallelization. One way to mitigate this is by splitting the dataset in multiple smaller files and store them in one folder, so later the Pig script can read from all files in the folder instead of a specific file. Nevertheless, this step again is usually very fast especially compared to the steps that comprise the actual algorithm, so we do not recommend to spend too much time on optimizing the file sizes for better parallelism.

Even though we can achieve parallelism while processing files stored on HDFS, the control of degree of parallelism is difficult, more involved and at very low-level. For instance, we if we have a large file then HDFS will automatically partition it and distribute it on different nodes. Be that as it may, we do not have control of how HDFS will do this, on how many partitions it will store it, where are they going to be distributed, etc. On the opposite side, if we have a small dataset file, it will not be partitioned at all. To have a better control on this one would need to manually split the file in the desired number of chunks and then let HDFS distribute them. Moreover, this process has to be repeated again and again if we have continuous stream of data.

On the other hand, HBase offers many other services built on top of HDFS, among which is a much better control of the degree of parallelism. This is due to the fact that the data in HBase is stored in a structured manner, while having various mechanisms that simplify random reads and writes from rows and columns. Namely, HBase tables are divided into potentially many regions, while one or more regions are serviced by a region server. The tables can be horizontally and vertically segmented while they are physically stored in HBase. Because many machine learning applications access the data by rows, in this paper we will continue to discuss only horizontal segmentation. As HBase was designed with very large tables in mind, a common use case is the following. A table at creation has only one region, which is serviced by one region server (a physical node in the Hadoop cluster). When this table is loaded with data it gets bigger and at some point it will become too big, so HBase will split its region into two regions. Then the new region will be assigned to the same region server or can be moved to another region server. The default splitting threshold is 10 GB. There are numerous reasons why HBase was designed that way, and we will not go into details about that. From parallelization perspective, this can pose a challenge, because for the automatic splits there are no guarantees that every region will contain equal amount of data, when are the splits going to occur exactly, are the regions going to be served by different region servers (nodes) etc. Further more, if one is using Hadoop for research purposes only then the dataset may not be that large, thus never overcoming the threshold for splitting. To overcome this challenge we can pre-split the tables on creation. This in turn means that the table can be configured at creation time to be stored on as many-regions as needed. Usually the number of regions is a multiple of the number of HBase region servers. The logic for having more region servers than acutal nodes is because the nodes are multi-core machines, so different threads on the same node can service different regions.

Before loading the dataset in HBase, we need to define the table structure and create it. Column names and data types are provided when storing data in each row, so at creation time we need to only specify a table name and a column family. There are some advanced configuration features that can be specified, but they are not topic of this discussion. Be that as it may, there is one very important decision that we need to make before loading data in the table. Because HBase tables, unlike SQL tables, cannot have secondary indexes, the primary key (row key) needs to be designed according to the usage patterns of the table. There are many considerations when designing the row key and they are very important for production use of HBase tables. However, for scientific use and for parallelizing machine learning algorithms, we need a simple design that allows uniform data distribution across nodes. In most scientific datasets the data instances (i.e. rows) do not have ids for their instances, or if they do they are not used for the actual machine learning. Nevertheless, in order to store a row in a HBase table, it needs a row key. For flat flies like CSV or ARFF the row key can be the line number of the instance. However, sequential row keys are very bad choice for HBase tables because the inserts will always be on the last region, therefore having no parallelism during the load, a problem called Region Server hotspotting. There are multiple ways of overcoming this problem, and one of them is a technique called salting [38]. With this technique each sequential id is salted with a prefix. The prefix is usually the modulo number of the original sequential id and the number of regions. Even though, this is very important topic, the step of loading the datasets in HBase is not the focus point of this paper.

Once the dataset files are loaded into HDFS we need to transform them if needed and store them in HBase. If we have totally $M$ rows in the dataset, and $R$ regions, then we would like to distribute the data uniformly so each region gets $M/R$ rows. This in turn means that we need to specify $R-1$ split points when creating the table. If we use sequential ids for the row key (like the line number in the file), than these split points would be: $M/R, 2M/R, 3M/R, ..., (R-1)M/R$. If we use a more sophisticated row key design, then the split points should reflect that design. For instance, if we take the modulo number of the id and the number of regions, then each region would get almost the same number of rows. This design of the row key allows fast random reads and writes, and additionally it facilitates addition of new data to the table at a later time without needing to redesign the table for equally dispersed load across regions. The following example shows how a table can be pre-splitted on creation. The row key design is described with the function in listing 1. It returns a tuple in which the first element is the padded modulo number and the second part is the padded sequential id. The numbers are padded with zeros so that they are lexicographically sorted.

```
(pad(seq_id % num_regions), pad(seq_id))
```

Listing 1. Row key design

Once the HBase table that should contain the dataset is created with appropriate split points for even data distribution across the cluster, we can start loading the data. One can write pure MapReduce jobs in Java or Python. If we choose that path, then we need to write a separate map and reduce function for each task. However, by using the scripting language Pig Latin [42, 43] we can write scripts from a higher-level perspective. These Pig scripts generate MapReduce tasks in the background so the programming effort is simplified and the development time is greatly reduced. The downside of using Pig is that when Pig scripts are compiled into MapReduce jobs, there is some overhead. Additionally one may write a more optimal implementation of map and reduce functions manually than the ones generated by the Pig compiler. Nevertheless, these are corner cases and for longer running MapReduce tasks the overhead is insignificant in the range of up to couple of minutes in the worst case. When loading the data usually only a map phase is required. It reads the data from the HDFS files and stores it in HBase tables. In most cases when loading the data there is no grouping of keys, so a reduce phase is not needed. During this step we can add various methods for data preprocessing like discretization, transformation and other methods that rely only on the value in one row of the dataset.

### D. Processing HBase tables

After the dataset is loaded in a HBase table we can continue implementing machine learning algorithms. In general, this phase can be comprised of several substeps or iterations of data processing, depending on the nature of the algorithm that is being implemented. For each of the intermediate steps that we need to store some data we need a HBase table that will also be pre-split at creation time, similar to what we described in the previous subsection IV-C. What happens in the background when a particular HBase table is being processed, is very peculiar. Pig will determine the number of regions of the table and it will start that number of map tasks. Then each map task will process the data of a particular table region on the node where the data resides, therefore leveraging data locality. Note that, in order to benefit from the principle of data locality, each node in the cluster should run HDFS, HBase and YARN (MapReduce) services. The number of reduce tasks is by default one, but this can be also manually specified and does not depend of the table structures. If we specify more than one reduce tasks, then this will solicit a merge phase which will combine the intermediate results from each reduce task. Usually, for smaller datasets specifying more than one reduce task does not improve performance, on the contrary, it can degrade performance. However, being able to specify the number of reduce tasks provides flexibility that can improve the performance for larger datasets or some specific problems.

Fig. 2. Data flow during the parallel computation of information gain

During this phase, depending on the type of algorithm that is being parallelized, many tables can be used by multiple MapReduce jobs. In the following section V we illustrate this by when we parallelize the computation of information gain.

## V. Parallel computation of information gain

In this section we illustrate how we can use the framework proposed in section IV for computing the information gain of a dataset. Fig. 2 shows the data flow during the steps of the framework. The first steps of loading the data to HDFS and subsequently into HBase tables corresponds to what we explained in subsections IV-B and IV-C. Then, after the dataset is loaded in a HBase table, the processing takes place in three phases explained in the following subsections and they correspond to the specific properties of the current algorithm. This is an illustration how the framework step described in subsection IV-D can contain multiple phases consisted of many different MapReduce tasks that read and store data from several HBase tables.

### A. Calculating entropy of a dataset

As explained in section III, the definition of information gain requires calculation of the entropy of the whole dataset. In order to calculate it, first we need to count the number of instances per class, and afterwards to sum the class probabilities. Notably this is a very simple step and does not require parallelization because its complexity is $O(N)$, where $N$ is the number of instances in the dataset. Moreover, if we are interested in only sorting the features without having the actual information gain for each of them, then we can eliminate the entropy from equation (3). Be that as it may, for other applications we need the actual information gain. If we decide to parallelize this step, despite of its simplicity, then we need two MapReduce jobs. The Pig Latin script shown in listing 2 performs this. Each parameter starting with *$* can be passed to Pig script when it is started. In line 2 we specify that we only want to read the cell where the class is stored, denoted as $\$label$. The first MapReduce job that calculates the counts per class and the class probabilities corresponds to the code from line 2 to line 16. Then from line 17 till the end of the script the second MapReduce job calculates the entropy of the dataset. Notwithstanding, the peculiar thing that is demonstrated here is how easy MapReduce jobs can be combined into a flow. In like manner, one can combine many MapReduce jobs in one flow without any need of manual synchronization between them.

```
register '$udf_path' as paddingUDFs;
pfdata_tmp = LOAD '$table_dataset' USING
    org.apache.pig.backend.hadoop.
hbase.HBaseStorage('r:$label',
       '-loadKey=true'
) AS (rowkey:tuple(prefix_padded:chararray,
    id_padded:chararray),
  class:int);
pfdata_class_group = GROUP pfdata_tmp BY
    class;
pfdata_class = FOREACH pfdata_class_group
    GENERATE
  flatten(group) as class,
  COUNT(pfdata_tmp.class) as count;
pfdata_class_prob = FOREACH pfdata_class
    GENERATE
  class,
  count,
  (count/$num_instances) as prob:double,
  ((-count/$num_instances)*
  UDFs.log2(count/$num_instances)) as
      entropy:double;
total_entropy_group = GROUP pfdata_class_prob
    ALL;
total_entropy = FOREACH total_entropy_group
    GENERATE
  SUM(pfdata_class_prob.entropy) as
      entropy:double;
STORE total_entropy INTO
    '$hdfs_export_entropy' USING
    PigStorage('\t');
```

Listing 2. Pig script for calculating entropy of a dataset

### B. Counting instances per feature index, feature value and class

After the entropy is calculated, the definition of information gain, as presented with (3), requires counts of instances per feature index, feature value and class. This step is the most computationally expensive step in the algorithm. The source code of this step is shown in listing 3 and it is based on the pseudo code we have reported in [32]. Parameters that are passed to the script are the table names, number of features, index of the class value, number of padding digits, etc. First we need to load the dataset from a HBase table (lines 3 through 6). A row of the dataset is represented by the row key, and the dictionary $r$ in which keys are the column names and values are the actual values. This representation allows us to store only the non-zero values of a dataset. Then we need to expand each row of the dataset (denoted as dictionary $r$) to tuples: *(feature index, feature value, class, 1)*. This is performed in lines 7 through 8 with the user-defined function *decode_sparse_row*. If the dataset has $M$ rows (instances) and $N$ columns (features), then from each row we will generate $N$ tuples because now also the zero-valued cells are also included. To summarize, when the whole dataset is processed $M \times N$ tuples will be generated. These tuples are afterwards grouped by the key *(feature index, feature value, class)* in lines 9 through 12, and finally the count is stored in another table (lines 13 through 15). All of the code in listing 3 is compiled in one MapReduce job. The number of generated map tasks will be equal to the number of regions of the input table (denoted by *$table_dataset* in the script), and the number of reduce tasks is set by the parameter *$parallel*.

```
1  register '$udf_path' using jython as UDFs;
2  set default_parallel $parallel;
3  pfdata_tmp = LOAD '$table_dataset' USING
       org.apache.pig.backend.hadoop.hbase.
4    HBaseStorage('r:*', '-loadKey=true') AS
5      (rowkey:tuple(prefix_padded:chararray,
          id_padded:chararray),
6      r:map[]);

```

Listing 3. Counting number of instances per feature index, feature value and class with Pig Latin

### C. Calculating the information gain

Having the counts calculated in the previous step V-B, this step only calculates the probabilities and entropies in (3) and stores this result in HBase or HDFS. Nevertheless, it is usually the second longest running step from this list. The code for this is shown in listing 4. First in the lines 3 through 8 it reads the tuples *(feature index, feature value, class, instance_count)* which were calculated in the previous step, and now are stored in the table *$table_feature_index_tmp*. This table was properly pre-splitted on creation so the Pig script will be compiled in one MapReduce job with multiple map tasks. In particular, if the number of features is $N$ and the desired number of regions of the table is $R$, then we specify $R-1$ split points, and in that way each region will contain the tuples for $N/R$ features. We acknowledge that this might not be ideal distribution because some features might have significantly more distict values then others, but nevertheless, it provides decent parallelism. Given that this step is not as computationally intensive as the previous, we did not consider it necessary to further optimize this table. Then when the MapReduce job is compiled, it will have $R$ map tasks and each of them will work with the data of the appropriate table region.

```
1  register '$udf_path' using jython as UDFs;
2  set default_parallel $parallel;
3  feature_value_class_counts_tmp = LOAD
       '$table_feature_index_tmp' USING
       org.apache.pig.backend.hadoop.hbase.
4  HBaseStorage('r:instanceCount',
5          '-loadKey=true'
6  ) AS (
7    id:tuple(feature_index:chararray,
        feature_value:int, class:int),
8    instanceCount:double);
9
```

```
10 feature_value_class_counts = FOREACH
       feature_value_class_counts_tmp GENERATE
11 flatten(id) as (feature_index, feature_value,
       class),
12 instanceCount;
13 feature_index_group = GROUP
       feature_value_class_counts BY
14      (feature_index);
15 feature_index_info_gain = FOREACH
       feature_index_group GENERATE
16    flatten(group) as feature_index_padded,
17    flatten(UDFs.
18    calc_feature_info_gain(($entropy), group,
          feature_value_class_counts,
          ($num_instances))) as info_gain:double;
19 STORE feature_index_info_gain INTO
       '$table_feature_index_info_gain' USING
       org.apache.pig.backend.hadoop.
20 hbase.HBaseStorage('r:ig');
```

Listing 4. Calculating information gain with Pig Latin

The most peculiar part in the script in listing 4 is at line 13. Here all tuples are grouped by feature index. When the Pig Script is translated into a MapReduce job, the during the map phase the feature index is emitted as a key, and during the reduce phase all tuples that are for the same key (in this case the feature index) are grouped together on the same node. The Python UDF *calc_feature_info_gain* utilizes this because for each feature it has the count of instances of all its values per class. Having that it is easy to compute the information gain by (3). Finally, the results can be stored in a HDFS file or in a HBase table. In this script we store them in the HBase table $\$table\_feature\_index\_info\_gain$, performed in the last line.

## VI. Experiments

With intention to monitor various aspects of the parallel implementation, a relatively large dataset was essential. Furthermore, we did not want to focus on significant preprocessing like discretization or transformation of values so we can easily compare our results with other research. The FedCSIS AAIA'14 data mining competition dataset [44] has exactly those properties. It is a sparse matrix with 50000 instances and 11852 numeric features, most of which are have the value 0 or 1. There are about 0.9% non-zero values in it. It represents a multi-label problem that has 3 binary labels, that can be merged with the powerset technique as used in [45] into one one-label multi-class problem that has 8 ($2^3$) possible classes.

We have tested the same dataset on three completely different Hadoop clusters. Each of them was running the same version of Apache Hadoop 2.3.0 (integrated in Cloudera CDH 5.3.0). This is an extension to what we did in [32], where we analyzed the speedup only on one on-premises cluster. Additionally in this paper we analyze the effect of the number of reduce tasks, while in [32] we have used only one reduce task. Finally, the most important difference is that we have evaluated the scalability of the approach by replicating the dataset 80 times. We have performed this by replicating the dataset horizontally so from each instance there are 80 exact copies. This in turn results in a dataset that has 4 million instances and almost 12 thousand features. It should be noted that the computational complexity of the algorithm depends only on the dataset size and not on its sparsity or feature types.

Keeping in mind that our goal is to evaluate the execution time and speedup based on the cluster size, the expansion of the dataset serves this purpose.

The first cluster (denoted by *Amazon32* in the remaining of the paper) was deployed on Amazon AWS. It contained a total of 32 nodes, each of them a m1.xlarge instance with 15GB RAM and 8 compute units (4 cores with 2 compute units each). From the 32 nodes, 8 were hosting HBase Region Servers and HDFS Data Nodes, 3 were specifically dedicated to HDFS Data Nodes and 19 were running only YARN. We acknowledge that this configuration may not be optimal for the current task, but we were given access to this cluster without the ability to modify its configuration. Therefore we have decided to run tests using up to 8 nodes at a time, because when using more it would be difficult to estimate the speedup.

The second cluster (denoted by *FCSE24* in the remaining of the paper) was deployed on-premises at the Faculty of Computer Science and Engineering (FCSE) at the Ss.Cyril and Methodius University, Skopje, Macedonia. It had a total of 24 nodes, each of them an Intel Xeon Processor E5640 with 12M Cache, 2.66 GHz, 24 GB RAM, 4 cores and 8 threads. From them 21 were configured to run the following services: HBase Region Servers, HDFS DataNodes and YARN MapReduce NodeManagers. The remaining nodes were used for other Hadoop and Cloudera management services.

The third cluster (denoted by *FCSE65* in the remaining of the paper) was also deployed on-premises and it was an extended version of the second, containing a total of 65 nodes, of which 54 were running the following services: HBase Region Servers, HDFS DataNodes and YARN MapReduce NodeManagers. A variant of this cluster with 59 instead of 54 active nodes was also used for the experiments presented in [32].

During our tests none of these clusters was executing other tasks. On all of them we ran tests with different table structures in order to simulate clusters with smaller sizes. By pre-splitting the HBase tables to a specific number of regions we were able to force Pig Latin to start the desired number of map tasks for each job. For all these configurations we are computing the speedup of the parallelization against a cluster with one node. We are simulating the one-node cluster by configuring the tables to have only one region, thus all MapReduce jobs that read from those tables have only one map task. We have tested using different number of reduce task by setting a configuration property in the Pig scripts. The remaining of this section is divided in two, VI-A containing summary information for all steps that are fast and did not benefit significantly from the parallelization, and VI-B containing detailed information about the step described in V-B, which was the most computationally expensive. Table I shows the information gain of the top 50 features which can be used for verification of the correctness of our implementation. In the following subsections we describe the results from our experiments.

### A. Computationally cheap steps

The dataset was stored in two files: one containing the data in EAV (entity attribute value) format, and one containing the labels. The EAV format greatly reduces the file sizes to 72 MB compared to 1.1 GB when stored in full format as CSVs.

TABLE I. TOP 50 FEATURES ORDERED BY INFORMATION GAIN

| 21 | 675 | 0.0282140 | 46 | 5925 | 0.0231852 |
| 22 | 73 | 0.0273487 | 47 | 8114 | 0.0225087 |
| 23 | 7275 | 0.0266788 | 48 | 5330 | 0.0223354 |
| 24 | 7419 | 0.0266100 | 49 | 1156 | 0.0219374 |
| 25 | 1244 | 0.0262854 | 50 | 2701 | 0.0218273 |

The effect is that copying them to HDFS is very fast (about a second). The step described in subsection IV-C was actually two MapReduce jobs. The first is for loading the labels which took 58 to 70 seconds, and the second for loading the data which took 130 to 145 seconds on the on-premises and 175 to 195 seconds on the Amazon cluster. Calculating the entropy of the dataset, described in section V-A, took 118 to 152 seconds on both clusters. The step described in subsection V-B is analyzed in more detail in the following subsection VI-B. After it completed and stored the results in a pre-splitted table, calculating the information gain of each feature, described in subsection V-C, took 69 to 97 seconds on both clusters. The final step, the export of the list of information gain of all features, took 46 to 70 seconds. All of the MapReduce tasks had an overhead of up to 60 seconds for compilation of the Pig script, generating JAR files, distributing them on the cluster and negotiating resources.

When preparing the 80 times replicated dataset we stored it in a slightly different format so we can later process the data and the labels at the same time. Namely, each line of the enlarged file contains pairs of the column indexes and values of all non-zero features. This representation takes 3 GB, whereas if we stored it in pure EAV format we would need about 5.5 GB (80 × 72) owing to the redundancy of line numbers. This does not have effect of any of the other steps except of how is it stored in HDFS. This file when copied on HDFS was automatically fragmented on 24 nodes (not counting the nodes for replication). On Fig. 3 is shown the data load time depending on the cluster configuration. It should be noted that even though there are 54 active nodes in the cluster in some cases we have intentionally created tables with more table regions (108, 162 and 216) aiming to leverage the multiple cores on each node.

Important to realize is that the 24 HDFS nodes on which the file is dispersed is an upper bond to the maximum number of map tasks when processing the file from HDFS and storing it in HBase tables. As a result, even though some tables have more than 24 regions during this phase it does not have an effect of the parallelism. Nevertheless, in the next steps when the data source is an HBase table, its number of regions dictates the number of generated map tasks. Another important thing to notice is that when using less nodes than 24 for the HBase tables, the number of map tasks is still 24 because this is dictated by the data source (HDFS file) and not by the destination (HBase table). From Fig. 3 it is evident that the load time is not reduced when more than 24 nodes HBase table regions are used. Also we see that when using less then 24 table regions the bottle neck is during the writes to the HBase tables. Finally, we want to emphasize the HBase table with only one region (the right-most case on Fig. 3). Even tough it was configured to have only one region by not specifying any split points for it at creation time, during the load it got larger than some configurable threshold, so HBase automatically splitted in two regions. Nevertheless, those two regions are on the same node.

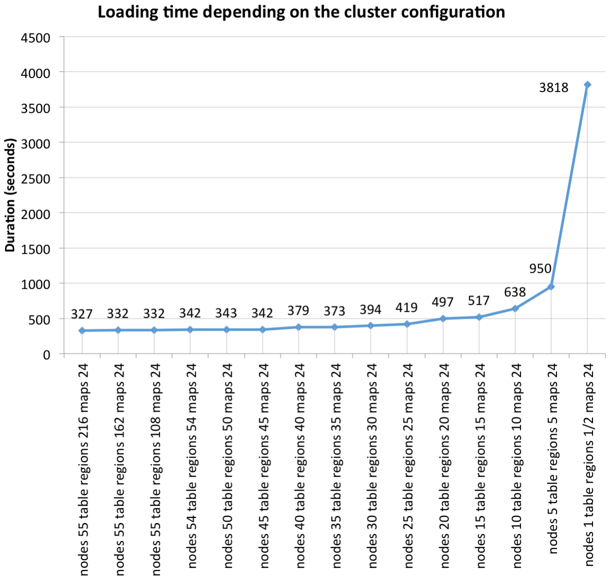

Fig. 3. Data load time for the 80 times replicated AAIA'14 dataset depending on cluster configuration

### B. Computationally expensive step - Calculating counts

The step described in subsection V-B was the most complicated and the speedup for it varied significantly depending on the cluster size and configuration. The remaining of this subsection describes details of the impact of the parallelization of this step and all listed speedups and durations are only for it.

First, we conducted experiments using the original AAIA'14 dataset on the FSCSE65 cluster. These results were published in [32], so here we are only reviewing them. These experiments were using only one reduce task, the default in Pig Latin. Also here we used more map tasks than actual nodes because each node is a multi-core machine. The results confirmed that indeed using more map tasks is beneficial, which is intuitively logical. Nevertheless, when we further increase the number of map tasks, the performance gradually degrades. The explanation for this is that as the number of map tasks gets larger, the operating system on the nodes needs to spend more time on task switching, swapping, while

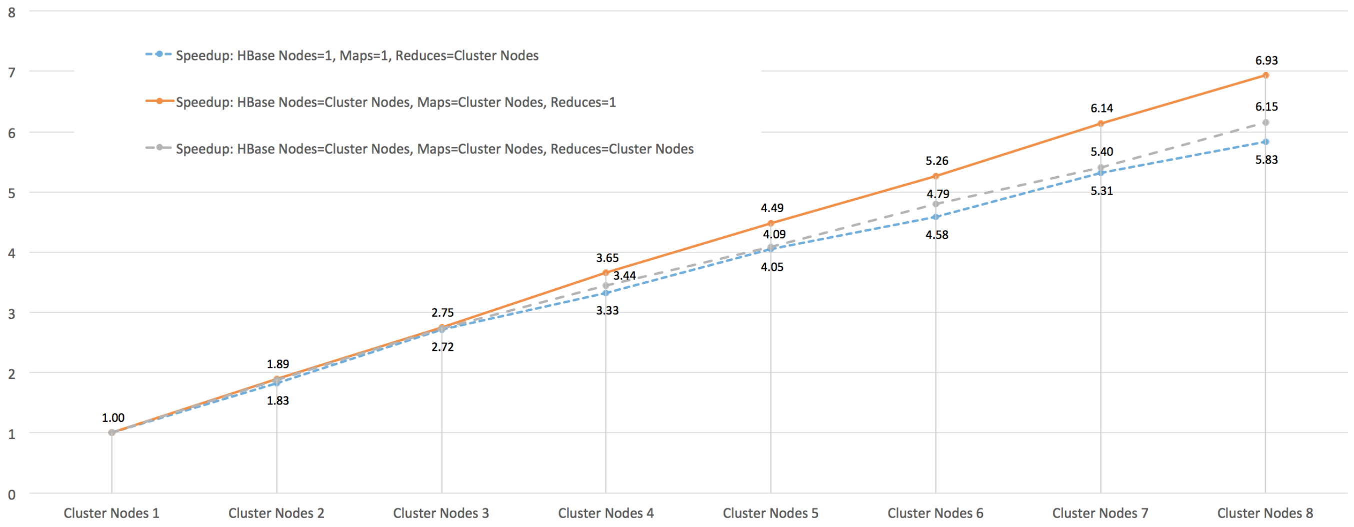

Fig. 4. Speedup depending on the number of active nodes, map and reduce tasks on the Amazon32 cluster

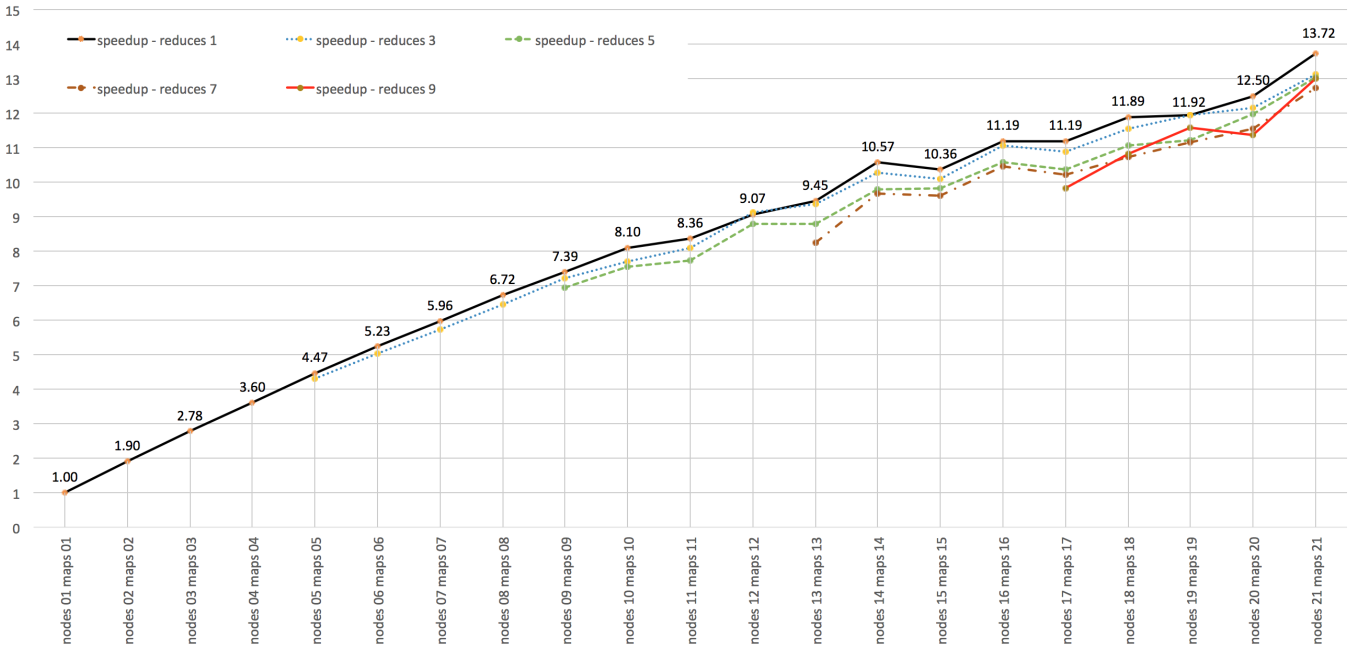

Fig. 5. Speedup depending on the number of active nodes, map and reduce tasks on the FCSE24 cluster

also needing to run many Hadoop and other services in the background. The total duration of this step on the one-node cluster was 3656 seconds, while the quickest solution obtained when using 59 nodes and 177 map tasks took 129 seconds on this cluster and the corresponding speedup was 28.34.

Then we continued our experiments on the Amazon32 cluster, trying to determine the impact of the number of nodes, maps and reduces. We have tried three options when trying to utilize the nodes of the cluster: use as much as possible nodes to run map tasks and have only one reduce task; use as much as possible nodes to run both map and reduce tasks; and use only one node for one map task and use all available nodes for reduce tasks. The speedup compared to the one-node cluster depending on the available nodes using these three options are shown on Fig. 4. It indicates that for this dataset it is best to have only one reduce phase, but use as many nodes as possible for the map tasks. This, in fact, makes sense because the work is performed during the map phase and during the reduce phase these results are only grouped together. Having more than the default of one reduce task actually increases the duration because the partial results in each reduce task need to be merged together. The total duration of this step on the one-node cluster was 4732 seconds, while the quickest solution with speedup of 6.83 took 693 seconds.

Aiming to confirm these findings we continued testing on the FCSE24 cluster, using the same approach. Additionally

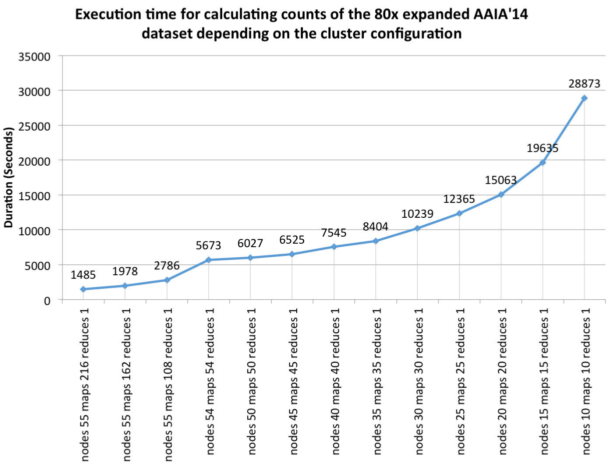

Fig. 6. Execution time for calculating counts of the 80x replicated AAIA'14 dataset depending on the cluster configuration

we have tried using 1,3,5,7 or 9 reduce tasks, depending on the number of available nodes. Our intent was to confirm that using only one reduce task (the default value in Pig Latin) will be more appropriate for a dataset of this size. The charts shown on Fig. 5 indeed confirm this assumption. The greatest speedup was always achieved when using only one reduce task, regardless of the number of available nodes. The total duration of this step on the one-node cluster was 3637 seconds, while the quickest solution with speedup of 13.72 took 265 seconds.

Finally, we have analyzed the execution time on the FCSE65 cluster using the 80 times replicated dataset. We have started experimenting using 54 nodes and gradually reducing the number of nodes by 5. When using 54 nodes we have also tried used 2, 3 and 4 times more table regions than actual nodes. Fig. 6 shows the execution times depending on the various configurations. In all cases the number of reduces was 1. Owing to the fact that this dataset is quite large, executing this step on smaller clusters took a significant amount of time. Additionally because HBase splitted the table on the one node cluster to two regions, using that execution time for calculating speedup would have been inconsistent with the previous setups. Therefore, for this experiment on Fig. 6 we are reporting the execution time and not the speedup. By performing this experiment we have confirmed that the proposed parallel implementation is scalable to large datasets for which the processing with a sequential implementation would be quite difficult if not impossible.

## VII. Conclusion and future work

In this paper we have reviewed the applications of the metric information gain for ranking individual features, discretization of continuous valued features, improving decision tree performance, localization, rough sets, etc. In a Big Data setting those tasks become a significant challenge, and therefore the need for its parallelization. In this paper we have proposed a parallel implementation of it. In oder to facilitate this, we have proposed a generic framework for data parallelization and then all steps from the algorithm for computation of information gain were parallelized using it. The benefits from using the scripting language Pig Latin were evident by the code listings which allowed fast development of MapReduce jobs. We have also demonstrated how can we manually set the degree of parallelism by pre-splitting the HBase tables so they have optimal number of regions and even data distribution across regions. The experiments confirmed that for this type of algorithm it is best to use only one reduce task. We have also validated that the multi-core nodes are providing increased performance when they execute more map tasks simultaneously. By deploying the implementation on Amazon AWS and on-premises clusters we have demonstrated the portability of the approach. The correctness of the implementation was verified by comparing the ranked features with the results we obtained from WEKA. Not to neglect were also the findings related to the scalability of the approach to an even larger dataset with millions of instances and dozens of thousands of features.

In our future work we plan to utilize the proposed implementation for other task In that manner, we also need to propose valid data transformation and normalization techniques, so we can generalize the approach and make it available for datasets that contain non-discretized continuous or nominal features. Additionally, we aim to apply the current parallelization for building decision trees. Finally, we plan to parallelize other more advanced feature selection algorithms using a similar framework.

## Acknowledgment

This work was partially financed by the Faculty of Computer Science and Engineering at the Ss.Cyril and Methodius University, Skopje, Macedonia.

*Abstract*—**We investigate whether language models used in automatic speech recognition (ASR) should be trained on speech transcripts rather than on written texts. By calculating log-likelihood statistic for part-of-speech (POS) n-grams, we show that there are significant differences between written texts and speech transcripts. We also test the performance of language models trained on speech transcripts and written texts in ASR and show that using the former results in greater word error reduction rates (WERR), even if the model is trained on much smaller corpora. For our experiments we used the manually labeled one million subcorpus of the National Corpus of Polish and an HTK acoustic model.**

*Index Terms*—**automatic speech recognition, morphosyntactic language model, written and spoken language comparison**

## I. Introduction

STATISTICAL language models (LM) are employed in various natural language processing applications, such as machine translation, information retrieval, ASR [21], or part-of-speech tagging [20]. Generally, they describe relations between words (or other tokens), thus enabling to choose most probable sequences. This proves to be especially useful in speech recognition, where acoustical models usually produce a number of hypotheses, and re-ranking them according to a language model can substantially improve recognition rates [20],[4],[6].

Despite extensive research into alternative techniques, n-gram models remain a technology of choice for most modern ASR systems. They are based on Markov assumption, which states that probability of a certain word is dependent only on its n-1 predecessors. It should be noted that efficiency of n-gram models is heavily language dependent. They correspond well to grammatical structure of positional languages (such as English), but in case of Polish and other highly inflected languages, words order is not a key indicator of relations between them [8]. The main difficulty in language modelling and learning problems in general is the curse of dimensionality. Higher-order models are usually more accurate, but with more dimensions the volume of space increases so fast that available data quickly become insufficient [2]. This problem is amplified in case of Polish due to complex inflectional rules resulting in a variety of word-forms.

Several techniques were proposed to account for long-span word dependencies and address the data sparsity problem. One of them are part-of-speech (POS) n-grams, which cluster words into categories based on grammatical classes [12], [14]. Such models are easy to build and allow the use of higher order n-grams, since there are far fewer grammatical categories than words. Furthermore, they can be trained on much smaller corpora, which is especially important for under-resourced languages. Written texts are usually easier to obtain than speech transcripts and consequently language models are commonly trained on the former [5] [18].

## II. Motivation

There has been a lot of studies in the humanities and social sciences dealing with the comparison of speech and text. It is known that there are fundamental dissimilarities between oral and written language in terms of grammatical structures, sentence lengths, choice of words etc. [3]. Whether those differences can be captured by means of statistical analysis, remains an open question.

The main motivation behind our study was to investigate whether LM based on written texts are an appropriate source of information about spoken language for automatic speech recognition. We conducted a comparative analysis of two corpora. One of them consisted of speech transcripts, while the other contained only written texts. We were looking for general features allowing to distinguish between two channels of communication (speech vs. text) rather than stylistic differences resulting from distinct language domains. That is why traditional methods of corpus comparison based on word frequencies were not applicable [15]. We therefore decided to compare POS n-grams in order to find grammatical patterns typical of either spoken or written language. Our initial hypothesis holds that there are statistically significant differences between those two n-gram sets. If this assumption is correct, it would imply that training LM solely on speech transcripts could lead to greater WERR in ASR systems.

## III. Related Work

The idea of comparing speech and text corpora in terms of POS tags was motivated by previous research concerning the use of morphosyntactic n-grams in speech recognition of Polish. Until recently, there was little interest in using POS tags in ASR. In [22] a POS tagger was tested as a possible improvement in speech recognition of Polish. The results were negative, because the tagger frequently produced ambiguous output. This issue was later addressed in [11] by reducing model specificity (only grammatical classes were taken into account). It was concluded that simplified POS tags can be very useful for building statistical models of Polish.

In [12] an optimal set of grammatical categories was experimentally derived. Thirteen trigram language models were built, each employing both grammatical classes and one selected grammatical category. Then they were compared to a model based only on grammatical classes (hereinafter called POS-only model) in terms of WERR. Only three categories (gender, number, and case) offered significant improvements over the POS-only model. Surprisingly, combining those categories resulted in a model performing insignificantly better than the POS-only model. For this reason, our research is mostly based on the POS-only model, although we also take into account three aforementioned categories.

## IV. Data Preparation

The National Corpus of Polish (NKJP) is divided into two parts: manually annotated 1-million corpus (1MC) and automatically annotated 1-billion corpus (1BC). Texts are labeled on several lavels: word and sentence boundaries, morphosyntactic tags, named entities, and syntactic groups. Annotation in 1MC is conducted very strictly, as each element was labeled by two independent researchers and then corrected by a super-annotator in case of a tie. The corpus includes diverse materials: classic literature, daily newspapers, scientific journals, and a variety of short-lived and Internet texts. Most importantly, it also includes speech transcripts from parliament proceedings, real-life conversations, radio, and television [13]. The proportion of speech transcripts to text data in 1MC is 109 919 (speech) vs. 1 091 981 (text) tokens.

Each segment in NKJP belongs to one of 35 grammatical classes. They are far more detailed than traditional parts of speech (for example there are 14 distinctive verb classes and 4 adjective classes). Obtaining information about grammatical classes was straightforward and required parsing XML label files. Unfortunately each paragraph is described by several label files stored in a separate directory, so they had to be processed individually. Although rather inconvenient, this design prompted us to take advantage of parallel processing, which will later be useful in case of 1-billion corpus.

Extracting grammatical categories was a more demanding task, mainly because category tags take a form of a single, colon-delimited string. For example, the word objęcia has a following tagging: ger:sg:gen:n:perf:aff. The first element is the grammatical class (POS) tag, followed by a set of grammatical category tags. This notation is further complicated by the fact that each grammatical class has a different set of categories. For example, adjectives have gender, number, case, and degree, while verbs are described by their number, person, and aspect. As it has already been said, only gender, number, and case were taken into account, as they play primary role in agreement relation.

It should be noted that we ignored all non-lexical backchannels and other noise in the transcripts. We also discarded all utterances containing incomprehensible words, as we wanted to focus on grammatical properties of the spoken language.

## V. Statistical Comparison

Selecting appropriate statistical tools was yet another challenge. We considered three methods: the Spearman's coefficient, χ2-test and log-likelihood statistic. We concluded that the first method is not applicable to POS n-grams because of its tendency to overestimate differences for rare units. We also rejected the χ2-test because its null hypothesis is that compared corpora comprise words drawn randomly from a larger population. Since words in texts are obviously not random, the null hypothesis is defeated for almost all common words [9]. It is especially problematic for POS n-grams, where there are typically several very common units (which can be expected to give high χ2 values) and a lot of rare units (for which the χ2 test is not applicable). We decided to use the third method, as it is applicable to corpora of different sizes and has been reported to work well with POS n-grams [15]. Given the frequency lists, we build a contingency table for each POS n-gram:

Table I.
Example contingency table.

| | **Corpus A** | **Corpus B** |
|---|---|---|
| Count of unit: | $n_A$ | $n_B$ |
| Count of other units: | $N_A-n_A$ | $N_B-n_B$ |
| Total: | $N_A$ | $N_B$ |

Values $n_A$ and $n_B$ are called observed values (O). We then calculate expected values (E) according to the formula:

$$E_i=\frac{N_i\sum_i O_i}{\sum_i N_i} \qquad (10$$

Using the data from Table 1, we obtain $E_A=\frac{N_A(n_A+n_B)}{N_A+N_B}$ and $E_B=\frac{N_B(n_A+n_B)}{N_A+N_B}$. The log-likelihood value is then calculated according to the following formula:

$$2\sum_i O_i \ln\left(\frac{O_i}{E_i}\right) \qquad (2)$$

In our case this equals:

$$2n_A \ln\left(\frac{n_A}{E_A}\right) + 2n_B \ln\left(\frac{n_B}{E_B}\right) \tag{3}$$

The higher this value, the more significant is the difference between two frequency scores. LL of 3.8 or higher is significant at the 5% level. For the purpose of comparison, we used five corpora of written texts and five corpora of speech transcripts (full corpus, two half-corpora and two smaller samples). We then performed a round robin comparison: for each pair of corpora we calculated the number of units for which the LL value was greater than 3.8. Averaged results are presented below. S-S and T-T denote intra-corpus comparisons (speech and text, respectively). S-T denotes a comparison between speech and text corpora.

TABLE II.
AVERAGE NUMBER OF N-GRAMS WITH DIFFERENCES IN FREQUENCY SIGNIFICANT AT 5% LEVEL. VALUES IN BRACKETS ARE STANDARD DEVIATIONS.

| n | S-T | S-S | T-T |
|---|---|---|---|
| 1 | 30.3 (2.0) | 14.1 (5.1) | 17.2 (3.6) |
| 2 | 418.8 (42.6) | 127.2 (28.2) | 182.5 (49.0) |
| 3 | 2281.4 (482.7) | 1205.1 (215.8) | 1628.4 (274.3) |

The log-likelihood analysis reveals large differences in frequencies of POS-tags. The LL scores were significant at 5% level for more than 30 unigrams (out of 35). This number is much lower in case of intra-corpus comparisons. The same holds true for higher-order n-grams (bigrams and trigrams). As stated before, we used five corpora for speech and text (resulting in 10 intra-corpus comparisons and 25 inter-corpus comparisons), so observed differences are not an effect of differing corpus sizes. Qualitative analysis of POS tags with highest LL score could reveal usage patterns characteristic for written and spoken language.

Another test involved calculating the percentage of common n-grams in the set of k most popular units:

$$\frac{|K_1 \cap K_2|}{|K_1 \cup K_2|} \cdot 100 \tag{4}$$

In the above formula, K1 and K2 denote sets of k most popular n-grams in compared corpora. We considered unigrams, bigrams, and trigrams. We decided to set k in relation to the total number of units (5%, 10%, and 20% of all units). Table 3 presents calculated values. “S-T” denotes a comparison of full speech corpus vs. full text corpus. “S-S” and “T-T” denote a comparison between two halves of the same corpora (the split was made by randomly assigning each paragraph into one of two subcorpora).

The test reveals significant differences in POS n-gram distributions. The values in the first column (speech vs. text) are not only lower, but also decreasing with the model complexity. The values in the second and third column (speech vs. speech and text vs. text) are much higher and stay the same as the order of n-grams increases. This shows that grammatical patterns typical for spoken or written language can be captured with morphosyntactic n-gram models.

TABLE III.
PERCENTAGES OF COMMON UNITS AMONG K MOST POPULAR N-GRAMS.

Unigrams

| k | S-T | S-S | T-T |
|---|---|---|---|
| 2 | 100.0 | 100.0 | 100.0 |
| 5 | 100.0 | 100.0 | 100.0 |
| 10 | 90.0 | 100.0 | 100.0 |

Unigrams with categories

| k | S-T | S-S | T-T |
|---|---|---|---|
| 20 | 85.0 | 100.0 | 100.0 |
| 40 | 87.5 | 95.0 | 98.0 |
| 80 | 85.0 | 97.5 | 98.8 |

Bigrams

| k | S-T | S-S | T-T |
|---|---|---|---|
| 35 | 78.6 | 94.3 | 100.0 |
| 70 | 77.1 | 95.7 | 100.0 |
| 140 | 74.3 | 93.6 | 98.6 |

Bigrams with categories

| k | S-T | S-S | T-T |
|---|---|---|---|
| 400 | 70.6 | 88.8 | 97.8 |
| 800 | 72.8 | 87.4 | 95.8 |
| 1600 | 70.5 | 85.9 | 94.6 |

Trigrams

| k | S-T | S-S | T-T |
|---|---|---|---|
| 250 | 64.6 | 89.2 | 97.2 |
| 500 | 63.9 | 90.2 | 96.4 |
| 1000 | 64.6 | 89.2 | 95.8 |

## VI. PERFORMANCE IN ASR

The results of statistical analysis indicated that language models trained on speech transcripts or written texts would have different properties and therefore give different results when applied to ASR. In order to test this hypothesis, we have built several language models and employed them in rescoring of the hypotheses produced by HTK (without any LM or grammar) for several hundred Polish sentences. For tagging we used Concraft-pl, a conditional random field tagger for Polish which had proved to be particularly effective in ASR applications [17],[12]. The rescoring was done by combining the probabilities of the acoustic and morphosyntactic model

$$P(h_i)=P(h_i)_{LM}^{\alpha}\cdot P(h_i)_{AM}^{1-\alpha} \qquad (5)$$

where

$P(h_i)$ – the probability of the i-th hypothesis,

$P(h_i)_{LM}$ – the probability of the i-th hypothesis according to the language model,

$P(h_i)_{AM}$ – the probability of the i-th hypothesis according to the acoustic model,

$\alpha$ – the weight of the LM component.

The models were tested on several audio corpora. The first one (K1) includes 107 sentences spoken by one male voice, without any added noise, but recorded in an office with working computers. It consists of political speeches and spoken fragments of political song lyrics. The second corpus (K2) includes 23 samples spoken by a young female professional speaker. The third corpus (K3) consists of 221 short utterances recorded during various tests of speech/speaker recognition systems at AGH University of Science and Technology with addition of recordings from meetings of the Department Council. This corpus includes many various voices (one speaker says no more than six sentences) and recording devices, often with a natural random noise due to bad acoustic conditions (reverberation, voices in the background, traffic from outside etc.) We also used some recordings from LUNA, a corpus of telephone conversations from a call center of Warsaw public transport [10]. 192 samples of various female voices (K4) and 226 of male voices (K5) were used. These are informal utterances with many questions. The corpus is full of grammar mistakes, very common in natural conversations. The last test corpus (K6) consists of 86 recordings randomly chosen from Polish Global Phone corpus [16]. It is a corpus of speech dictated from an everyday journal.

The union of the corpora was divided into two subsets: a tuning set containing 15% randomly chosen sentences, used to estimate the alpha parameter, and a testing set, containing the remaining sentences. The text and the speech corpora were used to build two language models (LMs): one containing only POS tags (POS-only) and the other containing POS tags together with gender, number and case tags (POS-gnc). In each case a trigram model was built, smoothed using Witten-Bell method [19], due to their small size.

The comparison of speech and text based LMs was conducted by measuring the Word Error Rate Reduction (WERR) obtained with a given model. The results of the test are given in Table 4. LMs with Speech prefix are based on the Speech sub-corpus of 1MC, with Text prefix – on the Text sub-corpus, and with Text-sample, on a text sub-corpus of the same size as the Speech sub-corpus. The best result is obtained for the LM based on the speech corpus using POS, gender, number and case tags. The difference between the best result and the second result (Text-sample-POS-gnc) is statistically significant (paired Student's t-test, n=724, P < 0.028). Interestingly, although the Speech-POS-only LM performs better than the Text-POS-only LM, the difference is not statistically significant.

Table 4.
Performance of different LMs in ASR.

| LM | WERR [percentage points] |
|---|---|
| Speech-POS-gnc | 29.5 |
| Text-sample-POS-gnc | 28.0 |
| Text-POS-gnc | 27.8 |
| Speech-POS-only | 27.1 |
| Text-POS-only | 26.5 |
| Text-sample-POS-only | 25.9 |

## VII. Conclusions

Building language models based on POS n-grams is a promising technique in ASR of highly inflected languages. Benefits include simple structure, substantial dimensionality reductions, and noticeable improvements in performance of ASR systems [12]. Our analysis shows that it is possible to discriminate between speech and text data using only POS n-grams. It implies that morphosyntactic models trained on written texts do not accurately reflect the grammatical structure of spoken language. This hypothesis was confirmed by the ASR experiments. The Speech-POS-gnc model outperformed all text-based models, even those trained on ten times more data. The experiment also show that grammatical categories (gender, number, and case) carry important information about the structure of inflectional languages. Including them improved recognition rates in all cases.

# Towards the automatic motion recovery using single-view image sequences acquired from bike

Jakub Kolecki
AGH University of Science and Technology
al. Mickiewicza 30, 30-059 Kraków, Poland
Email: kolecki@agh.edu.pl

***Abstract*—This paper describes the design, implementation and results of the image-based ego-motion estimation algorithm. As a source data the images captured from the bike platform are used. The device is supposed to be a part of a mobile mapping system prototype. Firstly the feature detection and matching is carried out providing the set of characteristic points in all images in the sequence. The 5-point solution based on the Gröbner basis is used to solve for essential matrices and to reject outliers. Least-square relative pose model fitting is accomplished using quaternion-based bundle adjustment. In the next step the modified Horn formula is used to recover bike trajectory up to the absolute orientation. Within this step the scene structure recovery is provided in the form of a point cloud. Finally ground control information is used to obtain data geo-referencing and the accuracy analysis. Obtained results provide satisfying robustness and accuracy. However some improvements and development scenarios are suggested.**

## I. Introduction

CURRENTLY imaging sensors are extensively used as components of mobile mapping systems (MMSs), mobile robots and unmanned aerial vehicles. Each camera is a source of usually large number of images, captured with the specified frequency. Acquired image sequences may be processed to provide automatically extracted mapping information using algorithms refered as a dense point cloud generation or structure from motion (SFM). Additionally images may be utilized to estimate motion trajectory of the vehicles. Such application is often called the visual odometry. The real-time trajectory estimation is applied in the navigation. The visual navigation can take place autonomously or together with the inertial/GNSS sensors, completing a multi-sensor navigation system. Parallel navigation and mapping are sometimes combined together in the SLAM procedure.

Basically mapping applications do not require real time computation of a trajectory. The accurate trajectory computation is conducted in the post processing and is a crucial step in the mobile mapping workflow as it greatly influences the accuracy of final products. Processing of the image sequences can be divided into two main steps:

- feature detection and matching
- ego-motion estimation, based on the detected features

In the machine vision feature detectors try to imitate humane vision to search for some characteristic points (keypoints), that are suitable to be traced in subsequent images. The feature correspondence is tested using descriptors and detectors that try to simulate the mental process [1]. Corners are a typical example of features suitable for tracing. The result of a feature detection is a list of keypoints' IDs and their coordinates provided in the image 2D coordinate frame. Evaluation of particular feature detectors are not within the scope of this work, but generally a set of automatically measured keypoints has a large number (sometimes over 50%) of outliers i.e. missmatched features. The first approach to deal with outliers is to prevent false matches using the external information about image geometry. This information can come from positioning sensors such as GPS/INS systems [2], [3]. If the orientation of two images acquired with calibrated camera is approximately known, location of corresponding features is held down to the neighborhood of epipolar lines associated with those points (Fig. A1). However more robust approach to prevent false matches is to use multi-view camera configuration providing multi-view image sequences [4], [5], [6]. Commonly two cameras are applied. As a result of a system calibration the accurate orientation of the second camera in the coordinate frame of the first camera is known. This enables the accurate epipolar line location for a certain keypoint (Appendix A).

In the case of single-view sequences, the keypoint matching cannot really benefit from the epipolar constraint (Appendix A). If no GPS or IMU are available, only the approximate motion characteristic is known, constraining corresponding keypoint searching to region of interests (ROI) rather then lines. As a result a significant number of outliers may occur. Approaches to the outlier rejection are based on the epipolar constriant imposed on the fundamental matrix ($F$) or the essential matrix ($E$) (Appendix A). Snavely, Seitz and Szeliski [7] propose the estimation of the $F$ matrix using the 8-point algorithm inside the RANSAC [8]. As a result a set of 8 image points that best fit the fundamental matrix model is found in each image pair. At the same time outliers can be detected and rejected. Bartelsen and Mayer [9] prefer to use the essential matrix instead of the fundamental matrix. In contrast to the fundamental matrix, the essential matrix estimation requires the knowledge about the camera calibration but remains robust to the critical configurations met in the

Researchers conducted within founds of Department of Mining Surveying and Environmental Engineering (AGH University of Science and Technology) no. 11.11.150.949

978-83-60810-66-8/$25.00©2015, IEEE

planar scenes. It also requires smaller number of coresponding points. The 5-point algorithm developed by Nister [10] and the locally optimized RANSAC [11] are proposed as a solution method. Finally the $E$ or $F$ model fitting can by carried out based on inliers only, using least-square approaches.

Applying the epipolar constraint cannot eliminate badly matched points that are located near the corresponding epipolar lines. A 3D information is necessary to detect the remaining, relatively small number of outliers. To solve the problem, the ray intersection (Appendix B) is carried out for each image model to calculate the spatial coordinates of the tie points (Fig. A.1). Sequential orientation of the subsequent images [2] using for example the DLT approach [12] inside the RANSAC procedure or formation of image triplets [9] allows to complete the rejection of outliers. Overlapping triplets can be linked to recover orientation of every image in the sequence. However the recovered orientation suffers from the drift effect. Besides it can be determined only up to the absolute scale, rotation and translation. Aforementioned 7 parameters, if needed, can be estimated based on ground control information such as the GPS coordinates of the image projection centers [9] or coordinates of the control points. Finally to estimate the orientation of the images more accurately the least square bundle adjustment can be applied. For the real time scenario the good solution to the drift reduction is the detection of loop closures [13].

A terrestrial mobile mapping can be carried out from almost every vehicle. Cars are used commonly in case of commercial systems. However data acquisition using cars is restricted to streets and their surroundings only. To overcome those limitations systems designed for smaller vehicles are developed, among which bikes seem to fill the gap between hand-held systems, mobile robots and cars. Bikes can access many more location than cars and move faster then pedestrians and mobile robots. Probably the most famous bike system for mobile data acquisition was developed by Google in the Street View project. Besides, students from Stuttgart University designed the prototype of the bike mobile mapping system with the laser scanner and two-antenna GNSS/INS unit [14].

Similarly to other mapping or visual odometry systems, bike systems can be a source of image sequences. Automatic processing of image data acquired from bike can be used to determine trajcetory and finally to reconstruct the geometry of objects. However it should be noticed that the bike movement is different to the car movement. When cycling it is more difficult to keep constant speed and direction than in case of driving. The turn rate of bike is small when compared to car. In case of single-view sequences with no information about approximate image geo-referencing, motion estimation from image data is supposed to be much more challenging task than in case of the multi-view systems and the smoother movement.

Works addressed in this paper aim to provide the solution to the problem of the automatic orientation of a single-view image sequences. It is beyond the scope of this study to examine the hardware potential as well as the achieved processing time. However the study offers some important insight into the analytical approaches and their practical aspects, providing at the same a kind of overview of the existing solutions. The following sections describe the consecutive steps of the algorithm, starting from keypoint detection and matching proceeding to the relative orientation and finally to the absolute orientation. The fifth section describes the experiments. Then the results and discussion are provided.

## II. Feature detection and matching

As this step of the algorithm is still under the development, only the outline of the matching strategy is provided. In the urban environment corner points are likely to occur in almost every image and can be detected using one of many available detectors. Proposed algorithm uses Kovesi's implementation [15] of Noble's version [16] of Harris feature detector [17]. After completing the detection, features are matched using the monogenic phase approach [18], [19] with the set of parameters proposed by Kovesi [15]. Assume a certain corner is detected and matched in the initial pair in the sequence. Matching algorithm searches for the corresponding point in the third and subsequently in the next images. At the same time new corners appear in consecutive images. As the approximate image-to-image distance and the scene depth are known, some simple geometric constrains like row and column limits can be imposed on a searching area greatly reducing the computation time.

Corner points are generally detected as the maxima in the image that is the result of applying Harris operator. The absolute maximum value (AMV) constraint can be set to limit the number of keypoints. However applying this simple constraint leads to nonuniform distribution of detected points. This is the result of variations in the scene content. Some parts of the scene like trees, windows, cars etc. are "rich" in keypoints, while others like flat walls contain no keypoints at all. To overcome this problem the image is divided into blocks of equal sizes. In the addressed case study the 24 blocks (4 × 6) are used . Besides absolute value of Harris maxima, two other parameters are set to provide more favorable distribution of detected features: maximum number of points in each block (PIB) and minimum distance between points (DBP). Decreasing the AMV and the PIB and at the same time increasing the DBP leads to the more uniform distribution of points. Exemplary values of feature detection parameters, applied in the refereed case study were as follows: AMV = 10 (Kovesi suggested 200 [15]), PIB = 60, DBP = 50.

As the result of matching procedure a list of points and their pixel coordinates is provided, allowing computation of the relative orientation of consecutive images.

## III. Relative orientation

### A. Essential matrix computation

The relative orientation of two images acquired with calibrated camera is encoded in the 3 × 3 essential matrix $E$. Derivation of the essential matrix from the relative orientation parameters - translation and rotation ($t$,$R$) and the camera matrix can be found e.g. in Krauss [20], or in the simpler form in the Appendix A. However the solution of the inverse problem is not so trivial as there are 4 possible solutions that have to be tested for cheirality [21]. The essential matrix as well as the fundamental matrix satisfies the well known complanarity constraint [20], [21]:

$$x'^{\top} E x = 0 \tag{1}$$

where $x$ and $x'$ are the column vectors of homogenous image coordinates. The rank deficiency of essential matrix implies the following constraint:

$$\det(E) = 0 \tag{2}$$

The $E$ matrix has two non-zero singular values that are equal. This constraint can be expressed in the algebraic form as [22]:

$$2EE^{\top}E - \mathrm{tr}(EE^{\top})E = 0 \tag{3}$$

It is advantageous to compute the essential matrix using one of few available close-form solutions using minimal, i.e. 5, number of corresponding points [10], [23], [24], [25]. Using the close-form solution requires no prior approximation and can be easily tested for outliers using the RANSAC procedure. The algorithm developed by Stéwenius, Engels and Nistér [25] was adopted within proposed solution because of its relatively simple implementation. Using equation (1) and finding its four-dimensional null-space, the essential matrix can be parametrized with three unknowns $x$, $y$, $z$:

$$E = xE_1 + yE_2 + zE_3 + E_4 \tag{4}$$

Inserting equation (4) into (2) and (3) produces the system of 10 3rd degree polynomial equations in three unknowns. This system is solved using the Gröbner basis. Up to 10 solutions for $E$ exist but only the real ones are of the further interest.

### B. Detection of outliers

In the proposed approach the essential matrix is estimated inside the RANSAC procedure. This enables detection of outliers. Assume that for the subsequent image pairs in the sequence $N$ samples are chosen, each consisting of 5 point pairs. As there are up to 10 real solutions for $E$, in the worst case there can be $10N$ possible solutions. According to the typical RANSAC each point in the image pair is classified as inlier or outlier according to the specified threshold value. In the addressed solution a kind of locally optimized RANSAC [11] is used. All points in each sample get a score that is inversely proportional to the distance from the model value. If the distance is higher than the threshold, the score is zero and the point is classified as outlier. The sample with the highest total score wins.

The easiest way to score each point is to calculate distance to the epipolar line using (1) (see Appendix A). However it may happen that due to mismatching, a point that is projected near the epipolar line lies behind the camera. To avoid treating such points as inliers it was decided to recover the rotation matrix ($R$) and the translation vector ($t$) of the second image from each real $E$ [21] and to calculate coordinates of keypoints in three dimensional coordinate frame of the first image using intersection of rays (Fig. A1, Appendix B). Now only the keypoints with negative $Z$ coordinates are going to be tested further. Given $R$, $t$ and estimated 3D coordinates of keypoints, the projections to images are found so that the 2D euclidean distances to the measured locations can be computed.

Assume three consecutive image pairs: [$k$,$k$+1], [$k$+1,$k$+2], [$k$+2,$k$+3]. A certain feature is matched correctly in pair no. 1. Subsequently this feature is matched incorrectly in pair no. 2. As a result it is classified as outlier. Nevertheless this keypoint may not be rejected because it could happen that incorrectly matched feature in image $k$+2 is correctly matched with the feature in image $k$+3. As a consequence this keypoint is recognized as two separate keypoints and gets separate id's in images forming pairs 1 and 3. It won't be used in relative orientation of pair no. 2.

### C. Estimation by least square fitting

The sample with the best score provides good estimations of $R$ and $t$ but it does not take into account all inliers. To utilize all available information, the least square adjustment can be carried out using all points classified as inliers. The image coordinates of keypoints are treated as observations and explicitly related to the parameters in the form of well known colinearity equations (see e.g. [20]). As a consequence the system of nonlinear equation is formed. The elements of $R$ are not treated as parameters directly. To avoid possible singularities resulting from parametrization in terms of Euler angles [26], the entries of the $R$ matrix are expressed as functions of the elements [27] of a quaternion. Both quaternion and $t$ are assumed to have unit norms that leads to the additional constrains imposed on the parameters. Finally the 3D coordinates of all tie points complete the set unknowns. The $R$, $t$ and 3D coordinates of tie points resulting from the RANSAC should be accurate enough to linearize the equation system and subsequently solve it in only one iteration.

## IV. Sequence orientation

### A. Model-to-model transformation

As a result of the relative orientation the $R$ and $t$ are provided for each image pair in the sequence. Such relatively oriented image pair is called a model. Assume image $k$ forming the model with image $k$+1.The consecutive model is formed by images $k$+1 and $k$+2. Common points are now used to stitch both models. In this way the orientation of a short, 3 image, sequence is recovered. Subsequently the algorithm proceeds to the transformation of the third model based on the reference points that appear in the previously created block. Model stitching is carried out further, until all images are oriented.

Each model is oriented according to the Horn algorithm [26] and involves estimation of 7 parameters: 3 for the rotation, 3 for the translation and finally the scale. The Horn approach consists of the following steps. At first the centroids in both point sets are calculated. Coordinates of all points are reduced to respective centroids. Secondly the rotation that maximizes the dot product of vectors pointing from centroids to corresponding points is found. The rotation is parametrized in terms of four elements of the unit quaternion. Once the quaternion is known, it is possible to align vectors in both frames to make them nearly parallel. Vectors won't never be exactly parallel due to outliers. Finally the scale is recovered using translated and rotated vectors. Three different approaches to scale computation are proposed depending on which point set is assumed to have better accuracy. The approach of Horn deals with minimal 3-point case as well as with greater number of points. It fulfills the condition of the least sum of squared residuals. Finally no approximation of the parameters is needed.

It should be mentioned that in addition to the terrain points (keypoints), adjacent models have one additional common point, namely the projection center of the common image - $k$+1 in the later example. This point lies far away from the rest of points and certainly has a worse reliability. Applying a standard Horn solution would cause that even a small errors in 3D coordinates of the tie points can result in large residual of projection center locations incorporating relatively large errors to the estimated motion. Therefore during the minimization of the dot product the utilization of the model frame coordinates is preferred to the usage of coordinates reduced to their centroids. In fact such modification means that the translation is simply calculated, not estimated, hence the estimation of remaining four parameters is more reliable i.e. less sensitive to the influence of erroneous tie point locations.

During the model-to-model transformation the sparse point cloud of keypoints is being formed. Besides points used inside the Horn algorithm, each stitched model incorporates a set of new points. If this points appear also in the next model, they are used as the reference. However some points exist that appear only in one model. The correctness of the location of such points cannot be fully checked. As a result some erroneous points in the sparse point cloud appear.

### B. *Absolute orientation*

Until now the image sequence was oriented up to the scale, absolute rotation and absolute translation. If the missing parameters are to be recovered, the external information need to be utilized. Basically there are two approaches to provide the external orientation to images: direct measurement and geo-referencing through ground control points (GCPs) referred as the indirect approach. To measure the external orientation directly one can use GPS and inertial sensors. If the GPS is used alone, the estimation of absolute orientation parameters takes place using the coordinates of projection the centers recovered in the previous step and the reference trajectory line recorded by a receiver [9]. Geo-referencing through control points usually requires the manual measurement of terrain features, the coordinates of which are known from other survey. In case the terrain coordinates of control points are known from a geodetic survey the indirect approach is assumed to be more accurate. In the presented study the second approach was utilized as no GPS measurements were available. After completing the absolute orientation it is possible to smooth the results and increase accuracy by performing the bundle adjustment. In such a case the loop closures, if only present, can be taken into account for the further accuracy increase.

## V. Experiments

### A. *Preparatory works*

The accuracy of the motion recovery from single view sequences strongly depends on the imaging geometry. In case of corridor sequences, when camera looks forwards or backwards, the intersection angles between correspondent rays are narrow, leading to the large errors of tie point locations. As a result the recovered camera orientation tends to drift quickly. In contrast to the corridor sequences a sequences with camera looking perpendicular to the moving direction (aside-looking sequences) should allow to achieve a better accuracy. In the following tests only the motion recovery from the aside looking sequences is covered, however the algorithm is supposed to deal with the geometry of any kind.

To test the proposed approach the decision was made to acquire the image sequence of the test-field area located at the AGH University Campus (Fig. 1). This test field is equipped with the number of natural GCPs, that are to be used to evaluate the accuracy. GCPs are located mostly at the building façades. It was decided to use the wide angle camera to be able to capture the façades from top to bottom. In addition to the large overlap, even in case of wide baseline, the wide angle lens provides increased accuracy of depth component of the tie point location in space. This is of the fundamental importance for the process of model stitching as the drift is supposed to accumulate slower. Besides, the obtained sparse point cloud would have better accuracy than in case of using the narrow angle lenses. In addition to better accuracy the wide angle lens performs better when imaging in motion. It guarantees a large depth of field allowing imaging with small aperture and short exposure time. Taking all the above into consideration the Nikon D5200 camera with the Sigma 10-20 mm f/3.5 rectilinear lens was chosen as the imaging sensor. In addition to the acquisition of a high resolution 24 megapixel (4000 × 6000) images the sensor of the camera allows HD video recording. The focal length was set to 12 mm providing the horizontal viewing angle about 90 °. The principal distance was fixed by blocking the focusing ring. The camera was calibrated to determine the interior orientation parameters and the distortion.

### B. *Data acquisition*

Initially the tests involving acquisition of HD videos were made, but because of low quality of extracted frames it was decided to switch the camera to the time-lapse mode, choosing the highest possible frequency of 1 Hz. However it came out quickly that capturing images with the 1 Hz frequency makes the camera buffer stuck - the shutter is not released until the last image is saved. Lowering the frequency would either lengthen the imaging base, possibly leading to the problems with feature matching or force decreasing the cycling speed

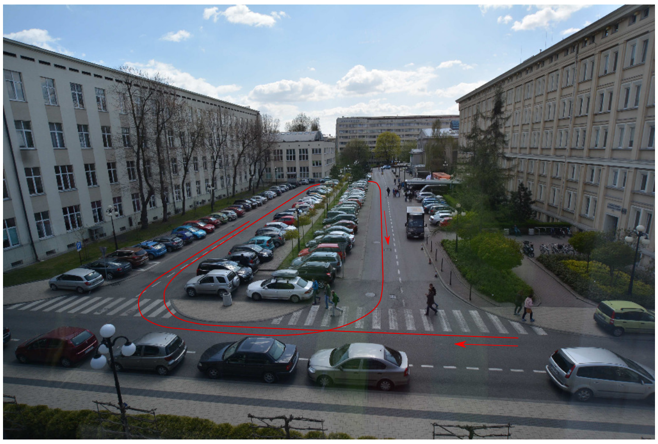

Fig. 1. Planned trajectory line imposed on the image of the test-field

resulting in extension of the overall acquisition time. The reasonable solution to avoid the above mentioned effects was to switch to the lower resolution of 13.488 megapixel.

The camera was fastened to the bike using a specially constructed device consisting of the 3 DOF head, allowing sequence acquisition from freely selectable viewing angle. The camera was inclined to look slightly upwards and perpendicular to the cycling direction. The test sequence was acquired in the aperture priority mode. The aperture value was set to 5 resulting in the exposure time between 1/2000 and 1/1000 second. The planned trajectory line is shown in the Fig 1. The test sequence was to have the shape of a loop. With the aim of comparison a part of the loop was to be cycled twice. The decision had to be made which side the camera should look at. Choosing the right direction provides convergent image configurations within all the turns and a good overlap. However in the case of the test-field the test were carried out in (Fig. 1) it was better to look left as to capture the façades lying closely to the trajectory line, providing advantageous distribution of keypoins. The disadvantages of such configurations are the occurrence of the divergent images within the turns leading to decrease in the overlap and occurrence of the narrow angles of intersecting rays.

After applying all the above mentioned settings the sequence of 195 images was acquired.

### C. Data processing

After collecting the data, the keypoint detection and matching algorithm was tested. The rough motion characteristic was known allowing to restrict the location of possible matches to the ROIs of a fixed size. The imposed constraint was supposed to reduce the number of possible outliers. The keypoint matching is followed by the relative pose estimation of consecutive image pairs. The least square relative orientation was tested but due to a very long computation time it was not applied in the final solution. Four image pairs, each located within the turns were not oriented properly due to the very high outlier rate and improper keypoint distribution. In this case the problem was fixed by adding some tie points manually.

Having the relative pose of the subsequent models estimated, the sequence formation was carried out. The first model in the sequence was chosen as a starting model. As the relative pose estimation constrains the base vector to equal 1, all the linear quantities calculated within this stage such as translations, residuals, errors are expressed in the unit of the length of the first base. The threshold parameter of the RANSAC procedure, i.e. the linear residual of the tie point, was set to 0.1.

For now the orientation of all of the images in the sequence was estimated up to the absolute quantities (translation, rotation, scale). To solve for the missing parameters and provide the accuracy analysis the 26 natural control points were used. Each control point was measured in the selected model (image pair). The accuracy assessment was provided by the residuals of the control point coordinates. Finally the sparse point cloud provided in the global coordinate frame was examined visually to look for previously undetected mismatches. The extent of the inconsistencies observed as a result of cycling the same part of the loop twice were to be analysed deeply.

## VI. Results

Despite applying the ROI-restricted matching a large number of outliers was observed in almost all image pairs (Fig. 2). During the RANSAC-based estimation of the relative pose it came out that the number of outliers considerably exceeds 50%. Besides the limitations of the monogenic phase matcher the reason of such a high outlier rate could be simply the content of the scene. For instance a number of corners appearing on the similar windows' frames are hard to be matched correctly. In addition the epiploar lines are nearly parallel to the horizontal edges of windows' elements so that even solving for relative pose cannot eliminate some outliers. It can also be noticed that there are quite a lot of trees in front of the façades (Fig. 1, Fig. 2, Fig. 3). As a results a number of a false keypoints is detected at the intersections of branches and twigs. Some of them are also incorrectly matched. The similar happens for keypoints detected in the reflections appearing in the window panes (Fig. 2). Also a lot of corner points detected at the grainy structure of the asphalt are matched incorrectly. Using the 5-point algorithm inside the RANSAC allows to eliminate most of the outliers. Fig. 2 and Fig. 3 are provided as an example.

It was decided to examine the influence of the drift (accumulation of the errors within the sequence formation stage) on the accuracy of the absolute orientation. The results are provided in the table 1. At the beginning the sequence of 10 images was oriented using four GCPs. The centimeter-level errors were obtained. Afterwards the number of images was increased until the appearance of a next group of available control points. Finally the sequence of 158 images was oriented. As no GCPs were measured in the further images, the last row of the table 1 represents the accuracy of the absolute orientation of the whole sequence. Performed analysis shows that generally

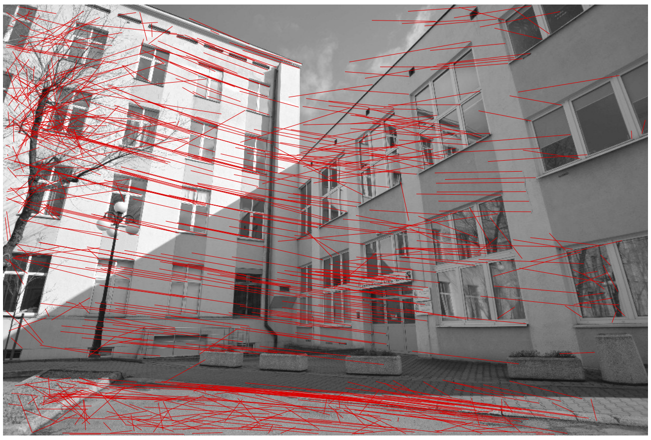

Fig. 2. One of the images from the southern part of the sequence and the vectors showing the displacement of the keypoints to the the next image. Results before applying the 5-point relative pose estimation algorithm inside RANSAC.

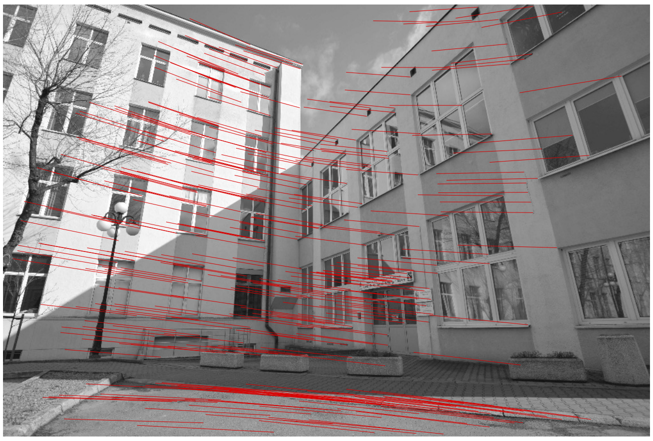

Fig. 3. One of the images from the southern part of the sequence and the vectors showing the displacement of the keypoints to the the next image after automatic rejection of outliers

while increasing the length of the sequence errors tend to increase, however not in the regular way. The worst results were obtained for the $Y$ coordinate and the best for the $Z$.

Fig. 4 shows the sparse cloud of tie points obtained as a result of the sequence formation. The colour of points changes from blue to red as to show the inconsistencies in the point cloud resulting from the orientation drift. The first matched keypoint in the first image pair is coloured in blue. The last matched keypoint in the last model is coloured in red. The black spots represent the location of projection centres. The black line represents the trajectory. The total length of the trajectory is 232.58 m. The arrows show the cycling direction

The façades are clearly visible in the cloud as well as the kerbs and the trees. During the data acquisition there was not as many cars parked as it can be seen in the Fig. 1. Few of them can also be visible in the cloud. There are also quite a lot of points that seem to be located inside the buildings. This tie points may represent mismatched keypoints located only in two images, occupying consistent epipolar lines. Such points pass the RANSAC testing, carried out within the model formation, but cannot be tested in the model stitching procedure. As a result of capturing certain parts of the scene twice, the inconsistencies in the resultant point cloud appear. To show them in details two parts of the cloud bounded by green rectangles are shown in the greater scale in the Fig. 5 and Fig. 6.

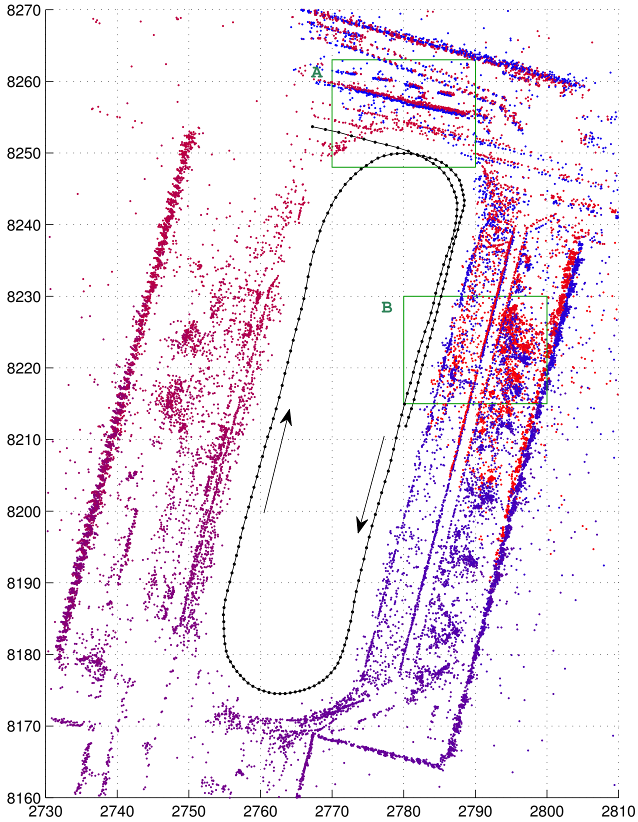

Fig. 4. The trajectory line and the point cloud. The arrows point the cycling direction. Green rectangles A and B mark the areas that will be referenced further. Orientation: north, units: meters.

The thickest strip of points in the Fig. 5 represents the front edge of the hedge, part of which is visible at the bottom of the Fig. 1. Points forming four segments parallel to the hedge are likely to be located at the crowns of the trees and the items used to shape them in the espalier-like form - see the very bottom of the Fig.1. In front of the hedge there are some points at the pavement. Some of them form a linear features that may represent kerbsides. Two linear features that lie behind the trees represent the railings of the ramp that belongs to the building the image in the Fig. 1 was captured from. Looking at the points located at the hedge it can be noticed that the red points are shifted with respect to the blue ones. The shift is about 40 cm in the south-north direction. When looking at the trees and railings and finally at the façade (Fig. 4) this shift seem to decrease.

TABLE I
ACCURACY OF THE ABSOLUTE ORIENTATION OF THE SEQUENCES OF A DIFFERENT LENGTH. THE LAST COLUMN PROVIDES THE RMS ERRORS OF THE 3D CONTROL POINT LOCATION.

| **Num. of images** | **Distance [m]** | **Num. of points** | $RMSE_X$ **[mm]** | $RMSE_Y$ **[mm]** | $RMSE_Z$ **[mm]** | $RMSE_P$ **[mm]** |
|---|---|---|---|---|---|---|
| 10 | 15.31 | 4 | 6 | 16 | 12 | 21 |
| 34 | 42.94 | 7 | 63 | 33 | 30 | 77 |
| 55 | 75.82 | 9 | 87 | 71 | 60 | 127 |
| 73 | 95.48 | 12 | 99 | 111 | 60 | 160 |

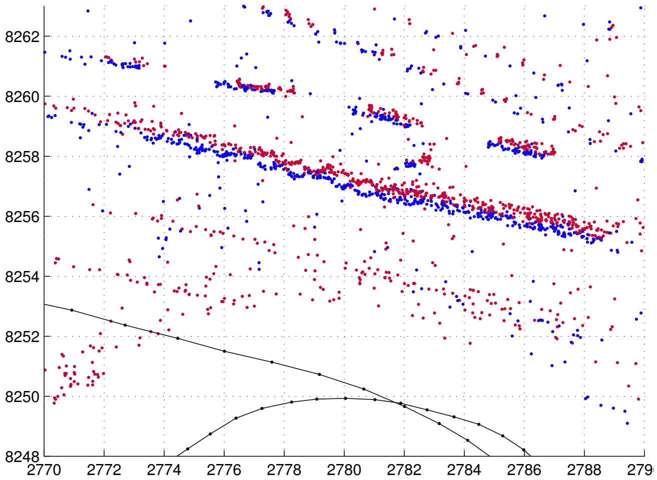

Fig. 5. Inconsistency of the point cloud within the area A

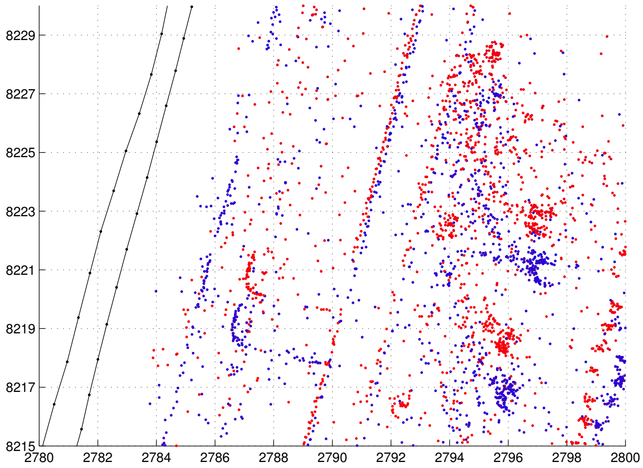

Fig. 6. Inconsistency of the point cloud within the area B

In the Fig. 6 the points located at the car body can be observed as well as linear features representing kerbs. There are groups of points representing trees that grow in the front of the building the façade of which can be seen in the bottom right corner of the figure. Looking at the points representing the car one can notice a considerable inconsistency in the point cloud. The red points are shifted about 2 meters with respect to blue points. The reason why the shift increased to such a high value can be the unfavourable imaging geometry (divergent camera axes, decreased overlap) at the north-east turn. Finally it can be found quite unexpected that no drift in the heading component of the angular orientation can be noticed - the blue and red linear features visible in Fig. 5 and Fig. 6 stay almost exactly parallel.

## VII. DISCUSSION

In this paper the new solution to the automatic orientation of single-view image sequences is proposed and the results of the tests conducted based on the data acquired from bike are presented. The solution assumes the calibrated camera case to achieve more robust performance in outlier detection and better accuracy. Modifications to the model-to-model stitching procedure are proposed as to achieve better reliability of the sequence formation, which result in more robust trajectory estimation.

The conducted tests allow the examination of certain steps of the proposed solution. The first step i.e. the feature detection and matching seem to perform quite well for images with a similar angular orientation. However it tends to fail for images captured within turns so that even the manual point measurement was to be carried out to fix the problem. To improve the keypoint matching firstly a more robust feature descriptors and matcher can be applied. Secondly the matching should be integrated with the relative pose solution. The $E$ matrix is quite accurately estimated using the proposed method, even in the presence of outliers, so that the equations of epipolar lines can be used to impose a stronger constraints for the feature re-matching (Appendix A). Afterwards features can be re-matched after solving for the essential matrix. Then the refined essential matrix is to be estimated and the solution can proceed in the iterative manner. Having the robustness improved one can think about improving the accuracy by using the sub-pixel corner measurement. Additionally the motion recovered within the process of model stitching can be smoothed using the bundle adjustment, however this approach may take quite a lot of computation time.

Assuming no real time application it is also better to select a different starting model for the sequence formation. Probably choosing the model near to the middle of the sequence would reduce the error as the drift is to accumulate on distances of about the half distance of the sequence.

The improvement of the orientation procedure is going to be followed by integration of other sensors like GPS or IMU. It would demand changing the imaging sensor from SLR to the industrial camera. Besides providing the time synchronization interface the industrial camera allows imaging at the higher frequency and at the same moment allowing real-time image data processing. Generally at this stage of the research the obtained results can be found satisfactory and consist a good starting point for developing a bike MMS equipped with the visual orientation unit. There exists a field to improve the robustness, accuracy and operational performance of the solution by improving both algorithms, implementation and a hardware.

## Appendix

### A. Essential matrix the and epipolar constraint for a calibrated camera

Assume that the two images of approximately the same scene were taken with calibrated camera (Fig. A.1). Assume this two images form photogrammetric model. Relative orientation of the second image with respect to the first image can be parametrized by the orthonormal rotation matrix ($R$) of the second camera frame and translation vector ($t$) of the second camera projection center (O'). The translation vector simply equals the base vector ($b$). The relative orientation can be estimated up to scale factor. Usually $b$ is assumed to be the unit vector.

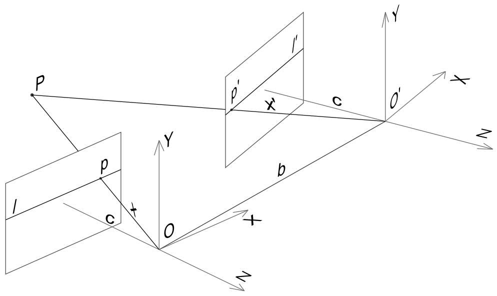

Fig. A.1. Two metric images forming the model

Point $P$ is located in the scene and projected into images to form points $p$ and $p'$. Assume two vectors $x$ and $x'$ that originate in projection centers $O$ and $O'$ and point at points $p$ and $p'$. Cooridinates of those vectors are given in the reference frame of respective cameras so that the third coordinate is equal to the principal distance of camera with the minus sing and for metric images is assumed to be the same, i.e.:

$$x = \begin{bmatrix} \xi \\ \eta \\ -c \end{bmatrix}, x' = \begin{bmatrix} \xi' \\ \eta' \\ -c \end{bmatrix} \tag{A.1}$$

Now the coplanarity constraint reads as follows:

$$x^\top (b \times Rx') = 0 \tag{A.2}$$

Coordinates of $b$ fill the elements of skew-symmetric matrix $B$:

$$B = \begin{bmatrix} 0 & -b_z & b_y \\ b_z & 0 & -b_x \\ -b_y & b_x & 0 \end{bmatrix} \tag{A.3}$$

so that:

$$x^\top BRx' = 0 \tag{A.4}$$

and consequently:

$$x'^\top Ex = 0 \tag{A.5}$$

where $E$ is the essential matrix. The projection center $O$ and point $P$ define a ray that is projected into second image as the line $l'$ (Fig. A1). The equation of this line is obtained by inserting the coordinates of $x$ into equation (A.5). In the similar way the equation of the epipolar line $l$ can be derived.

### B. Intersection

Assuming the $R$ and $t$ are known, it is now possible to estimate the coordinates of point $P$ in the model coordinate frame, i.e. the coordinate frame of the first camera (Fig. A.1). If points $p$ and $p'$ represent two correctly matched keypoints, theoretically both rays should meet in point $P$. However due to measurement errors rays are not going to intersect. Knowing the $x$ and $x'$ vectors (A.1) the location of point $P$ can be determined by least square solution. Collinearity equations for two corresponding keypoints are as follows:

$$\begin{bmatrix} X \\ Y \\ Z \end{bmatrix}_P = \lambda_1 \begin{bmatrix} \xi \\ \eta \\ -c \end{bmatrix} \tag{B.1}$$

$$\begin{bmatrix} X \\ Y \\ Z \end{bmatrix}_P = \begin{bmatrix} b_x \\ b_y \\ b_z \end{bmatrix} + \lambda_2 R \begin{bmatrix} \xi' \\ \eta' \\ -c \end{bmatrix} \tag{B.2}$$

where $\lambda_1$ and $\lambda_2$ are unknown scale coefficients. After elimination of $\lambda_1$ and $\lambda_2$ from (B.1) and (B.2) followed by term's rearrangement the observed 2D coordinates of the keypoint can be written using explicitly elements of the relative orientation as the functions of unknowns:

$$\begin{bmatrix} \xi \\ \eta \\ \xi' \\ \eta' \end{bmatrix} = \begin{bmatrix} -c\frac{X_P}{Z_P} \\ -c\frac{Y_P}{Z_P} \\ -c\frac{R_{1,1}(X_P-b_x)+R_{2,1}(Y_P-b_y)+R_{3,1}(Z_P-b_z)}{R_{1,3}(X_P-b_x)+R_{2,3}(Y_P-b_y)+R_{3,3}(Z_P-b_z)} \\ -c\frac{R_{1,2}(X_P-b_x)+R_{2,2}(Y_P-b_y)+R_{3,2}(Z_P-b_z)}{R_{1,3}(X_P-b_x)+R_{2,3}(Y_P-b_y)+R_{3,3}(Z_P-b_z)} \end{bmatrix} \tag{B.3}$$

This system of equations can be rewritten in the linear form. The solution provides coordinates of point $P$. In case of erroneous measurements in $x$ and $x'$ the projection of estimated $P$ point into images won't coincide with points $p$ and $p'$ so that the residual vectors will appear.

***Abstract*—Nowadays the big challenge in simultaneous localization and mapping (SLAM) of mobile robots is the creation of efficient and robust algorithms. Significant Number of SLAM algorithms rely on unique features or or use artificial landmarks received from camera images. Feature points and landmarks extraction from images have two significant drawbacks: CPU consumption and weak robustness depending on environment conditions. In this paper we consider performance issues for landmark detection, introduce a new artificial landmark design and fast algorithm for detecting and tracking them in arbitrary images. Also we provide results of performance optimization for different hardware platforms.**

## I. Introduction

LANDMARKS are generally defined as passive objects in the environment that provide a high degree of localization accuracy when they are within the robot's field of view [1]. Artificial landmarks may carry additional information about the environment and may be used to assist a robot in localization and navigation. Although this approach requires environment preprocessing, it makes developers free to choose a type of landmark and information it holds. Furthermore, a developer could use any design for the landmark that can be sensed in small (with respect to an entire environment) location, but since artificial landmarks are supposed to simplify extraction of location features, appropriate landmark should satisfy the following requirements:

- can be reliably detected in a given environment. Detection should be robust for bad lighting conditions, glares, wide spectrum detection angles;
- can be identified;
- can be easily created and fixed in a given environment.

It this paper we analyze existing approaches for landmarking and introduce new kind of color landmark for fast and robust detection. The paper is organized as follows. In the next section quick response codes [2] and detection methods for them are discussed. In Section III. new design for color landmark is introduced and detection algorithm is suggested. In Section IV. tracking approach is introduced. In Section V. algorithm performance and detection rate are discussed. Finally, in Section VI. a summary of this paper and some issues for further development are listed.

## II. Artificial landmarks

One possible option for artificial landmark is a visual printed landmark, e.g. QR codes. This kind of landmarks has several advantages comparing to RFID and other technologies: it doesn't consume power, requires only camera which most mobile robots are already equipped, cheap and easy to produce.

There are several ways to detect QR codes in an image. In [3] the Viola-Jones framework based on Haar features is used to detect QR finder patterns (FIPs). Found FIPs are aggregated into a graph by their size and distance between them. The graph is searched for 3-cycles that satisfy the orientation criterion and represent QR codes. Unfortunately, the QR code plane must be almost orthogonal to the camera axis to reach the claimed 90% detection rate. In addition, this algorithm gives no information about the QR code position in the space.

Another approach that is described in [4] utilizes a special line parametrization called PClines which is a variant of the Hough transform. This parametrization uses a parallel coordinate system and allows faster accumulation than the basic Hough-transform method. The image is searched for the specific parallel lines pattern that is declared as QR code. The algorithm can handle various orientations of QR codes in images, tolerant to uneven illumination and allows real-time processing but is unable to detect QRs from far away or in blurred images. It's also unclear whether the algorithm can detect several QRs on the same image.

Some other algorithms (e.g. [5], [6]) assume that there is only one QR code in the image, so they are not suitable for our problem as the robot may see several landmarks simultaneously.

In order to estimate performance and resource requirements a variant of the QR detection algorithm described in [3] have been implemented. It uses cascade classifier to find both the finder and alignment patterns in the detected QR code. The last is necessary since 4 points are needed in order to compute position of the landmark in the space, but the existing algorithm gives only 3 points. Experiments have shown that the usage of bare QR codes as landmarks has following significant drawbacks:

- it's rather difficult to detect and extract bare QR code when it is far enough (more than 1 meter, which is quite often condition for indoor mobile robots);

978-83-60810-66-8/$25.00©2015, IEEE

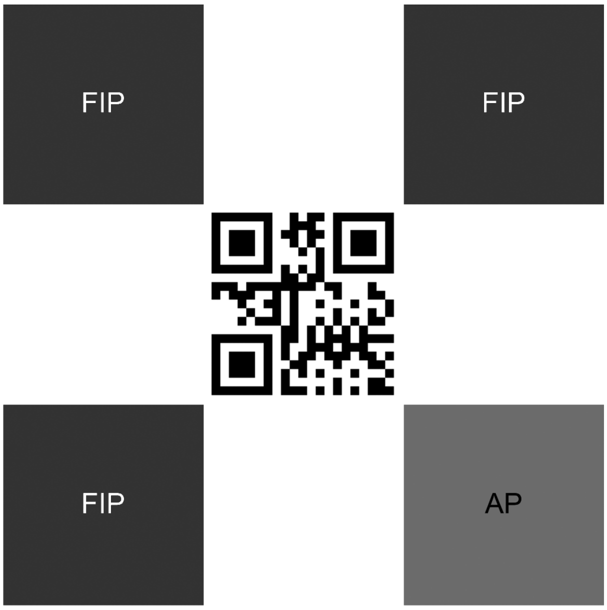

Fig. 1. Landmark design

- detection quality turns out to be very sensitive to the angle between camera and QR code plane.

So it was decided to create a new type of landmark that can be easily and reliably detected (i.e. chance of detection doesn't depend much on the camera position) and allows to carry extra information (like position or point identifier in the environment, or even instructions for mobile robots).

Various types of such visual landmarks are discussed in [7]. Besides good discussion of existent landmark types, this work introduces a landmark design based on QR code. According to it QR code is placed into blue rectangle that has three colored circles around it. Landmark of proposed design is scalable, special algorithm is introduced to extract inner area from outer circle for further QR code detection. Provided evaluation claims that landmark with diameter of outer circle equal to 20 cm can be reliably detected from 2 meters while its horizontal angle lies in range $[-60°; 60°]$.

The aim of our work is to propose a landmark that can be detected in broader horizontal angle range and has smaller size at the same time. The novel design was inspired by QR code detection algorithm described in [3] and [8]. The last one introduces artificial striped landmark. Two colors are used for stripes, each stripe has neighbours of different color.

## III. Landmark design and detection

In this section the new artificial landmark design and detection algorithm are described.

### A. Landmark layout

A general idea for a new landmark is based on QR code layout extended with color markup. The suggested layout consists of 3 blue squares called finder patterns (FIP) and one red square – alignment pattern (AP) – on the white background (in fact, any 2 easily distinguishable colors may be used). They are located on the landmark like FIPs and APs in QR codes (see Fig. 1). The significant feature of such layout is that the landmark looks like 4 light squares on a dark background in the saturation channel of the HSV color space in daylight (Fig. 3b). This allows to run some edge detection algorithm on the saturation channel to find contours in the image (Fig. 3c) and some of the detected contours are chosen to be FIP or AP candidates for the landmark.

### B. Detection algorithm

The full algorithm pipeline is shown in Fig. 2. Below we discuss each stage of the algorithm.

To select FIP candidates consider bounding rectangles of the detected contours in the RGB color space. For each candidate all pixel values within the bounding rectangles are accumulated separately for each channel. Then the following conditions should be checked:

$$\sum blue > a \cdot \sum red \quad \text{and} \quad \sum blue > b \cdot \sum green$$

If these conditions are satisfied then the contour is pushed into the list of FIP candidates. If the similar conditions are met for the red channel then the contour is stored as an AP candidate. The coefficients $a$ and $b$ in the formula above are called a color ratio and determine significance of the color component within the contour bounding rectangle: higher coefficient values discard more candidate contours at this stage. On the other hand, the farther from the camera the landmark is the lower the coefficient values should be to detect a FIP. The coefficient values from the range $[1.2; 1.6]$ are reasonable to use in practice. The output of this stage is shown in Fig. 3d.

Note that the found contour is not checked to be rectangular: due to optical or perspective distortions the specific shape of a FIP might be hardly recognizable. So there is no constraints

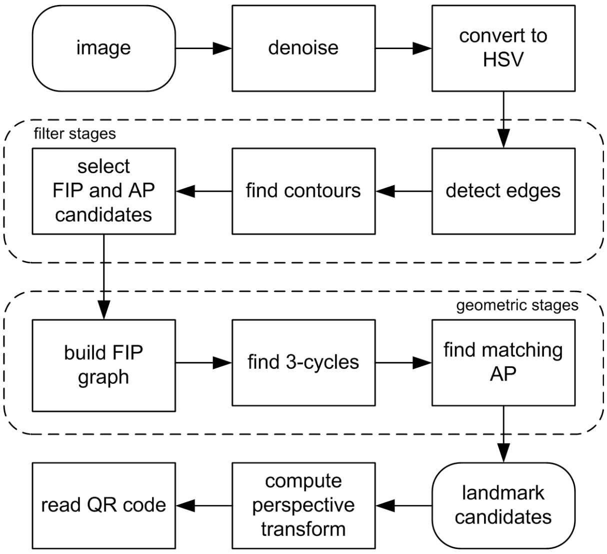

Fig. 2. Detection algorithm pipeline

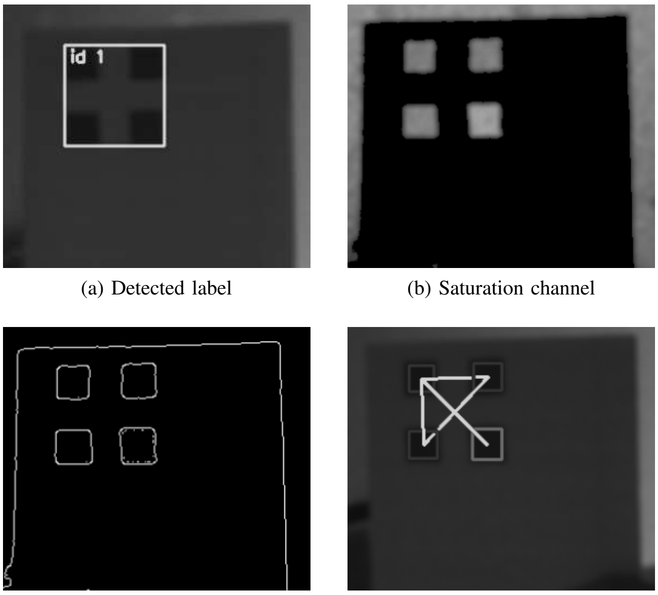

(a) Detected label

(b) Saturation channel

(c) Edge detector output

(d) Detected FIPs and APs

Fig. 3. Detector output

on the landmark shape at all. In our case, discarding contours by color is more robust than by geometric features, though this method is very sensitive to the external lightning and FIP selector parameters should be adjusted depending on the environment conditions.

After obtaining the lists of FIPs and APs quadruples (3 FIPs and 1 AP) are formed from candidates using landmark geometric features. At first, the graph is constructed in the following way: vertices are FIPs and an edge connects FIPs if they satisfy two types of constraints:

1) the minimum and maximum distance between FIPs:

$$\begin{cases} D_{min} \cdot width < |X_{FIP1} - X_{FIP2}| \\ D_{min} \cdot height < |Y_{FIP1} - Y_{FIP2}| \\ |X_{FIP1} - X_{FIP2}| < D_{max} \cdot width \\ |Y_{FIP1} - Y_{FIP2}| < D_{max} \cdot height \end{cases} \tag{1}$$

where $width$ and $height$ are the size of a FIP pair; $X$, $Y$ – FIP position; $D_{min}$, $D_{max}$ – constraint coefficients;

2) the difference in height and width:

$$\begin{cases} W_{min} < width_{FIP1}/width_{FIP2} < W_{max} \\ H_{min} < height_{FIP1}/height_{FIP2} < H_{max} \end{cases} \tag{2}$$

where $width$ and $height$ – FIP size; $H$, $W$ – size ratio coefficients.

Parameters in these constraints may vary and their actual values depend on the layout of the landmark. In our case a distance constraint is from 1 to 3 FIP sizes and a FIP size ratio is from the range $[0.5; 1.5]$. The resulting graph is searched for 3-cycles that are considered to be landmark candidates.

Finally, the last component of the landmark is added – AP. From all of the AP candidates we choose one that meets the constraints on the location (the top-left corner or center must be inside the bounding rect of the three selected FIPs) and which size is closest to the selected FIPs. Note that the constraint on the top-left corner doesn't allow detecting upside down landmarks. If an appropriate AP is found then the landmark candidate is accepted.

The output on each stage of detection is shown on the Fig. 3. Note that a small saturation threshold is used on Fig. 3b. It amplifies the difference in intensity of light and dark regions on an image and slightly improves the edge detection quality. Fig. 4 shows detection with weak constraints – it results in many false positive FIP detections, but the landmark still can be accurately detected.

There are several parameters that can be adjusted in the detection algorithm, but the exact set of parameters depends on the filtering that is applied to the input image:

- geometric constraints – the distance between FIPs and APs and their size ratio;
- color constraints – the color ratio used in FIP detection;
- filter parameters – for example, Canny's threshold, saturation threshold, blur kernel size, etc.

Given the location of FIPs and APs the perspective transformation can be computed in order to get orthogonal projection of the landmark and its position in the space. A QR code located in the center of the landmark can be extracted using that orthogonal projection and can be decoded using any QR code decoding algorithm (e.g. [3], [4]). It's clear that it still can't be done from far away, but the robot can always drive up to the landmark if it knows where the landmark is. An example of QR code extraction is shown in Fig. 5. Some postprocessing has been applied to the extracted QR code to get the image in Fig. 5b and most bar-code readers can decode the resulting QR, though the additional rectification may be applied.

## IV. Landmark tracking

Landmark tracking is the next step for increasing detection robustness and quality. A robot can change the physical posi-

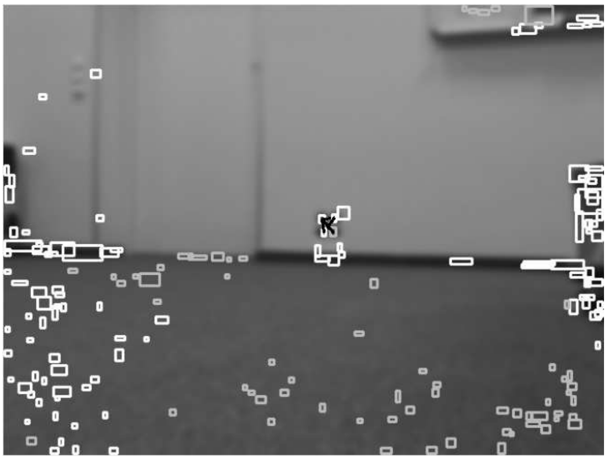

Fig. 4. Detection with weak constraints. The landmark in the center of the image still can be detected

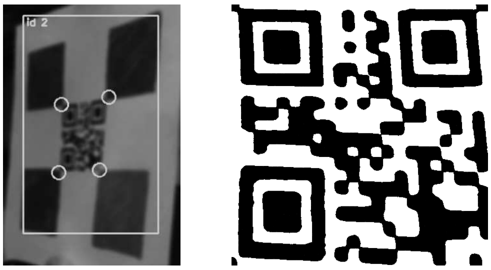

(a) Detected label (b) Extracted QR code

Fig. 5. QR code extraction

tion of observation relatively smooth so the detected landmarks in the camera video stream will be relatively close on the two consecutive frames and therefore the detected landmarks may be tracked in a sequence of images. This can be done in the following way:

1) Initially there is an empty object (landmark) pool. Lifetime is assigned to every landmark and allows to keep the landmark in the pool for some time even if it isn't detected in several frames. The landmark is kept in the pool while its lifetime is less than the fixed maximum value.
2) Processing the next frame obtains a new set of landmarks. There are 3 different cases possible:
    a) If the object pool is empty then all new landmarks are stored in the pool and assigned ids.
    b) If the new set of landmarks is empty and the pool is not then the lifetime of all landmarks is increased and obsolete landmarks are removed.
    c) If both the pool and new landmark set are non-empty then it's required to solve the assignment problem where the pool landmarks are agents and the new landmarks are tasks (or vice versa), and the cost is the distance between a pool landmark and new one. So the total distance between old and new landmarks is minimized.
3) The obtained solution is checked to meet certain restrictions:
    - mapped landmarks are of similar sizes;
    - distance between them doesn't exceed the maximum value.

    If the mapped landmarks meet these restrictions then the position of the pool landmark is updated and its lifetime is reseted. Otherwise the lifetime of the pool landmark is increased and the new landmark is added to the pool.
4) All new landmarks that don't map to the pool landmarks are added to the pool.

Landmark tracking example is shown in Fig. 6. This algorithm is pretty standard and has 3 parameters that can be adjusted:

1) the landmark maximum lifetime depends on camera frame rate, but total time of 1 second looks appropriate;
2) the maximum distance between landmarks;
3) the landmark size ratio.

Specific settings of these parameters depend on robot physical features: maximum speed, camera frame rate, etc.

## V. Evaluation

In this section the detection algorithm performance and robustness as well as some algorithm drawbacks are discussed.

### A. *Performance*

The detection algorithm is supposed to be used on simple mobile robots with limited resources, so the testing environment based on popular low cost, credit-card sized computer Raspberry Pi [12] and Robotic Operation System (ROS) has been created.

ROS (Robot Operating System) [11] is a framework for robot software development that provides various system services such as hardware abstraction, low-level device control, implementation of commonly used functionality and message-passing between processes. Set of ROS processes is represented in a graph architecture where processing takes place in nodes that may receive and post sensor, control, planning and other messages. Simplified structure of the developed robot is shown in Fig. 7. The detector node works as a service that is polled by the main controller from time to time. Note that

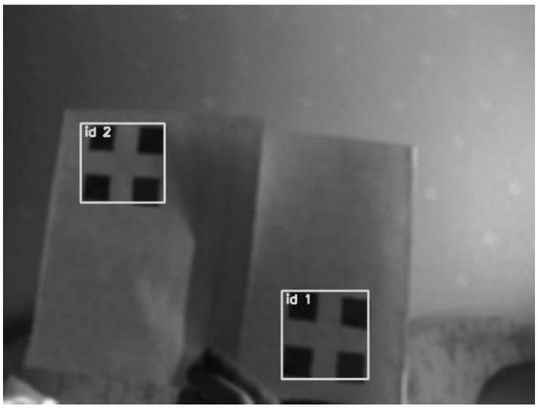

Fig. 6. Tracking example

the ROS itself is not a real-time OS and message passing introduces some overhead.

In the initial implementation of the detection algorithm all image processing operations have been performed by OpenCV framework [10]. The performance of this algorithm implementation on the Raspberry Pi that utilizes 700 MHz CPU is around 1-2 FPS and when the detector is integrated in the whole robot-control system it handles only 0.5 frames per second. Profiling has shown that the most computationally expensive parts of the algorithm are denoising, HSV color space conversion and tresholding and edge detection. All these operations can be easily performed by GPU, so it was decided to transfer some parts of the algorithm to GPU.

There are several options for GPU computations:

- GPU-specific tools and technologies (e.g. nVidia CUDA) allow achieving high performance but only on the limited set of devices;
- OpenGL shaders are cross-platform but it's hard to perform non-image processing on shaders;
- using GPU assembler it's possible to achieve the maximum performance on the specific device but the development process is very effortful.

The second option has been chosen because it allows parallel development and testing on desktop computer and mobile robot. Currently only Gaussian blur, saturation extraction and Canny edge detector are ported to OpenGL. Algorithm testing has been performed on the following set of hardware:

- OpenCV implementation:
  - Intel Core i5 3210M, 2.5 GHz;
  - ARM1176JZF-S, 700 MHz (Raspberry Pi CPU);
- OpenGL implementation:
  - Intel HD Graphics 4000 (integrated);
  - nVidia GeForce 650M (discrete);
  - VideoCore IV (Raspberry Pi GPU).

Testing results for filter stages are shown in the Table I and for geometric stages – in the Table II. All timings are in milliseconds. In the Table I in column "Total" for GPU implementations the image transferring overhead is indicated.

The results show that for desktop systems the image transferring overhead is greater than the speed gain in filters especially for the integrated GPU, but as expected, on the big images GPUs are still more efficient than CPU.

On Raspberry Pi the usage of GPU gives 4.5x gain in overall performance that increase to 6x gain when increasing the image size. Unfortunately, the algorithm cannot process big images due to RPi limitations. Thereby the detector with GPU optimization can process 8-10 frames per second which is sufficient for simple mobile robots, but further optimizations may be investigated.

### B. Robustness

To estimate detection rate we use two landmarks with 9 and 15 cm side and determine the maximum angle between landmark and camera planes at which 95% landmark detection rate can be reached. Results are shown in Fig. 8. Detector parameters have been tuned for every measurement so the graph shows the maximum reachable angle for reliable detection. In practice, static detector parameters adjusted to the environmental conditions allow to detect 9 cm landmark in $[-60°; 60°]$ horizontal angle range from 1.5 meters and 15 cm landmark in $[-75°; 75°]$ horizontal angle range from 2.5 meters.

The maximum distance at which landmark can be detected is determined by camera resolution. We used 0.3 MP webcam for testing and 9 cm landmark is indistinguishable in the image from approximately 2.5 meters and 15 cm landmark – from 4.5 meter. Thereby the landmark size is determined by the used camera and working environment features. In relatively small rooms with good lightning a 10-12 cm landmark is sufficient.

TABLE II
TOTAL DETECTION ALGORITHM PERFORMANCE (640X480)

| | Filter | Geometry | Total | FPS |
|---|---|---|---|---|
| Intel Core i5 | 13.546 | 0.057 | 13.633 | 73 |
| GeForce 650M | 10.623 | 0.042 | 10.686 | 93 |

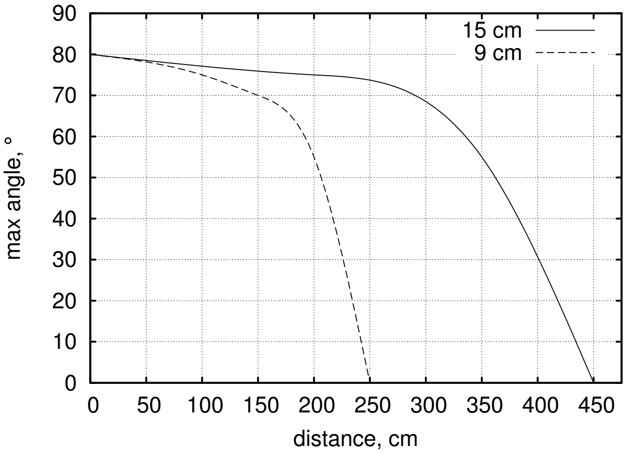

Fig. 8. Maximum angle for reliable detection

### C. Drawbacks

The proposed landmark detection algorithm suffers from image noise like any other algorithm based on edge detection. Various denoising algorithms can be applied (Gaussian blur in our case), but there is a trade-off between overall performance and image quality. For example, large blur kernels can affect edge detection quality, but good denoising algorithms like non-local means [9] run extremely slow.

Another disadvantage of the algorithm is that it relies on color features that depend on external lighting. The landmark looks like light squares on a dark background in daylight and completely different in dim light. So detection algorithm parameters should be adjusted depending on the ambient conditions.

## VI. Conclusion

The proposed landmark fits good landmark criteria: it is easy to create, set up, detect and identify. Although identification often requires approaching the landmark to read QR code, the fact of landmark(s) presence narrows amount of potential positions during localization process.

Described design and detection algorithm have various opportunities for enhancement:

- adaptive filters that can adjust their own parameters depending on environmental conditions;
- video stream for image stabilization, noise reduction and label tracking;
- experiments with colored FIPs and APs width can be performed to increase reliable angle range.

All programs and algorithm implementations are published as Open Sources Software and can be accessed by the following link: http://github.com/OSLL/landmark-detection.

## Acknowledgment

Authors would like to thank JetBrains company for provided support and materials for working on this research. The paper has been prepared within the scope of project part of the state plan of the Board of Education of Russia (task # 2.136.2014/K).

***Abstract*—This document presents a method of a logical links structure recognition between elements on diagrams. The applied approach intuitively mimics a human way of recognition that relies on merging already found connectors into more complex ones. This procedure is modeled by our method where simple and obvious connectors and gradually extended to more complex structures. Each iteration may lead to modification of connectors set obtained so far. The modifications are managed by a rules set describing logical and graphical constraints that should be satisfied by the connectors structure. If the extension leads to violation of constraints defined by the rules then the modification is not carried out. In this way, the recognized diagram structure is consistent with the assumed principles. The method was experimentally validated using the set of diagrams from three domains. In conclusions, method's advantages and drawbacks are discussed.**

## I. Introduction

In the last years there is a big interest in similar content image retrieval. There is plenty of research in this area. A deep survey is presented in [1]. The similar content image retrieval can be very helpful in automatic image annotation, in story illustration, copy detection, web image search and art image analysis.

It can be also helpful in searching similar text documents if they contain images. Usually, images illustrate the content of document. They contain information included in document in condensed form and there is less problems with unambiguous comparison of expressed idea. This explains a strong interest in its application to similar patents search in order to speed up the procedure of patenting and to protect intellectual property rights. For automatic querying it is necessary to convert the information in the images into a high-level description. Usually, in the case of technical documents, images represent engineering drawings, diagrams, algorithms, operations and processes shown as charts. Images of this kind present the structure consisting of certain elements and connections between them. Automatic recognition of the connections structure is the first step towards further automatic analysis or even machine understanding of images. The problem is important and challenging, because the documents have highly-complex structure, tabular and graphical information is embedded and they contain conflicting technical jargon. Processing embedded images can aid to solve the problem.

Typically, to apply such approach it is necessary to find images in the whole document. Then, images are processed in order to classify them to various classes: charts, diagrams, schemes, flowcharts, plots and photos. Next, a method dedicated to a given class of images is applied in order to recognize particular elements and their interconnections.

It is worth noting that such image interpretation allows to write the content of an image in the electronic form, which facilitates its storage and further processing and comparison.

In our research we focus on connectivity of elements in diagrams and flowcharts. The methods dedicated to this kind of graphics have to find: a) types of elements shown (various depicted shapes), b) segments of lines not belonging to found shapes, and c) connections created by these segments. Because diagrams usually contain texts embedded in diagram elements, it is also necessary to detect text areas, recognize it by applying OCR techniques and finally assign recognized texts to graphical diagram elements.

The aim of the research described in this paper was to find a method that is able to retrieve logical links between elements depicted in the diagram. This logical structure is then expressed in an XML file. It is a difficult task especially when we consider that one connection may exist between more than two elements and the line segments constituting connectors can intersect.

The paper consists of six sections. The next section describes related works. Section III formulates problem to solve. The subsequent section presents the developed method. Section V experimentally validates our approach. Finally, some conclusions and recommendations related to further works are presented.

## II. Related Works

Early survey of works in this area is described in [2]. The author writes that diagram recognition faces many challenges, including the great diversity in diagrammatic notations, and the presence of noise and ambiguity during the recognition process. Despite the flow of time from the year of this publication, all mentioned above features characterizing diagram interpretation constantly cause problems in chart recognition now.

The paper [3] reviews research from the last decade. The authors present the whole process of chart recognition: chart segmentation, chart classification, chart interpretation and discuss existing solutions.

Relatively many works are devoted to online flowcharts recognition. In [4], the analysis to label each stroke of the flowchart and to group the strokes depending on the symbol they belong to is presented. The same area of research is

978-83-60810-66-8/$25.00©2015, IEEE

represented in the paper [5]. In this paper the search for a suitable interpretation of the input is formulated as a combinatorial optimization task containing the max-sum problem. The recognition pipeline consists of two main stages. First, groups of strokes possibly representing symbols of a sketch (symbol candidates) are segmented and relations between them are detected. Second, a combination of symbol candidates best fitting the input is chosen by solving the optimization problem. The work [6] also concerns online charts but is focused on hand-drawn electric circuit diagram recognition using 2D dynamic programming. The paper [7] presents another approach to hand drawn organizational diagrams that is based on Bayesian conditional random fields (BCRFs) that jointly analyzes all drawing elements in order to incorporate contextual cues. The classification of each object affects the classification of its neighbors. BCRFs allow flexible and correlated features. The online recognition of diagram is mainly applied in order to automatically check student tests.

Currently there is a great interest in flowchart recognition in the context of patent search. The paper [8] describes measures for assessing the effectiveness of flowchart recognition methods in the context of patent-related use cases. A survey of approaches can be found in [9]. A system for semi-automatic chart ground truth generation is introduced in the paper [10]. Using the system, the user is able to extract multiple levels of ground truth data.

Some works are devoted to chart recognition in documents. They apply various classification methods. In [11] spiking neural networks are used. The paper [12] presents a system for recognizing a large class of engineering drawings characterized by alternating instances of symbols and connection lines. The class of considered images includes domains such as: flowcharts, logic and electrical circuits, and chemical plant diagrams. The output of the system includes a list identifying the symbol types and interconnections. It may be used for design simulation or as a compact portable representation of the drawing. The method consists of two steps. First, domain independent rules are used to segment symbols from connection lines in the drawing image that has been thinned, vectorized, and preprocessed in routine ways. Then a drawing understanding subsystem works together with a set of domain-specific matchers to classify symbols and correct errors automatically. They also proposed an interface to correct residual errors interactively.

Another important problem in diagram recognition and its automatic interpretation is recognition of texts appearing on diagrams. Separation of textual and graphical layers simplifies the further diagram structure analysis by reducing a number of involved graphical elements. It also makes it possible to attach textual information attributes to detected graphical elements of the diagram. In our approach we used the text separation method described in [13]. The method consists of three stages. In the first stage the text region candidates are elicited based on connected components analysis and some simple geometrical properties of connected components clusters. At the second stage, pattern recognition methods are applied to the set of candidates to discriminate between true text areas and other "false" candidates. Finally, OCR is applied to candidate regions and the final text region set is refined based on the analysis of the contents of the OCR-recognized strings.

## III. Problem formulation

In the further part of this article by a *diagram* we will mean a drawing that shows a set of entities - *diagram elements* (DEs) and connections between them. In the literature, the term "diagram" is used interchangeably with "chart", but diagram seems to be more general. We will be considering diagram images created with appropriate software or precisely drawn manually using drawing tools (rulers, drafting templates) and then converted into raster images by scanning. Hand-sketched diagrams are out of the scope of this article due to big inaccuracies appearing in this type of drawings. Our aim is to retrieve the logical structure of the diagram, so that it corresponds to intents of the diagram author. Informally, by the logical structure of the diagram we mean here the links between diagram elements. Diagram elements represent various items appearing in the real world modeled by the diagram. Their meaning depends on the domain of application. In the case of program flowcharts they can represent: statements, code blocks, conditions, data sources etc. In a logical circuit diagram they represent gates and functional blocks like: registers, multiplexers, flip-flops, etc. In organizational charts their elements are usually officials or departments. Although the method described here can be applied to any kind of diagrams, we mainly focus on organizational charts and program flowcharts. The element of the diagram is depicted by a simple 2D geometric shape like: rectangle, circle ellipse, rhombus, diamond. There are some attributes assigned to diagram elements. The basic attributes of an element are the kind of 2D shape and the textual description (the text usually inscribed into the element shape). Additional attributes that can be easily retrieved from the diagram image are: the shape interior color, shape line color and the shape border line width. They can be meaningful in certain types of diagrams, in other types of diagrams they may be ignored. The methods used to recognize shapes appearing in diagrams and to evaluate their attributes will be shortly described in the section IV-I.

The link in the diagram represents a logical relation or an association between DEs. Links are graphically represented by polylines or sets of intersecting or connected polylines, which endpoints are in the close vicinity of DEs being connected. Depending on an application domain, various types of links can be distinguished. The simplest links are one-to-one links which represent the association between a pair of DEs. The many-to-many link is the more complex case that associates the larger set of DEs. The links can be undirected or directed. In directed links some polyline endpoints are arrows. The directed link usually indicates the information flow or organizational subordination. If directed links are used the many-to-many association may turn into one-to-many association where only the single endpoint of the link is not arrowed, while all remaining endpoints are arrows. The graphical representation of the link will be further called *connector*. The connector is therefore the set of polylines that intersect each other or constitute T-style junctions. Finding connectors that are known to represent one-to-one links is a simple technical problem. Also in the case where it is known that the connection of polylines belonging to a common connector is indicated by dots (or other graphical marks) placed at connection points, the problem only lies in reliable connection marks recognition. It is however much more complicated if we cannot assume that connections of polylines belonging to a connector are graphically marked by connection marks. In such case the recognition of diagram structure must be based on the trial to "guess" the diagram author intention. In the further part of the paper, we will describe the method that deals with this kind of diagrams.

We are considering here the method which starts with vectorized diagram image on its input. The vector representation of the original (raster) image is obtained by applying the sequence of image processing operations followed by the vectorization procedure that converts a binary image into the set of line segments (vectors). Let us also assume that DEs have been already successfully found. In our approach we used the shapes recognition method based on vector sequence matching to basic shapes defined either by rules or algebraically, as described shortly in section IV-I. The vectors constituting found DEs were identified and extracted from further considerations. Let $E = \{e_1, e_2, ..., e_N\}$ denote the set of found DEs and let $L$ denote the set of line segments (called later *edges*) not assigned to any detected DE. The edge is a pair of 2D points being its ends on the plane $l_j = (p_{0j}, p_{1j})$, $p_i = (x_i, y_i)$. Line segments in $L$ possibly belong to connectors. Formally, a connector is a subset of connected edges from $L$. Our aim at this stage is to gather as many as possible edges into disjoint subsets $C_i \subseteq L$ corresponding to connectors, while leaving as little as possible lines unassigned, i.e. belonging to the unassigned set $U$. The result is the family of subsets $\{C_1, C_2, ..., C_M\}$. The construction of connector sets can be considered as a rule-based process, where rules define some constraints that must be satisfied in order to put a certain subset of edges into a connector, as well as principles that force inclusion of some edges in a single connector. Rules determining principles of reasonable construction of connectors were derived from the analysis of diagram structures appearing on typical diagram images. The analysis has been carried out using the set of diagram images from various domains, that we used for testing of our diagram analysis methods. The rules defining the construction of a connector $C_i$ of $L$ are as follows:

- the elements of $C_i$ are coherent (i.e. for each pair of edges in $C_i$ there is a sequence of other edges in $C_i$, possibly empty, that connects them);
- if there is an edge in $C_i$ that has a vertex not shared with other lines in $C_i$ (i.e. it is the endpoint of a polyline which elements are within $C_i$) then it must be close to one of detected DEs from the set $E$, such a vertex is a *terminal vertex*;
- there are no two vertices of edges in $C_i$ that are terminal vertices and are close to the same DE (the connector consisting just of a single edge cannot link the DE with itself);
- there are no cycles in the graph defined by the set $C_i$, i.e. there are no polylines in $C_i$ that intersect with themselves;
- if there is an edge $l_a$ in $C_i$ that has a common vertex with another edge $l_b$ in $L$ and $l_b$ is not assigned to any other connector $C_j$ then $l_b$ must also belong to $C_i$ (no connectors ending in the middle of polylines);
- if $p$ is an internal vertex shared by two edges belonging to $C_i$ then it cannot be closer than $\epsilon$ to an internal vertex shared by two edges belonging to another connector $C_j$ (connectors cannot touch each other, except of the case that the terminal edge endpoint touches a terminal edge endpoint of another connector);
- each edge is uniquely assigned to one of subsets $C_i$ or to $U$ (edges are not shared by connectors);
- the longest path connecting two terminal vertices in $C_i$ cannot be longer than assumed threshold i.e. 8 (no connectors of very complicated shape);
- the angle between two adjacent edges in $C_i$ which do not share the common vertex with any other edge within the same connector is not smaller than the right angle (no acute angles in the polyline segments of connectors);
- width of each edge within $C_i$ does not differ by more than 30% from the weighted average line width in the connector;
- two elements $e_i, e_j \in E$ cannot be connected along more than one path within the single connector (they can be however connected by many paths, provided that they belong to different connectors).

Because it seems reasonable to merge connectors into more complex ones, as far as it does not lead to violation of rules presented above, then the ultimate aim is to partition the set $L$ into the family of subsets $\{U, C_i : i = 1, ..., M)\}$ so as to minimize the number of subsets $C_i$ with the additional constraint that the set $U$ does not contain any subset of edges that constitutes a valid connector.

For practical purposes related to automatic analysis of the diagrams it is essential not just to find connectors (being the sets of edges) but rather to determine the sets of connected DEs which are connected by individual connectors. Therefore, the final result of the structure recognition procedure is the family of sets of DEs, where each set defines elements connected by the single connector. Additionally, because each connector endpoint can be marked with an arrow, this information should be also retrieved and included in the data structure being the output of the recognition procedure. Each endpoint of the connector is described by a pair $(e, t)$ where $e \in E$ and $t \in \{true, false\}$ indicates whether or not the endpoint of the connector linked to $e$ is an arrow. The elements connected by the single connector $C$ can be specified by the multiset $V_C = \{(e_i, t_i) : e_i \in E, t_i \in \{true, false\}\}$. The expression $t = true$ denotes the arrow appearance and $t = false$

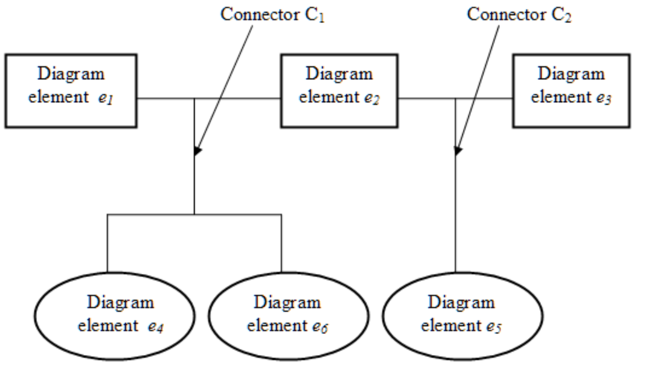

Fig. 1. Exemplary diagram consisting of two connectors sharing a common element $e_2$.

denotes arrow-less connector endpoint. Multisets are applied here instead of simple sets because the diagram element can be connected with itself. In such case there exist two connector endpoints associated with the same element. It leads to the appearance of the pair containing this element twice in $V_C$. Finally, the product of the diagram structure recognition is the set of connectors and the family of corresponding multisets of connected diagram elements:

$$(\widehat{C}, \widehat{U}) = (\{C_i : i = 1, ..., M\}, \{V_{C_i} : i = 1, ..., M\}), \quad (1)$$

where $M$ is the number of detected connectors. A DE may belong to more than one multiset $V_{C_i}$ if it is connected with other DEs by various connectors. The case where the central element is shared by two connectors is shown in Fig.1. The elements of the diagram are connected by two connectors: $C_1$ and $C_2$. In this case, the structure recognition procedure builds the following diagram description:

$$\begin{aligned}(\widehat{C}, \widehat{U}) = (&\{C_1, C_2\},\\ &\{\{(e_1, false), (e_2, false), (e_4, false), (e_6, false)\}, \quad (2)\\ &\{(e_2, false), (e_3, false), (e_5, false)\}\}).\end{aligned}$$

## IV. Description of the method

Unfortunately, the formulation of the diagram structure recognition problem does not lead to an efficient solution, other that "brute force" approach based on exhaustive search of all subsets of $L$, which is obviously infeasible in most practical cases. Therefore, we propose simplified suboptimal solution that leads to construction of a connector set $\{C_1, C_2, ..., C_M\}$, which however does not guarantee that the minimal number of connectors are found. On the other hand however, it applies some intuitive principles that humans typically apply when trying to read a structure on a diagram presented on an image. Experiments described in section V show that diagram structure recognized with the proposed algorithm is close to the human interpretation of test diagram images.

The approach taken consists in the observation that when a human tries to find connectors in a diagram by sight, it intuitively starts with long edges and tries to interpret them as "simple connectors" connecting pairs of DEs. Then a human tries to find "branches" that connect other DEs to previously found simple connectors. Next, one tries to find inter-connectors, i.e. polylines that connect previously found connectors. Finally, we (humans) try to merge already found connectors into more complex ones by finding intersecting lines belonging to various connectors that are candidates for merging. It is a process that starts with simple and obvious connectors and gradually extend them to more complex structures. This process can be modeled as a procedure implemented in a computer. Each stage outlined above is in fact an iterative operation that processes successive items (edges, polylines, simpler connectors - depending on the stage), where each iteration may lead to modification of the connector set obtained so far. The modification is however conditioned on the rules set presented in the previous section. If it leads to violation of constraints defined by the rules then the modification is not carried out. In this way, at each stage of the procedure we have the diagram structure that is consistent with the assumed principles.

Now the procedure will be described in more details. The input to the procedure is the set of diagram elements $E$ and the set of line segments (vectors) obtained from the raster image vectorization procedure (vectorizer). The applied vectorization procedure is based on the algorithm described in [14]. We will not deal here with the details of methods of shape recognition used to obtain the set $E$. They are briefly described in the subsection IV-I. In the proposed algorithm, the set of constants usually applied as thresholds are utilized. Values of these thresholds were estimated experimentally by analyzing a set of typical diagram images from the validation set. The selected validation set is disjoint from the testing set used in order to evaluate the method performance.

The connectors finding method consists of the following steps:

### A. Edge detection

The aim of this step is to create the set of edges $L$ from the set of line segments fetched by the vectorizer. We use the term "edge" to emphasize the difference in relation to the notion of simple line segment which is the direct product of vectorization. The line segments created by the vectorizer should not be used directly in further steps of the procedure. Our experiments showed that there are some troublesome artifacts, especially at intersections of relatively thick lines or at vertices of polylines. They are short line segments of the length of single pixels that connect longer line segments. Such geometrical structures need a kind of smoothing in order to obtain longer and straight line segments, most likely being "true" lines in the original diagram. Here we call such smoothed and merged line segments "edges". An example of an erroneous line segment structure created by the vectorizer is presented in Fig.2. The unwanted artifacts are indicated by blue circles.

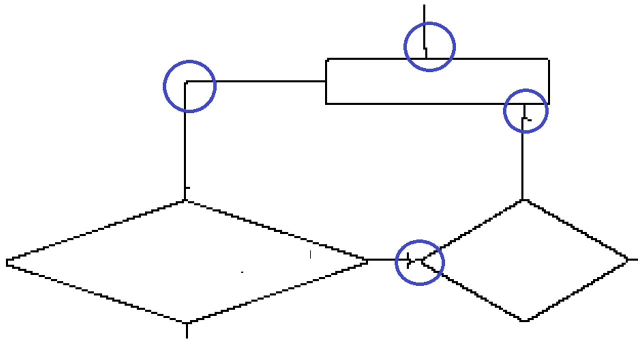

Fig. 2. Examples of inaccuracy artifacts introduced at the stage of image vectorization

The procedure takes the line segment that is not yet assigned to any element in $E$ nor to any edge in $L$ and tries to extend it to a longer edge by building a polyline being a sequence of interconnected line segments. In each iteration the algorithm tries to attach the next line segment that is adjacent to one of end points of the already created polyline. This segment is selected that is most collinear with the straight line approximating already created polyline. The attachment criterion is used to select candidates for extension. It takes into account the angle between the candidate segment and already approximated line and the length of the candidate. Short segments (being probably artifacts of the vectorization procedure) can be connected even if the angle is relatively big. The logical predicate used as the extension criterion is as follows:

$$\angle(e,c) < \alpha_{max} \vee len(l_t) \leq l_{min} \vee len(c) \leq 1.5 * w, \quad (3)$$

where $e$ is the edge (single line segment) approximating the polyline created so far, $c$ is the line segment - the candidate for extension, $l_t$ is the terminal line segment in the polyline that is adjacent to $c$ and $len(\bullet)$ is the length of the line segment. $w$ is the average width of the line segments already attached to the polyline. $\alpha_{max}$ was experimentally set to $10°$.

According to the criterion (3), the angle between connected segments must be small enough or at least one of adjacent segments (the candidate one or the terminal segment) is short enough. This alternative makes it possible to use residual vectors of the length of 1-2 pixels that are artifacts of the vectorization procedure. Such residual vectors often are oriented at big angles with the relation to its (longer) neighbors. The procedure iteratively tries to extend the polyline until no new segments can be attached. After each extension the new linear approximation of the polyline (denoted by $e$ in the formula 3) is evaluated by least square fitting of points on the polyline to the approximating line.

### B. Preparation to processing

The aim of this stage is to identify DEs that are close enough to endpoints of edges created in the previous stage. In this way it is possible to identify edges that are candidates for terminal edges of connectors. The terminal edge of the connector is the edge directly attached to the element connected by a connector. Then for all edge vertices the closest DE is found that is within assumed maximal allowed distance from the vertex. The tolerance is estimated depending of the shape and edge line widths. By analyzing the set of exemplary diagrams we assumed that the tolerance should be evaluated as $min(3 * max(w_e, w_s), 0.25 * s_{BB})$ where $w_e$ is the width of the edge line, $w_s$ is the width of the line of the DE shape and $s_{BB}$ is the smaller of $x$ and $y$ sizes of the bounding box enclosing the element. The angle between the closest element edge and the connector edge is also taken into account to avoid considering as very close an edge that is almost parallel to an edge of DE. As the result of this stage, each edge endpoint is annotated either with the index of the close diagram element or with "dummy" index, denoting that there is no close element to the edge endpoint. Additionally, the "edge structure" is created, that makes it possible to quickly find all edges in $L$ adjacent to a given vertex.

### C. Finding simple connectors

At this stage simple connectors are being found, where two DEs are directly connected by a single edge. It lies in finding edges with two endpoints marked with various diagram elements. Cases where the edge connects the shape with itself and is completely within this shape bounding box are excluded by applying one of constraints defined in Section III.

### D. Finding polyline connectors

This stage consists in finding edge sequences (a polyline consisting of edges) that connect two shapes. The procedure used here starts with a polyline consisting of a single edge that is not yet assigned to any connector. It iteratively tries to extend the polyline by attaching its left/right endpoint neighbors until no further extension is possible or the attached edge is connected to an element. Backtracking is applied in cases where there are many neighboring edges adjacent to the terminal edge in the polyline and extending edge selection in certain iteration leads to the polyline that neither can be further extended nor it terminates with the edge adjacent to any DE.

The procedure is being repeated, each time starting with an edge that is not yet assigned to any connector. If it leads to the polyline connecting two diagram elements then it is assumed to be the polyline connector. The new connector is then created and all edges are labeled as assigned to this connector.

### E. Finding inter-connectors

In the previous stages only such connectors (or fragments of connectors) were recognized which link pairs of DEs. In the next phase, new polyline connectors are tried that connect already found connectors with other connectors or diagram elements. The interconnector appears for instance in the diagram in Fig.1. At the first stage, the simple connector between elements $e_1$ and $e_2$ is found. The polyline connector linking elements $e_4$ and $e_6$ is detected in the second stage. In the current stage the interconnector that links this two simpler connectors will be recognized. The case of "branch"

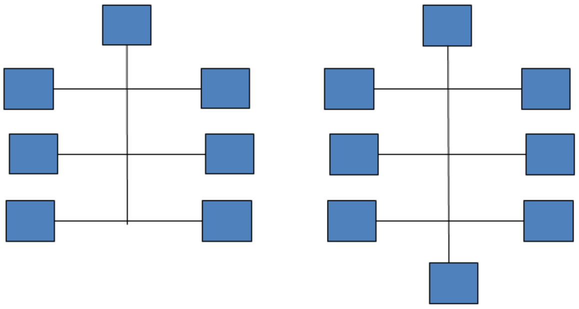

Fig. 3. Pine-like connector structures

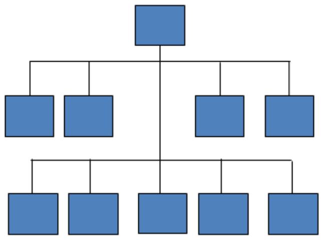

Fig. 4. Comb-like connector structures

that extends simpler connectors appears in Fig.1 in the case of the single connector that links elements $e_2$ and $e_3$. The branch consisting of the vertical edge in the right part of the diagram links the simple connector with the element $e_5$.

The procedure iterates until a single iteration does not result in any extension of the obtained connector sets. The single iteration in turn, consists of subiterations that iterate over all unassigned line segments, where each unassigned segment is tried to be extended into a polyline connecting two earlier detected connectors or a connector and a diagram element. Typically, this stage creates T-connections. T-connection is the connection of edges, where one edge perpendicular to another one touches them in the middle. The connection between the edge linking $e_2$ with $e_3$ and the vertical edge adjacent to $e_5$ is a typical T-connection.

The next two stages are aimed on merging connectors found earlier into more complex ones. Pairs of connectors that are candidates to merging must have intersecting edges. Merging all connectors having intersecting edges in many cases would lead to a structure not intended by the diagram author. Actually, the problem of simpler connector merging seems to be the hardest one in the process of diagram structure recognition. We distinguished two specific graphical configurations of edges that are typically used when composing diagrams and we perform connector merging only if the merged connector conforms to the one of these specific configurations. We called these configurations *pine-like* and *comb-like* structures. The structures are shown in Fig.3 and Fig.4

### *F. Constructing pine-like connectors*

In this step, the specific type of connector is detected which consists of a simple single edge that intersects other connectors. It is assumed that in such case the diagram creator intention was to depict the situation where elements connected by such a connector are connected each to another.

In order to find pine-like connectors, the simple connectors (being just single edges) are tested against intersection with edges of other connectors, let us call it *trunk*. All other simple connectors that intersect the trunk are merged to the group containing the trunk.

### *G. Constructing comb-like connectors*

The comb-like structure is presented in Fig.4. It consists of the vertical trunk connector intersected by one or more "combs". Comb is a connector with the principal horizontal edge to which a series of simple vertical edges (branches) are T-connected. Additionally, it is required that comb teeth are approximately of to the same length in the interval $< 0.1 * l_{pr}, 0.7 * l_{pr} >$ where $l_{pr}$ is the length of the principal comb edge. The comb-like structure must also have trunk - the vertical line being a connector that have a single DE at its top and the trunk length must be at least $2 * l_{t_{min}}$, where $l_{t_{min}}$ is the shortest tooth length of the comb. The procedure of comb-like connector construction consists in finding connectors that satisfy aforementioned conditions. The set of connectors that satisfies it is replaced in the set $\{C_1, C_{@}, ..., C_M\}$ by the product of the merge operation.

### *H. Merging connectors by dot-markers*

Finally, all these pairs of connectors are merged that contain lines that cross one with another, where there is a dot-marker at the intersection of lines belonging to various connectors. In order to consider two line segments as marked for merging, the following conditions must be satisfied:

- intersecting lines are approximately of the same width $(0.5 \leq w_1/w_2 \leq 2.0)$, where $w_1, w_2$ are widths of lines;
- lines are approximately of the same color, the color tolerance is defined for the components of 24-bit RGB color space;

$$\begin{aligned} R_{max} - R_{min} &< 30, \\ G_{max} - G_{min} &< 30, \\ B_{max} - B_{min} &< 30, \end{aligned} \tag{4}$$

- the angle between intersecting lines is approximately the right angle (with the tolerance range from 80° to 100°);
- the four diagonal pixels at the distance $\sqrt(2) * max(w_1, w_2)$ from the lines intersection point are closer in colors to the average lines color than to the background color.

The last condition is responsible for detecting the dot intersection marker at the lines intersection point.

### *I. Diagram elements recognition*

Because this paper is mainly focused on the recognition of connections between diagram elements, we will only briefly describe methods used in order to recognize diagram elements. We assume that diagram elements are: a) polygons, b) circles, ellipses or arches of ellipses and c) shapes being combination of a) and b), e.g. the symbol of a drum often used in flowcharts to denote mass storage. Methods used to recognize polygonal shapes are based on rules that define the mutual geometrical relations between line segments constituting polygon edges. For example, the parallelogram not being just a rectangle is defined as the sequence of 4 edges $(l_0, l_1, l_2, l_3)$ defined by their endpoints $(p_i^{(B)}, e_i^{(E)}), i = 0, ..., 3)$ that satisfy the set of constraints:

- $\mid p_i^{(E)} - p_{i \oplus 1}^{(B)} \mid \leq \epsilon$ for $i = 0, ..., 3$;
- either $p_i^{(E)} = p_{i \oplus 1}^{(B)}$ or $p_i^{(E)}$ is connected with $p_{i \oplus 1}^{(B)}$ by a chain of short line segments that are entirely included inside the bounding box defined by $p_i^{(E)}$ and $p_{i \oplus 1}^{(B)}$;
- $l_0 \parallel l_2$ and $l_1 \parallel l_3$;
- $\angle(l_0, l_1) \leq 90° - \alpha_{toll}$ or $\angle(l_0, l_1) \geq 90° + \alpha_{toll}$,

where $i \oplus 1 = (i+1) \mod 4$ and $\alpha_{toll}$ denotes the tolerance for right angles. The last constraint makes it possible to distinguish between rectangles and other parallelograms.

The procedure of shape recognition starts with a line segment from the vector set created by the vectorization procedure and successively tries to extend it to a sequence of segments, so that the constraints defined for allowed shapes are satisfied. It may happen that certain sequence of line segments satisfies constraints for more that single shape. For example, due to drawing inaccuracies, a quadrilateral found in the diagram may satisfy both constraints for the rectangle, the trapezoid as well as for the rounded vertices rectangle. In such a case, the measure of inaccuracy for all candidate shapes is computed and this shape is finally selected for which the inaccuracy measure is lowest. The procedure is repeated, each time starting with a next line segments that is not already assigned to any shape, until all unassigned line segments are tried.

In the case of ellipses and arches the procedure starts with a candidate edge and tries to extend it to a polyline that best approximates the ellipse fragment. Only axis-aligned ellipses are considered. Let $S = (l_1, l_2, ..., l_n)$ be a sequence of line segments that approximate an ellipse arch. At each stage the procedure tries to extend it with one of line segments that is adjacent to $l_1$ or $l_n$. Such extending segment is selected for which the ellipse approximation error is the lowest. The approximation error is the average distance of pixels constituting the polyline $S$ to the best fitting ellipse. The pixel set used for approximation is created by applying Bresenham line drawing algorithm to all lines in the set $S$. The axis-aligned ellipse is defined by four parameters: coordinates of the ellipse center $(x_c, y_c)$, the length of $x$-axis $d_x$ and the shape factor $a$ - the ratio of $x$ and $y$ axes lengths $a = d_x/d_y$. The best fitting ellipse is found using the method described in [15]. The parameters of the optimal ellipse as assumed to be within the reasonable ranges determined in relation to the image size, e.g. the ellipse $(x_c, y_c)$ center must be within the range defined by the image resolution and both ellipse axes must be not longer than the corresponding image size along $x$ or $y$ axes. If the parameters computed by the optimization procedure are out of these ranges then the approximation is assumed to fail and another extending line is tried. The extension is continued until the closed ellipse is obtained or no more lines can be attached. The final ellipse arch is accepted if it constitutes at least 50% of the complete ellipse. This acceptance threshold may seem to be high, but shapes that we consider here as diagram elements never consist of shorter ellipse fragments. On the other hand, setting too low value of the threshold may lead to false recognition of other shape elements as ellipse fragments.

## V. Experiments

### *A. Evaluation of diagram structure recognition accuracy*

The accuracy of diagram structure recognition can be assessed by the complexity of operations necessary to convert the recognized structure into the correct one (ground truth). This complexity can be measured by the summed cost of elementary operations that can be used in order to turn the recognized structure into the correct one. We focus here on the evaluation of the multiset $\widehat{U}$ as defined in (1). Let us assume that the recognized structure described by $\widehat{U}$ is to be converted into the correct structure $\widehat{U}^*$ by applying the sequence of elementary operations. In the result, the sequence of structures is created: $(\widehat{U} = \widehat{U}_1, \widehat{U}_2, ..., \widehat{U}_K = \widehat{U}^*)$ where $\widehat{U}_k$ is converted into $\widehat{U}_{k+1}$ by applying one of the following elementary operations from the set $\mathfrak{O} = \{o_C, o_S, o_M, o_C, o_E, o_R, o_A, o_D\}$ defined as follows:

- $o_C$ - creating a new connector that links two DEs;
- $o_S$ - splitting the multiset $U_i \in \widehat{U}_k$ into two multisets $U_i^1, U_i^2 \in \widehat{U}_{k+1}$ - it corresponds to dividing the compound connector into two simpler ones;
- $o_M$ - merging two multiset $U_i, U_j \in \widehat{U}_k$ into the single multiset $U_l \in \widehat{U}_{k+1}$ - it corresponds to merging two connectors;
- $o_E$ - adding a branch to a diagram element to a connector, i.e. replacing $U_i, \in \widehat{U}_k$ by the new multiset $U_i' = (U_i \cup (e,t)) \in \widehat{U}_{k+1}$;
- $o_R$ - removing a branch to a diagram element from a connector, i.e. replacing $U_i, \in \widehat{U}_k$ by the new multiset $U_i' = (U_i \setminus (e,t)) \in \widehat{U}_{k+1}$;
- $o_A$ - changing the arrow status of the connector endpoint for a certain element descriptor $(e,t)$ in a certain multiset $U_i, \in \widehat{U}_k$.
- $o_D$ - discarding of the whole result of recognition, i.e. replacing of $\widehat{U}_1$ by the empty set.

The last operation is only allowed as the first one in the conversion sequence and can be applied if the recognition result is extremely different from the ground truth diagram structure. Each operation has its cost. The accuracy of the recognized diagram structure can be assessed by the total cost of the least costly operation sequence that converts $\widehat{U}$ into $\widehat{U}^*$. This concept is similar to the edit distance widely used e.g. in automatic speech recognition accuracy evaluation or spelling errors correction ([16]). The value computed in this way is however the absolute measure of labor amount necessary to make a correction to the recognized structure. Certain value of the edit distance may indicate quite good accuracy in the case of very complex diagram, while it may correspond to a poor accuracy in the case where the diagram consists just of few elements and connector edges. Therefore the relative measure related to the actual diagram complexity seems to be more appropriate. The diagram complexity can be measured by the cost of operations necessary to build the set $\widehat{U}^*$ from very beginning, i.e. from the empty family of multisets, using only elementary operations. Let $p_o$ denote the cost of the operation $o$, and $n_o^{(\widehat{U}_1)}$ and $n_o^{(\emptyset)}$ denote the counts of the operation $o$ that must be applied to obtain the correct diagram description $\widehat{U}^*$ from the actual recognition result $\widehat{U}_1$ and from the empty set correspondingly. The total costs of corrections and building from the very beginning are:

$$P_{corr} = \sum_{o \in \mathfrak{O}} p_o * n_o^{(\widehat{U}_1)},$$

$$P_{build} = p_D + \sum_{o \in \mathfrak{O}} p_o * n_o^{(\emptyset)}. \tag{5}$$

and the final recognition accuracy can be computed as:

$$Q = \frac{P_{build} - P_{corr}}{P_{build}} \in < 0, 1 > . \tag{6}$$

The value of $Q$ is normalized into $< 0, 1 >$ interval. If the diagram is perfectly recognized then $P_{corr} = 0$ and $Q = 1$. On the other hand, if the recognition procedure totally misses then the cost of correction is not higher that discarding all recognition results (operation $o_D$) and building the structure from the very beginning. In this case $P_{corr} = P_{build}$ and in result $Q = 0$.

### B. Hardware environment and efficiency issues

The described algorithm was implemented in C++ language. Tests were carried out using the PC equipped with Intel i7 3610QM CPU and 16GB of RAM. The execution time of the algorithm varies depending on the image contents. For simple diagrams consisting of just a few DEs connected by simple connectors the algorithm is executed in less than a single second. The longest execution time (17.6 sec.) was observed in the case of the complex diagram consisting of 58 DEs. The average processing time (including image vectorization) of a single diagram was 2.4 sec. Currently the algorithm implementation is fully sequential.

### C. Results

The accuracy of diagram structure recognition was tested using three types of diagrams that differ in the complexity of intersecting connectors: a) flowcharts, b) organizational charts and c) digital circuit block diagrams. The test set consisted of 11 digital circuit diagrams, 15 flowcharts and 17 organizational charts. Flowcharts seem to have simplest connector structures, while in the case of digital circuits the intersecting connectors appear very often. Hence, the later type of diagrams is the most difficult to recognize. Because in this article we are dealing merely with the problem of connectors recognition, we selected for the tests only such diagrams, where there were no mistakes in diagram elements recognition. For each recognized diagram structure the counts of operations from the set $\mathfrak{O}$ that are necessary to correct the structure were determined as well as the number of operations necessary to build the diagram from the very beginning. We assumed that in the process of construction of the diagram only the operations of new connector creation ($o_C$) and extension of the existing connector with an additional branch ($o_E$) were used. Finally the recognition quality $Q$ was computed for each diagram. We assumed that the unit cost $p_o$ of each operation $o$ is equal to 1.0. The results are presented in Table I. Columns in the left part of the table include numbers of individual correcting operations from the set $\mathfrak{O}$, summed by types of diagrams. The meaning of operation symbols used in Table I were explained in the previous section. The column containing costs of correction/creation contain average costs for individual types of diagrams. The bottom row presents the results analogous to described for individual types of diagrams, but now they are prepared for the whole set containing all types of diagrams.

The small number of diagrams used in the tests do not give rights to create very general conclusions, although the average result for all diagrams equal to 92% is very promising. From the perspective of diagram classes, the worst average result (88% - which seems to be pretty good) was obtained for the class of digital block diagrams. This set contains the most difficult intersecting connections. Our subjective evaluation of the obtained results is very optimistic. Most errors were caused by low image quality and inaccuracies in drawing. It can be observed that there were no errors consisting in detecting neither "false" (i.e. actually not existing) connectors nor branches. The most typical error consisted in omitting connector branches to some DEs. Detailed analysis of missing branches revealed that in most cases errors of this kind were caused by too wide gaps between a diagram element and a terminal endpoint of the connector branch.

Table II presents the results of diagram structure recognition of the exemplary organizational diagram. Fig. II.1 shows the original image. All detected connectors are drawn in Fig. II.2. The connectors are drawn with thick blue lines. Remaining figures show selected individual connectors detected in this diagram. Some simple connectors were omitted and only more complex ones are presented. It is clear that intersecting connectors were properly separated and complex connectors with "branches" were constructed as intended by the diagram author. In the case of this diagram all connectors were recognized correctly.

## VI. Conclusion

The subjective and objective evaluation of the method gives us good perspective for further development of the method,

TABLE I
STRUCTURE RECOGNITION ACCURACY EVALUATION ON THREE TYPES OF DIAGRAMS

| **Diagram type** | **Correction (number of correcting operations)** | | | | | | **Construction (number of constructing opeartions)** | | | **Q** |
|---|---|---|---|---|---|---|---|---|---|---|
| | $o_C$ | $o_S$ | $o_M$ | $o_E$ | $o_R$ | Correction cost | $o_C$ | $o_E$ | Construction cost | |
| Digital circuits | 3 | 0 | 8 | 0 | 19 | 30 | 191 | 22 | 224 | 0.88 |
| Flowcharts | 2 | 0 | 1 | 0 | 10 | 13 | 178 | 12 | 205 | 0.94 |
| Organizational diagrams | 2 | 0 | 1 | 0 | 12 | 15 | 308 | 14 | 339 | 0.96 |
| Total: | 7 | 0 | 10 | 0 | 41 | 58 | 677 | 48 | 768 | 0.92 |

although we realize that the set of diagrams used in order to asses the quality of structure recognition is quite small and conclusions drawn from described experiments may be disturbed by the random factor. In future, significantly bigger set of diagrams will be manually annotated and used for reliable accuracy estimation.

The main weakness of the proposed method seems that it utilizes the set of constants-thresholds, in most cases defining tolerances of various graphical attributes (lengths, angles, widths, distances etc.). It makes possible to correctly recognize some structures that are drawn inaccurately but, on the other hand, it may also lead to recognition errors. In our experiments we tuned these constants intuitively, so as to obtain best recognition results on the validation image set (which is disjoint from the test set). We cannot however assure that these parameter values are selected optimally. In future works, other method of parameter tuning should be applied that will make it possible to find suboptimal parameter values without the engagement of a human. Image processing methods used at the stage of diagram image binarization and vectorization should also be improved, so that low quality images as well as images with background patters or containing "decorated" shapes can be more reliably analyzed.

Some problems encountered in determining connections between diagram elements are caused merely by low quality of scanned images, while others follow from complicated shapes of connectors that intersect each other. In future, an experiment will be carried out which will compare the average accuracy achieved in a set of scanned images with the accuracy achieved in a set of images directly converted to the raster format, e.g. by saving the image created in a graphic diagram editor.

***Abstract*—The following paper presents a simple and fast liveness detection method based on gaze direction estimation under a challenge-response user authentication scenario. To estimate a line of sight, a procedure composed of several steps, including face and eye detection, derivation of gaze direction representation and subsequent classification, has been proposed. The proposed, novel gaze orientation descriptor is easy to compute and it provides sufficiently accurate estimates for the considered task. To assess a probability of genuine biometric trait presentation, recorded gaze direction responses induced by presentation of a randomly generated on-screen object, are matched against expected patterns.**

## I. Introduction

ONE OF the main threats that exist for unattended biometric authentication systems are so called 'presentation attacks', where a system is presented with a biometric artefact. The problem becomes especially severe when easy-to-spoof biometric traits are considered, such as e.g. fingerprints, face or iris images. To enable unattended (including remote, by means of popular mobile devices) user verification, biometric systems must cope with the stated problem. For this purpose, a methodology aimed at verification of biometric trait authenticity, referred to as liveness detection, has been developed.

Existing liveness detection approaches can be broadly categorized into two main groups: methods that exploit physiological properties of tissues and organs subject to analysis and various challenge-response schemes. Liveness detection is therefore trait-specific and many diverse ways for its assessment have been proposed so far. For example, several different tests are available for iris image authenticity verification, such as application of varying intensity illumination levels to check for iris physiological responses (this approach combines challenge-response scheme and physiology), analyzing presence of saccades or analyzing spectra of reflected light. Approaches considered for liveness testing in case of face-based recognition include blink detection [1], detection of eye-movements [2] detection of presence of facial expressions [3] or lip motion detection [4]. A natural means against presentation of photos provides 3D face recognition (however, it clearly becomes vulnerable if 3D masks are used). Fingerprint validity can be assessed by analyzing perspiration processes. For some biometric traits, such as vein pattern structure, liveness detection is an intrinsic component of the adopted recognition methodology, as vein imaging (blood-flow imaging) is possible only for living tissues.

Widespread availability of mobile devices equipped with cameras and microphones brought up an interest in exploiting face images and voice in remote biometric authentication, despite their well-known limitations. One of the main problems that needs to be addressed in this scenario is clearly liveness detection. One of the most natural liveness detection schemes used in case of speaker recognition is a challenge-response procedure, where a speaker is prompted to utter some randomly generated text, and only after positive verification of the response, a biometric system proceeds with user-verification procedure. An application of a similar challenge-response scheme in video based face analysis have been proposed in [5], where a challenge requires a user to make voluntary blinks and mouth movements (opening and closing). Another interesting example of challenge-response scheme that utilizes gaze tracking and that is intended as a secure method for logging to computer systems has been proposed in [6]. A set of icons, which includes a randomly scattered subset of previously memorized ones, is displayed to a user, who is supposed to trace (with her/his eyes) a path, that defines a convex hull built upon known icons.

The presented paper proposes a simple liveness detection method that is based on verification of line-of-sight trajectory compliance (a response) with some expected pattern (a challenge). The pattern is defined by subsequent locations of a marker that gets displayed at random locations of a screen. The main element of the proposed method is a novel gaze direction estimation algorithm, which is computationally inexpensive, enabling its real-time application even on machines with limited computing power, such as mobile devices. Simplicity of the proposed gaze detection method results from its specific context: horizontal line-of-sight displacement evaluation is sufficient for execution of liveness detection procedure.

The proposed gaze detection method conforms to a general framework of the domain and includes two phases: derivation of eye-image representation that correlates well with gaze direction, followed by gaze direction evaluation. As widely available devices are considered for the method implementation, gaze tracking is performed using regular visible light cameras (the best performing gaze tracking

methods exploit near infrared range and typically use infrared light sources [7]).

Several different eye image representations have been proposed for the purpose of gaze tracking applications. They belong to two broad categories: representations based on mutual locations of salient geometric eye features, such as inner and outer eye corners, iris/pupil centers, and appearance based representations (a broad review of relevant methods can be found e.g. in [8]). Gaze direction assessment exploiting features from the former group is basically a regression problem that can be solved using e.g. Support Vector Regression (SVR) [9] or neural networks [10]. For appearance-based descriptors, gaze direction assessment is made e.g. by computing between-region correlation coefficients [11] or using mean-shift algorithm [12]. The proposed algorithm for line-of-sight direction estimation is based both on salient feature detection and appearance-based eye modeling, and it is followed by regression based analysis, so it combines both of the presented general methodologies.

A structure of the presented paper is the following. The proposed gaze detection algorithm has been introduced in Section 2. Section 3 presents a background used for challenge-response liveness detection. Finally, experimental evaluation of the proposed method has been presented in Section 4.

## II. Gaze Estimation Algorithm

Block diagram of the proposed algorithm has been depicted in Fig. 1. A general idea of the proposed line-of-sight direction estimation is to confront information extracted from two eye images, where one of them is mirrored, so that deviations from a central fixation point (determined during a calibration phase of the procedure) get amplified.

The procedure begins with face detection, followed by eye-region detection, both performed using a well-known Viola-Jones algorithm [13]. The detected regions (containing the left and the right eye) are further refined by vertical and horizontal cropping, performed to increase processing speed and to facilitate subsequent analyses by eliminating complex yet unrelated structures, such as eyebrows. The resulting regions of interest (ROI) become a domain for gaze direction assessment, which uses a quantitative descriptor that estimates eye disks horizontal offset from their ’neutral’ position (forward gaze). The descriptor is derived from Fourier spectra of marginal distributions of vertical projections of eye image intensities and gaze direction is represented by a value of a phase shift between fundamental frequencies that approximate the considered functions. The presented approach is detailed in the following subsections.

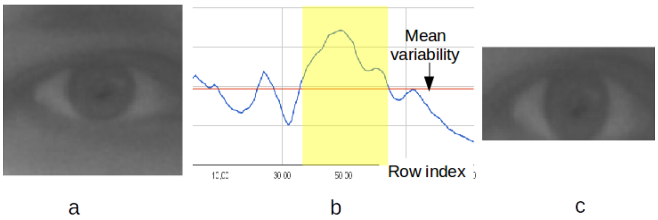

Fig. 2. Determination of vertical bounds for a rectangular image analysis window: an initial eye region produced by Viola-Jones algorithm (a), sample plot of horizontal intensity variance with the selected row interval (b) and the resulting analysis window (c)

### A. ROI Derivation

An objective of vertical cropping of initial eye regions is elimination of irrelevant upper and lower image structures, such as e.g. eyebrows. To adjust initial eye regions vertically, we propose to analyze horizontal image variability. As eye images always contains regions of extreme intensities (white cornea versus black pupil), variability of image intensities along these rows is expected to dominate over the remaining regions. A criterion for selection of vertical bounds of a rectangular window that will be used for gaze analysis is based on analysis of horizontal variance projection function. We propose to extract from an initial eye region only the widest strip, composed of rows with gray-level variability above the average level, computed for the whole region (see Fig. 2).

An objective of horizontal cropping is to produce a normalized image analysis domain, where two landmarks: inner and outer eye-corners determine a system of reference. A use of eye corners as landmarks has important advantages (they are distinctive and separated by a fixed distance from each other, which offers a basis for pose estimation).

The proposed eye-corner detection method operates on vertically-cropped image eye-regions. To compensate for illumination variations, prior to further processing, eye region images are normalized in intensity. The algorithm begins with corner detection procedure, which seeks for image points with large contents variability. Two well-known methods that differ in the adopted decision criterion were examined to do the task: Harris [14] and Shi-Tomasi [15] detectors. Both methods were able to correctly detect all salient image points, including eye corners (see Fig. 3). However, as the Shi-Tomasi method favors features that are easier to track (this is an important aspect from the standpoint of computational efficiency of the algorithm), it has been selected in further analyses.

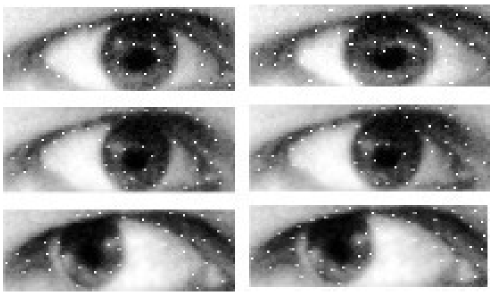

Fig. 3. Corner detection results in input images produced using Harris detector (left column) and Shi-Tomasi detector (right column).

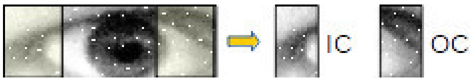

Fig. 4. Eye corner search domains (IC - inner corner search region, OC - outer corner search region).

As it can be seen from Fig. 3, corner detection procedure results in identification of a large set of salient points. To find eye corners, elements of this set are subject to subsequent analysis. Firstly, its domain gets restricted, so that inner and outer eye corners are sought only in feasible eye subregions, defined as boundary vertical bands of width set to 25% of eye image (Fig. 4).

To identify eye corners among a set of available salient points, a descriptor that summarizes image appearance within a square, 15×15 neighborhood around a salient point, has been generated. The neighborhood is divided into quadrants of size $r \times r$, $r$ =8 (with overlapping boundaries), and mean image intensity gradients are evaluated within each quadrant. A descriptor of a salient point $\mathbf{P}^{i,j}$, located in $i-$th row and $j-$th column of an image, is thus a collection of four vectors:

$$\mathbf{S}^{i,j} = \left[\mathbf{g}_{\mathrm{TL}}^{ij}, \mathbf{g}_{\mathrm{TR}}^{ij}, \mathbf{g}_{\mathrm{BL}}^{ij}, \mathbf{g}_{\mathrm{BR}}^{ij}\right] \quad (1)$$

where subscripts T,B,L,R label quadrants (top, bottom, left and right) and the mean gradient of pixel intensities $I(k,l)$ in a quadrant XY ($\mathbf{g}_{\mathrm{XY}}^{ij}$) is given by:

$$\mathbf{g}_{\mathrm{XY}}^{ij} = \frac{1}{r^2} \sum_{k,l \in \mathrm{XY}} \nabla I(k,l) \quad (2)$$

Descriptor gradient vectors were finally normalized in length, so that they sum up to unity. Salient points are matched against eye-corner models. Four separate eye-corner models (inner and outer for the left and for the right eye), of the same structure as given by (1), were generated from a set of manually labeled images (five images per each corner - see Fig. 5). Descriptors derived for training images for particular eye corners were averaged, forming the corresponding eye-corner models $\mathbf{C}^{\mathrm{IL}}, \mathbf{C}^{\mathrm{OL}}, \mathbf{C}^{\mathrm{IR}}, \mathbf{C}^{\mathrm{OR}}$, where I,O,L,R denote inner, outer, left eye and right eye respectively. As it was the case for salient point descriptors, also eye-corner model gradients were analogously normalized in length. The derived models were matched against salient points that are present in the corresponding eye-image bands (i.e. inner left eye-corner model was applied to salient points present in the 'IC' region of the left eye image etc.). A matching score was defined as a sum of dot products between components of a corner's $\alpha, \beta$ model descriptor and some considered salient point's descriptor:

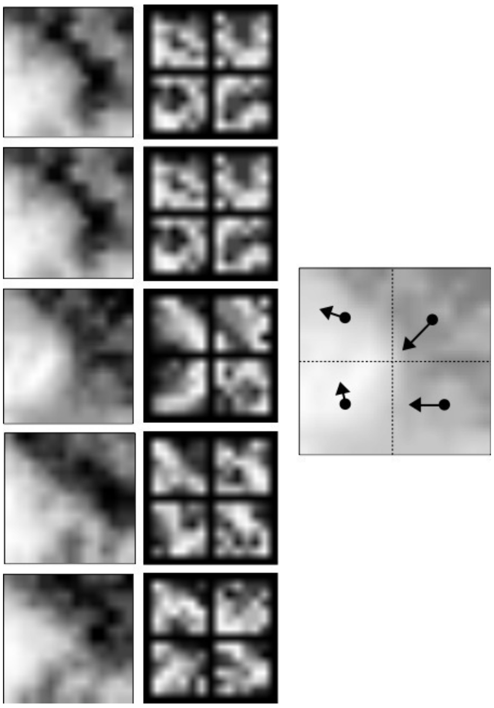

Fig. 5. Generation of eye-corner model: manually selected instances of inner left eye corner (left column), gradient magnitudes derived for quadrants (middle) and the resulting gradients (right).

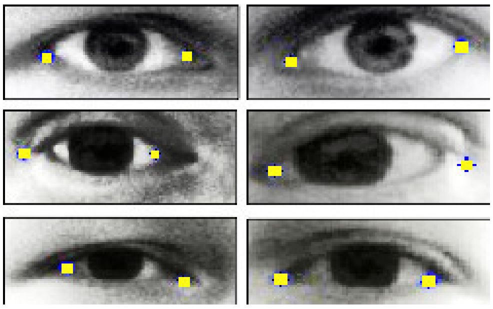

Fig. 6. Sample eye corner detection results performed for three different persons using the presented algorithm.

$$F_{\alpha,\beta}^{ij} = \sum_{k=0}^{3} \langle \mathbf{S}^{i,j}[k], \mathbf{C}^{\alpha,\beta}[k] \rangle \quad (3)$$

The score (3) gets maximized for salient point neighborhoods that match a particular eye-corner model. Sample results of eye-corner detection have been presented in Fig. 6.

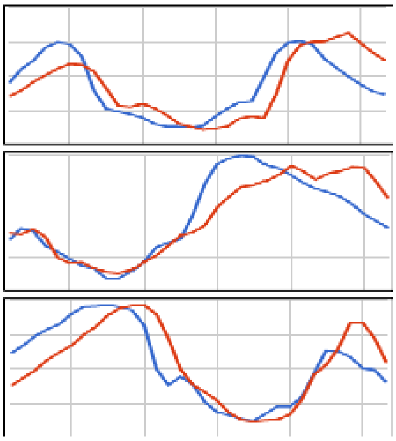

Fig. 7. Plots of image intensity distribution accumulated along a vertical axis for three different gaze directions: forward (top), left (middle) and right (bottom), for left (red) and right (blue) eyes.

### B. Line-of-sight Direction Assessment

Regions of interest, derived for both eyes, provide domains that comprise information relevant for gaze direction assessment. To provide fast and accurate estimation of gaze direction, an appropriate descriptor that can be easily computed and that is robust against possible image artifacts, needs to be derived.

To meet the formulated goals, we decided to generate gaze direction descriptor based on differences in general appearance of left and right eye strips in horizontal direction. The appearance of a strip can be summarized using marginal distribution of strip pixel intensities accumulated in vertical direction. One can observe that a general shape of the resulting function is line-of-sight direction specific (see Fig. 7). Such a general shape can be easily quantified by using leading components of any of possible signal orthogonal transformations, such as e.g. Discrete Fourier Transform (DFT). DFT has been chosen as a basis for eye appearance representation and spectra of marginal distributions of vertically accumulated intensities, derived for different images (see Fig. 8), were analyzed. We found that the first periodic component appears to be an attractive means for summarizing eye appearance, as its phase shows good correlation with a gaze direction. Examples of approximation of marginal gray-level distributions by means of a fundamental component of its DFT decomposition have been shown in Fig. 9.

To amplify sensitivity of the representation, we decided to confront the approximation produced for marginal distribution derived for one of the eyes with an approximation produced for the mirrored marginal distribution of the other eye (see Fig. 9). Thus, a final descriptor of gaze direction is a phase difference between two first harmonics, where the first one approximates the marginal intensity distribution derived for the left eye and the second one approximates a mirrored distribution derived for the right eye.

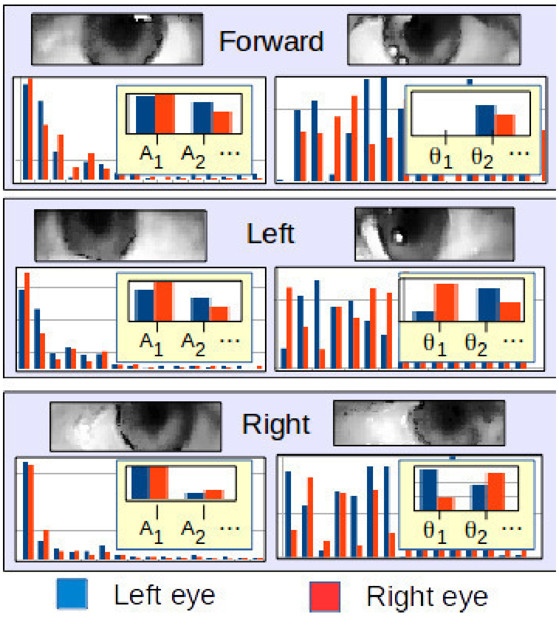

Fig. 8. Magnitude (left column) and phase (right column) spectra derived for marginal distributions of vertical image intensities for three gaze directions: forward (top), left (middle) and right (bottom) (magnitudes and phases of the two first periodic components have been enlarged for illustration clarity).

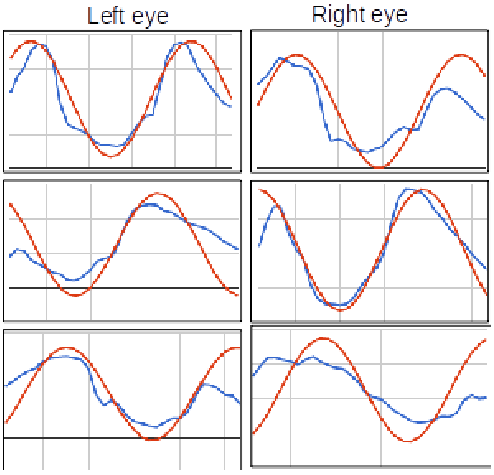

Fig. 9. Marginal distribution approximations using the first DFT harmonic component for three different line-of-sight directions: forward (top), left (middle) and right (bottom).

## III. Liveness Detection Procedure

Challenge-response scheme has been used as a framework for liveness detection, where the challenge is an on-screen presentation of a marker (a circle) in time-varying locations and the expected response is a corresponding line-of-sight direction adjustment. Objects are presented at random locations and the system is attempting to determine the induced gaze direction, thus verifying a required reaction. If probability of correct gaze detection exceeds 0.5, one can expect that successive repetitions of the procedure will eventually provide a required level of confidence that a user actually responds to a challenge. To derive a quantitative estimate of number of trials that are required for getting some predefined confidence level, we assume that the considered liveness detection scheme can be expressed in terms of a Bernoulli process. The main error in gaze direction estimation results from erroneous detection of eye corners, that can happen equally likely for any viewing angle, we assume that probabilities of correct gaze detection are the same, regardless of this angle. This justifies adoption of the Bernoulli scheme and allows to define the two outcomes required by the process in the following manner. A success occurs if a response (estimated line of sight) falls within an expected angular interval around actual position of a marker (we assume that an angular range of on-screen locations is evenly split into an even number of intervals). Otherwise, we consider that an outcome of an experiment is a failure. Given this framework, and given success and failure probabilities, we can estimate a number of challenge repetitions that is required to meet some predefined confidence level (or equivalently, liveness detection error probability). It can be shown [16] that probability of correct classification of at least $\frac{n+1}{2}$ elements of $n$-element sequence $Q$, given probability of correct entry classification $p > 0.5$ :

$$p(Q,n) = \sum_{i=1}^{(n+1)/2} \binom{n}{\frac{n-1}{2}+i} p^{\frac{n-1}{2}+i}(1-p)^{\frac{n+1}{2}-i} \qquad (4)$$

converges to unity as $n \to \infty$. Therefore, it is always possible to find such $n$ that provides some desired confidence level $T$ of an affirmative decision.

## IV. Experimental Evaluation of the Procedure

The experimental setup used for proposed algorithm evaluation was the following. An application for generating a challenge draws a single marker at time-varying, seventeen equidistant discrete locations (a marker is a circle of a fixed size). Locations of the marker change every 2 seconds. During gaze direction detection accuracy tests marker locations were periodically updated in an oscillating manner. During liveness detection tests, marker locations were randomly selected. A user was situated in front of a screen at a fixed distance, so that marker is observed within a range of angles starting from -30 degrees to +30 degrees. A simple web camera, positioned centrally atop a screen was monitoring user's responses (challenge generation and image acquisition processes were synchronized). Each recorded frame was subject to a separate analysis (no object tracking mode was used, to provide more data for evaluation of all procedure steps).

Two databases were used throughout the experiments. The first one was prepared by the Authors and comprises 415 low resolution (640 × 480) test images of three subjects with manually labeled four eye corners and with labeled line-of-sight orientations. The second source of experimental material was a CAVE database [17]. 1176 high resolution (5,184 × 3,456 pixels) images of 56 different persons, with known gaze directions, were used.

TABLE I
Eye corner detection accuracy evaluation (column labels identify a corner: OL - outer left eye corner, IL - inner left eye corner, IR - inner right eye corner, OR - outer right eye corner).

| | All | OL | IL | IR | OR |
|---|---|---|---|---|---|
| Detected | 96% | 99% | 100% | 96% | 96% |
| Identified | 79.4% | 86% | 94% | 93% | 84% |

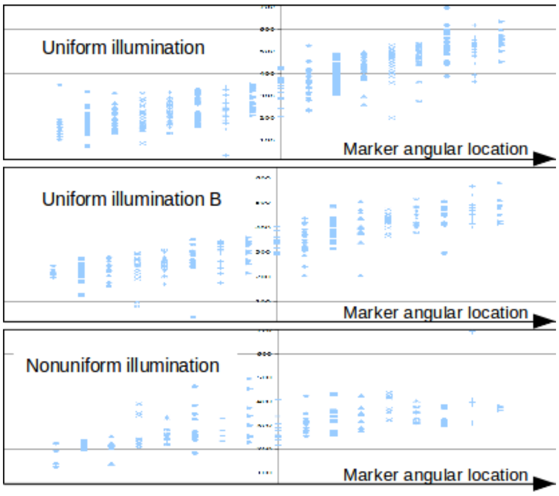

Fig. 10. Plots of estimated gaze directions with respect to actual ones for three different sets of experimental data.

The first phase of the evaluation was aimed at estimating accuracy of ROI derivation procedure. Results of eye-corner detection have been summarized in Table I. The first row shows performance of Shi-Tomasi algorithm - eye corner detection has been considered successful if any of produced salient points was sufficiently close to the considered landmark (within its 5x5 neighborhood). The second row of the table specifies performance of correct salient point identification. The first column of Table I indicates percentage of correct detection for all corners, whereas the remaining ones show scores for individual eye-corners.

The second set of experiments was concerned with evaluation of gaze detection accuracy. A set of three video sequences of a user asked to eye-track the oscillating marker were recorded and a functional relation between actual marker angular positions and positions calculated using the presented algorithm was derived. The sequences were differing in adopted illumination conditions: the first two sequences were taken under uniform illumination of different intensity, whereas in the third case a face was lit from aside. For every sequence a total of 510 frames were analyzed (an average of 30 frames per marker location). The results are summarized in Fig. 10, where plots show the computed marker locations against their actual locations. As it can be seen, there exist significant variations in gaze direction estimation, however one can identify angular intervals that can be exploited for liveness detection.

Given gaze-estimation results, it has been assumed that a marker will be displayed randomly at three different locations of a screen: two extreme positions and in the middle. An average probability of successful detection of gaze direction was evaluated to be $p \approx 0.66$. It follows from eqn. (4) that a number of required presentations of a marker necessary for obtaining a $T = 95\%$ level of confidence that a subject is actually following the marker equals 23.

The last part of experiments was concerned with evaluation of computational complexity of the proposed algorithm. The method was implemented in C++ programming language and executed on a desktop computer with i7, quad core processor, running at 2.4 GHz. The presented algorithm, excluding an initial phase of face detection and preliminary eye-region detection (both performed using Viola-Jones algorithm) took on average only 3 milliseconds to execute (the result was averaged for processing of 721 images). Although the aforementioned, initial preprocessing can be time consuming, one needs to note that it can be significantly accelerated if face tracking mode will be used for analysis of frames that follow the first one.

## V. Conclusion

The proposed algorithm proves that liveness detection can be performed using line-of-sight estimation, by using a simple camera for image acquisition. Computational complexity of the procedure is low and we believe that it can be implemented on popular mobile device platforms. There exist several elements of the procedure that need to be explored to increase gaze-direction assessment accuracy, which is important to reduce a required duration of liveness detection procedure. The main directions of further exploration will be concerned with improving eye-corner identification performance (e.g. by applying multi-resolution analysis) and with modifying the adopted eye-image representation (e.g. by including more components of DFT decomposition of eye images).

## Acknowledgment

The Authors wish to thank Dr Piotr Duch for his invaluable help in formulating the presented concepts.

***Abstract*—The head movement based control methods in the 3D graphic applications requires the real-time face position estimation. Therefore, the tracking method at the high speed and with the minimal latency is needed. This is especially hard to achieve when the face is tracked with the use of the high resolution video image on mobile devices. In the article, we present several methods for an acceleration of the face position estimation method based on the fuzzy skin color classifier and other color-based face tracking methods. The acceleration is achieved through a highly parallel GPU computation, the precalculation of the classifier weights and through the combined computations on the GPU and the CPU. The achieved computation time is independent of the used skin color classification method, allowing for use of very complex classifiers. The presented methods provides the robust head position tracking on the high resolution video image of 1920x1080 pixels, at 300 frames per second, on the mobile device with a low computing power.**

## I. Introduction

THE head position tracking can be used as a multiplatform control method on desktop computers, laptops, game consoles and hand-held mobile devices. In the latter case it is especially important as the available touch-based control methods are not suitable for many interactive applications, due to the low precision and the fingers obscuring the screen. Moreover, when we are using the hand-held mobile device, the change of a relative head position does not require the actual movement of the head and can be changed by the rotation of the device.

The face tracking can be used, inter alia, for three-dimensional imaging technique called the *Head-Coupled Perspective* (*HCP* abbreviated) [1][2][3][9] which gives the impression of the depth of the presented 3D scene by dynamically linking the perspective of the rendered scene with the current head position. The rough head tracking in three degrees of freedom is sufficient for this imaging technique. For the depth sensation more important than the face tracking accuracy are its smoothness (i.e. the lack of the jittering and the unnoticeable difference between two consecutive estimated head positions), a high frequency of tracking and its low latency (i.e. short time between the actual head movement and the application response). These requirements are difficult to achieve in the case of the face tracking on the high resolution video image. Also it must be taken into account, that the head tracking is just one of the costly calculations that the interactive application needs to perform in a real time. On the mobile devices the additional limitation is their low computing power.

On the mobile devices it is possible to estimate the relative position of the user's face on the basis of other internal device sensors like the accelerometer or the gyroscope [6][7]. The rotation and the orientation of the device can be determined based on the readings from these sensors and therefore the head position relative to the screen can be estimated. The information from these sensors is delivered quickly (with frequency of 200 Hz on Android devices) and do not require time consuming computations [19]. Moreover, the tracking range of the sensors is not limited by the camera field of view. The drawback of the sensor based tracking is that their readings are noisy, what is especially noticeable in the *HCP* technique where a slight head movement results in the big displacement of the far background of the scene. Filtering of the sensor signals takes into account earlier sensor readings and generates the additional delay in the application response to the head movement. Yet, it may be unnoticeable with use of the Extended Kalman Filter [19]. Still, sensors like accelerometer or gyroscope are not able to notice the actual movement of the head itself, omission of which can destroy the 3D impression. Therefore, the additional use of the video based head tracking can highly improve the quality of the sensor based tracking [6][7]. Unfortunately, the face tracking methods chosen in these articles, are too slow. The tracking is several times slower than the sensors input, so its usage is limited to the occasional sensor reading correction. The use of a very rapid head tracking method may provide the actual head movement tracking, as well as the signal noise reduction without the delay generation.

The article presents the face tracking method that is able to find face coordinates in a few milliseconds and is based on the fuzzy skin color classifier first proposed in [1]. The low computational time is achieved through the parallel calculations on the GPU and the CPU and through the precalculation of all possible color weights assigned by the fuzzy classifier.

In the next section the existing rapid head tracking method are discussed. The third section presents the face position

978-83-60810-66-8/$25.00©2015, IEEE

estimation method with use of the fuzzy skin color segmentation. In the fourth section we describe precisely the methods for accelerating the color-based head position tracking. The fifth section presents the test results of the proposed solutions and the sixth section contains the conclusions and considered future work.

## II. Related Works

Fast head position finding in the camera image is possible with various head tracking and detection methods. They can be based, among others, on the background subtraction [1][2][4], template matching [2], Haar-like feature based learning [16][17][18] or the Local Binary Pattern based learning [9][15].

In [2], for the head tracking the template matching method is used, which compares the low resolution face image with the input frame fragments. To reduce the search space, the background subtraction is performed to reject still, unchanged pixels. This method of the face tracking proved to be rapid, but the used subtraction is sensitive to the illumination changes, which is frequent in the natural light. It is not applicable on the mobile devices in which camera is not still and moves with the device. Additionally, the template matching method is sensitive to the head tilting, a natural movement when controlling the application with head movement.

For the fast head detection in the camera image, the most popular method is based on the Haar-like features, proposed by Viola and Jones [18]. Method is based on the detection of simple rectangular features, used then for the AdaBoost learning algorithm. With the use of the Integral Image, wherein each pixel represents the sum of values of all pixels from the input image above and to the left of it, it is possible to quickly evaluate the features on the given position and scale. Unfortunately the calculation of the Integral Image is time consuming and requires $2*N$ operations for the image of $N$ pixels. The complexity of the feature calculations is of $O(M*N)$ for features of $M$ scales. In [16] the acceleration of this method is proposed, with use of the GPU, but still it reaches only 19 fps for an image of 1280x960 pixels. In [17] a head tracking method based on Haar-like feature detection is proposed, working at theoretical 500 fps. The search of the entire frame of 512x512 pixels can be executed at 200 fps, on a rather powerful GPU (934 GFLOPS). The search frequency of the high-resolution image of 1920x1080 pixels, on the hand-held device would not exceed 20fps.

A faster tracking method, also based on the AdaBoost learning, but using the Local Binary Pattern is proposed in [9]. The LBP method considers the surroundings of the pixels. Thanks to the calculation on GPU and CPU [15], for a picture of 1024x1024 pixels, method can process at 10fps, but on the mobile device of very low computational power. On current hand-held devices even high-resolution image could be processed at about 25 fps.

Due to the low computational complexity and the possibility of use on the mobile devices, the face tracking methods based on the skin color classification are important[1][4][5][14]. Such a classifiers extract from the RGB space (or other color space) a subspace containing the RGB values corresponding to the possible shades of the skin color. Fuzzy classifiers that determines the pixel degree of membership may provide a smoother tracking with the same resolution image [1]. Multiplatform version of the method described in [1] is presented in Section III.

Despite the linear complexity of the skin color based tracking method, analysis of high resolution images still can be very time consuming, especially on hand-held mobile devices. In this article, we proposed accelerating methods, enabling face tracking on frame of 1920x1080 pixels at about 300 fps, even on the devices with a low processing power.

## III. The Fuzzy Skin-Color Classifier

To maintain the multiplatform usability of the fuzzy head tracking method, first proposed in [1], and to allow its usage on hand-held mobile devices, the omission of the background subtraction is necessary. It is impossible to use due to the continuous motion of the hand-held device and hence its camera.

In the proposed multiplatform head tracking method, the user's head position is determined based on the degree of membership $\mu_S(p)$ of all the pixels to the fuzzy skin-color pixels multiset $S$:

$$S = \{\langle p, \mu_S(p)\rangle : p \in X_{RGB}\} \tag{1}$$

$$\mu_S(p) = \max(0, \min(1, p_R \cdot f_R + p_G \cdot f_G + p_B \cdot f_B + f_D)) \tag{2}$$

Where:

$X_{RGB} = \{<r,g,b>: r,g,b \in [0,255]\}$ – the multiset of all the image pixels.

$p=<p_R ,p_G ,p_B>$ – the components $R, G, B$ of the pixel $p$.

$f=<f_R ,f_G ,f_B, f_D>$ – the vector of the color filter.

The vector of the color filter, specified in the classifier calibration, defines a plane in the RGB space. This plane separates most of the skin color pixels from the background pixels that we are trying to discard. The filter vector specifies also the "positive" side of that plane and tells us which of the two subspaces contains skin-color pixels. The fuzziness of the multiset $S$ provides a gradient boundary between the subspaces. The further the pixel color resides from the plane on its "positive" side, the higher is its degree of membership.

The usage of the RGB space instead of other color model, in which the skin colors are easier to distinguish and isolate, is motivated by the additional computation time needed to perform the transformation from the original RGB image provided by the camera to the more preferable color model.

The usage of just two components (e. g. H and S in HSV model) does not compensate this time in the processing. As the skin tone is separable in the RGB space, the computational complexity remains the major factor in choosing the color model.

To determine the position of the face on the image and its distance from the camera, it is necessary to calculate the cardinality of the $S$ multiset, defined as the sum of the degrees of membership of all $N$ image pixels:

$$|S| = \sum_{i=1}^{N} \mu_S(p_i) \tag{3}$$

We are using all the N pixels of the image as the skin-color face pixels, because the background pixels with the degrees of membership equal 0 does not affect the results. This degrees (Eq. 2) are also the weights of the pixels used to determine the coordinates $C_X$ and $C_Y$ of the centroid $C$ of all the skin-color pixels, calculated as the ratio of the weighted sum of the image pixel coordinates to the cardinality of multiset $S$:

$$C_X = \frac{1}{|S|} \sum_{i=1}^{N} \mu_S(p_i) \cdot x_i \tag{4a}$$

$$C_Y = \frac{1}{|S|} \sum_{i=1}^{N} \mu_S(p_i) \cdot y_i \tag{4b}$$

Where:

$x_i, y_i$ – coordinates of pixel $p_i$

The found centroid coordinates are considered the coordinates of the head center in the image and are used to determine face position in the plane parallel to the screen and the camera. The ratio of the cardinality of the $S$ multiset to the cardinality of multiset of all the image pixels can be used as the $A$ measure of the face area in the image and used to calculate the head distance from the screen:

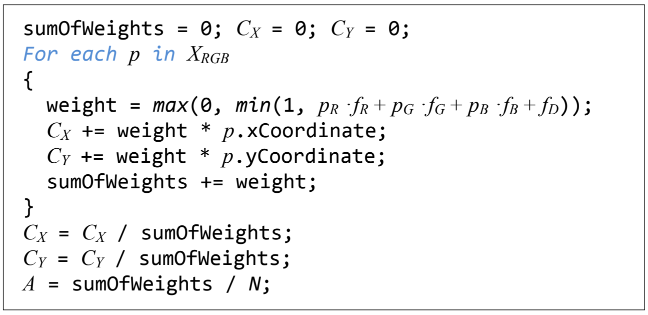
$$A = \frac{|S|}{|X_{RGB}|} \tag{5}$$

What is, according to (Eq. 3):

$$A = \frac{1}{N} \sum_{i=1}^{N} \mu_S(p_i) \tag{6}$$

The algorithm of finding the face position on the camera image is shown in the Fig. 1. The non-modified algorithm is later referred to as "*Version CPU 1"* in comparison with the accelerated variants of the algorithm.

The filter $f$ (Eq. 2), in contrast to most of the skin-color classifier methods, is not designed to match all colors that may belong to the skin of any person, of any race, skin tone, in all possible lightning condition. The primary objective of the filter $f$ is to extract the user face from the current environment visible in the camera. It requires determining the optimal values of the filter parameters for each application usage.



```
sumOfWeights = 0; $C_X$ = 0; $C_Y$ = 0;
For each $p$ in $X_{RGB}$
{
  weight = max(0, min(1, $p_R \cdot f_R + p_G \cdot f_G + p_B \cdot f_B + f_D$));
  $C_X$ += weight * $p$.xCoordinate;
  $C_Y$ += weight * $p$.yCoordinate;
  sumOfWeights += weight;
}
$C_X$ = $C_X$ / sumOfWeights;
$C_Y$ = $C_Y$ / sumOfWeights;
$A$ = sumOfWeights / $N$;
```

Fig. 1 The algorithm of finding the face position on the camera image (pseudocode).

Manual finding of the optimal values may be hard task for the user, and certainly it is uncomfortable and time-consuming. Therefore, in [8] we proposed the automatic method of finding the optimal values of skin-color filter. The method of automatic parameters calculation is based on the analysis of the image with arbitrarily marked area of the face. The user moves the head to place it in the oval-shaped mask visible in the preview of the camera. Once approved, several consecutive frames of the video image are capture for the analysis. Pixels of the obtained images are then use as factors in the objective functions *G(f)* which maximum is searched. To accelerate the computation of the optimum parameters the clustering of the input data transformed to the RGB space is performed with fast grid-based clustering method proposed in [8] where the entire process is described in detail.

The automatic parameters calculation allows for extracting most of the face pixels even from a difficult background with colors close to the skin tone or in the poor lightning. The automatically calculated parameters provide the method stability, ensuring that the $|S|$ value in the Equations (4a) and (4b) does not tend to zero. Still, in some particularly difficult conditions the method does not filter out all of the background pixels, assigning a small part of these pixels with high weights. In practice, the tracking is then still effective. Although the unfiltered pixels "attract" the found centroid to their center of gravity, reducing the amplitude of the estimated head movement determined by the tracking, still the direction of the motion is preserved and its speed is proportional to the actual speed of the head movement. As a result, the perspective of the virtual scene can still be coupled with the head movements, resulting in an immersive sense of depth in the Head-Coupled Perspective technique or effective control in other applications. Therefore, although the method is error-prone in cases when additional skin-colored body parts (e.g. neck or chest) or other faces are visible to the camera, the method still provides sufficient results for proposed applications. Especially on the hand-held mobile devices, the user head is always the biggest skin-colored object visible to the camera and cannot be dominated by other objects. When the head leaves the field of view, due to the device rotation, it may be also recorded by other internal sensors which can then substitute the head tracking.

To minimalize the resulting errors of classification in the particularly difficult conditions, we can utilize more computationally complex skin-color models, like described in [14] Gaussian model or used in [10] elliptical Gaussian chrominance probability density function. We can also transform pixel colors to another color space, e.g. *HSV,* normalized *RGB* or *CIE-XYZ* (with all components divided by the sum of all components), or proposed in [10] the *STV* space. The possible skin colors in these spaces are easier to separate [10] and the impact of the lightning on the classification is reduced. Unfortunately, both methods of improvement increase the computational cost of calculating the pixels weights, almost proportionally increasing the computation time, which actually need to be reduced. Therefore, besides the direct computation time reduction, it is desirable to decouple the head tracking cost from the complexity of the used skin color classifier.

## IV. Accelerating the Head Position Tracking

The computational cost of the presented above head tracking method is of the order *O(N)*, where *N* is the number of image pixels. The method requires a few operations per pixel, and each is processed once and individually. Although the linear computation cost seems to be low, for high resolution video image of 1920 x 1080 pixels the processing of the full frame in the real time is hard to achieve, even without the additional CPU load.

The accelerating methods that decrease the problem size, reduce at the same the tracking quality. The downscaling of the input image [15][16] requires additional computation, decreases the number of input data and reduces the angular resolution of the tracking. Searching for the face only in the neighborhood of the previously found head position [9][16][17] makes the tracking sensitive to the fast motion of the head, providing just a slight acceleration, due to the large area occupied by the face on the image of the narrow-angle camera.

The described below accelerating methods reduce the computational cost of the head tracking without decreasing the number of the analyzed pixels, to maintain high quality of the tracking. When the lower quality of the tracking is allowed, these methods can be successfully combined with the problem size reduction for the further tracking acceleration.

### *A. The Head Tracking Acceleration on the GPU*

The acceleration of the head tracking can be achieved by transferring the calculations to the graphics processor unit, which allow for the parallel analysis of many pixels. Besides the possible computation time reduction, this approach may additionally decrease the energy usage of the mobile devices during the frame processing [9]. The use of the Nvidia® CUDA® framework allow for using the full capabilities of graphics processors compatible with this architecture. Such GPUs are widely installed on the laptop computers and they are recently available on the hand-held mobile devices. The tests of the methods described below are performed on the laptop computer equipped with the Intel® Core™ i5-2450M mobile processor and the Nvidia® GeForce® GT 630M mobile GPU.

As the classification of the pixel colors in our method is performed for each pixel individually, the acceleration is seemingly easy to achieve by performing the computations on the graphics card. The parallelization of the calculation of the pixels degrees of membership to the skin-color multiset *S* is trivial on GPU. Each thread must calculate the weight of one pixel, according to Equation 2. A part of the kernel (i.e. a function in CUDA executed in parallel by multiple threads on GPU) responsible for the pixels weights calculation is as follows:

```
uint index=threadIdx.x + blockIdx.x*blockDim.x;
Pixel p=frame[index];
float weight=f[0]*p.r + f[1]*p.g + f[2]*p.b+ f[3];
if(weight>0.0f){ if(weight>1.0f)weight=1.0f; }
else weight=0.0f;
[…]
```

A constant delay is generated by the transfer of the image to the GPU memory. For an image of 1920x1080 pixels, the transfer takes about 2 milliseconds.

For the further analysis, the calculation of the head position is split into two parts:

1) Calculating the degrees of membership from Eq. 2.
2) Finding the centroid coordinates (Eq. 4) and the sum of all the pixel weights need in Eq. 6.

On the CPU, the second part of the calculation represents only a small fraction of all the computations. Conversely, on the GPU the computation of the second part can be several times longer than the first part. The time of 2) on the graphics processor depends largely on the used algorithm. Below, different methods of accelerating computation on GPU are compared.

#### *1) Version GPU 1 – Atomic adding to one global value*

In the naive approach to calculate the coordinates of the centroid, all the threads can add its calculated values directly to the output sums, using the *atomic* add function:

```
[…]
atomicAdd(x,weight*(index%width));
atomicAdd(y,weight*(index/width));
atomicAdd(w,weight);
```

*Atomic* functions in CUDA allows multiple threads to modify common data, with the guarantee of receiving the correct result, which means that every thread perform the operation exactly once, without data loss from the simultaneous access to the output value.

Unfortunately, in this approach the summing is performed sequentially, as only one thread at a time increases the output sum. Moreover this variant requires a very frequent access to the very slow global memory. It is very inefficient approach, which do not use the full power of the GPU and prolongs the calculation compared to the CPU computing.

### *2) Version GPU 2 – Atomic adding to the shared memory*

The acceleration can be obtained when first the thread values are atomically added to local sums of the blocks in the faster shared memory, and then only this local sums are atomically added to the global output values, by one thread per block:

```
__shared__ float sX,sY,sW;
sX=0.0f;
sY=0.0f;
sW=0.0f;
[…]
atomicAdd(&sX,weight*(index%width));
atomicAdd(&sY,weight*(index/width));
atomicAdd(&sW,weight);

__syncthreads();

if( 0 == threadIdx.x )
{
  atomicAdd(x,sX);
  atomicAdd(y,sY);
  atomicAdd(w,sW);
}
```

In this approach a part of the internal aggregations is executed in parallel between several thread blocks. Therefore this variant is more than three times faster than the *Version GPU 1.*

### *3) Version GPU 3 – Parallel aggregation with divide and conquer*

Although in *Version GPU 2* part of the summation is performed in parallel between blocks, still only one thread per block can add its value to the local sum at the same time. To execute more parallel addition inside a thread block it is possible to use the divide and conquer method, decreasing the complexity order of the summation for each *N*-thread block from *O(N)* to *O(logN)*. In this case, half of the block threads must sum up pairs of values calculated by the consecutive threads. In the next steps, the sums from previous step are summed in pairs until there is only one final sum of all the block values (Fig. 2).

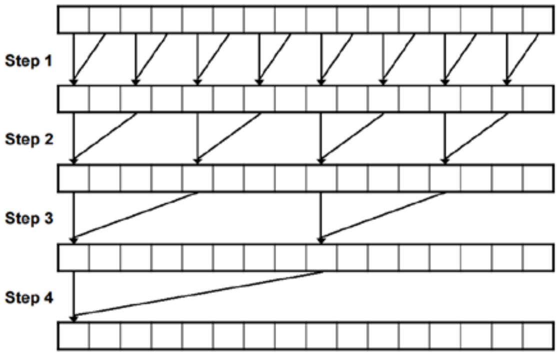


Fig. 2 The parallel aggregation in block

The kernel realizing directly this approach is as follows:

```
__shared__ float tempX[THREADS_PER_BLOCK];
__shared__ float tempY[THREADS_PER_BLOCK];
__shared__ float tempW[THREADS_PER_BLOCK];
[…]
uint s,temp;
for(s=1;s<THREADS_PER_BLOCK;s<<=1)
{
  if(0==threadIdx.x%(s<<1))
  {
    __syncthreads();
    temp=threadIdx.x+s;
    tempX[threadIdx.x]+=tempX[temp];
    tempY[threadIdx.x]+=tempY[temp];
    tempW[threadIdx.x]+=tempW[temp];
  }
}
if( 0 == threadIdx.x )
{
  atomicAdd(x,tempX[0]);
  atomicAdd(y,tempY[0]);
  atomicAdd(w,tempW[0]);
}
```

This approach decrease the computational time by 40% compared with the *Version GPU 2*. The acceleration is less than expected due to the highly divergent branching of the code in the condition `(0==threadIdx.x%(s<<1))`, what is discussed by Harris [11] on an analogous example.

### *4) Version GPU 4 – Without divergent branching*

Further acceleration can then be obtain by alternatively engaged threads, as shown in Fig. 3.

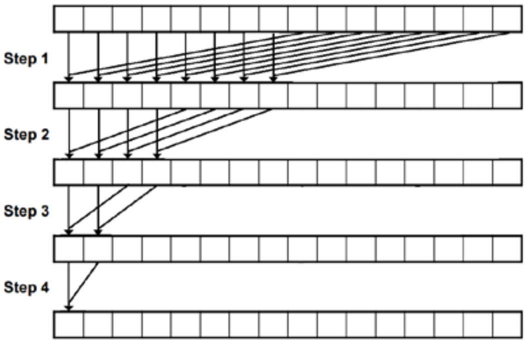

Fig. 3 The parallel aggregation without the divergent branching and bank conflicts

This approach omits the problem of divergent branching, without additional shared memory bank conflicts. Analogous solution for similar problem was used in [13].

The internal aggregation in this version looks as follows:

```
[…]
uint s,temp;
for(s = THREADS_PER_BLOCK>>1; s>0; s>>=1)
{
     if(threadIdx.x<s)
     {
       __syncthreads();
       temp=threadIdx.x+s;
       tempX[threadIdx.x]+=tempX[temp];
       tempY[threadIdx.x]+=tempY[temp];
       tempW[threadIdx.x]+=tempW[temp];
     }
}
if( 0 == threadIdx.x )
{
  atomicAdd(x,tempX[0]);
  atomicAdd(y,tempY[0]);
  atomicAdd(w,tempW[0]);
}
```

This variant is 2.5 times faster than *Version GPU 3*.

### *5) Version GPU 5 – Multiple aggregation per thread*

In the *Version GPU 4* during the iterative aggregation an average of ¾ of the block threads is idle, from the half in the first iteration, to all but one in the final aggregation. At the same time, due to the limit of thread number per block, we receive a large number of blocks. The possible solution, proposed by Harris for similar problem [11], is to use threads to iteratively add up a greater number of values. In our case it requires also the calculation of more pixel weights (i. e. degrees of membership to skin color multiset) per thread. Such a solution can significantly better harness the GPU computational power. Before we get to the inter-thread aggregation, all the threads are engaged in a long non-synchronized work.

After this modification, kernel is as follows:

```
__shared__ float tempX[THREADS_PER_BLOCK];
__shared__ float tempY[THREADS_PER_BLOCK];
__shared__ float tempW[THREADS_PER_BLOCK];
uint ti = threadIdx.x;
uint index = ti+blockIdx.x * THREADS_PER_BLOCK;
uint gridSize = THREADS_PER_BLOCK * gridDim.x;
Pixel p;
float weight;
tempX[ti]=0;  tempY[ti]=0;  tempW[ti]=0;
while(index<N)
{
  p=frame[index];
  weight=f[0]*(p.r)+ f[1]*(p.g)+ f[2]*(p.b)+ f[3];
  if (weight>0){if(weight>1.0f) weight=1.0f;}
   else weight=0.0f;
  tempX[ti]+=weight*(index%width);
  tempY[ti]+=weight*(index/width);
  tempW[ti]+=weight;
  index+=gridSize;
}
uint s,temp;
for(s= THREADS_PER_BLOCK>>1;s>0;s>>=1)
{
  if(ti<s)
  {
    __syncthreads();
    temp=ti+s;
    tempX[ti]+=tempX[temp];
    tempY[ti]+=tempY[temp];
    tempW[ti]+=tempW[temp];
  }
}
if( 0 == ti )
{
  atomicAdd(x,tempX[0]);
  atomicAdd(y,tempY[0]);
  atomicAdd(w,tempW[0]);
}
```

Due to the reduced number of blocks, this variant is 2.5 times faster than *Version GPU 4*.

### *6) Version GPU 6 – Double memory access*

Further acceleration by about 10% can be obtained by adding two values per iteration and grouping operations. It is the result of the GPU's memory access, where reading two consecutive 4-bytes words has a similar cost to reading just one word [12]. The number of blocks is halved:

```
uint index = ti+blockIdx.x*THREADS_PER_BLOCK * 2;
uint gridSize = gridDim.x*THREADS_PER_BLOCK * 2;
[…]
while(index<N)
{
 index2=index + THREADS_PER_BLOCK;
 p=frame[index];
 p2=frame[index2];
 weight=f[0]*(p.r)+ f[1]*(p.g)+ f[2]*(p.b)+ f[3];
 weight2=f[0]*(p2.r)+f[1]*(p2.g)+f[2]*(p2.b)+f[3];
 if (weight>0){ if(weight>1.0f) weight=1.0f; }
  else   weight=0.0f;
 if(weight2>0){if(weight2>1.0f) weight2=1.0f;}
  else weight2=0.0f;
 tempX[ti]+=weight*(index%width)
           +weight2*(index2%width);
 tempY[ti]+=weight*(index/width)
           +weight2*(index2/width);
 tempW[ti]+=weight + weight2;
 index+=gridSize;
}
```

### 7) Version GPU 7 – Aggregation in local memory

In versions *GPU 5* and *GPU 6* designed on the basis of [11], highly ineffective is the iterative aggregation of all the values calculated by the thread to the shared memory. During this aggregation other threads do not need any access to this temporary sum. Our proposed solution is to aggregate the thread values in its local memory, as it is faster than the shared memory. Only the final thread sum should be copied to the shared memory for access of other threads.

```
[…]
float tX,tY,tW;
tX=0;  tY=0;  tW=0;
while(index<N)
{
 […]
 tX+=weight*(index%width)+weight2*(index2%width);
 tY+=weight*(index/width)+weight2*(index2/width);
 tW+=weight + weight2;
index+=gridSize;
}
tempX[ti]=tX;
tempY[ti]=tY;
tempW[ti]=tW;
[…]
```

This approach decrease the computational time by 10% compared with the *Version GPU 6*.

### 8) Version GPU 8 – Multiple pixels per thread with atomic adding to shared memory

The divide and conquer parallelization in the *Version GPU 4* leads to a four times faster computing, compared to *Version GPU 2,* where the tread values are atomically added to the block sum. But since each thread aggregates weights of hundreds of pixels, the synchronization of threads before each iteration of inter-thread summing is very time consuming. It appears that the atomic summation to one value is more effective in that case. Even though the acceleration of such approach is only about 3%, the additional profit is the reduction of the shared memory occupancy and a slight kernel code simplification:

```
__shared__ float tempX,tempY,tempW;
if(0==threadIdx.x)
{
  tempX=0; tempY=0; tempW=0;
}
uint ti=threadIdx.x;
uint index=ti+blockIdx.x* THREADS_PER_BLOCK *2;
uint gridSize = THREADS_PER_BLOCK *2*gridDim.x;
Pixel p;
float weight,weight2;
unsigned int index2;
float tX,tY,tW;
tX=0;  tY=0;  tW=0;
while(index<N)
{
 index2=index + THREADS_PER_BLOCK;
 p=frame[index];
 p2=frame[index2];
 weight=f[0]*(p.r)+ f[1]*(p.g)+ f[2]*(p.b)+ f[3];
 weight2=f[0]*(p2.r)+f[1]*(p2.g)+f[2]*(p2.b)+f[3];
 if(weight>0) { if(weight>1.0f)  weight=1.0f;}
  else weight=0.0f;
 if(weight2>0){if(weight2>1.0f) weight2=1.0f;}
 else  weight2=0.0f;
 tX+=weight*(index % width)
     +weight2*(index2 % width);
 tY+=weight*(index / width)
     + weight2*(index2 / width);
 tW+=weight + weight2;
 index+=gridSize;
}
atomicAdd(&tempX,tX);
atomicAdd(&tempY,tY);
atomicAdd(&tempW,tW);
__syncthreads();
if( 0 == ti )
{
  atomicAdd(x,tempX[0]);
  atomicAdd(y,tempY[0]);
  atomicAdd(w,tempW[0]);
}
```

The final version of the kernel is almost 45 times faster than the *Version GPU 1.*

## B. The Head Tracking Acceleration on the CPU

Although the computation of head position on the GPU can be very fast (with frame computation below 5 ms), it can be insufficient in the 3D graphic applications like video games, where the 3D rendering loads the GPU to its limits. To maintain the performance of the application, we may need to limit the GPU computations.

Unfortunately, the head position estimation on the CPU is time consuming, as its computational cost is of the order *O(N).* Even with an effective implementation of the algorithm (Fig. 1), on the testing platform the 30 fps is not achieved (see Table 1). Therefore it is desirable to accelerate also the CPU computing.

### 1) Version CPU 2 – The weights precalculation

The acceleration on the CPU can be obtain with the precalculation of all the possible values of $\mu_S(p)$ (Eq. 2) and referring to them instead of calculating this value for every input pixel individually. The number of all the RGB colors with 8-bits channels is limited and amounts to $256^3$. It is 8 times more values than in a frame of 1920x1080 pixels, but the precalculation can be performed only once before the start of the application, as the colors weights change only when the filter *f* values change.

The precalculated weights assigned by the classifier to all the RGB values, can be stored in an array *W*[], in which the pixel *p* weight is located at the given position:

$$W\left[p_R \cdot 256^2 + p_G \cdot 256 + p_B\right] = \mu_S(p) \qquad (7)$$

With the indexing relevant to the input pixel format (i. e. its byte order), the integer value written on the four bytes of the pixel is also the position in the array *W,* at which the pixel weight is stored.

With the use of the precalculated weights, the CPU computations are faster only by 35%. Even though this solution is interesting for other reason. As was mentioned in the previous section, it is desirable to decouple the computing time from the color classification method, for the possible classification improvement without the reduce of the tracking speed. With this solution, the usage of more complex color model or the transformation to the other color space, increases only the once performed precalculation time and the tracking time remain unchanged, so that aim is fully achieved.

Applying this concept for the GPU is not recommended, as it results in prolonged, twice as long calculation time. This is caused by the "random", irregular access to the array *W,* as the adjacent pixels can have different colors, distant in the RGB space. As a result the global memory access time is increased, slowing the entire computing. Moreover, on the GPU computation cost is already almost independent of the used color model. A slight gain from the precalculation may be achieved only with use of a very complex color classifiers.

### *2) Version CPU 3 – The precalculation and multicore processing*

The parallelization of the calculations is not limited to the GPU computing. Most modern CPUs have at least two independent processing units (called *cores*). Therefore, the equal distribution of the calculations to more threads may results in almost direct proportional time reduction.

By dividing the problem, i.e. the input frame, between multiple CPU cores, we can compute pixel weights from each part of the image, and the centroid of these pixels. The centroid of all the partial centroids is also the centroid of the whole image.

### *3) Version GPU 8 + CPU 3– The joint GPU and CPU calculations.*

As in the above example, the problem can be divided into two parts, one of which is implemented on the CPU, and the second on the GPU. Such division may be dictated by the GPU limitation, or by the need for utilizing all the available computing power for the further tracking acceleration.

In the second case, in order to achieve the greatest acceleration, the division of the problem between the CPU and the GPU should not be symmetrical as in multicore processing. For the highest resulting speed, the two processors should complete their computations at the rather same time. If average times of the full frame computation on CPU and GPU are respectively $T_C$ and $T_G$, and they analyze sub-images $I_C$ and $I_G$ of the image I (I= $I_C$ +$I_G$), than the sizes of the sub-images should be:

$$I_C = \frac{T_G}{T_C + T_G} \cdot I \qquad (8a)$$

$$I_G = \frac{T_C}{T_C + T_G} \cdot I \qquad (8b)$$

Hence, in our case, at the testing laptop, the highest speed is achieved when 70% of the image pixels is processed on the GPU (with *Version GPU 8*) and 30% on the CPU (with *Version CPU 3*). The comparison of the computation times of all the methods is presented in the next section.

### *4) Other possible acceleration methods*

The possible further acceleration of the computation may be achieved by the replacement of the floating point operations with the fixed point calculations and especially integer operations. In order to do this, we must upscale filter *f* values by *u* to the integer values. The maximum weight assigned by the classifier (1 in the Equation 2) must also be upscaled by the same *u* value. This way the *S* multiset would no longer meets the definition of the fuzzy set, but the results of head position estimation would not change if we only divide the *A* (Eq. 5 and 6) by the *u*. The problem of this solution is that we may must restrict the maximum resolution of the image or the resolution of the classifier (i.e. number of different weights it may assign) to ensure that we do not exceed the maximum of the 32 bits variables. Yet, it may be acceptable in some applications and the resulting acceleration may be significant.

Another way to accelerate CPU computation may be the usage of Streaming SIMD Extensions which allow for parallel processing of up to four values. However the usage of SSE may be restricted and may depends on the target platform. Altough this solution was not applied it is worth consideration.

## V. RESULTS

The fast head position tracking methods proposed in the Section IV were compared with the original algorithm of *Version CPU 1* shown in Fig. 1. The tests was performed on the laptop computer equipped with the mobile processor Intel® Core™ i5-2450M (2x2,5GHz) with processing performance of 34,5 GFLOPS and the mobile GPU Nvidia® GeForce® GT 630M with 307,2 GFLOPS processing performance.

The comparison of the average computation times for frames of 1920x1080 pixels is shown in the Fig. 4 and in the

Table 1. Although the times of CPU and GPU should not be compared due to the different architectures, the scale of the possible acceleration of the head tracking can be seen in the Fig. 4. The computations on the GPU (*Version GPU 8*) are over seven times faster, including the time of transfer to the GPU memory, and it allows for tracking at 200 frames per second. In an architecture where the camera image is saved directly in the GPU memory, without need for additional copying, over 300 fps can be achieved.

The acceleration methods basing on the CPU also give good results and over three times faster computing compared to the original algorithm. Using CPU with more processing cores, the further acceleration is possible.

When the processing powers of GPU and CPU are not restricted, the method combining the calculations on both units may result in the greatest tracking speed. On the testing platform the analysis of the full frame was performed in about 3,6 milliseconds (Fig. 4 and Table 1).

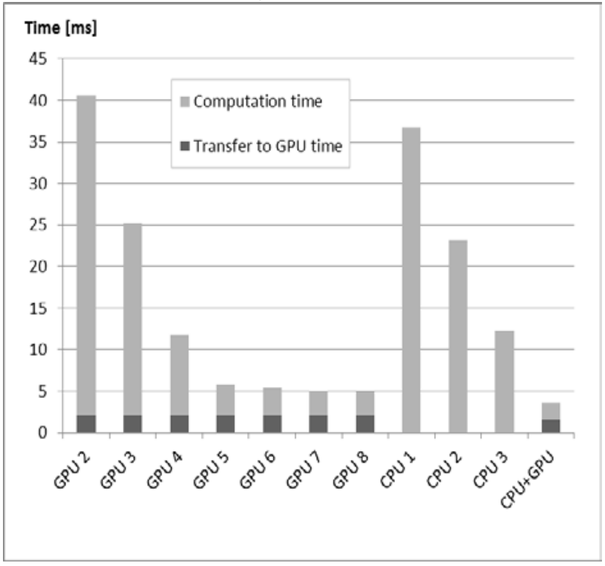

Fig. 4 The processing times of one frame of 1920x1080 pixels (average of 100 trials).

## VI. Conclusions and Future work

Although the device used in the tests was not a hand-held device, its CPU and GPU has respectively 50% and 15% lesser processing performance than the Nvidia® Shield™ Tablet with Tegra K1 mobile processor equipped with CPU ARM Cortex-A15 R3 (4x2,3GHz), with the processing performance of 70,4 GFLOPS and CUDA-enabled GPU Kepler with 364,8 GFLOPS processing performance. Also, the popular smartphone processors Qualcomm® Snapdragon™ 810 has a similar processing performance. Hence, the testing laptop computer represents well the computing power of the today hand-held devices.

The achieved head tracking times leave a large margin of error for the real-time tracking with over 60 fps, even in the case of a highly loaded GPU and CPU or when performed on the devices with a lot less computing power. With the achieved tracking times it becomes possible to use the found head position for effective Head-Coupled Perspective implementation in combination with the interactive 3D applications on hand-held mobile devices.

The future work includes testing the proposed methods on the actual hand-held devices and designing the model for determining the head position relative to the device with use of the internal sensors (accelerometer and gyroscope) combined with the proposed fast head tracking method.

Email: andrzej.sluzek@kustar.ac.ae

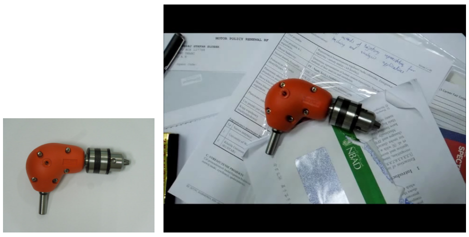
***Abstract*—Visual search for objects of interest in complex environment is an important (and still challenging) problem in mobile robotics. In particular, the usage of *content-based visual information retrieval* (CBVIR) methods, which are a natural choice for such tasks, is often constrained by the real-time requirements, and the mobility of searching agents is sometimes not sufficiently exploited in the search model. In this paper, a CBVIR-based scheme is proposed, which takes into account motion of the searching agents to achieve a low-cost and high-speed detection of objects of interest in cluttered scenes, with good overall performances. We combine standard CBVIR tools, i.e. MSER detector and SIFT descriptor (quantized into sufficiently large vocabularies) assuming additionally that objects become *objects of interest* only when approached closely enough by the mobile agent, i.e. when seen at an adequately large scale. Thus, an object of interest is considered detected only if a sufficient number of keypoints from the current video-frame are matched (including the corresponding matches of scales) to the keypoints from the database images of the object. Preliminary experiments on a limited-size dataset confirm performances of the scheme, although in the classical task of video-frame retrieval the scheme cannot compete with more sophisticated CBVIR algorithms. The scheme can prospectively become more flexible if combined with a range-finding device so that the approximate distances to the scene components within the currently inspected part of the image can be used to proportionally modify the scale correspondences.**

## I. Introduction and Background Works

Visual search for unpredictably located objects of interest (where such object are represented by their exemplary images) remains one of important tasks for mobile robotics. Understandably, CBVIR is a natural source of algorithms for such a task. Actually, one of the fundamental CBVIR concepts of *visual words* was originally proposed for videos [1]. Algorithms for sub-image retrieval (where the objective is to identify images containing fragments near-duplicate to the query image) are particularly important. Those algorithms are usually based on detecting keypoints and, subsequently, comparing their visual words. Generally, however, three major differences exist between real-time visual search by mobile agents and classical CBVIR tasks:

1) In CBVIR, infrequently arriving query images (submitted by the users) are matched against large/huge datasets, e.g. [2], [3], while in a camera-based visual search very small datasets (template images of objects of interest) are matched against large numbers of continuously arriving queries (video-frames acquired by a single camera or by simultaneously working multiple cameras attached to a mobile agent).
2) Because of (1), the computational costs of image preprocessing (i.e. keypoint detection and description, quantization into visual words, etc.) are in visual search as critical as the complexity of the actual image matching and retrieval. In classical CBVIR, the costs of image preprocessing are considered negligible.
3) In visual search, the objective is to detect all instances of interesting objects, where each instance is represented by a sequence of frames in the input video stream. However, not all such frames have to be perfectly identified. Thus, in the video search (unlike in standard CBVIR tasks) *recall* of individual frame retrieval can be compromised, but *precision* should be as high as possible.

As an illustrative example, Fig. 1 shows an object of interest and an exemplary video-frame returned by the search algorithm.



(a) (b)

Fig. 1. The object of interest (a) and an exemplary frame containing it (b).

In this paper, we propose and preliminarily evaluate a scheme which exploits the above characteristics of visual search (and mobility of the searching agent) to achieve at low costs a high performance object detection in cluttered scenes. As the basic components of this scheme, we use standard CBVIR tools, i.e. MSER detector [4] and SIFT descriptor [5] (in its RootSIFT variant [6]). Descriptors are quantized into a large vocabulary of one million words (to assure satisfactory *precision*). To avoid high costs of descriptor quantization into words, a simple quantization method based on the statistical properties of descriptors is used. Details of the image preprocessing phase are described in Section II.

978-83-60810-66-8/$25.00©2015, IEEE

Image matching is performed using the most straightforward criterion, i.e. the number of keypoint correspondences (e.g. [7], [5]) where a match is defined by identical visual words. However, we reject matches for which the ellipses of MSER keypoints are not in the correspondingly similar scales. Because the search is conducted by mobile agents, this requirement indicates that the agent finds an object at a specific distance (defined by the scale of the object images in the database). More details and explanations are given in Section III.

In Section IV, preliminary experimental results of the proposed approach are overviewed. In particular, performances of the method are compared to alternative solutions.

## II. Principles of Image Pre-processing

For a feature-based real-time visual search, efficient detection and description of keypoints is a critical factor. In particular, the number of keypoints should not be excessively large (and controllable in some sense). Thus, we use MSER detector which is affine invariant, has good performances (as reported in [8]), low complexity (which can be further reduced by using special techniques proposed for MSER detection in video sequences, e.g. [9]) and a few tuning parameters to control the numbers of detectable keypoints. Actually, recent implementations of MSER detectors in hardware, e.g. [10], [11], achieve a throughput approaching hundreds of frames per second, which indicates that MSER keypoint extraction is not a critical factor in a real-time image pre-processing, even if several cameras are simultaneously used.

Hardware implementations of SIFT descriptors (and detectors too) have been reported as well (most recently in [12]). Notably, development of a system-on-chip SIFT descriptor for affine-invariant keypoints is currently under way in our organization as well. Therefore, the feasibility of real-time SIFT description of detected keypoints can be considered documented. Even the Matlab implementation of MSER detector combined with a SIFT description module in C++ provide a throughput of 2-3 frames/sec (including all disk read/write overheads) which can be accepted as near real-time performances for slowly moving agents.

The final step of image pre-processing for CBVIR is *quantization* of descriptors into *visual words*. The size of vocabularies can be very diversified, typically ranging from a few thousand to a few million. Although small vocabularies provide better *recall* of keypoint matching, *precision* is generally unacceptably low. *Precision* obviously improves (at the expense of *recall*) with the growing size of vocabulary, but if the vocabulary becomes too large, the quantization intervals could be smaller that natural fluctuations of descriptors, and it might be difficult to find matches even in pairs of almost identical images.

Published results (e.g. [13], [3]) indicate that the recommended sizes of visual vocabularies are in the range of millions of words, especially if *precision* is more important than *recall* (which is the case in visual search by mobile agents, see Point (3) in Section I). Thus, RootSIFT descriptors are quantized into a vocabulary of 1M words (although tests have been conducted using smaller sizes as well - see Section IV). For such a large vocabulary, the standard quantization of descriptors into words by the (approximate) nearest neighbour approach could be a bottleneck in real-time processing of video frames. Instead, the descriptor space has been partitioned off-line into hypercubes of similar probabilities (the probability density was estimated using over 500 million keypoints from diversified images). Then, the descriptor quantization requires only a small number of additions and comparisons, and the processing time is negligibly small.

## III. Image Matching and Object Detection

In visual search, the objective is to identify video fragments (sequences of frames) containing the object(s) of interest, regardless the background visual contents. From CBVIR perspective, this is a problem of *partial near-duplicate* detection, for which a fully satisfactory solution has not been found yet. Nevertheless, most of the *state-of-the-art* methods seem to follow the same two-step approach. First, similarities between individual keypoints are established (using descriptors or visual words). Then, the geometric consistencies between groups of preliminarily matched keypoints are verified to detect clusters of similarly transformed keypoints (which are considered the near-duplicate fragments). Either more advanced algorithms, like the Hough transform, RANSAC, etc. are used (e.g. [14], [15], [16], [17]) to provide more credible results at higher computational costs, or simplified approaches (e.g. [18], [2], [3]) more suitable for large-scale applications are alternatively employed to verify the consistencies.

In the proposed scheme, we detect partial near-duplicates (presumably representing the objects of interest) in a way that merges the first step with a very simple variant of the geometric verification (where only the scale consistency of matching keypoints is verified). Altogether, the level of similarity between a query image (i.e. a video frame) and a database image of an object is defined by the number of keypoint correspondences, where two MSER keypoints $K_1$ (a query keypoint) and $K_2$ (a database keypoint) match if:

Definition 1.

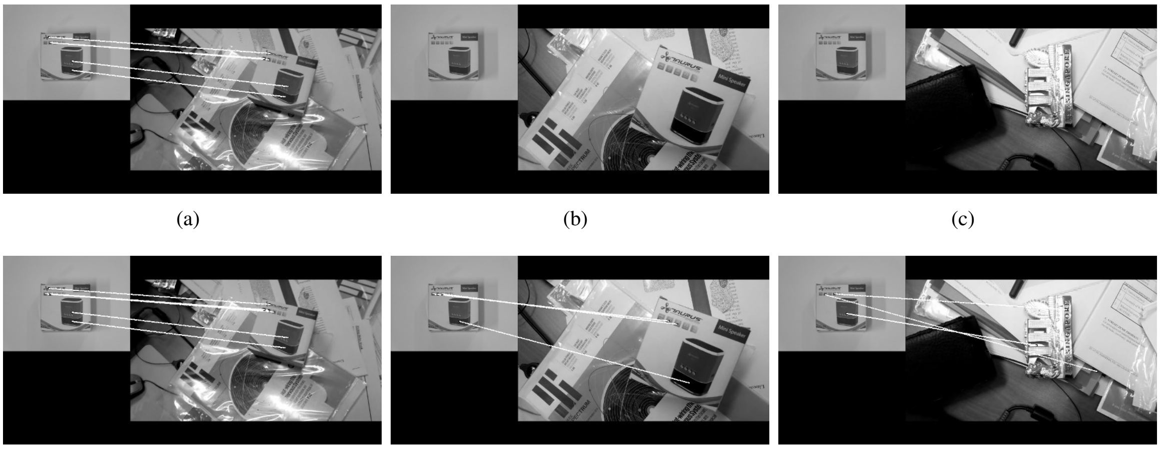
1) The keypoints are described by the same visual word, i.e. $word(K_1) = word(K_2)$.
2) The keypoints have similar scales. Assuming that $M$ and $m$ indicate, correspondingly, the length of major and minor axes of the keypoint ellipses, the conditions for the scale consistency are:

$$0.8M(K_2) \leq M(K_1) \leq 1.2M(K_2), \tag{1}$$

$$0.8m(K_2) \leq m(K_1) \leq 1.2m(K_2). \tag{2}$$

The second requirement of the above definition can be justified as follows:

> *The visual scale of an object in a captured video obviously corresponds to the distance between this object and the camera. When a mobile agent explores its environment, it is expected to recognize*



(a) (b) (c)

(d) (e) (f)

Fig. 2. Exemplary matches obtained by using the scale verification (a, b, c), and without such a verification (d, e, f). A vocabulary of 1M words is applied. In (b) the object is not detected because its scale is too large (but it is detected in (e) where the scale is not verified). In (c), scale verification prevents detection of a non-existing object (falsely detected in (f)).

*objects of interest when they are approached at a sufficiently close distance, i.e. at least at a predefined threshold distance. Thus, the database should contain images of objects of interest in the* ***reference scales*** *approximately corresponding to such threshold distances. The images in larger scales are not needed because the objects should be detected earlier (at the threshold distance) while smaller scales represent objects too distant to be interesting for the agent. Therefore images in larger or smaller scales are not included in the database.*

The axes length tolerance in Eqs 1 and 2 is rather wide (and taken independently for major and minor axes) so that not only small scale deviations but also minor viewpoint changes (up to approx. $30^o$) are generally accepted by the matching algorithm.

A similar philosophy (although with much less efficient tools for keypoint detection and matching) was behind the results presented in [19].

Eventually, two images are considered partial near-duplicates (i.e. a part of the query frame matches the object of interest) if at least 4 pairs of keypoint correspondences are found according to Definition 1. This is the minimum number of matches needed for the verification of affine transformation consistency between images (three pairs to build the transformation, and the fourth one to verify it). Although currently only the scale consistency is applied, such a geometric verification might be used in the future for more advanced tasks (e.g. in determining the number of the same objects of interest in a single video frame).

This matching method is sufficiently fast for visual search tasks considered in this paper. If the images are pre-processed (i.e. MSER keypoints are extracted and assigned visual words, which are very fast operations as outlined in Section II) even the Matlab implementation provides a throughput of approx. 50-60 video frames of VGA resolution per second (i.e. the search can be conducted using 2-3 simultaneously working cameras).

Examples in Fig. 2 highlight the principles and specific characteristics of object detection using the proposed image matching technique.

## IV. Experimental verification

The proposed scheme has been preliminarily verified on a number of short (i.e. $30 - 60$ seconds) videos captured in heavily cluttered indoor environments. A small collection of objects of interest has be arbitrarily proposed (see Fig. 3).

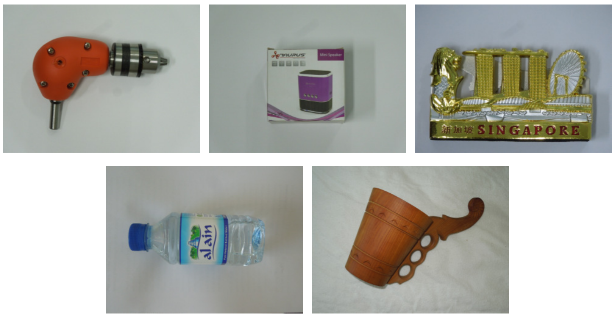


Fig. 3. Examples of objects of interest.

The objective is to identify all instances (but not necessarily all frames of the video) of the objects which are seen for some time at the reference or larger scale (i.e. more distant appearances of the objects are not counted). Fig. 4 shows a few frames from an exemplary beginning (when the object becomes sufficiently large) and from an exemplary end (when the object becomes too small and/or disappears from the field of view) of such instances. In all cases, the ground truth data, i.e. the initial and terminal frames of the instances, are established manually.

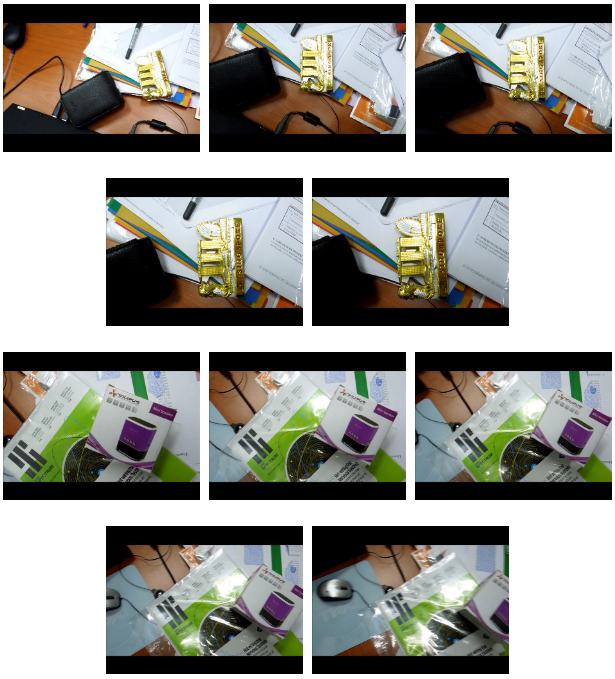

Fig. 4. Examples of frames from a typical initial part (two top rows) and a typical terminal part (two bottom rows) of a ground-truth instance of an object of interest.

The scheme's performances are evaluated by comparing *ground-truth instances* and so-called *active sequences* extracted by the scheme.

Definition 2.

> An *active sequence* is initiated whenever the algorithm identifies a frame matching (according to the specification in Section III) a database image of an object (e.g., Fig. 2A). Then, the active sequence continues until there are at least five consecutive frames which do no match the same object database images.

The value 5 has been established empirically; it corresponds to approx. 0.2sec during which the object may be temporarily invisible (due to sudden flashes of light, temporary camera defocusing, etc.). However, when an active sequence is terminated, it does not mean the object is not visible anymore. Actually, the following cases are possible:

- The object is too close to the camera so that its scale is too large for a match with database images.
- The object becomes too distant (its scale is too small for a match) which means it is no more an object of interest.
- The object actually disappears from the field of view.

Regardless the reason for which an *active sequence* is terminated, the following requirements define a fully reliable object detection scheme:

(a) Each *active sequence* is fully enclosed within a *ground-truth instance*, i.e. non-existing objects are never detected.

(b) Each *ground-truth instance* overlaps at least one *active sequence*, i.e. each genuine instance of an object is detected at least by a single active sequence.

Using the above specifications, we straightforwardly define *precision* (*PA*) of active sequence extraction and *recall* (*RI*) of ground-truth instance detection in a visual search process by a mobile agent as follows:

$$PA = \frac{AS_{(a)}}{AS}, \tag{3}$$

where $AS_{(a)}$ is the number of active sequences satisfying the above Requirement (a), and $AS$ is the total number of extracted active sequences.

$$RI = \frac{GTI_{(b)}}{GTI}, \tag{4}$$

where $GTI_{(b)}$ is the number of ground-truth instances satisfying the above Requirement (b), and $GTI$ is the total number of ground-truth instances.

It was mentioned in Section I that in object detection by visual search *recall* of the individual frame retrieval can be compromised, but *precision* should be as high as possible. However, both *RI recall* and *PA precision* values should be at the highest possible levels to reliably detect object instances.

Performances (based on Eqs 3 and 4) of the scheme for the test dataset of videos and objects are summarized in the top row of Table I. To illustrate advantages of the proposed scheme over the other choices, we include in Table I the results for three alternative scenarios. First, the same vocabulary of 1M words is used but without the scale verification (the second row of Table I). Secondly, a much smaller vocabulary of 64k words is used (with the scale verification) instead of the proposed 1M vocabulary (the third row of Table I). The last scenario included in Table I will be discussed later.

Although each of the three schemes detects all instances of objects visible within the test dataset of videos, there are significant differences in the numbers of extracted active sequences, and (consequently) in the reliability of detection. When scale verification is ignored, or the size of vocabulary is significantly reduced, the number of active sequences grows disproportionally ($5-6$ times in our experiments) and *PA precision* falls dramatically. The explanations are similar for both cases. On one hand, credibility of individual keypoint correspondences is limited (even for larger vocabularies) if no means of geometric verification are used. On the other hand, if the vocabulary is small, the number of keypoint correspondences can be so large that even the scale verification is unable to delete all false positives. As a result, large numbers of false active sequences are extracted from the incoming stream of frames. Even though most of those incorrect active sequences are short ($1-2$ frames) they should not be ignored because there are some cases when the ground-truth instances are represented only by such short active sequences.

Fig. 5 shows examples of incorrect matches (some parts of Fig. 2 are also illustrative) including a rather unusual (since *PA precision* is equal to 98.8%) case of a false positive for matching with 1M words and scale verification.

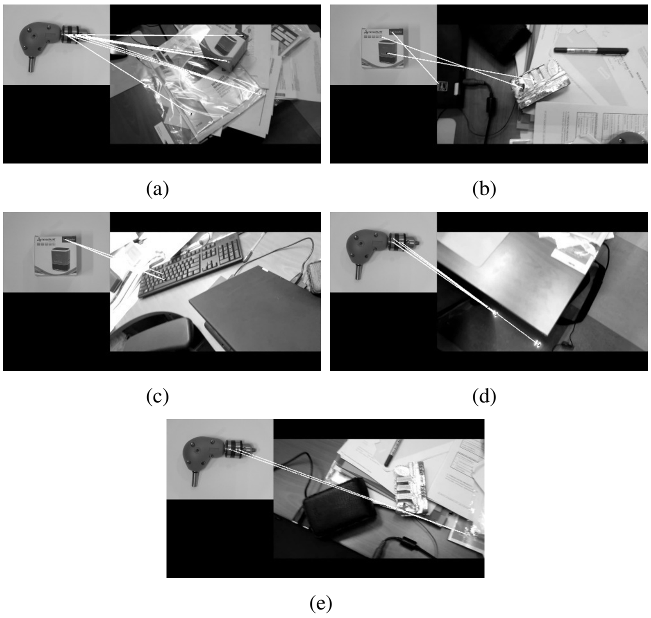
It should be emphasized that high performances of the proposed low-complexity scheme are achievable for object

TABLE I
PERFORMANCES OF OBJECT DETECTION USING THE PROPOSED SCHEME AND THREE ALTERNATIVE SCHEMES.

| **Scheme** | Ground-truth instances | Active sequences | *RI recall* (Eq. 4) | *PA precision* (Eq. 3) |
|---|---|---|---|---|
| **1M words with scale verification** | 58 | 329 | 100.0% | **98.8%** |
| **1M words without scale verification** | 58 | 1886 | 100.0% | 20.6% |
| **64k words with scale verification** | 58 | 1618 | 100.0% | 15.6% |
| **the method from [16]** | 58 | 117 | 60.3% | 100.0% |

TABLE II
PERFORMANCES OF INDIVIDUAL FRAME RETRIEVAL. IF THE SCALE VERIFICATION IS USED, ONLY THE FRAMES CONTAINING THE OBJECT IN APPROX. THE REFERENCE SCALE ARE CONSIDERED THE GROUND TRUTH.

| **Method** | Ground-truth frames | Retrieved frames | *Recall* | *Precision* |
|---|---|---|---|---|
| **1M words with scale verification** | 5429 | 1342 | 22.1% | 89.4% |
| **1M words without scale verification** | 15479 | 19741 | 60.1% | 47.1% |
| **64k words with scale verification** | 5429 | 18078 | 73.3% | 22.0% |
| **the method from [16]** | 15479 | 7514 | 47.9% | 98.6% |



(a) (b) (c) (d) (e)

Fig. 5. Examples of false positive matches. In (a,b) 1M words without scale verification are used, while in (c,d) a vocabulary of 64k words is applied with scale verification. A very unusual case of a false positive for 1M words with scale verification is shown in (e).

detection task only. For a classical CBVIR problem of relevant frame retrieval, i.e. detection of ALL frames partially near-duplicate to the database images of objects of interest, the results are much poorer as shown in Table II presenting performances of various schemes in such a classical *relevant frame retrieval* task (using standard CBVIR definitions of *precision* and *recall* as the scores). Thus, as the last scenario, we included a high-performance (and high-complexity) image matching method proposed in [16] (the original executables of this method have been used). The last row of Table II clearly illustrates superiority of this advanced CBVIR method. The approach proposed in this paper satisfy only the requirement of high *precision*. Therefore, it is not surprising that methods similar to the proposed approach are rather seldom considered for typical CBVIR tasks.

Nevertheless, the algorithm of [16] performs poorer in the problem of object detection. As shown in the last row of Table I, its *RI recall* of instances detection is at unsatisfactory level of only 60%, which is much less than all other schemes presented in this table (which score 100%). Admittedly, it achieves 100% of *PA precision* but (as mentioned earlier) both parameters should be as high as possible in a reliable object detection scheme.

## V. CONCLUDING REMARKS AND FUTURE RECOMMENDATIONS

The paper proposes a CBVIR-based scheme for visual detection of predefined objects of interest in cluttered environments. The scheme seems to be an attractive option for low-cost mobile agents equipped with vision devices. The proposed scheme provides (as preliminarily confirmed by our limited-scale experiments) sufficiently high performances using only low-complexity CBVIR mechanisms (borrowed from a classical CBVIR problem of partial near-duplicate retrieval). Additionally, we assume that the encountered objects become *objects of interest* when seen from a sufficiently short distance. This threshold distance defines the scale at which the database template images of objects should be recorded. Then, a frame containing an object would be recognized as an interesting one if two conditions are met. First, it is similar to a database image of some object of interest (i.e. numerous keypoint correspondences defined by identical visual words from a sufficiently large vocabulary exist) and, secondly, a significant number of those matching keypoint pairs are in approximately the same scale (i.e. the object is approached at approximately the threshold distance).

The second requirement can be considered a limitating factor, especially if the threshold distance (or rather the scale corresponding to this distance) cannot be specified or it fluctuates, e.g. because of the camera zoom. However, in typical modern applications (in robotics in particular) the mobile agents are usually equipped with some kind of range-sensing devices which can provide the agent with the depth data, e.g. [20], [21]. Then, an estimate of the distance to the observed part of the environment can be used to correspondingly modify the reference scale to be applied in the scheme (so that an adaptive reference scale is used). The only modification needed is a minor change in Eqs 1 and 2, which should be rewritten as

$$0.8M\,(K_2) \leq S_F \cdot M(K_1) \leq 1.2M(K_2), \tag{5}$$

$$0.8m\,(K_2) \leq S_F \cdot m(K_1) \leq 1.2m(K_2), \tag{6}$$

where $S_F$ is the scale adaptation factor which can be estimated using the depth data from a range sensor and/or the current camera focus data.

# 5th International Workshop on Artificial Intelligence in Medical Applications

THE workshop on Artificial Intelligence in Medical Applications – AIMA'2015 - provides an interdisciplinary forum for researchers and developers to present and discuss latest advances in research work as well as prototyped or fielded systems of applications of Artificial Intelligence in the wide and heterogenious field of medicine, health care and surgery. The workshop covers the whole range of theoretical and practical aspects, technologies and systems based on Artificial Intelligence in the medical domain and aims to bring together specialists for exchanging ideas and promote fruitful discussions.

## Topics

The topics of interest include, but are not limited to:

- Artificial Intelligence Techniques in Health Sciences
- Knowledge Management of Medical Data
- Data Mining and Knowledge Discovery in Medicine
- Health Care Information Systems
- Clinical Information Systems
- Agent Oriented Techniques in Medicine
- Medical Image Processing and Techniques
- Medical Expert Systems
- Diagnoses and Therapy Support Systems
- Biomedical Applications
- Applications of AI in Health Care and Surgery Systems
- Machine Learning-based Medical Systems
- Medical Data- and Knowledge Bases
- Neural Networks in Medicine
- Ontology and Medical Information
- Social Aspects of AI in Medicine
- Medical Signal and Image Processing and Techniques
- Ambient Intelligence and Pervasive Computing in Medicine and Health Care

## Event Chairs

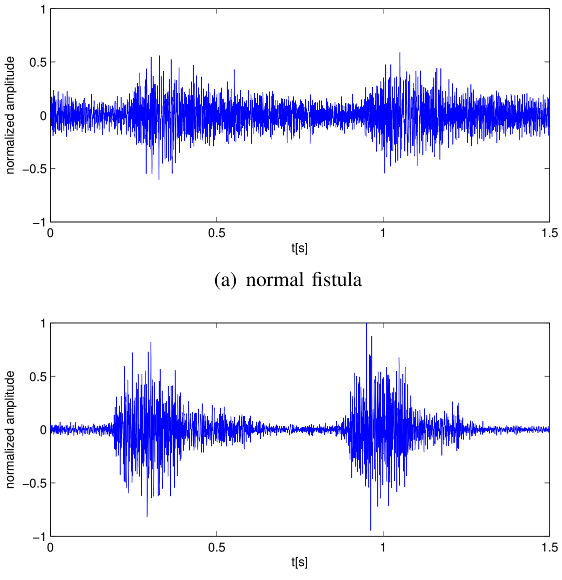
***Abstract*—The paper presents a concise report on the comparison of the classifiers k-NN and SVM in the case of a fuzzy classification of the arterio-venous fistula based on audio recordings. What has been used in the studies are the acoustic signals taken from both healthy patients as well as those diagnosed with the narrowing of a fistula in a mild and major degree of stenosis. In the publication there have been selected two features, each presenting one- time and frequency domain, which enable a quite clear depiction of the classification result. The aim of the study is to develop a solution enabling the detection of fistula's pathologies at an early stage.**

## I. Introduction

THE MAINTENANCE of a properly functioning arterio-venous fistula is extremely important for those who undergo a haemodialysis. Its good condition providing an access to arterial blood with a great degree of flow enables an efficient process of extracorporeal blood filtration. The condition of a fistula is examined by a stethoscope auscultation each time before connecting the patient to a dialysis apparatus. In particular examples diagnostics may be extended to USG examination with the Doppler's facility. Unfortunately, the most abnormalities in functioning of a fistula are diagnosed when they are so advanced that they might be detected just with a use of a stethoscope. The most frequent problem is a deformation of a fistula's vessel which result in a decreasing of its diameter. The narrowing causes a decrease of an arterial blood supply and as a result it could lengthen the process of haemodialysis or even it could make it impossible. That is why it is crucial to determine the methods of an early detection of any pathology within a fistula.

According to the studies conducted, the character of a sound emitted by the blood flowing inside a fistula's vessel vary depending on the state of a fistula. The blood flowing through a fistula in a normal state is continous and it undergoes a very slight changes in a heart rhythm period. As a result a noise of a flowing blood can be heard well all the time. In a stenosed fistula a blood flow is hindered, what effects in rhythm changes of the intensity of a sound, compatible with a heart rhythm. The amplitude of changes is then even bigger and the stenosis of a fistula is more advanced. The differences in the picture of an acoustic signal of a properly working fistula as well as a pathologically changed fistula are presented in the fig.1.



(a) normal fistula

(b) stenosed fistula

Fig. 1. An image of the time-domain audio signal emitted by the arterio-venous fistula

Not all anomalies which may occur within the fistula's area result in a decreasing of the flow. When it comes to the hyperkinetic fistula the blood flow increases excessively, what may result in cardiological complications or even strokes. However, each change of geometry of a fistula causes the change in a character of the flow of the transported blood. Usually, the flow becomes turbulent and causes changes in a frequency spectrum of a signal, what has been show in the fig.2.

Presented examples of trajectories in both the time and the frequency domain represent extreme cases, moreover, the fistula diagnosed as pathological qualifies for a reconstruction through a surgical treatment. Another problem is detecting an anomaly in an early stage, what enables a preventive

intervention enabling a suppression of unwanted changes. In order to do that what should be determined ,apart from the collections of data from extreme cases, are concentrations of data referring to average cases with the use of which the classifier should be trained enabling their proper assessing.

## II. Materials and Methods

The research material has been collected from 9 patients, all male, age from 35 to 52. Two patients were diagnosed with an extreme malfunction (occlusion) of a fistula, another two had stenosis in various degrees of development, in the case of the last five, the fistula was normal. The examination concerned only end-to-side radio-cephalic fistulas located in a wrist. The acoustic signal was taken from the distance of 5 cm from the anastomosis point. The point of a signal intake is pictured in the fig.3

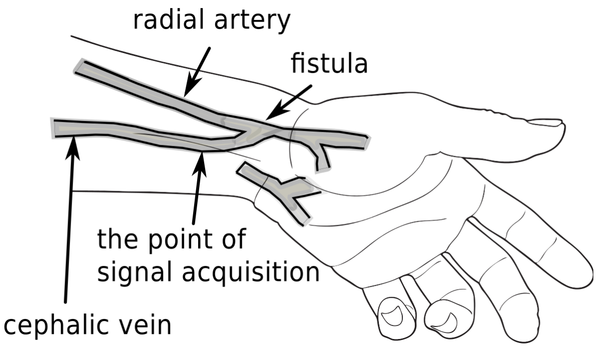

Fig. 3. The point of a signal intake

The material has been taken with the use of a specially created measuring area (fig.4) which includes:

a) A header made from the ABS material which is shaped in a way that it enables the most possible anatomic position of its end during the signal intake. Inside the main body of the header electret microphone Ringford CZ034 has been installed with responsivity -42dB (0dB=1V/Pa, 1KHz, 8mV/Pa) and S/N ratio better than 60dB.
b) A PC computer with Xubuntu Linux 14.10 operating system, equipped with a sound card Sound Blaster PCI 64 constructed according to the Ensoniq AS1371 chip. Dedicated application serving as an registrant of a sound written in C++ with the use of the Qt library, communicating also with the equipment thanks to the ALSA sound server. The sample rate was determined on 8kHz level, with a resolution 16 bits per sample.
c) Headphones used for the organoleptic monitoring of the quality of the recorded material.

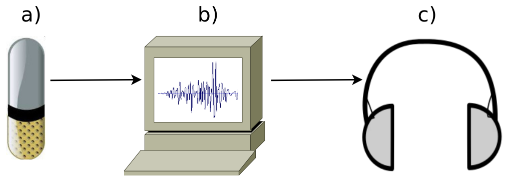

Fig. 4. data acquisition system diagram

From the taken material there have been isolated 100 samples from each group. The material has been randomly divided into a training sets including 60 samples of each kind and the testing set having 40 samples of each kind.

A common problem in classifiers building tasks is a great difference in the amount of positive and negative training patterns. In order to receive a set pattern with a similar number for each of the classes there have been registered more samples for each person with a stenosed or occluded fistula.

Registered material has been divided into parts corresponding to a single heart rhythm period, next, there has been distinguished properties being components of vector's features.

Altogether, there have been determined over 20 properties in a time domain and a frequency domain, and for the visualization needs of this elaboration, two have been chosen, each from one domain-time and frequency.

### A. A property in a time domain.

When it comes to time domain, there has been chosen one property based on a difference between the maximal and the minimal value of the envelope of a signal (fig.5).

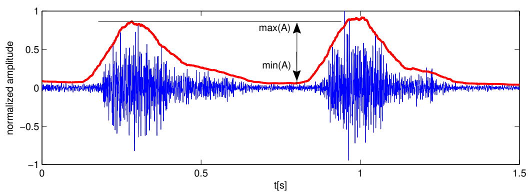

Fig. 5. A property in a time domain

In order to get an envelope signal, it has been straighten and filtrated with the use of a low-pass filter. A moving average filter with the length of 1000 elements has been used.

This property has been marked as $f_1$ and calculated from the equation (1).

$$f_1 = \frac{A_{min}}{A_{max}} \tag{1}$$

The initial analysis has shown that in the case of a fully efficient fistula, the flowing blood generates a sound of a slightly reducing intensity during the whole heart rhythm period. The intensity of a sound emitted by a stenosed fistula definitely characterizes with a greater fluctuation, as a result of a periodical decrease of a flowing blood speed. In connection to that, for an efficient fistula the value of its properties $f_1$ will be higher than in the case of a narrowed fistula.

### B. A property in a frequency domain

In order to get the properties in a frequency domain, a signal had been firstly divided into fragments corresponding to the heart rhythm and then transformed to the frequency domain with using FFT transformation. In order to eliminate a spectral leakage the Hamming time window has been used.. From the spectral module possessed, there have been distinguished two divisions: $FR_1 = [125HZ, 175Hz]$ and $FR_1 = [375Hz; 425Hz]$ (fig.6).

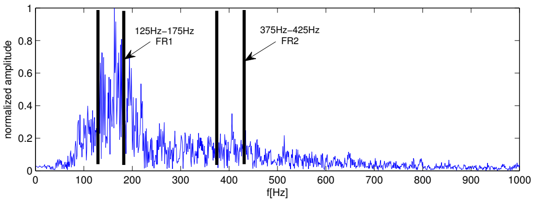

Fig. 6. A property in a frequency domain

The value of a spectral amplitude within these divisions have been summarized and calculated its property $f_2$ according to the equation (2).

$$f_2 = \frac{FR1}{FR2} = \frac{\sum_{f=125}^{175} fft}{\sum_{f=375}^{425} fft} \tag{2}$$

An analysis of signals coming from normal as well as stenosed fistulas, has shown that in the case of those stenosed ones, the value of a $FR2$ factor is definitely higher. Therefore, the value of a $f_2$ property will be smaller when the condition of a fistula will be better.

### C. The use of an SVM classifier in a fuzzy classification task

The classifier used in the elaboration comes from the libSVM library in 3.2 version by Chih-Chung Chang and Chih-Jen Lin. The library is written in the C++ language owns interfaces which enable using with various programming languages, including the "m" language in Matlab and Octave environment, which were used in order to work out the results of this elaboration.

The used classifier in the classifying tasks gives back the value of -1 or 1 indicating the adjunction of an examined feature vector in a particular category. In the regression tasks what is given back is the real value, which may go beyond the $[-1, 1]$ interval.

$$y_{SVM} = \begin{cases} -1 & \text{for } SVM_{out} < -1 \\ SVM_{out} & \text{for } SVM_{out} \in [-1; 1] \\ 1 & \text{for } SVM_{out} > 1 \end{cases} \tag{3}$$

Taking the specifics of the examined problem, it became necessary to limit the set of values given back through the interval classifier $[-1, 1]$. It has been accomplished by an application of a function described as (3) pattern, where $SVM_{out}$ is a regression value calculated through the classifier.

### D. The use of the classifier k-NN in a fuzzy classification task

Normally, the algorithm k-NN is used in classification tasks, what means it gives back a discreet value determining an adjunction to the one of the classes determined beforehand. On the account of the requirements determined by the assumptions of this elaboration, it has become necessary to create an own implementation of the k-NN algorithm in a way that it gives back a real value from the continuum between two extreme cases.

In order to do that, after having found the k-nearest neighbors and calculating their Euclidean distance from the examined point, the transformation described with a equation (4) has been applied, where $d(n)$ is a distance of the umpteenth pattern from the examined point.

$$s(n) = \frac{e^{-d(n)}}{\sum_{i=1}^{k} e^{-d(i)}} \tag{4}$$

In effect, the distance measurement has been changed into the proximity measure $s(n)$, simultaneously receiving

$$\sum_{n=1}^{k} s(n) = 1$$

to calculate definitively an expected degree of belonging of the examined point to the model classes.

$$y_{k-NN} = \sum_{n=1}^{k} s(n)X(n) \tag{5}$$

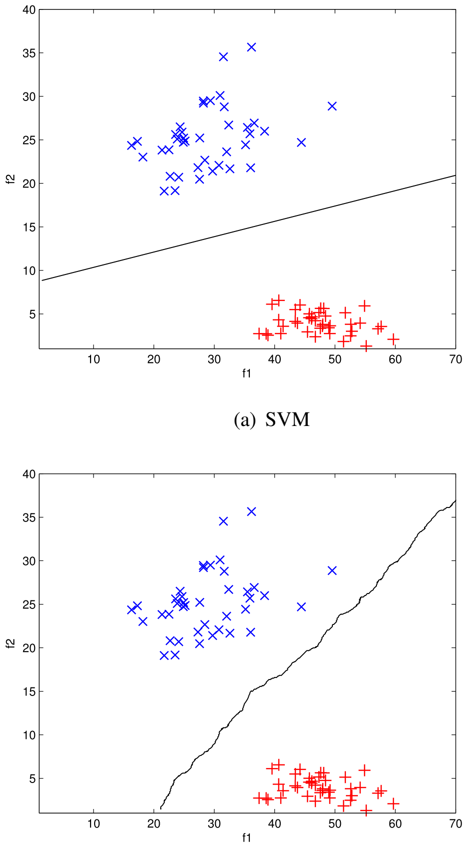
Assuming that all the model vectors are ascribed to the classes from the range $[-1, 1]$, the result of operation of such constructed classifier will be within the same range.

## III. Results and discussion

The SVM and k-NN classifiers have been compared in three cases of using. For each case the accuracy has been determined and the analysis with the use of a confusion matrix has been conducted. In the first example the classifiers have been used in a model classification task, however in two other cases in a fuzzy classification task. For the k-NN classifier, the k=19 parameter has been established and used in all three cases. In the first two cases for the SVM classifier the parameter c=1 has been established and there hasn't been any transformations of the feature's space used. In the third case, because of the lack of a linear separation of the data, for the SVM classifier the parameter C=100 has been established and a kernel transformation with the use of the Gauss's function has been used.

### A. Classification

In this task, the classifiers have been trained with a training set including only the extreme data, namely, ascribed to one of the two sets labeled "-1" or "1". Since the sets of data of both classes are substantially distant from each other and moreover, linearly separated, none of the classifiers had any problems with their proper division, what is presented in the fig.7.



(a) SVM

(b) k-NN

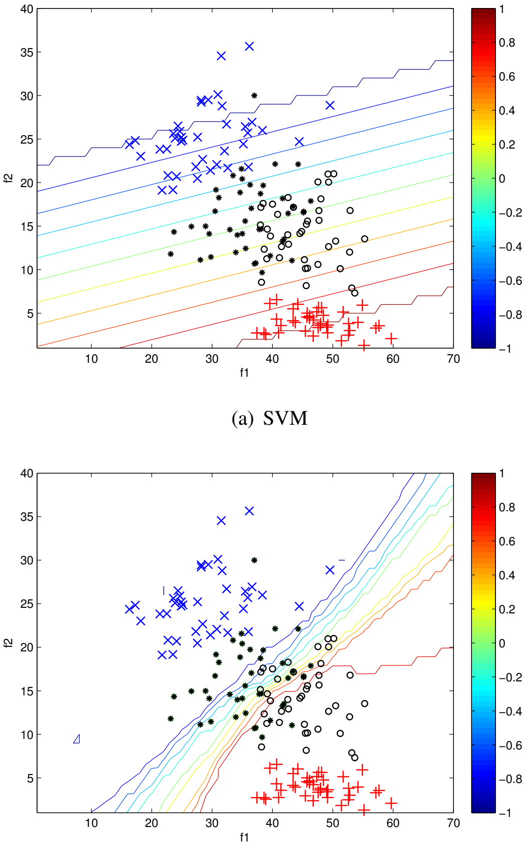
Fig. 7. Classification

In both cases, all the examined points have been accurately recognized in both classes, what gave 100% of accuracy. The classifiers differs only in the course of hyperplane of the division of the classes, what happened to be irrelevant in this particular case.

### B. The fuzzy classification - version 1

In cases of a real assessment of an arterio-venous fistula's condition classifiers cannot determine the adjunction of the examined point to one from the two extreme classes. The task is problematic since it requires determining the position of an examined point in a space between the extreme cases. Therefore, as a result of its operation, a classifier cannot give back the value of -1 or 1. It is necessary to adjust a classifier in a way it could give back the value from the $[-1, 1]$ range. These values indicate a degree of adjunction of an examined point to the extreme classes.

In the first version of a fuzzy classification a teaching set containing only extreme cases has been applied. In effect, the functions mapping the $[f1, f2]$ features' space in the $[-1, 1]$ range has been obtained as presented graphically in the fig.8.



(a) SVM

(b) k-NN

Fig. 8. Fuzzy classification - version 1

In testing, the set containing average cases have been used, marked on a basis of an expert's assessment with the labels -0.33 and 0.33, what gave, in total, four classes of training patterns labeled with: $\{-1, -0.33, 0.33, 1\}$.

In order to make the analysis the values given back by the classifiers have been digitized to four ranges corresponding to four entering classes, and next, compared with the real adjunction of the testing patterns. The assignation of the ranges of the starting classifiers to the appropriate classes is shown in the table.I

TABLE I
ASSIGNATION OF THE RANGES OF THE STARTING CLASSIFIERS TO THE APPROPRIATE CLASSES

| range | class |
|---|---|
| $[-1, -0.66)$ | -1 |
| $[-0.66, 0)$ | -0.33 |
| $[0, 0.66)$ | 0.33 |
| $[0.66, 1])$ | 1 |

The result of the operation of the classifiers has been compared in the table II and table III.

TABLE II
CONFUSION MATRIX - K-NN 0/1

| accuracy:0.59 | | Actual value | | | | |
|---|---|---|---|---|---|---|
| | | -1 | -0.33 | 0.33 | 1 | class precision |
| Predicted | -1 | **40** | 19 | 1 | 0 | 0.67 |
| | -0.33 | 0 | **7** | 3 | 0 | 0.70 |
| | 0.33 | 0 | 7 | **8** | 0 | 0.53 |
| | 1 | 0 | 9 | 28 | **40** | 0.52 |
| | class recall | 1.00 | 0.17 | 0.20 | 1.00 | |

TABLE III
CONFUSION MATRIX - SVM 0/1

| accuracy:0.78 | | Actual value | | | | |
|---|---|---|---|---|---|---|
| | | -1 | -0.33 | 0.33 | 1 | class precision |
| Predicted | -1 | **35** | 1 | 0 | 0 | 0.97 |
| | -0.33 | 5 | **24** | 11 | 0 | 0.60 |
| | 0.33 | 0 | 15 | **26** | 0 | 0.63 |
| | 1 | 0 | 9 | 3 | **40** | 0.93 |
| | class recall | 0.88 | 0.60 | 0.65 | 1.00 | |

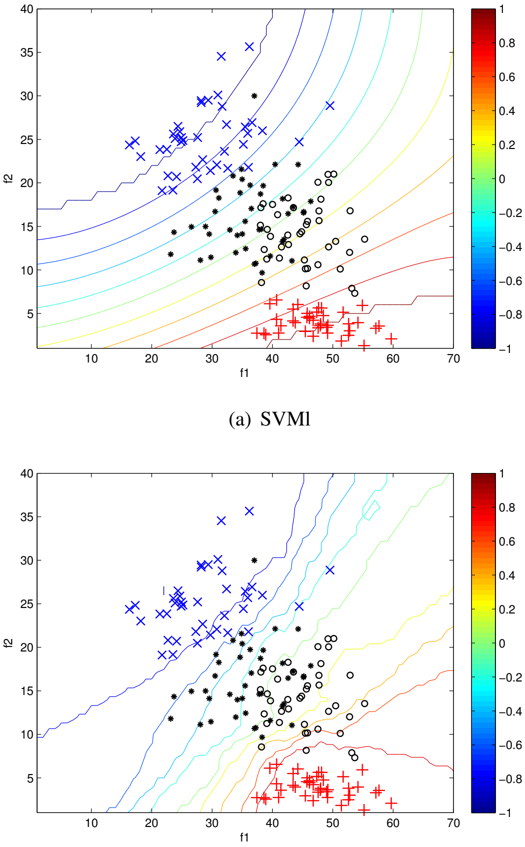
The analysis of the confusion matrix shows definitely better parameters of the SVM classifier. Although in the case of the extreme classes labeled with -1 and 1 recall for the classifier k-NN equal 100% and it is better than for SVM, for the average classes, the values between ten and twenty percent disqualify the k-NN classifier completely. However, the level of accuracy of 80% obtained for the SVM classifier is also not very satisfying, all the more, for the classes labeled negative it has a tendency to make a better diagnosis.

### *C. The fuzzy classification - version 2*

In order to improve the classifiers' parameters, the next step was to insert the vectors from the sets labeled -0.33 and 0.33 into the training sets. In effect, the functions mapping the features' space $[f1, f2]$ into range $[-1, 1]$ has undergone a significant modification what has been pictured in the fig.9.

The modification improved the quality of operating of both of the classifiers. The comparison of the results of the classifiers' testing is presented in the table IV and table V.

For the SVM classifiers the improvement is slight. The accuracy increased from 78% to 81%, similarly, the class precision and the class recall parameters have undergone in some cases a slight correction down.



(a) SVMl

(b) k-NN

Fig. 9. Fuzzy classification - version 2

TABLE IV
CONFUSION MATRIX - KNN FUZZY

| accuracy:0.85 | | Actual value | | | | |
|---|---|---|---|---|---|---|
| | | -1 | -0.33 | 0.33 | 1 | class precision |
| Predicted | -1 | **37** | 2 | 0 | 0 | 0.95 |
| | -0.33 | 3 | **29** | 6 | 0 | 0.76 |
| | 0.33 | 0 | 9 | **30** | 0 | 0.77 |
| | 1 | 0 | 0 | 4 | **40** | 0.91 |
| | class recall | 0.93 | 0.72 | 0.72 | 1.00 | |

The results of the operation of the k-NN classifier have undergone a significant improvement. The accuracy increased from 59% to 85% and it exceeded the value obtained by the SVM classifier. Only class recall for the "-1" class has slightly reduced.

In both cases what can be observed is unfortunately the problem of an accurate classification of the average classes.

## IV. CONCLUSION

As a result of the conducted tests, what has been tentatively stated is that both the SVM and the k-NN classifiers can be applied in a task of an estimation of a fistula's condition and enable obtaining a relatively high co-factor of accuracy. What provides proper operation of the examined classifiers is putting into a set of pattern data not only extreme patterns determining the limits of a case's space but also, when it is possible, the whole continuum. On the basis of obtained results it cannot

TABLE V
CONFUSION MATRIX - SVM FUZZY

| accuracy:0.81 | | Actual value | | | | |
|---|---|---|---|---|---|---|
| | | -1 | -0.33 | 0.33 | 1 | class precision |
| Predicted | -1 | **37** | 1 | 0 | 0 | 0.97 |
| | -0.33 | 3 | **27** | 12 | 0 | 0.64 |
| | 0.33 | 0 | 12 | **24** | 0 | 0.67 |
| | 1 | 0 | 0 | 4 | **40** | 0.91 |
| | class recall | 0.93 | 0.68 | 0.60 | 1.00 | |

be stated which of the applied classifiers will be the best for the task. The differences in the accuracy of the classification are slight and in most cases they are within the limits of the statistical error.

In order to obtain more reliable results in continuing of the examinations, the realization of a few conclusions seems to be essential:

- it is necessary to collect a significantly greater number of an overall data since a small amount of data used in testing does not guarantee a solution of the problem,
- the signal samples have to be taken from the greater number of patients,
- it is recommended to obtain the possible biggest amount of data from the fistula's in an average state between the fully efficient to the occluded ones,
- it should be considered to widen or to change the set of the features' signal included in the analysis of the features' vector.

The application of the above-mentioned conclusions gives a great chance for the fruitful continuation of the examinations and in effect obtaining a solution enabling identification of pathological states within a fistula in the earliest state possible.

*Abstract*—**Breast cancer is one from various diseases that has got great attention in the last decades. This due to the number of women who died because of this disease. Segmentation is always an important step in developing a CAD system. This paper proposed an automatic segmentation method for the Region of Interest (ROI) from breast thermograms. This method is based on the data acquisition protocol parameter (the distance from the patient to the camera) and the image statistics of DMR-IR database. To evaluated the results of this method, an approach for the detection of breast abnormalities of thermograms was also proposed. Statistical and texture features from the segmented ROI were extracted and the SVM with its kernel function was used to detect the normal and abnormal breasts based on these features. The experimental results, using the benchmark database, DMR-IR, shown that the classification accuracy reached (100%). Also, using the measurements of the recall and the precision, the classification results reached 100%. This means that the proposed segmentation method is a promising technique for extracting the ROI of breast thermograms.**

## I. Introduction

BREAST cancer is the most common one among women, and it most likely cause of women death in the world wide. In the United States, one death of 4 is due to cancer [1]. There are many breast imaging techniques used for identifying early stage of breast cancer. One of them is mammography. It is most commonly used for screening of breast cancer. However the false negative rate can reach up to 30% in addition it expose patient to ionizing radiation effect [2]. Thermography uses a special heat-sensing camera to measure and map the heat on the surface of the breast [3], [4].

As long as cancerous tumors have an increased blood supply and cell growth they tend to be warmer than the surrounding normal tissue and it is the idea behind using Thermal images instead mammogram. Thermography play an important rule as a visualization technique that can be used in many different fields of physics and science. Unlike mammography, there is no compression of the breast so women may find it more comfortable, thermal imaging does not expose the woman to any radiation, as occurs with mammography (a type of X-ray), fast, low cost and sensitive method [5].

The extraction of the Region Of Interest, ROI segmentation, from the breast image is very important for detecting the cancer from the breast images. ROI segmentation aims to separate the regions of the breast from the other parts of the body. It can range from a completely manual to a fully automatic process [6]. Once the breast region is separated from the rest of thermal images, then some features are extracted. Then some kindS of artificial classifications algorithms are applied to classify the organs in analysis as normal or abnormal [7].

For the automatic segmentation approaches [7], [8], the level set technique [9] used to extract the blood vessels in a thermal image. The level set function is evolved using the gradient magnitude and direction of an edge map provided by few initial points selected in region of interest. In [7], automatic segmentation approach is proposed using active contour and level set method without re-initialization. It is used to extract the breast regions from breast thermograms. Before applying the level set, a statistical based noise removal and contrast-limited-adaptive histogram equalization are used to improve signal to noise ratio and the contrast of thermal images. Verification and validation of the segmented results are carried out using 60 images against the ground truths. The segmented areas are observed to be in good correlation with the ground truth areas as the correlation coefficient was 98%.

For breast abnormalities, several attempts [10], [11], [12], [13], [14] have been made to demonstrate the ability of different features in detecting breast cancer abnormalities. Texture features have been used to detect abnormal thermograms using support vector machine (SVM) [11] and artificial neural networks [12]. Statistical features ranging from first order statistical to higher order statistical features have been extracted for automatic classification of abnormal breast conditions using different classifiers like SVM [13], linear discriminant classifier, minimum distance classifier and Parzen window [14].

This paper proposes an automatic breast segmentation approach based on the distance between body and camera is 1 meter (dynamic protocol). In order to evaluate the accuracy of the proposed segmentation approach, different selective

978-83-60810-66-8/$25.00©2015, IEEE

features were extracted from the segmented regions and then the SVM classifier was used to detect the breast abnormalities

This paper is organized as follows. Section II reviews the existed segmentation and the extracted features methods. Section III gives overview of the thermal imaging protocols of breast cancer while Section IV presents the proposed approach to segment region of interest. In Section V the proposed segmentation is used to detect the abnormalities of thermogarms images and IN Section VII the experimental results are discussed. Finally, we conclude the paper and gives some future directions in Section VIII.

## II. Literature Review

To make our proposed approach, in this paper comparable with its related work, we have limited this related work to the efforts done using the DMR-IR database [15]. These efforts can be classified into two classes: automatic segmentation of breast regions [7]] [8] and classification based on the asymmetry analysis to normal and abnormal cases [16], [17], [18].

For the automatic segmentation [7], [8], the level set technique [9] has been used to extract the blood vessels in a thermal image. The Level set function was evolved using the gradient magnitude and direction of an edge map provided by few initial points selected in region of interest. In [7], an automatic segmentation approach, using active contour and level set method without re-initialization, was proposed to extract the breast regions from breast thermograms. Before applying the level set, a statistical based noise removal technique and contrast limited adaptive histogram equalization were used to improve signal to noise ratio and contrast of thermal images. Verification and validation of the segmented results were carried out using 60 images against the ground truths. The segmented areas were observed to be in good correlation with the ground truth areas as the correlation coefficient was 98

Another automatic segmentation approach has been proposed in [8] to segment the frontal breast tissues from breast thermograms. This approach made use of the Modified Phase Based Distance Regularized Level Set (MPBDRLS) method. The method was further modified by adopting an improved diffusion rate model. The segmented region of interests was evaluated using 72 gray scale images of size 320 X 240 pixels and against the ground truth images. The overlap measures showed that the average similarity between four sets ground truths and segmented region of interests was 97%.

The asymmetric-based classification is based on the asymmetric abnormalities which can be identified by comparing the features extracted from the breast regions (right and left). Several statistical and fractal features are found to be useful features in identification of pathological conditions of breast tissues [18]. Using DMR-IR database, in [16], an approach was proposed to classify the normal and abnormal (carcinoma, nodule and fibro adenoma) breast thermograms Gabor wavelet transform. First, the segmentation of the breast tissues was performed using ground truth masks and the raw images. Gabor features [19] were then extracted for the detection of the abnormalities. The results showed that from total of 20 images, used of the approach evaluation, there were 9 images with carcinomas, 6 with nodules, and 5 with fibro adenomas.

## III. INFRARED IMAGING PROTOCOLS

Infra-red imaging protocols in general have the following parts: Recommendations to the patient, conditions of the examination room; preparation, cooling and positioning of the patient; capturing positions and parameters. For recommendation to the patient, patient asked to avoid: Alcohol, caffeine, physical exercises, and nicotine for at least two hours before the examination process. And for condition of examination room, Room temperature must be maintained between 20°C and 22 °C, no airflow directed to the patient no windows, no opening.

For preparation of the patient, she is asked to remove earrings, necklaces or other accessory. The patient's body temperature is checked by clinical thermometer and her hair stuck with a cap. The patient is positioned in front of the camera with the hands on the head. And for capturing positioning and parameters, the standard distance between the camera and the patient is 1 $m$. But it depend on the size of the patient, a distance of 0.8m or 1.2m is adopted for a better frame of the region of interest (breast and armpit) in the image. The distance, room temperature and the relative humidity of the air are recorded and inserted as parameters in the IR camera settings [20].

In all reproduced protocols, the initial procedures are equal to each volunteer. These procedures are i) to check the central temperature by a clinical thermometer; ii) to check whether the volunteer followed the recommendations of the protocol which are at least two hours before: iii) to ask the patient to remove beads, earrings and other accessories which can be viewed in the thermal images and hold the hair with a shower cap; and iv) to ask the patient to remove clothing from the waist up.

In all protocols below the volunteer stays with his hands on his head during the whole process.

1) First Static Protocol: The volunteer rests for 10 minutes to stabilize the skin temperature of the breasts and armpit. After that, a frontal image is captured.
2) Second Static Protocol: Similar procedures of the previous protocol, but in this, the volunteer rests per 15 minutes.
3) First Dynamic Protocol: An electric fan is turned on and directed to the volunteer's breasts and armpits per 2 minutes. After this, six images are captured, one each minute.
4) Second Dynamic Protocol: Alcohol is applied at the region of the volunteer's breasts and armpits, then an electric fan is turned on and guided to this region per 30 seconds. After this, six images are captured, one each minute.

## IV. The New Segmentation Method

The proposed segmentation method depends on the predefined parameter (i.e. th distance between camera and patient) of the data acquisition protocol used to collect thermal breast image in [20]. In our case, the breast's region occupies nearly half of the image height while the other areas include women shoulders and stomach. Figure 1 confirm these facts.

The main idea of the proposed segmentation method is based on the following facts [20]:

1) The distance between body and camera is 1 meter (dynamic protocol).
2) As can be seen from Figure 1, the image includes only the upper part of the patient that contains a part of the stomach and arms with nick.
3) The breast engaged a specific position in human body which is nearly at the center of the image, see Figure 1.

As a result of these facts, we followed the algorithm as see in Algorithm (1).

**Algorithm 1** Segmentation Method

```
Read original grayscale thermal image, $I$
Read M = I's height
Read N = I's width
Read the corrdinates $Y_1$ and $Y_2$ where $Y_1 = 1/4 * M$ and $Y_2 = M - 0.2 * M$
Extract the ROI where $ROI = imcrop(I, [X_1, X_2, Y_1, Y_2])$, where $X_1 = 0$ and $X_2 = N$
Convert the ROI to binary image by using threshold with value equal to 0.4 (trial and error) to differentiate body from background
Remove columns from the image width having $value = 0$
```

In case, as a women body is not always at center of image then after getting initial ROI extracted, threshold will be used to binaries the image. Then full column with zero value will be removed in order to focus on breast region. Figures 3 and 2 show the extracted ROI from original grayscale thermal image in case of normal and abnormal.

To explain how this new segmentation method works, we give the following example. Suppose, there is an image with 480 height and 640 width as seen in Figure 4. Based on Algorithm (1), the coordinate of the ROI are $X$ where $X$ ranges form 1 to 640 and $Y$ where $Y$ from 120 to 384.

## V. Breast Abnormalities Detection Approach

To evaluate the new segmentation method, we proposed a breast abnormalities detection approach. As shown in Figure 5, this approach consists of four phases: ROI segmentation, ROI enhancement, feature extraction and classification.

*a) ROI Segmentation:* : At this phase, our method, introduced in Section (IV) will be applied to extract the ROI (i.e. the breast region) from original grayscale thermal image.

*b) ROI Enhancement:* Image enhancement is important step in image processing. It used to bring out detail that is obscured, or simply to highlight certain features of interest in an image. Then histogram equalization is used to enhance contrast of the image and increase classification accuracy.

*c) Features Extraction:* Two types of features (first order statistical and texture) are extracted from the enhanced ROI of breast thermograms. The first order statistical features include *mean, standard deviation, median, mode, skewness and kurtosis* whereas the texture ones consists 15 features which were extracted from gray-level co-occurrence matrix (GLCM) [21] with the distance parameter $d = 1$. These features are *Energy, Contrast, Correlation, Sum of square variance, Homogeneity, Dissimilarity, Inverse difference moment (IDM), Inverse difference normalized (INN), Information measure of correlation1 (IMC1), Information measure of correlation2 (IMC2), Difference entropy, Difference variance, Sum entropy, Sum variance and Sum average*. So, the total extracted features is 21 features.

Table I and Table II show the features extracted from the ROI of both normal an abnormal cases. To increase the performance of the proposed approach, before using these features in the classification phase, they were analyzed using student's $t$ hypothesis testing the mean of two independent samples. The features with $P > 0.05$ were selected for the classification process. Based on this test, as seen Table I, the Median, Mode and Standard deviation are statistically insignificant where $P > 0.05$ whereas the Mean, Skewness and Kurtosis are found to be statistically significant where$P < 0.05$. Also, form Table II Homogeneity and Information Measure of Correlation1 (IMC1) are found insignificant features and the Energy, Contrast, Correlation, Sum of square variance, Dissimilarity, Inverse difference moment (IDM), Inverse difference normalized (INN), Information measure of correlation2 (IMC2), Difference entropy, Difference variance, Sum entropy, Sum variance and Sum average were found highly significant features where $P < 0.05$. Therefore, only 16 out of 21 features were used in the classification phase.

TABLE I: First order statistical features analysis for normal group (NG) and abnormal (AbG) group

| Feature | Average of NG | Average of AbG | p |
|---|---|---|---|
| Mean | 105.622 | 123.905 | 0.023 |
| Median | 110.485 | 126.742 | 0.061 |
| Mode | 59.885 | 68.571 | 0.581 |
| Standard Deviation | 14.123 | 16.169 | 0.089 |
| Skewness | 0.8105 | 1.8128 | 0 |
| Kurtosis | 15.245 | 31.415 | 0 |

*d) Classification:* The Support vector machine (SVM) were used to evaluate the feature extracted from the ROI. The SVM is a supervised learning method that transforms input data to high-dimensional feature space using various kernel functions (Linear, polynomial, RBF, and quadratic) such that the transformed data becomes more separable that that of the original input data [22][23][24]. The SVM was first trained with the selected 16 features (i.e. features with $p < 0.05$) to

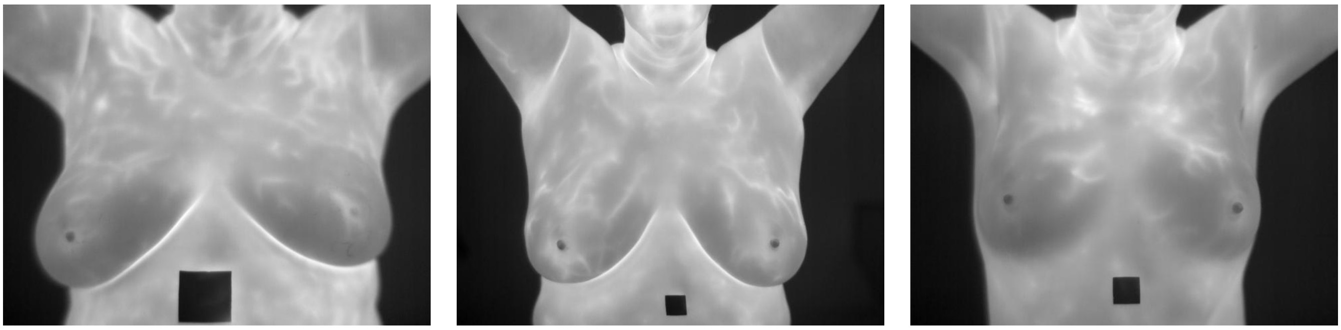

Fig. 1: Original Patient Image

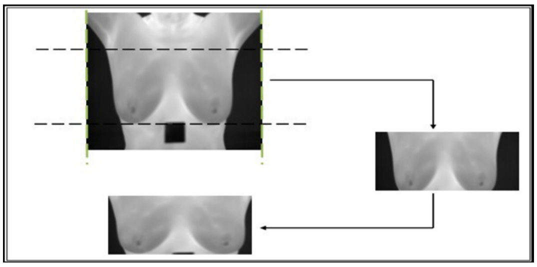

Fig. 3: Normal Segmentation Case

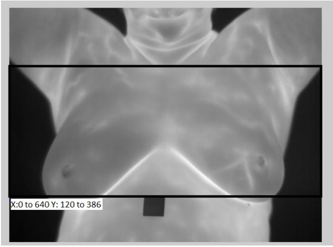

Fig. 4: Segmented ROI

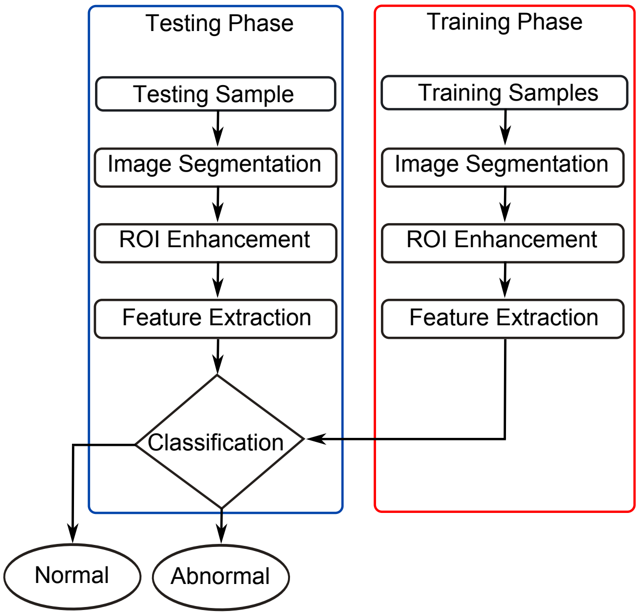

Fig. 5: Proposed Approach Model

build a classification model which was then used in the testing phase to classify breast image to normal or abnormal.

*e) Support Vector Machine (SVM):* SVM is one of the classifiers, which deals linearly or non-linearly to classify unknown objects based on increase the margin between classes. It deals successfully with high dimensional datasets ([19], [25]).

Given a training dataset or a feature matrix, $x_i$ and $y_i$, where $i = 1, 2, 3, \ldots, N$, $N$ represents the number of training samples, $x_i$ is a feature vector, and $y_i$ represent the class labels of the training sets. In case of binary classification $y_i \in \{-1, +1\}$ is the target label, $y = +1$, for samples belong to class $C_1$ and $y = -1$ denotes to samples belong to class $C_2$. The default SVM deals linearly with the classification problem, but using different kernels it may solve the problem of non-linear classification [19]. SVM algorithm tries to find an optimal hyperplane with the maximal margin to separate two different classes, which requires solving the optimization problem in Equation (1).

$$\begin{gathered} maximize \sum_{i=1}^{n} \alpha_i - \frac{1}{2} \sum_{i,j=1}^{n} \alpha_i \alpha_j y_i y_j . K(x_i, x_j) \\ \text{subject to: } \sum_{i=1}^{n} \alpha_i y_i, 0 \leq \alpha_i \leq C \end{gathered} \tag{1}$$

where, $\alpha_i$ represents the weight assigned to the training sample $x_i$ (if $\alpha_i > 0$, then $x_i$ is called a support vector); $C$ is a

TABLE II: Second order statistical features analysis for normal group (NG) and abnormal (AbG) group

| Feature | Average of NG | Average of AbG | p |
|---|---|---|---|
| Energy | 0.0025 | 0.0027 | 0.044 |
| Contrast | 0.0369 | 0.047 | 0.013 |
| Correlation | 0.7951 | 0.9288 | 0.028 |

regulation parameter; and $K$ is a kernel function, which is used to map or transform the features into higher dimensional space to discriminate between different samples

## VI. Experimental Results

### A. Breast cancer Dataset

A benchmark database [20] used to evaluate our proposed approach. This public database are constructed by collecting the IR images from UFF University's Hospital and publicly published under the approval of the ethical committee where every patient should sign consent. 63 IR single breast images (640 × 480 pixels) from this database were used in this paper (29 healthy and 34 malignant).

### B. Experimental Results

This section presents two type of the results: segmentation results obtained by our new segmentation method and the classification results based on this new method.

*a) Segmentation Results:* Due to the fact that there are different size of the breast of each woman and this is the case of the DMR-IR database [20], four scenarios ( small size breast, medium size breast, large size breast, and the asymmetric breast size) were designed to evaluate our new segmentation method against these different cases. The segmentation results of all these scenarios using our new method are shown in Figure 6 which shows that automatic segmentation of the ROI of thermograms under the various image cases.

*1) Classification Results:* In order to test the efficiency of segmentation results obtained by our new method, two main scenarios were designed. The first scenario was planned to understand the effect of using different number of images for the training and testing on the accuracy of the classification when using statistical and texture features. Different combinations between the number of training and testing images are illustrated in Table III.

TABLE III: Various scenarios for evaluating the proposed approach at different training and testing thermograms

| Scenarios | Training Data | | Testing Data | |
|---|---|---|---|---|
| | *Normal* | *Abnormal* | *Normal* | *Abnormal* |
| **1st Scenario** | 19 | 24 | 10 | 10 |
| **2nd Scenario** | 14 | 19 | 15 | 15 |
| **3rd Scenario** | 8 | 15 | 21 | 19 |
| **4th Scenario** | 4 | 9 | 25 | 25 |

All the scenarios are evaluated by the SVM functions, i.e. Linear, polynomial, RBF, and quadratic, and the summary of their results are given Table (IV), and Table (V).

The second scenario was designed to investigate whether the integration between the features of texture and statistical is better for detecting the abnormalities in thermograms. Under the same sub-scenarios illustrated in Table (III), the results, evaluated by the accuracy, are shown in Figure (7. The accuracy is calumniated according to Equation (2),

$$Accuracy = \frac{T_P + T_N}{T_P + T_N + F_P + F_N} \tag{2}$$

where $T_P$ represents true positive, $T_N$ represents true negative, $F_P$ represents false positive and $F_N$ represents false negative.

## VII. Discussion

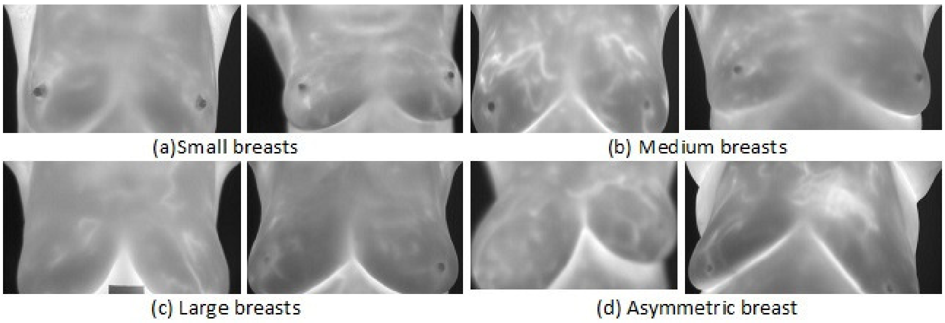
As shown in Figure 6, it can be seen that the new segmentation method can successfully extract the ROI (the breasts area) of thermograms. We have some cases where a small part at the bottom of the breast is not included in the extract ROI. However, this part would not affect on the diagnosis of breast abnormality. As reported in [26] that the pectoral region is the most important part for brest cancer diagnosis and it is reported that near 50% of the breast cancer is located in this region which is successfully extracted by our new segmentation method.

The results of this segmentation method was further evaluated by classifying the segmented ROI to normal and abnormal and the results of different scenario are shown in Tables (IV and V) and Figure (7). From these results, it can be seen that the combination between the statistical and texture features of the ROI gave 100 % which is much better than using each of them individually.

$$Recall = \frac{T_P}{T_P + F_N} \tag{3}$$

$$Precision = \frac{T_P}{T_P + F_P} \tag{4}$$

The results of the feature combination were further evaluated in terms of the recall and precision described in equation (3) and (4) and the results of these recall and precision are summarized in Figure (8) and Figure (9), respectively. From these two tables and Table (7), it can be noticed that (a) the SVM-RBF gave the best results (100%) (b) the more training images were used, the high accuracy was obtained as in the first scenario where the accuracy, the recall and the precision reached 100%. These excellent classification results based on



(a)Small breasts
(b) Medium breasts
(c) Large breasts
(d) Asymmetric breast

our new segmentation method means that this method could be used for the automatic segmentation of the thermal breast cancer images.

## VIII. Conclusion and future research directions

In this paper, an automatic segmentation methods for themograms have been proposed. This method is based on the data acquisition protocol parameter (the distance from the patient to the camera) and the image statistics. The proposed segmentation results prove its reliability in extracting the ROI for different cases. This method was evaluated using the segmented ROI in a proposed approach for the detection of the abnormalities of breast thermograms. This approach made use of statistical and texture features from the segmented ROI and the SVM with its kernel function was used to detect the normal and abnormal breasts. Based the experimental results, it was found that the SVM-RBF gave the best results (100%). Also, using the measurements of the recall and the precision, the classification results reached to 100%. These excellent classification results, based on our new segmentation method, concludes that our segmentation method could be used for the automatic segmentation of the thermal breast cancer images. In the future, we plan to increase the dataset used in order to test the reliability of the proposed segmentation method and the classification approach.

***Abstract*—This paper presents a new data-driven classification pipeline for discriminating two groups of individuals based on the medical images of their brain. The algorithm combines deformation-based morphometry and penalised linear discriminant analysis with resampling. The method is based on sparse representation of the original brain images using deformation logarithms reflecting the differences in the brain in comparison to the normal template anatomy. The sparse data enables efficient data reduction and classification via the penalised linear discriminant analysis with resampling. The classification accuracy obtained in an experiment with magnetic resonance brain images of first episode schizophrenia patients and healthy controls is comparable to the related state-of-the-art studies.**

## I. Introduction

The last two decades have witnessed an explosive growth in the ability to “understand the human brain” – a key to progress in neuroscience, to promote and protect brain health, and to develop treatments for restoring, regenerating, and repairing diseased brain functions. The motivations for that are clear: as populations inevitably grow older, mental disorders will increase dramatically – implying economic and social implications. The identification, characterization and validation of biomarkers for the major mental disorders would facilitate accurate prediction of disease risk, course, and therapeutic responses and ultimately lead to knowledge-based treatment and preventive strategies.

Computational neuroanatomy is a growing field of powerful applications of imaging modalities and computational techniques in neuroscience. It promises an automated methodology to characterize neuroanatomical configuration of structural magnetic resonance imaging (MRI) brain scans. One of the crucial techniques in this methodology is image registration. Its task is to find a spatial transformation which maps each point of an image onto its corresponding point of another image. Atlas-based registration is a special technique of computational neuroanatomy – not seen widely in other fields of biomedical imaging. It performs the task of spatial normalization of images according to a common reference anatomy termed as a brain atlas. Together with techniques adopted from inferential statistics and hypothesis testing, it allows to uncover brain regions with significant morphological differences between normal and clinical populations. Such techniques have been already used also in modern psychiatry research to seek for biomarkers and neurobiology of various mental diseases [1]–[4].

The real challenge for psychiatry is, however, to move from group analysis between patients and healthy volunteers to computer aided diagnostics on the level of an individual patient. Although pioneering works employing machine learning techniques have recently borne fruit in case of neurological diseases, this is extremely difficult in mental diseases. For instance, in schizophrenia – a disease with a complex neurobiology – the brain-imaging measurements in patients show considerable overlap with the normal range [5].

Algorithms, which have been proposed in the diagnostics of neurodegenerative disorders, relied on brain image data classification between patients and healthy controls. The most commonly used classification methods have been the linear discriminant analysis (LDA) [6]–[10], support vector machines (SVM) [11]–[13] or the k-nearest neighbour algorithm [14]–[16]. Due to the large amount of features obtained from 3-D medical images, the classification is often preceded by data reduction performed by principal component analysis [17], independent component analysis [18], selection of regions of interests (ROI) [6]–[8], and other data reduction methods. So far, only few studies have presented complex pipelines for data reduction and classification, such as the COMPARE method [19], which combines deformation-based morphometry with machine learning methods (watershed segmentation algorithm and support vector machine-recursive feature elimination

This work was supported by the grant IGA MH CZ NR No. NT 13359-4/2012.

technique). In [19] the COMPARE algorithm, classification of schizophrenia patients with very high classification accuracy (91.8% for female subjects and 90.8% for male subjects) was applied. Thus, the complex pipeline seems to enable classification with a higher efficiency than other commonly used methods that have reported classification accuracy between 70% and 90% [5]–[18].

The aim of this paper is to present a new data-driven complex classification pipeline consisting of deformation-based morphometry (DBM) and penalised linear discriminant analysis (pLDA) with resampling. The DBM-pLDA algorithm enables efficient data reduction and subsequent classification as it is based on sparse representation of the original image data. The algorithm starts with an application of the DBM on original MRI data to create 3-D deformations, which are then log-transformed and used in the pLDA with resampling to identify the brain regions with different local volumes in patients and controls. The last step comprises of classifying the brain images into groups of patients and healthy controls based on the features representing automatically detected brain regions.

The pLDA has been successfully employed in our previous imaging-genetics study [20] in which image phenotypes, using pre-selected pLDA, were used for searching the genotypes most associated with Alzheimer's disease. To our knowledge, this is the first study that uses pLDA for selecting brain imaging features for the purposes of distinguishing diseased individuals from healthy controls in schizophrenia research.

The rest of the paper is organized as follows. In Section II, we describe all the necessary steps in the classification pipeline. Section III shows the application of the proposed DBM-pLDA algorithm on T1-weighted MRI data of first-episode schizophrenia patients and healthy controls. Section IV discusses the results and concludes the paper.

## II. Methods

The proposed data-driven algorithm for image classification is based on combining the deformation-based morphometry and penalised linear discriminant analysis with resampling. In the DBM, high-resolution nonlinear registration [21] of 3-D brain images with a digital brain atlas is performed. The resulting 3-D deformations represented by the displacement fields or their Jacobian determinants clearly show how the brain anatomy of a subject differs from the normal template anatomy in terms of local volume contractions and expansions. After logarithmic transformation, the 3-D deformations tend to be sparse, i.e. numerous voxels have zero or close to zero values. The sparse representation of the image data together with pLDA with resampling leads to effective selection of the most discriminating regions, as explained below. The selected brain voxels are then used as features in image classification. The DBM and pLDA are described in more details in the following two subchapters.

### *A. Deformation-Based Morphometry*

Here, a brief summary is given on our algorithm for high-resolution deformation-based morphometry with the underlying registration method, based on a spatial deformation model that allows for large deformations while preserving the topology of the images. Details can be found in [21].

The registration method operates directly on image intensity values with no data reduction by segmentation or classification. The 3-D displacement field which maximizes global mutual information between a reference image and a floating image is searched in an iterative process that involves computation of the local forces as a gradient of point similarity measures and their regularization using the spatial deformation model. The regularization involves two Gaussian spatial filters forming the combined elastic-incremental model [22]. The first spatial filter regularizes displacement improvements that are proportional to the applied forces. These displacements are integrated into the final deformation, which is done iteratively by summation. The second part of the model represents the property of elastic materials in which displacements wane upon retracting the forces. This is ensured by a second Gaussian smoother. The resulting deformations preserve the topology of the images, i.e. only one-to-one mappings, termed diffeomorphic, are obtained. This requirement is satisfied by controlling the standard deviations of the Gaussian filters that affect the behaviour of the spatial deformation model. Standard deviations are incremented each time the minimum Jacobian determinant drops below a predefined threshold. The deformation should capture subtle anatomical variations among the studied images; therefore, the standard deviations of the Gaussians are decremented as well whenever the minimum Jacobian determinant starts rising during the registration process.

### *B. Penalised Linear Discriminant Analysis with Resampling*

Prior to the penalised linear discriminant analysis with resampling, the logarithms of the Jacobian determinants computed from 3-D deformation fields are transformed into 1-D vectors and arranged in $(n \times p)$ matrix $\mathbf{X}$, where $n$ is the number of individuals in a data set and $p$ is the number of voxels in each deformation. All columns of the matrix $\mathbf{X}$ are mean-centred and have unit variance. It is assumed that all $n$ individuals have been labelled as one of the two classes, which are denoted by $D$ (diseased individuals) and $H$ (healthy controls). The number of individuals in each class is $n_D$ and $n_H$, respectively, and $n = n_D + n_H$.

The common LDA aims at finding a direction vector $\mathbf{v}$ that best discriminates two classes within a data sample via maximizing the between-class variance and simultaneous minimizing of the within-class variance. The between-class scatter matrix, denoted as $\mathbf{S}_B$, is calculated as:

$$\mathbf{S}_B = (\mathbf{m}_H - \mathbf{m}_D)^T(\mathbf{m}_H - \mathbf{m}_D), \tag{1}$$

where $\mathbf{m}_H = \frac{1}{n_H}\sum_{i=1}^{n_H}\mathbf{x}_{i.}$ is the mean vector of class *H*, $\mathbf{m}_D = \frac{1}{n_D}\sum_{i=1}^{n_D}\mathbf{x}_{i.}$ is the mean vector of class *D* and $\mathbf{x}_{i.}$, $i = 1, ..., n$, are rows of the matrix $\mathbf{X}$.

The within-class scatter matrix, denoted as $\mathbf{S}_W$, is defined as:

$$\begin{aligned}\mathbf{S}_W &= \sum_{i=1}^{n_H}(\mathbf{x}_{i.} - \mathbf{m}_H)^T(\mathbf{x}_{i.} - \mathbf{m}_H) \\ &+ \sum_{i=1}^{n_D}(\mathbf{x}_{i.} - \mathbf{m}_D)^T(\mathbf{x}_{i.} - \mathbf{m}_D).\end{aligned} \tag{2}$$

The direction vector **v** is then a solution of the following optimization problem:

$$\max_{\mathbf{v}}\{\mathbf{v}^T\mathbf{S}_B\mathbf{v}\} \text{ subject to } \mathbf{v}^T\mathbf{S}_W\mathbf{v} = 1. \tag{3}$$

In the penalised LDA [23], a penalty is imposed on the $l_1$ norm of the direction vector **v** which leads to setting of coefficients $\mathbf{v}_j$, $j = 1, ..., p$, of the least discriminative features to zero. If the input data into the pLDA are already sparse, the amount of selected features (i.e. features with non-zero coefficients) is smaller and the classification results tend to be more stable than while using original brain images in the data analysis. In pLDA, the optimisation problem changes to:

$$\max_{\mathbf{v}}\left\{\mathbf{v}^T\mathbf{S}_B\mathbf{v} - \lambda\sum_{j=1}^{p}s_j|v_j|\right\} \text{ subject to } \mathbf{v}^T\mathbf{S}_W^*\mathbf{v} = 1, \tag{4}$$

where $\mathbf{S}_W^*$ is the diagonal estimate of $\mathbf{S}_W$, $\operatorname{diag}(\mathbf{S}_W) = (s_1^2, ..., s_p^2)$ and $\lambda$ is the regularization parameter that controls the number of selected features. Specifically, when $\lambda$ is exactly zero, no penalty is imposed and all *p* features contribute in the direction vector **v**. As $\lambda$ increases from zero, less features contribute in **v**. At its maximum value $\lambda_{\max}$, all coefficients of **v** are set to zero. A common approach for tuning $\lambda$ involves cross-validating the prediction error for a grid of values of $\lambda$ and selecting the value of $\lambda$ that leads to the smallest cross-validated error. However, this approach may be prone to sampling errors. Therefore, we opted for a resampling method proposed in [24] for sparse predictive modelling. This procedure aims to calculate selection probabilities for each feature by repeatedly fitting the pLDA model on random subsets of the data set, while keeping track of the features associated to non-zero coefficients of **v**. The final set of the most discriminative features consists of voxels with selection probability higher than 0.5.

It should be noted that by using the data resampling, a set of features over the range $[\lambda_{\min}, \lambda_{\max}]$ with stable classification results is selected instead of tuning the regularization parameter $\lambda$ [24]. The final set of selected features is then used for classification of individuals into the class *D* or *H* using LDA.

## III. Experiment and Results

### *A. Imaging Data Used in the Experiment*

The proposed classification pipeline was tested in an experiment with magnetic resonance brain imaging data of 52 male patients with first-episode schizophrenia and 52 sex- and age-matched healthy control subjects. The median age of the patients and controls was 22.9 years (range 17-40 years) and 23.0 (range 18-38 years), respectively. Thirty-nine patients and the same number of controls took part in our previous study [25]. All subjects signed an informed consent before entering the study.

All 52 patients were recruited from males hospitalised in the all-males unit of the Department of Psychiatry, Masaryk University in Brno for first-episode schizophrenia. The diagnosis was established during a clinical interview guided by the International Statistical Classification of Disease and Related Health Problems (ICD-10) research criteria and was focused on information about the family and personal history, the somatic conditions, substance abuse, pharmacological history and the current treatment, previous psychiatric conditions and, finally, on the current clinical manifestation, the presenting symptoms, the duration, and the functional impact. Next, the patients were physically examined, including blood (haematology and biochemistry) and urine analysis (biochemistry and toxicology). If abnormal findings were present, their origin was traced by additional examination. A fully trained senior psychiatrist (board certified in psychiatry) reviewed all information, established the diagnosis and suggested the case for inclusion in the study. MRI examination was performed during the first episode, that is, all patients were treated with antipsychotics for 3-14 weeks only at the time of MRI.

The 52 healthy control subjects without substance dependence, family or personal history of axis I psychiatric conditions, neurological or somatic conditions affecting the structure or function of the brain, and contraindications for MRI examination, were recruited from the community, the local staff and medical students.

All subjects were scanned with 1.5T Siemens Symphony machine. Whole head T1-weighted images were obtained using 3-D acquisition with IR/GR sequence, TR 1700 ms, TE 3.93 ms, TI 1100 ms, flip angle 15°, 160 slices, voxel size 1.17 × 0.48 × 0.48 mm, FOV 246 × 246 mm, and matrix size 512 × 512 voxels.

The 3-D T1-weighted images were checked for abnormalities and then pre-processed using SPM8 (http://www.fil.ion.ucl.ac.uk/spm/). Specifically, the images

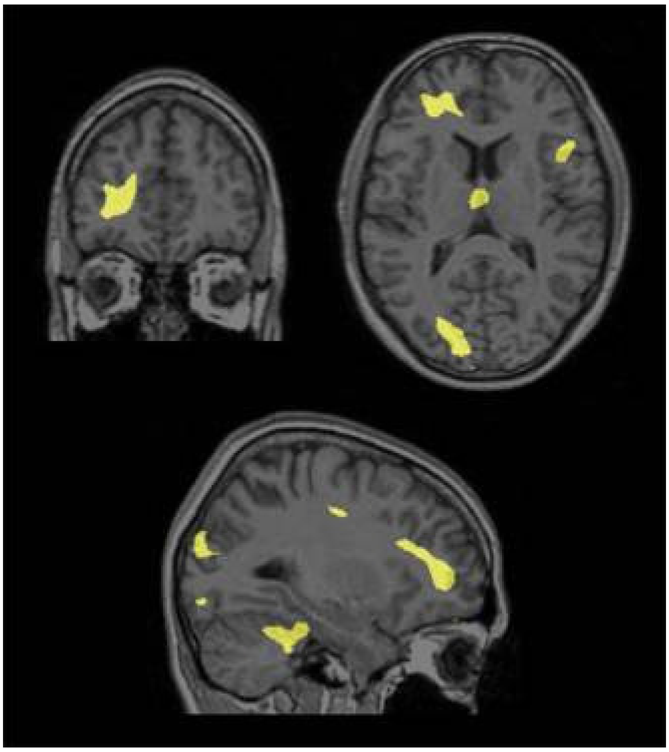

Fig. 1 Coronal, transversal and sagittal slices showing the automatically detected highly discriminative voxels (in yellow).

were corrected for bias-filed inhomogeneity and spatially normalised, i.e. transformed into stereotactic space.

### B. Classification efficiency

The DBM-pLDA algorithm was applied on the pre-processed images. The classification efficiency of the DBM-pLDA algorithm was evaluated with the leave-one-out cross-validation technique to avoid biased results. Consecutively, each of the $n$ subjects was selected as a testing subject and the remaining $n$-1 subjects were used for training the classifier. The testing subject was classified into the patient or healthy control class. Then, the resulting class was compared to the true classification label. The classification performances for all subjects were combined in order to create the overall classification performance measures, namely accuracy, sensitivity, specificity and precision, defined as:

$$sensitivity = \frac{TP}{TP+FN}, \tag{1}$$

$$specificity = \frac{TN}{TN+FP}, \tag{2}$$

$$accuracy = \frac{TP+TN}{TP+TN+FP+FN}, \tag{3}$$

$$precision = \frac{TP}{TP+FP}, \tag{4}$$

TABLE I
NUMBER OF SELECTED VOXELS AND CROSS-VALIDATED CLASSIFICATION PERFORMANCE MEASURES IN PERCENTAGE FOR VARIOUS $\lambda_{\min}$ VALUES.

| | $\lambda_{\min} = 0.3$ | $\lambda_{\min} = 0.4$ | $\lambda_{\min} = 0.5$ | $\lambda_{\min} = 0.6$ |
|---|---|---|---|---|
| # voxels | 315,123 | 107,967 | 30,461 | 5,113 |
| Accuracy | 82.7 | 84.6 | 85.6 | 83.7 |
| Sensitivity | 84.6 | 86.5 | 84.6 | 78.8 |
| Specificity | 80.8 | 82.7 | 86.5 | 88.5 |
| Precision | 81.5 | 83.3 | 86.3 | 87.2 |

where $TP$, $TN$ represent numbers of true positive and true negative results respectively, and $FP$, $FN$ represent numbers of false positive and false negative results respectively.

### C. Experiment Results

The performance measures obtained in the classification of 104 schizophrenia patients and healthy controls are summarized in Table I. Our results demonstrate that the classification accuracy is stable for meaningful ranges of $\lambda$, i.e. ranges leading to an adequate number of selected voxels. In this experiment, $\lambda_{\max}$ was fixed to 0.9 and so, the table shows the results for the ranges $[\lambda_{\min}, 0.9]$. The best cross-validated classification accuracy was 85.6% (sensitivity 84.6%, specificity 86.5%) while selecting about 30,000 most discriminative voxels. The selected features composed of the most discriminating voxels are shown in Fig. 1. They form connected regions in the left prefrontal cortex, the right anterior insula, the medial parts of the thalamus, and the cerebellar cortex.

In order to compare the proposed DBM-pLDA algorithm to other classification methods, the leave-one-out cross-validation procedure was carried also with other classifiers, which have been used on neuroimaging data frequently: (i) LDA and (ii) SVM with linear kernel. Features for these classifiers were selected with the use of mass univariate analysis (Student's t-test, $p < 0.01$), so that only the significant local volume changes in patients when compared to healthy controls were input to the classifiers. The resulting classification performance measures are summarized in Table II. The results show an improved classification efficiency of the proposed DBM-pLDA algorithm, when compared to both DBM-LDA and DBM-SVM algorithms.

## IV. DISCUSSION AND CONCLUSIONS

A classification pipeline for discriminating two groups of individuals based on brain images has been presented. The fully automated data-driven algorithm consists of deformation-based morphometry and penalised linear discriminant analysis with resampling. Firstly, sparse representation of the original brain images using logarithms of deformations, that are the results of high-dimensional nonlinear registration of the brain images with a digital brain atlas, is acquired. Secondly, the sparse data is reduced using

TABLE II
CLASSIFICATION EFFICIENCY OF THE PROPOSED DBM-PLDA ALGORITHM COMPARED TO DBM-LDA AND DBM-SVM ALGORITHMS.

| | Accuracy | Sensitivity | Specificity | Precision |
|---|---|---|---|---|
| DBM-pLDA | 85.6 | 84.6 | 86.5 | 86.3 |
| DBM-LDA | 66.3 | 59.6 | 73.1 | 68.9 |
| DBM-SVM | 70.2 | 69.2 | 75.0 | 73.5 |

pLDA with resampling and then classified into the group of patients or healthy controls.

To our knowledge, this is for the first time when pLDA is used for selecting highly discriminative brain imaging features in schizophrenia. In our previous study, pLDA was successfully applied for selecting image phenotypes that were used in searching for genotypes most associated with Alzheimer's disease [20]. Here, pLDA is used in combination with DBM in the pipeline for the classification of MRI data of patients with first episode schizophrenia (FES) and healthy controls. Only FES patients were used in this study as it is known that longer duration of the illness leads to higher magnitude of morphological changes in the brain of schizophrenia patients [26]. Thus, the classification results can be overestimated if the data set contains chronic schizophrenia patients as well. To avoid biased results, only males were used in the analysis, as it was shown that there are differences in structural brain abnormalities in males and females [27].

The proposed algorithm uses the whole volume of the brain and is fully automated. Thus, it overcomes limitations of traditional ROI-based classification analyses. The ROI-based methods need prior knowledge about the regions that might be affected by the disease. As schizophrenia is a large-scale disorder of neurocognitive networks rather than confined to specific regions [1]–[4], whole brain analysis is more appropriate. Moreover, the fully automated method is less time consuming and error-prone than manual tracing of the ROIs.

High classification accuracy (85.6%) has been achieved while applying the proposed DBM-pLDA algorithm on T1-weighted MRI data of first-episode schizophrenia patients and healthy controls. The efficiency of the algorithm is comparable or superior to the other state-of-the-art studies dealing with the classification of schizophrenia patients [5]-[18]. However, the classification performance is smaller than in [19], in which the COMPARE algorithm enabled classification of schizophrenia and healthy females with accuracy equal to 91.8% and the classification of diseased and healthy males with accuracy of 90.8%. Nevertheless, Fan et al. [19] used a mixed data set of patients with first-episode schizophrenia and chronic schizophrenia. The fact that the morphological changes in chronic schizophrenia patients progress during the course of the disease, while the first episode schizophrenia is characterized only by subtle morphological abnormalities, could overestimate the results reported in [19].

A by-product of the classification pipeline is a selection of the most discriminating brain morphological features between patients and controls. The automatically detected discriminating brain regions were located in the left prefrontal cortex, the right anterior insula, the medial parts of the thalamus, and the cerebellar cortex. These results are consistent with those published in previous studies [1]–[4]. Moreover, it is known that these brain areas are involved in higher cognitive, integrative and regulatory functions that are impaired in schizophrenia [1]–[4].

Even though the results are promising, further experiments are necessary to investigate whether the DBM-pLDA algorithm can assist in the early diagnosis of schizophrenia. A limitation of this study might be the slightly limited sample size, as Nieuwenhuis et al. [12] recommend to use more than 130 subjects. However, our data set containing 104 subjects is larger than the data sets used in most of the schizophrenia studies [5]–[8], [11], [14]–[15], [17]–[19]. The next step in our research will be a replication using a completely independent set of schizophrenia subjects. We would also like to test the performance of the algorithm on other patient groups.

In conclusion, the associations between the automatically detected discriminating morphology features and their significance in the neurobiology of schizophrenia, as well as the high accuracy of classification of patients and healthy controls, demonstrate the face validity of our approach that combines DBM and pLDA with resampling.

*Abstract* — **Medical imaging techniques offer novel visualization and analysis methods of the vocal folds during phonation and automatic computation of indices aiding the phoniatrist in a more precise diagnosis of voice disorders. The aim of this study is to apply *computer vision algorithms for qualitative and quantitative analysis of vocal folds' vibrations. Videostroboscopic examinations of the larynx were carried out for 30 patients. Image pre-processing and image segmentation algorithms were applied to compute the glottis area during phonation.* The glottovibrograms which are spatio-temporal visualizations of the vibrating vocal folds were also built. The proposed indices allow for a quantitative and comparative analysis of normal and disordered phonatory processes. The conducted pilot study has confirmed the validity of the computer aided imaging methods for the qualitative and quantitative analysis of the videostroboscopic images of the phonatory motions of the vocal folds.**

## I. Introduction

Early diagnosis of occupational voice disorders is becoming one of the priorities in public health in Poland and in other countries of the European Union. Currently, European standards emphasize the need for a comprehensive assessment of voice disorders, including the assessment of the larynx function during the phonatory tests [1]. The test that allows the specialist to accurately assess the condition of the voice organ and is recognized as the gold standard is the laryngovideostroboscopy (LVS) [2]. The aim of our study is to apply computer image processing and analysis methods for quantification of vocal folds' phonatory activity by examining sequences of LVS images. In this communication we focus on examining videostroboscopic images of normophonic individuals with healthy vocal folds and patients with diagnosed nodules.

## II. Related Works

The standardization of automatic segmentation of vocal folds videostroboscopic images remains an unsolved problem since 1995 [3]. There have been several automatic segmentation methods of the vocal folds images proposed [4]-[6]. Many of the developed methods and algorithms are designed for specific image recording conditions and work properly only for local databases containing videos collected in a particular institute, hospital or health center. It has turned out to be a very difficult problem to work out an algorithm which would give satisfactory results for every given video presenting the vibrating vocal folds. Authors in [7] proposed a method based on supervised thresholding methods by applying the Fourier descriptors. This method is additionally combined with a glottal neighborhood descriptor which specifies distance–weighted color differences between the glottis and the surroundings tissues of the vocal folds. The additional knowledge of local color distributions increases the recognition quality.

The key task preceding the image analysis methods of the glottis is segmenting out the space between the vocal folds, termed the glottal area. The most popular and straightforward image segmentation method is thresholding. The threshold value is selected on the basis of the image histogram. Local minima of the multimodal histogram designate threshold values. In the simplest case the first histogram minimum assigns a threshold value that distinguishes the image regions belonging to the space between the vocal folds from the regions representing the background (glottis environment). More sophisticated threshold methods utilize the neighborhood information, adaptively adjusting the threshold value [8] or including wavelet transformation [9]. There are several methods which work properly for certain image classes i.e. region based, model based and their combinations. More complex methods are based on the so called active contour models. Active contours are energy minimizing flexible splines guided by hypothetical external forces influenced by the image content and internal forces arising from the curvature and continuity of the nodes forming the contour. Note, however, that the contour must be properly initialized near the object of interest [Marendic et al. 2001].

## III. Materials and methods

The general block diagram of the developed image processing and analysis algorithms for analysis of laryngostroboscopic images is shown in Fig. 1.

Computation of the Glottal Area Waveform (GAW) and the glottovibrogram
Fourier transformation of the glottovibrogram

Fig 1. Schematic of the algorithm for qualitative and quantitative analysis of the vocal folds' phonation from videostroboscopy

The algorithm was developed after numerous consultations with phoniatrists working in the Department of Audiology and Phoniatrics, The Nofer Institute of Occupational Medicine in Lodz, Poland. The algorithm allows the user to select the analyzed film and indicate the phonation region of the glottis. Then the algorithm proceeds with automatic computations of the following quantities and representations:

- fundamental frequency of the vocal folds' vibration and the vibration frequency at each level of the total glottis length,
- geometric and kinetic parameters of the glottal area (the space between the vocal folds) during phonation,
- relations between the opening and closing time of the glottis,
- the glottal area waveform (GAW), illustrating time variations of the glottal area,
- the glottovibrogram which is a time-space representation of the glottal gap (local distances between the vocal folds at different levels of the glottis) imaged as a grayscale image (see Figs. 4, 5),
- the Fourier transform of the glottovibrogram.

Videostroboscopic examinations of the larynx were carried out for 30 patients, i.e. for 15 individuals with no voice disorders (see an example in Fig. 2) and 15 patients with diagnosed nodules (see Fig. 3). At the outset of the analysis the phoniatrist is asked to select the reference sequence of images for analysis i.e. the starting and ending frame from the videostroboscopic film. This is the only user-dependent step in the proposed image analysis procedure. After defining the reference sequence the program determines the region of interest and adjusts processing parameters to the selected regions of the analyzed video and reduces the distortions due to movements of the camera versus the glottis.

The aim of the second step is to apply general image processing methods for image enhancement. Color images in the LVS sequence are converted from an RGB to a monochrome image format, by applying the following weighted average of the color components:

$$I = 0.299\,R + 0.587\,G + 0.114\,B \qquad (1)$$

in which $I$ is the level of intensity in the monochrome image and $R$, $G$, $B$ are the values of the red, green and blue components of the color image correspondingly. Digital image filtering is then applied to reduce noise and artifacts due to unwanted reflections and compression distortions. This step allows the residual adaptation of parameters for the varying shape and location of the region of interest (ROI) which undergoes the following distortions: non-uniform and time-varying illumination, loss of sharpness due to the vapor covering the camera lens, varying distance relative to the vocal folds and loss of camera focus. Preprocessing of the region of interest additionally improves results of the thresholding step.

Then, an automatic analysis of the LVS images starts with the detection of the ROI, i.e. a rectangular region containing the examined part of the glottis. Similarly to the approach adopted in [10] this was improved with morphological operations (erosion and closure) and basic filtering methods comprising median and lowpass filtering. Finally, the watershed image segmentation algorithm is employed to roughly determine the glottal area ROI. The watershed transformation enables extraction of areas in which there is continuity in terms of image features such as brightness or color. This transformation method is considered as one of the most effective methods of image segmentation [11]. It yields well designated areas of the image with clearly defined outlines. The behavior of this method lies in the distribution of the image gradient which separates areas of the image assigned to the seeds along the thresholded value of the gradient.

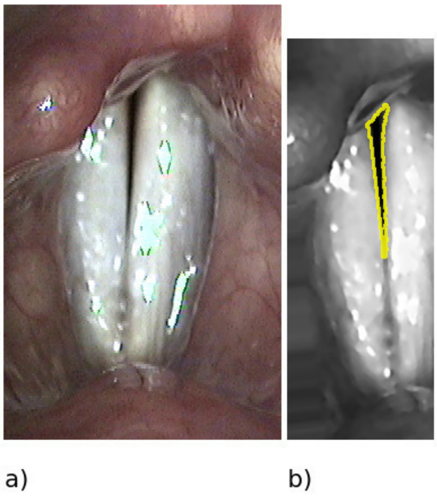

Fig 2. Stroboscopic images of the normophonic vocal folds (i.e. no diagnosed abnormalities): input image a), segmentation result b)

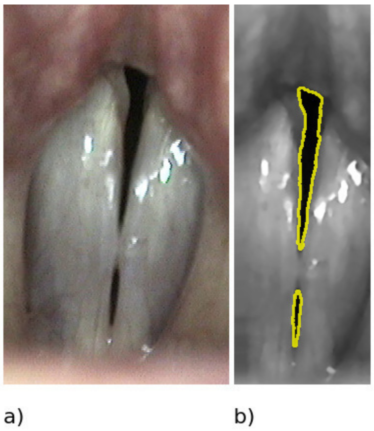

Fig 3. Stroboscopic images of the vocal folds with nodules: input image a), segmentation result b)

While being a robust segmentation method, the watershed algorithm features poor precision in determination of the glottis boundary. Thus, this segmentation method is adopted for the first frame of the image sequence only and serves as a reference location of the ROI (see block diagram in Fig. 1) After defining the coarse position of the ROI obtained by the watersheds, the precise contour, i.e. the boundaries of the vocal folds, is being extracted with the use of the *K*-means algorithm. The *K*-means algorithm is an iterative data clustering method in which the image content is partitioned into *K*-separate regions, in which each pixel of the image is assigned to the region with the nearest distance to the centroid of the region, i.e. according to the criterion:

$$minimum(S)=\sum_{i=1}^{K}\sum_{x\in S_i}||x-u_i||^2 \qquad (2)$$

where: $K$ – is the number of segmentation regions, $x$ – is grey level value of a pixel, $S_i$ – is the $i$-th segmentation region, and $u_i$ – is the centroid of pixels within $S_i$ [12]. The main advantage of the *K*-means algorithm is its computational simplicity yielding such a partitioning result that the shapes of the clusters are maximally compact.

In our application, at the first step we define two (*K = 2*) clusters of which the one with a lower mean value (darker) is assigned to the glottal area and the other to the remaining regions of the larynx image.

In videos taken from patients with vocal folds nodules there may occur a circumstance in which the glottal area is separated into two regions (see an image of vocal fold with nodules in Fig. 3b).

Further, the method is improved by applying an adaptive thresholding method for subregions of the ROI that contain the glottal area. Firstly an ellipse is fitted to the so far detected area that is based on a method which automatically sets a reference line along the hitherto designated area. Ellipse fitting is achieved by applying a built in OpenCV library function named “fitEllipse” [13]. After defining the center point of the fitted ellipse and its angle, a reference semi-major axis line is determined.

During the videostroboscopic examination of the larynx there is a continuous movement of the camera versus the glottis. An efficient way to eliminate unwanted motion from the video is to move each ROI of the image by a vector calculated for each video frame. ROI displacement vector can be determined by computing the matrix of correlation coefficients between adjacent image frames in the videostroboscopic film. In all subsequent image frames the detected glottal area is shifted to this reference location by the estimated displacement vector. The criterion of the maximum of the two-dimensional correlation function is applied for the best positioning of the consecutive image frames versus the first reference frame. By these means, in the preprocessed image sequence, the glottal area is positioned in a fixed location which significantly facilitates further image analysis procedures. The cross-correlation of adjacent images was determined by using a built-in OpenCV library function which calculates the matrix of correlation coefficients [14]:

$$r_{x,y}=\frac{\sum_{x,y}[P(x',y')-\overline{P}]\cdot[N(x+x',y+y')-\overline{N}]}{\sqrt{\sum_{x,y}[P(x',y')-\overline{P}]^2\cdot\sum_{x,y}[N(x+x',y+y')-\overline{N}]^2}}$$

(3)

where:

- $r_{x,y}$ - correlation matrix,
- $P(x,y)$ - ROI from the current video frame,
- $\overline{P}$ - mean value of pixel intensities in an image,
- $N(x,y)$ - next video frame image,
- $\overline{N}$ - mean value of pixel intensities in an image.

The correlation matrix indicates the level of the linear relationship between $P$ corresponding pixels in images and $N$.

After applying the multi-stage segmentation methods (the watershed algorithm followed by the *K*-means and adaptive thresholding) and removing image distortions due to movement of vocal folds the GAW and the glottovibrogram can be built (see Figs. 4, 5 and a more detailed explanation in Fig. 8).

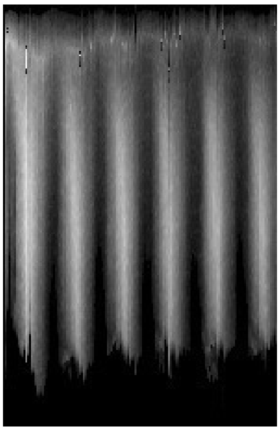

Fig 5. Glottovibrogram of the vibrating vocal folds of a healthy individual

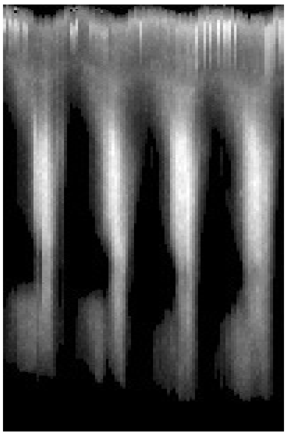

Fig 4. Glottovibrogram of the vibrating vocal folds of the patient with diagnosed vocal nodules

Such a representation termed, the glottovibrogram is a space-time image of the video sequence presenting vocal folds movements. The horizontal axis in the glottovibrogram is time (*t*) and the vertical axis represents the level (*l*) along the glottis (from the anterior commissure – bottom of the image to the posterior commissure – top of the image); each pixel value *g*(*t, l*), i.e. its brightness in the glottovibrogram, represents the value of width *g* of the space between the vocal folds (glottal gap) computed at level *l* of the glottis for time instance *t*. The GAW illustrates time changes of the instantaneous values of the glottal area.

A single phonatory cycle shown in the glottovibrogram or the associated GAW corresponds on average from 20 to 30 images taken by the stroboscopic camera. It is essential to gather at least 20 images for one cycle to determine the kinetic parameters of the vocal folds (opening, closing time and their ratios). Approximately 4 cycles are analyzed for each video sequence, so the glottovibrogram has an average length of 100 pixels. The stroboscopic films are recorded with a sampling rate of 25 frames per second, so the average length of the recording is about 4 seconds. The fundamental frequency of the vocal fold oscillation is provided by the videostroboscopic apparatus. This information enables to correctly scale the frequency axis of the Fourier transform of the glottovibrogram and visualize oscillation frequencies of the vibrating vocal folds (Fig. 6-7).

Thanks to the strobing frequency the information obtained from the videostroboscopic camera we can quantitatively estimate the frequencies taking part in the phonation. It is noteworthy that we analyze “virtual frequencies” which are aliases of the true frequencies of vocal folds' vibration, typically in the range of 150Hz (for men) and 250Hz (for women), reaching peak values of 450 Hz for singers.

The Fourier transformation of the glottovibrogram was calculated by applying the following equation:

$$G(s,l)=\frac{1}{N}\sum_{l=0}^{N-1} g(t,l)e^{-j\frac{2\pi l}{N}s} \qquad (4)$$

$$|G(s,l)|=\sqrt{\Re^2(G(s,l))+\Im^2(G(s,l))} \qquad (5)$$

where:

- $g(t,l)$ is the $l-th$ row of the glottovibrogram (y-axis, i.e. glottis level), $t$ determines the column (x-axis, i.e. discrete time),

- $G(s,l)$ is the Fourier transformed glottovibrogram, determining the frequencies,

- $N$ is the length of the glottovibrogram,

- $j$ is the imaginary unit.

After calculating the magnitudes of the transformation Eq. (5) the phoniatrist is able to gain access to the distribution of frequencies taking part of the vocal folds phonation. In case of the vocal nodules the pathology manifests itself in the form of a second harmonic frequency, significantly blurring the first amplitude peak.

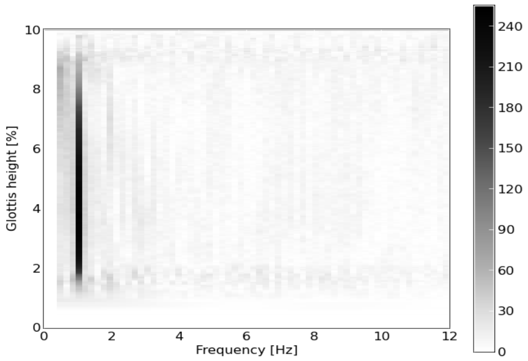

Fig 6. Fourier amplitude spectrum of the glottovibrogram of a healthy patient

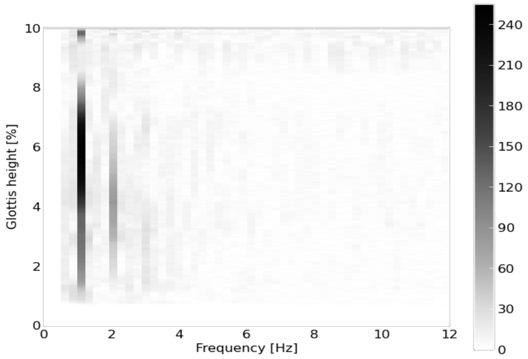

Fig 7. Fourier amplitude spectrum of the glottovibrogram of a patient with vocal nodules

## IV. Phonatory indices

Even after the correct segmentation and transformation process there is still an ambiguity in the relevance of different visualizations representing the phonation process. In this paper we propose a number of indices for quantifying the phonatory processes of the healthy vocal folds and folds with diagnosed nodules.

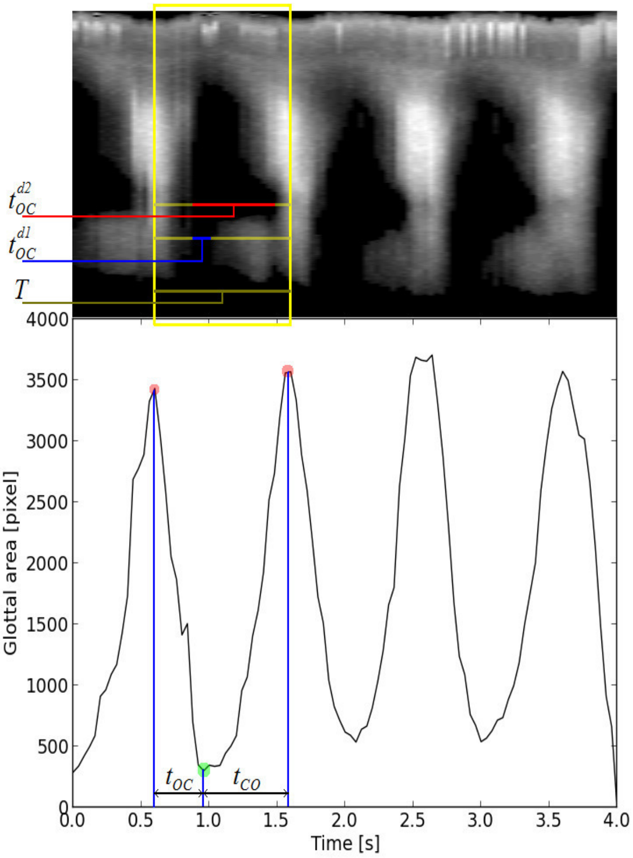

Fig 8. The glottovibrogram (upper panel) and the glottal area waveform (lower panel) with the indicated time intervals used in calculations of the phonatory indices (eq. (6, 7))

Table I.

Comparison of phonatory indices computed for the two studied groups of patients

| | d1 | d2 | d3 | CI | SI |
|---|---|---|---|---|---|
| Control group | 0.00 ± 0.00 | 0.88 ± 0.99 | 2.25 ± 2.65 | 0.10 ± 0.09 | -0.08 ± 0.30 |
| Vocal nodules | 2.10 ± 2.10 | 1.85 ± 1.96 | 4.42 ± 2.72 | -0.48 ± 0.26 | -0.14 ± 0.13 |
| Significance P (ANOVA) | 0.000 | 0.000 | 0.026 | 0.000 | 0.390 |

The *CI* (the closing index) is defined as follows (see also Fig. 8):

$$CI=\frac{t_{OC}^{d2}-t_{OC}^{d1}}{T} \tag{6}$$

where:

$T$ – total cycle time,

$t_{OC}^{d2}$ – is the closed time for the glottis gap measured at the level equal to 50% of the total length in case of normophonic patients, in case of patients with vocal nodules the value is measured for the level of the maximal closure (apparently the place where the vocal nodules occur),

$t_{OC}^{d1}$ – is the closed time of the glottis gap measured at 25% level of the glottis length for normophonic patients, and at the level placed between the maximal closure point and the posterior part of the glottis.

The speed index *SI* is defined by the following equation:

$$SI=\frac{t_{CO}-t_{OC}}{t_O} \tag{7}$$

where:

$t_O$ – opened interval,

$t_{CO}$ – vocal fold closed phase,

$t_{OC}$ – vocal fold closing phase.

In Table I the computed values of the indices proposed in this study are listed, where *d1*, *d2*, *d3* are the levels along the glottis length at which the indices were computed. Location of these levels are at the particular percentages of the total glottis length, correspondingly: 25%, 50% and 75%. The *SI* value in most patients assumes negative values indicating that the opening time of the folds is shorter than the closing time. However, this index yielded poor statistical significance values ($p < 0.36$ from the ANOVA analysis of variance) to use it as a differentiation index for the pathology in question. On the other hand, the computed values of the *CI* index clearly differentiate the patients with diagnosed nodules from the healthy individuals ($p < 0.026$) The *SI* value in most patients reaches negative values which indicates that the opening time is slower than the closing time. Comparison of the calculated parameters reveal that there are pronounced between-group differences and comparable within-group values.

## V. Conclusion

The main purpose of this work is to support the phoniatrist in diagnosis of the vocal folds. The computer image processing methods applied to laryngovideostroboscopic images allow for quantitative analysis of the vocal folds vibrations during phonation. It was shown that the proposed *CI* parameter proved to be viable in differentiation and quantification of the studied glottis pathology.

The program, although, in an early development stage allows for automation of the analysis process of the laryngovideostroboscopic films. Larger scale trials are required before a wider introduction of these computed image analysis techniques into the clinical practice.

***Abstract*—Whole body vibration (WBV) techniques are increasingly applied in rehabilitation processes to improve patients' functional mobility. Therapeutic usage of WBV reported enhanced muscular strength, power or even bone density. Therefore, the purpose of our study was to investigate immediate response of single WBV training unit on mobility of elderly patients with neurological disorders. Nineteen patients (66.74 ± 3.65 years, 6 males and 13 females) were assessed before WBV (10 min, 30 Hz, vertical 2 mm) and then 1 min afterwards. Individual changes in gait kinematics indicated positive effects of WBV, while kinematics of the gait was more symmetric considering right and left side. Individually, depending on the disease's severity, these changes were more or less significant. The improvements in gait kinematics convinced us that WBV can be carefully used in patients' therapy and it may be used together with individually planed rehabilitation processes to bring more satisfying results.**

## I. Introduction

Ageing of the population brings growing demands on social and health care systems due to the increased risks of various chronic diseases in older individuals. Health related quality of human life and loss of independence can be also affected by natural weakening of human body and its functional systems. This leads to more frequent falls and consecutive health and mobility problems [1-3].

Here, the disorders like sensory loss, vestibular dysfunction, impaired vision, muscular weakness, bone rarefaction or gait disorders are multi-factorial disorders that contribute to vulnerability and frailty of elderly persons. Moreover, elderly falls are usually reasons for additional medical interventions. Motor impairment syndromes are also associated with neurological disorders [4]. This group of clinically heterogeneous diseases causes severe problems in coordination, gait, balance, voluntary muscle control, power and strength [5, 6].

Strategies to prevent negative consequences of functional mobility diseases have to be widely discussed, assessed and applied in health care of elderly patients. Such strategies include also rehabilitation techniques and physical exercises. Here, due to the published results the WBV can be considered as reliable and effective tool in rehabilitation and sport medicine [7, 8].

Continuing in our previous pilot study [9] we hypothesize that the WBV may stimulate muscle activation in elderly patient with neurological disorders and that application of WBV will result in improvement of quality of their gait. Therefore, the purpose of this study was to investigate whether the single WBV session has any positive effects on gait kinematics.

## II. Whole Body vibration

Whole body vibration (WBV) has been extensively studied for its dangerous effects on humans, especially when exposed as occupational vibration at high amplitudes and specific frequencies [10-12]. However, WBV is also the concept that was already applied in many studies to confirm benefits for astronauts, athletes, wellness of healthy population, but also patients with various diseases [13-15].

Recent clinical works suggest that low amplitude and low frequency of mechanical stimulation of the human body is a safe and effective way to exercise musculoskeletal structures. The studies realized during past decade indicate that WBV may increase muscle strength, neuromuscular function, bone mass and mineral density [16-19], can be useful in improving physical capacity, cardiorespiratory functions, hormonal production, proprioception, and balance [20-22].

Despite of WBV positive effects presented in almost all related research studies, the authors interpret their results with caution. Also, the underlying mechanisms by which WBV enhance neuromuscular performance vary between studies and are still unclear. Inconsistency in presented results is caused by various training protocols and heterogeneity in study designs. However, several mechanisms should be considered as crucial. Vibration stimulates skeletal muscle by activating a stretch reflex analogous to the tonic vibration reflex. Thus the activated muscle spindle activity causes involuntary reflexive muscle contraction in an attempt to control the vibration imposed muscle length change. WBV also evoke changes in postural control strategy where the vibration stimulus generates postural instability and the body activates particular muscles to maintain body balance. Another mechanism is generated

978-83-60810-66-8/$25.00©2015, IEEE

when oscillations induce a muscle tuning response in an attempt to minimize the propagation of the vibrations throughout the body. Then, the muscles might activate to prevent further transmission of the vibration stimulus through the body.

There are various vibrating platforms available as commercial products used by many wellness centers and rehabilitation clinics. The main differences are in the type of vibration stimulation, frequency range, and amplitude of vibration [23, 24]. Most of the vibrating platforms vibrate sinusoidally. The subjects stand on the platform which oscillates only vertically or side alternating. Other types of vibrating devices uses two separate platforms to produce vibrations for each foot independently. While commercial usage promotes WBV as attractive and effective alternative to resistance training, the therapeutic applications should carefully consider duration of WBV exposure, main vibration characteristics as well as their effects on neuromuscular system respecting patients' physical capabilities. The rest periods between vibration trainings may also play a significant role in final WBV effects. The effect of vibration may be also tested using various modeling techniques [25].

## III. Material and Methods

### A. Patients

A group of nineteen elderly patients (age 66.74 ± 3.65 years, 6 males and 13 females) with various neurological disorders were included in the study. The inclusion criteria were ambulatory patients that are able to walk independently, had no cardiovascular disease or epilepsy, and had no prior experience in WBV training. All the patients were informed about the WBV training, about the tests to be realized and also about possible risks and benefits of the research. Prior to participation they gave written informed consent approved together with the study design by the University Hospital Ethics Committee.

All participants attended a familiarization session before the study and before the tests were performed. No other physical treatment or intervention was realized at least 24 hour before WBV training session. The anthropometric measures were also taken and registered in patients' experimental protocols. As for the aim of the study, the anthropometric characteristics of lower extremities were preferred, including thigh length (right: 44.89 ± 2.26 cm, left: 44.42 ± 2.14 cm), calf length (right: 41.89 ± 3.80 cm, left: 41.58 ± 3.91 cm) and foot length (right: 25.74 ± 2.82 cm, left: 25.89 ± 2.55 cm).

### B. Experiment

The experimental protocol was designed to discover potential immediate response of a single WBV training unit to the quality of gait kinematics in elderly patients. Training sessions were supervised by rehabilitation specialist and measurements as well as WBV sessions were conducted in the same thermally neutral room intended for physical training. All subjects did not engage in any therapeutic or rehabilitation procedures before testing.

The training session started with physical examination and short warming-up walk. Then, the patient's gait was captured and analyzed before WBV exposure. Participants were asked to walk at their natural waking speed along the 6 m long path. After reaching the end point of the path, they were asked to turn back (180°), i.e. to change the direction of gait, and to walk back to the starting point. Then, they turned back again and walked to the end point of the path, where the last turn back was realized and the patients finished walking in starting point of the path. In that sense, the subjects passed the length of walking path four times. WBV session followed one minute after this control gait was captured and analyzed. Here, each participant stood in static position on the vibration platform (VibroGym inSPORTline) with no shoes and socks and holding on the device handle. Erected posture with slightly bended knees was required during vibration test. The patients were asked to stop the training in the case of any pain responses to vibration. Duration of one WBV training unit was set to 10 min. Sinusoidal vertical vibration frequency was set to 30 Hz with amplitude of 2 mm. 1 min rest interval followed after this WBV exposure. Then, the patients walked again and the kinematics of their gait was captured and analyzed in the same way as it was before WBV session. Finally, the kinematics obtained before and after WBV training unit was compared to evaluate its effects on patients' gait.

### C. Parameters

Gait assessment was performed using our marker-free motion analysis system MAFRAN [26]. The system is based on motion tracking method in video sequence with no passive or active markers attached to the patients' bodies tries to minimize disadvantages of currently available marker–free systems, to bring new of motion analysis and to offer clinicians cheaper, but not worse alternative preserving all advantages of motion analysis.

Here, the patient's gait is captured in sagittal plane using common commercial video camera. Then, the raw record is used in the system to automatically reconstruct motion trajectories of human body anatomical landmarks, i.e. the trajectories of all lower extremity joints and adjacent segments. These trajectories are consequently used to calculate other kinematical parameters for detailed description of patient's gait. Here analyzed parameters include positions, velocities and accelerations of individual joints, hip flexion/extension, knee flexion/extension, and ankle plantar/dorsal flexion angles, gait cycle length, gait cycle time, gait cycle velocity, cadence (cycles per minute), stance phase and swing phase of the gait cycle.

### D. Statistics

All acquired kinematical parameters were analyzed individually within the patient and then within the group of here included patients as well. The kinematical characteristics of the patients were evaluated as differences between right and left side. The hypothesis was based on assumption that these differences should be smaller after WBV training comparing values obtained before WBV training. Otherwise, the WBV will probably have no immediate benefits for gait kinematics. Statistical methods included descriptive statistics and Student's paired t-test and were used to ascertain specific and significant differences. The significance level was set to P < 0.05.

## IV. Results

WBV session was well accepted by all elderly patients included in this continuing study. No one felt any pain or expressed any problems during WBV exposure. A first analysis was performed with anatomical joint angles of lower extremities in sagittal plane. Individually, no of the patients had the same curves of all tree joints comparing before and after WBV values. At least one joint's trajectory was changed either in positive or negative direction. An example of anatomical joint angles changes in 65 years old male patient with right hemiparesis is shown on following figures.

Figure 1 shows hip flexion/extension angle before and after single WBV training unit. A paired t-test determined that the mean decrease of differences (M=0.47, SD=4,29, N=51) was not significantly greater than zero, t(50)=0.78, two-tail p=0.441 (95% CL=1.208), providing evidence that the WBV was not effective in reduction of differences between right and left hip flexion/extension angle.

Figure 2 shows knee flexion/extension angle before and after single WBV training unit. Knee flexion/extension angle of the same patient showed that the mean differences between right and left side before and after WBV were decreased, but the mean decrease of differences (M=0.54, SD=8,207, N=51) was not significantly greater than zero, t(50)=0,47, two-tail p=0.643 (95% CL=2.308), providing evidence that the WBV was not effective in reduction of differences between right and left knee flexion/extension angle in this patient.

Figure 3 shows ankle plantar/dorsal flexion angle before and after single WBV training unit. The mean decrease of the right and the left side differences in ankle plantar/dorsal flexion angle of the same 65 years old male patient (M=3.79, SD=4,089, N=51) was significantly greater than zero, t(50)=6.63, two-tail p=0.000 (95% CL=1.150) provided evidence that the WBV was effective in reduction of differences between right and left ankle plantar/dorsal flexion angle.

Anatomical joint angles were analyzed in all participants of this study in the same way. The summary of right and lefts side differences in anatomical joint angles in elderly patients showed that the most significant changes were registered in the ankle plantar/dorsal flexion angle (89.47%), followed by hip flexion/extension angle (73.68%) and knee flexion/extension angle (57.89%). However, these significant changes include both the positive and the negative changes. The only significant positive changes were chiefly in hip flexion/extension angle (63.16%) followed by the knee flexion/extension angle (47.37%) and ankle plantar/dorsal flexion angle (47.37%).

Individually, there were thirteen patients (68.42%) who had at least two significant positive changes of these kinematical parameters or they had no significant negative

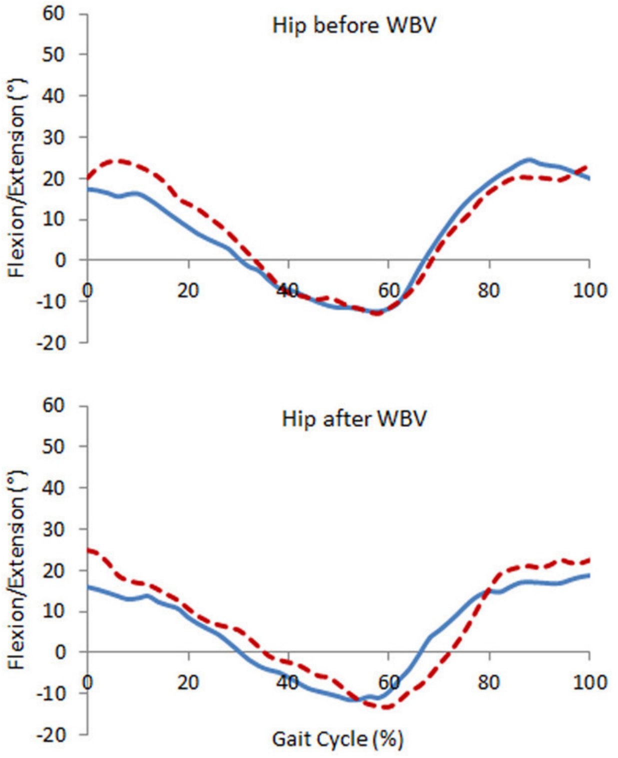

Fig. 1 Hip flexion/extension angle in 65 years old male patient with right hemiparesis before and after WBV exposure (solid line – right leg, dashed line – left leg).

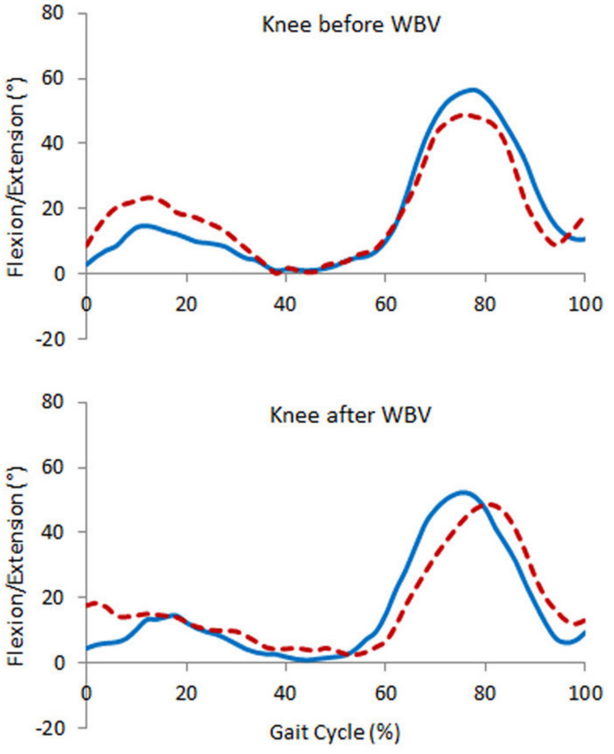

Fig. 2 Knee flexion/extension angle in 65 years old male patient with right hemiparesis before and after WBV exposure (solid line – right leg, dashed line – left leg).

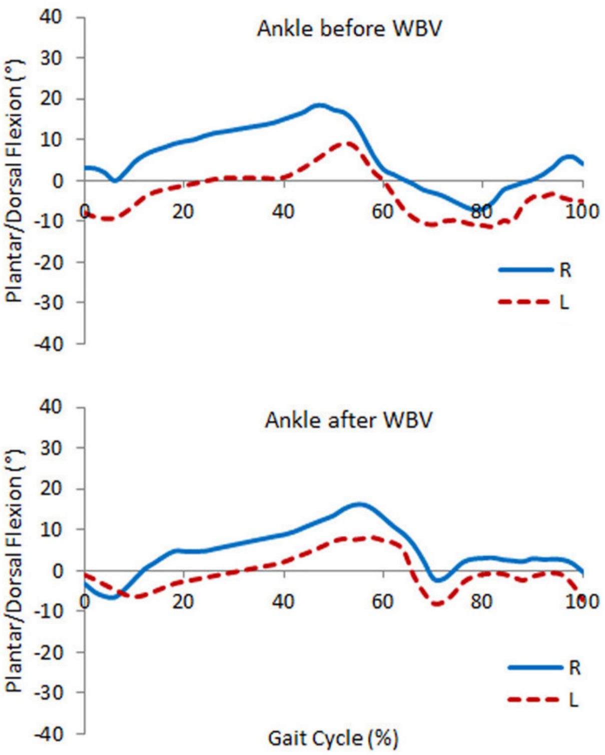

Fig. 3 Ankle plantar/dorsal flexion angle in 65 years old male patient with right hemiparesis before and after WBV exposure (solid line – right leg, dashed line – left leg).

changes (subjects 1, 2, 3, 5, 8, 9, 10, 13, 14, 15, 17, 18 and 19). Two patients (10.53%) had no beneficial improvements resulting from applied WBV exposure (subjects 6 and 12) and four patients (21.05%) of the elderly patient subgroup registered worsening because of no significantly positive or only significantly negative changes (subjects 4, 7, 11 and 16).

The second analysis was performed in spatial-temporal parameters. Here, the symmetry of all characteristics was examined and summarized. The mean differences between right and left sides and standard deviations of these parameters are listed in the table 1.

No of here analyzed parameters had significantly neither positive nor negative changes. Nevertheless, some of the parameters had positive and another negative tendency. The positive trends were shown in decreasing differences between right and left side in gait cycle length (1.470 ± 6.417) and velocity (0.016 ± 0.056). On the other side small increase was registered in cadence (-0.064 ± 1.507) and gait cycle stance (-0.885 ± 4.951 and swing (-0.907 ± 4.932) phase. Gait cycle time remained almost unchanged (0.002 ± 0.043).

## V. Conclusion

In this study, the effect of single WBV training unit was tested in elderly patients with neurological disorders including multiple sclerosis, Parkinson disease, cerebral palsy and radiculoneuritis. The significant improvement was confirmed mainly in anatomical joint angles rather than in spatial-temporal parameters. As we expected, the single whole body vibration training unit had only short-time effect as six of the beneficial patients were analyzed one week after the experiment and their kinematics was similar to the pre- exposure status. Utilization of WBV training in patients with neurological disorders may result in benefits for kinematics of human motion, but its significance and mechanism still remains unclear and undiscovered.

The results of this pilot study provided invaluable data for rehabilitation specialists as well as for development of further research programs in physiotherapy. Based on the results we obtained, it was also confirmed that an individual WBV training and supervised functional treatment should be specified for particular patient. Further research should be realized to clarify WBV specific benefits. The various training approaches including standing in different static positions, sitting on chair with legs on vibrating platform or performing exercises on the platform during therapy sessions should be investigated as well.

## Acknowledgment

This work has been elaborated in the framework of the project ”Support research and development in the Moravian–Silesian Region 2014 DT 1 – International research teams” (RRC/07/2014), financed from the budget of the Moravian–Silesian Region (50%) and in the framework of the project KEGA 020UK-4/2014 (50%).

Table I.
Spatial-temporal characteristics of patients' gait obtained before (Pre) and after (Post) WBV exposure (N=19).

| Parameter | Pre WBV | Post WBV | Delta pre/post |
|---|---|---|---|
| GC length (cm) | 5.751 ± 4.170 | 4.281 ± 4.708 | 1.470 ± 6.417 |
| GC time (s) | 0.086 ± 0.075 | 0.084 ± 0.077 | 0.002 ±0.043 |
| GC velocity (m/s) | 0.067 ± 0.038 | 0.051 ± 0.048 | 0.016 ± 0.056 |
| Cadence (GC/min) | 2.014 ± 1.284 | 2.078 ± 1.286 | -0.064 ± 1.507 |
| Stance phase (%) | 3.556 ± 2.944 | 4.441 ± 4.984 | -0.885 ± 4.951 |
| Swing phase (%) | 3.562 ± 2.942 | 4.469 ± 4.963 | -0.907 ± 4.932 |

*Abstract*— **Melanoma is the most deadly form of skin cancer. Early detection and successful treatment of this disease often is possible. The main goal of this paper is to present results of application of feature selection method to find the most important or all important features that characterize melanocytic spots on the skin and in this way defining of a new Total Dermatoscopy Score formula. Thus, it is possible to decrease dimensionality of that problem. Results gathered during research focus on about six from thirteen descriptive attributes which are the most relevant and are stated as core attributes. Based on these attributes a simple total scoring method could be applied to improve prediction (diagnosis) results, additionally also reducing complexity of problem. Results were acquired by application of six different machine learning algorithms and estimated using several evaluation measures.**

## I. Introduction

Melanoma is the most deadly form of skin cancer. The World Health Organization estimates that more than 65000 people a year worldwide die from too much sun, mostly from malignant skin cancer [1]. It is an increasingly common tumour, it is  the cutaneous tumour with the worst prognosis and its incidence is growing, because most melanomas arise on areas of skin that can be easily examined. Early detection and successful treatment often is possible, most dermatologists can accurately diagnose melanoma in about 80% of cases according to well-known ABCD process [2]. ABCD formula devotes to Asymmetry of lesions, their Border, Color and Diversity of structures (or Diameter in other approach), and in some cases the Evolving over time (the ABCDE formula). Based on these features dermatologists could prepare diagnosis by simply observation of investigated lesion.

Meanwhile the incorporation of dermatoscopic techniques, reflectance confocal microscopy and multispectral digital dermatoscopy have greatly enhanced the diagnosis of this cutaneous melanoma. While these devices and techniques could give dermatologists a closer look at suspicious skin lesions. This, in turn, can help dermatologists find suspicious lesions earlier than before and better determine whether a biopsy is needed. None of these devices can confirm that a suspicious lesion is melanoma. It is, however, not yet possible to tell if a patient has melanoma or any type of skin cancer without a biopsy. It is important to combine the classically ABCDs and biopsy to prevention and diagnosis of melanoma.

The five-year survival rate for people whose melanoma is detected and treated before it spreads to the lymph nodes is 99 percent. Five-year survival rates for regional and distant stage melanomas are 65 percent and 15 percent, respectively [3]. Thus the curability of this type of skin cancer depends essentially on its early diagnosis and excision. For that reason the ABCD (asymmetry, border, color and diversity of structure) clinical rule is commonly used by dermatologists in visual examination and detection of early melanoma. It is also used in development of diagnosis platforms such as DERMA [4] or IMDLS systems [5].

Previous research [5-8] focused on using of data mining and image mining techniques to provide early support to diagnosis of melanocytic lesions. Now, it is proposed to apply feature selection methods to find interesting features inside investigated melanocytic datasets. Thus, we could try to recognize the minimal set of important (relevant) features, but on the other hand we can calculate the importance of each feature used in ABCD formula in the domain of melanoma classification. According to Kohavi and John [9] feature X could be defined to be strongly relevant when removal of X alone from the data always results in deterioration of the prediction accuracy of the ideal Bayes classifier. Feature X is weakly relevant if it is not strongly relevant and there exists a subset of features S, such that the performance of ideal Bayes classifier on S is worse than the performance on S $\cup$ {X}. A feature is irrelevant if it is neither strongly nor weakly relevant. Improving the performance of machine learning classifiers for diagnosis based on feature selection is often applied [10,11]. In this paper additional application of FS methods is investigated.

## II. Dataset used during experiments

The medical dataset which was used in this research concerns melanocytic skin lesions that are a very serious skin and lethal cancer. It is a disease of contemporary time,

This work was partially supported by The Fund of Dean of the Faculty of Mathematics and Natural Sciences, University of Rzeszów

978-83-60810-66-8/$25.00©2015, IEEE

the number of melanoma cases is constantly increasing, due to, among other factors, sun exposure and a thinning layer of ozone over the Earth. Statistical details on this data are given in [12]. Investigated data consist of 326 case of *Benign nevus* and *Blue nevus*, 108 cases of *Suspicious nevus* and 114 cases of *Melanoma malignant*, a total of 548 cases. Descriptive attributes of the data were divided into four categories:

- *Asymmetry*, has three different values: *symmetric spot, one-axial asymmetry* and *two-axial asymmetry,*
- *Border*, is a numerical attribute with values from *0* to *8*,
- *Color* group, has six possible types: *Black, Blue, Dark brown, Light brown, Red* and *White*,
- *Diversity of structures* group, has five possible types: *Pigment dots, Pigment globules, Pigment network, Structureless areas* and *Branched streaks*;

Each of these 11 types of Color and Diversity have values 0 or 1, that is 0 means lack of the corresponding property and 1 means the occurrence of the property. In dermatology this set of features is known as ABCD formula and is also applied to calculated the so-called *Total Dermatoscopy Score (TDS)* [13,14]. The ABCD formula of dermoscopy was the first dermoscopy algorithm created to help differentiate benign from malignant tumors [14]. This algorithm was developed to quantitatively address the crucial question in dermoscopy of whether a melanocytic skin lesion under investigation is benign, suspicious (borderline), or malignant. Based only on four dermatoscopic criteria this method is relatively easy to learn and to apply. The ABCD method has been extensively studied and it has been shown that it improves the diagnostic performance of clinicians evaluating pigmented skin lesions.

The goal was to use selected machine learning methods to estimate hierarchy of importance of melanocytic symptoms. These symptoms are part of well-known parameter *TDS* (*Total Dermatoscopy Score*) that is a useful diagnostic tool for melanoma. The *TDS* is computed using the following formula (known as the ABCD formula):

$$\begin{aligned} TDS &= 1.3 * Asymmetry + 0.1 * Border + \\ &+ 0.5 * \sum Colors + 0.5 * \sum Diversity \end{aligned} \tag{1}$$

where A is a description of lesion’s asymmetry, B is a description of lesion’s border, C is a description of colors appearing in considered lesion, and D is a specification of lesion’s diversity.

## III. Methods of experiments

During research a following general procedure was applied:

*1. Selection of dataset and features for investigation*

*(a) Application of set of ranking measures to calculate rank of importance for each feature*

*(i) With set of contrast features*

*(ii) Without contrast features*

*(b) Definition (selection) of the most important feature subset*

*2. TDS calculation for all original features*

*3. New TDS calculation based on selected most important features*

*4. Application of different machine learning algorithms for classification of unseen objects using 10-fold cross validation method*

*(a) Using all descriptive features*

*(b) Using only selected, most important features*

*(c) Using all descriptive features with TDS added*

*(d) Using only selected, most important features with NewTDS added*

*5. Comparison of gathered results using different evaluation measures*

In the first step, dataset and features for investigation were defined. Then, different ranking measures were applied to estimate importance of each feature. In order to check specificity of the feature selection, the dataset was extended by contrast variables. It means that each original variable was duplicated and it’s values were randomly permuted between all objects. Hence a set of non-informative by design shadow variables was added to original variables. The number times when the shadow variables were selected as important gives estimate of the expected level of false discovery. These variables that were selected as important significantly more often than random, were examined further, using different test. To define level of feature importance six well-known ranking measures were applied: *ReliefF*, *Information Gain*, *Gain Ratio*, *Gini Index*, *SVM weight* and *RandomForest*. Additionally, a new parameter, called *RuleQualityFS* (see Table 1), were introduced. It is based on frequency of presence of different feature in rule model generated from dataset and also takes into consideration quality of the rules in which there is. Rank quality of $i^{th}$ attribute could be presented as follow:

$$Q_{A_i} = \sum_{j=1}^{n} Q_{R_j} \{A_i\} \tag{2}$$

where $n$ is a number of rules inside the model, $Q_{Rj}$ defines classification quality of rule $R_j$ and $\{A_i\}$ describe the presence of $i^{th}$ attribute, usually *0* or *1*.

In turn, quality of rule is defined as follow:

$$Q_{R_j} = \frac{E_{corr}}{E_{corr} + E_{incorr}} \tag{3}$$

where $E_{corr}$ depicts number of correctly matched learning examples by $j^{th}$ rule and $E_{incorr}$ depicts number of incorrectly matched learning examples by this rule.

In the second step, the standard *TDS* calculation were performed based on original values of attributes and using formula (1). It is standard procedure utilized by medical specialists.

However, in my research, the third step is crucial. In this point a *NewTDS* value is defined and calculated (see formula

4). According to acquired factors from the first step of experiments (Table 1), a new formula for *TDS* calculation were introduced:

$$\begin{aligned} NewTDS &= 38.72 * Border + \\ &+ 31.82 * Asymmetry + \\ &+ 23.22 * PigmentNetwork + \\ &+ 20.00 * BlueColor + \\ &+ 16.60 * BranchedStreaks + \\ &+ 15.50 * WhiteColor \end{aligned} \tag{4}$$

Six selected attributes were used according to Table 1. For each of them corresponding factor from this table (*RuleQualityFS* column) were inserted. In this way, new attribute which connects others into one value were added to original dataset.

During the fourth step test probing the importance of variables was performed by analyzing the influence of variables used for model building on the prediction quality. Four different combination of attributes were applied.

Six different machine learning model were applied to build different predictors: *Classification Tree (CT), Random Forest (RF), CN2 decision rules algorithm (CN2), Naïve Bayes (NB), k Nearest Neighbors (kNN)* and Support *Vector Machine (SVM).* During this step a 10-fold cross validation paradigm were used. Ten known evaluation measures were utilized in each predictor: *Classification Accuracy (CA), Sensitivity, Specificity, Area Under ROC curve (AUC), Information Score (IS), F1 score (F1), Precision, Brier measure, Matthew Coefficient Correlation (MCC)* parameter and finally *Informadness ratio* [11].

TABLE I.
RANKING OF FEATURES USING SEVEN DIFFERENT MEASURES

| Attribute | ReliefF | Inf. gain | Gain Ratio | Gini | SVM weight | RF | RuleQuality FS |
|---|---|---|---|---|---|---|---|
| Border | 0.03 | **0.17** | **0.09** | **0.03** | **4.93** | **3.74** | **38.72** |

## IV. Results of experiments

The first experiment revealed six variables, called *core features*, that were indicated as important by all, or nearly all, ranking measures, see Table 1. In this table, we can observe that *Border, Asymmetry, Pigment network*, *Blue color*, *Branched streaks* and *White color* features create stable and core set of features which have the highest values of seven measures of importance, particularly using *RuleQualityFS* measure, introduced in this investigation. In the same table, comparison with importance of contrast values (grey rows colored and *contrast* index) is also presented. The most important contrast feature is *Border (contrast)* for which *RuleQualityFS* measure, defined in earlier section, is equal to *12.50*. In this way, he is also treated as a threshold that separates the *core set* of attributes from all contrast features and other less informative attributes. Most of the measures used in this approach focused that selected core set of features has higher values of these parameters than gathered threshold attribute value. These values are denoted in bold style in Table 1. Hereby,

Table II.
Average classification results gathered using different classification quality measures applied to six machine learning models for four investigated sets of features combination

| Model | CA | Sens | Spec | AUC | IS | F1 | Prec | Brier | MCC | Informadness |

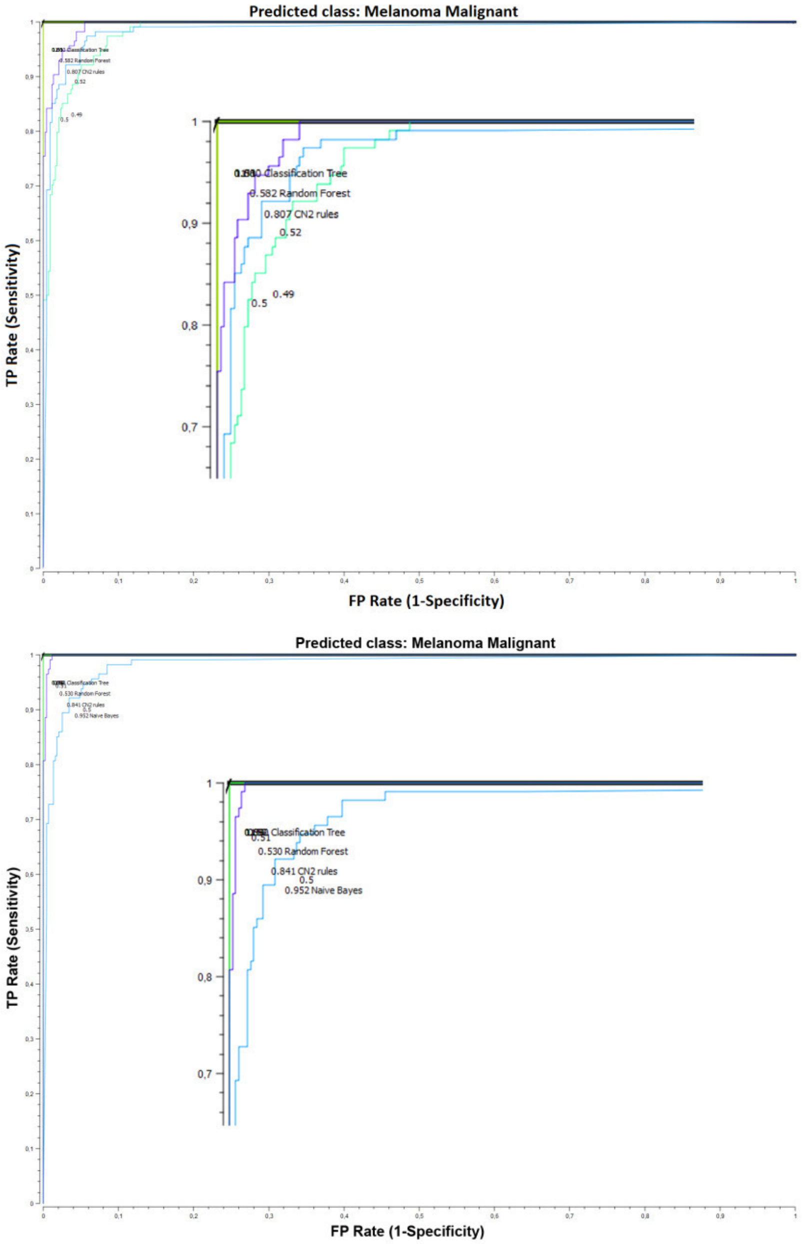
| AVG | **0.98** | **0.98** | **1.00** | **1.00** | **1.71** | **0.98** | **0.98** | **0.04** | **0.98** | **0.98** |

we can observe that different measures give different threshold, and it also shows that some other measures than *RuleQualityFS* include all original variables in core sets, e.g. *Information Gain, Gain Ratio, Gini index* and *Random Forest* application. Thus, we cannot extract smaller set of relevant attributes than the original one.

The second part of experiments focused on calculation of standard *TDS* and *NewTDS* defined earlier. Based on formula 1 and formula 4, these two values were obtained. Then, two datasets that include *TDS* and *NewTDS* respectively were investigated in next part of experiment.



The third part of experiment devoted to estimation of prediction quality of utilized machine learning algorithms described in section III. During this step six different algorithms were applied using 10-fold cross validation method. Average results are collected in Table 2. Procedure were utilized to four specified sets:

*(i)* *original set containing all descriptive features,*

*(ii)* *only selected core feature set based on its importance calculated in the first step,*

*(iii)* *original set containing all descriptive features with added standard TDS parameter,*

*(iv)* *core feature set with added NewTDS parameter.*

Additionally, to compare results, average values (*AVG*) of all evaluation measures were calculated.

Fig. 1 Comparison of ROC curves gathered for Melanoma malignant class using six learning algorithms by investigation of original dataset (top chart) and selected core features with added *NewTDS* attribute (bottom chart)

Based on acquired results (see Table 2), it could be stressed that core set of features which contains only 6 from 13 attributes has very similar prediction quality as it was observed with all original 13 attributes. For instance, popular measure in data analysis AUC decreased on average only from 0.95 to 0.93. However, average Classification Accuracy decreased rather significantly from 0.81 to 0.75, and also Informadness, which in itself connects Sensitivity and Specificity, decrease on average from 0.73 to 0.61. Next, if we tried to add calculated standard TDS values it is observed that AUC reached better average value, 0.99. This outcome could be also observed in form of Receiver Operating Characteristic curve. Comparison of ROC curves for original and with NewTDS feature set generated only for Melanoma malignant class is presented on figure 1. In turn, all other measures also increased significantly. By adding TDS values to dataset Informadness measure increased on average from 0.73 to 0.93. Thus, it could be said that this approach could be positively applied in other, different medical issues.

The last step of experiment shows that the feature space could be probably significantly reduced. It means, that we can use only six from thirteen descriptive attributes in connection with new total score parameter could be successfully applied. In Table 2, the average value of all evaluation measure increased significantly reaching almost limits. For example AUC and Specificity reached 1.0, in turn Informadness achieve 0.98, what is very good result. According to this results it could be stressed that this methodology improves prediction of learning models and additionally simplifies space of problems by reducing its dimensionality.

*Abstract*—**Artificial Neural Networks (ANNs) play a vital role in the medical field in solving various health problems like estimating the risk of cardiovascular diseases. The article concerns the process of developing ANNs for estimating the risk of arterial hypertension. ANNs proposed in this article use anthropometrical predictors, easy to control for everybody at home without special equipment. In the article we analyze four different models of ANNs and try to find out which model and set of anthropometrical predictors estimates the risk the most accurately. We use dataset of 2485 real cases of patients from the city of Lodz. The experiment was done in the Matlab environment. The performance of the proposed method in terms of accuracy and facility of use shows that ANNs can be effective tools for preliminary tests of arterial hypertension.**

## I. Introduction

ARTERIAL hypertension (HT) as a major risk factor for the development of cardiovascular diseases (CVD) constitutes an important problem of public health in Poland and other countries around the world [1]. Arterial HT is a disease that affects a wide range of the population, particularly the elderly after the age of 55. In compliance with the data given by multicenter Polish population health status study-WOBASZ, arterial hypertension appears among about 42.1% of men and 32.9% of women in Poland [2].

The diagnostics of HT as a sickness is based on:

a) the showing of increased values of blood pressure (based on their repeated measurement),
b) the estimation of the degree of the disease,
c) the differentiating of its etiology and results.

The value 140 mmHg for systolic blood pressure (SBP) and/or 90 mmHg the diastolic blood pressure (DBP) have been accepted for grown-ups as a border-line of hypertension [3]. The same classification is used for young, middle-aged and elderly subjects, whereas different criteria, based on percentilage for boys and girls according to their age and height [4]. The state of high risk of development of HT, the so-called pre-hypertension state (PHT), is defined when SBP amounts 120 - 139 mmHg and/or DBP amounts 80 - 89 mmHg. The patient with PHT needs the estimation of other cardiovascular risk and factors and modification of the lifestyle in the first instance.

Overweight and obesity are the most widespread occurrent environmental factor, that can cause the development of arterial hypertension (HT). The increased prevalence of obesity (especially visceral obesity) and other cardiovascular risk factors are closely associated with the rising incidence of CVD and type 2 diabetes mellitus. The enlarged quantity of the adipose tissue ties in with hyperinsulinemia and insulin resistance, which contributes to the level of blood pressure. Hormones and cytokines produced in adipocytes (eg. leptin, resistin, adiponektion, the interleukin-6, tumor necrosis factor-alpha and others) play a key role, and emitted to the circulation of blood system, regulate lipid and glucose metabolism [5]. In Framingham research 70% of men and 60% of women with HT and with coexisting overweight or obesity, had their systaltic blood pressure increased about 4.5 mmHg on every 5 kg of overweight [6].

Similar relations between the Body Mass Index (BMI) and arterial blood pressure were shown also in INTERSALT research [7]. With people having the similar body height, a 10 kg difference caused the increase of systaltic/diastolic pressure by 3/2.2 mmHg respectively.

In Poland, the result of the IDEA (The International Day for Evaluation of Abdominal Obesity) research on grown-ups aged from 18 to 80, showed that the frequency of appearing of both abdominal overweight and arterial hypertension is one of the highest in Europe [8].

Considerably more often than among our European neighbours, both from the North and West, one ascertained abdominal overweight (in Poland: 54% of women and 38% of men; in north-west Europe: 45% of women and 33% of men). Besides, it was observed that arterial hypertension more often appears among people with overweight or obesity when compared to their slim peers of the same age. Stout people more often suffered from diseases of the cardiovascular (CVD) system, diabetes and dyslipidemia. Very often these diseases coexisted with overweight or obesity. The investigation the IDEA concluded that both among men and women, abdominal obesity and the BMI tie in with CVD independently.

In spite, of the well-known correlation between HT and overweight, controversies about which anthropometrical factors (general and abdominal overweight and other such pa-

978-83-60810-66-8/$25.00©2015, IEEE

rameters as age and sex determine the most effective model of HT prediction) exist all the time.

In our work, we used ANNs, and the data from the research adults aged from 20 to 80 from the city Lodz, and we executed estimations of the efficiency of HT diagnostic for different models and anthropometrical data.

## II. Dataset for Artificial Neural Networks

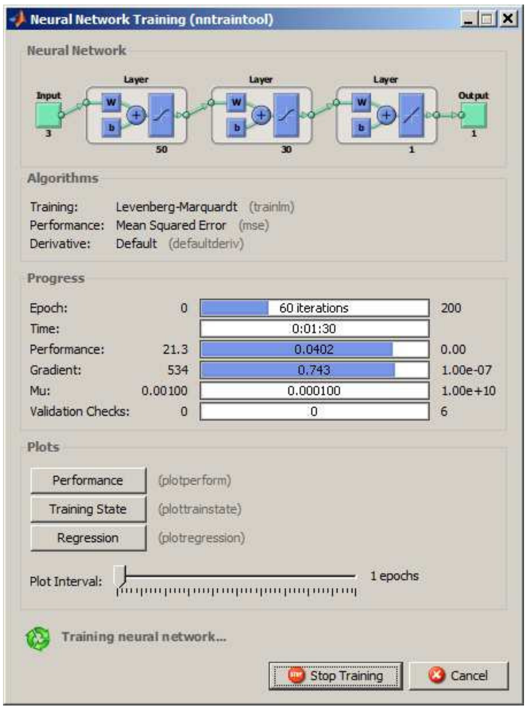
The Artificial Neural Networks (ANNs) are constructed using various predictors, to be trained, tested and validated using the respective data sets. In experiments we used the set of real data concerning patients from the city of Lodz, aged from 20 to 80. The set of data embraced 2485 cases of patients, 1197 men and 1288 women. Patients who did not have hypertension is the largest group (1370 cases, whereof 624 is men and 746 is women). In the group of patients with the 1-st stage of hypertension, there were 569 cases (315 men and 254 women). The group of patients with the 2-nd stage hypertension embraced 464 cases (221 men and 243 women). The least numerous group of patients was the one with the 3-rd stage of hypertension and if consisted of 82 cases (37 men and 45 women).

The dataset was divided into a training set and a test set. The training set was used for neural network training, that is for adjustment of weights between neurons. The test set was used after the network was trained, to test ANNs accuracy on new data (not used for training).

## III. Models of the Artificial Neural Networks

Artificial Neural Networks (ANNs) are algorithms inspired by function of the human brain. ANNs are usually presented as systems of interconnected "neurons" divided into a few layers. Each neuron can compute values from inputs and is capable of machine learning. Each neuron has a certain number of inputs, a real number associated with each connection (the weight of the connection), and has its own transfer function. The behaviour of an ANN depends on the weights and the transfer function. Most of the algorithms used in training ANN employ some form of backpropagation method. In supervised learning, a given set of input/output pairs is presented to the network. A learning algorithm tries to adjust connection weights to minimize the average squared error between the network's output and the target value for all the example pairs. ANNs can produce the values between 0 and 1 for any input vector. The advantage of ANNs is their ability to learn from the observed data. They can be used to infer a function from observations. This is useful in complex applications or tasks, where discovering such a function by hand is impractical or impossible.

All the experiments were done in the Matlab environment. In the experiments we used three-layer artificial neural networks. The number of neurons in input, hidden and output layers was fixed to 50, 30 and 1 respectively. The proposed structure of the network was obtained as a result of a series of initial tests during which we were testing different structures. The hyperbolic tangent sigmoid transfer function (tansig) was used in the input and hidden layers, and the linear function (purelin) in the output layer. A Levenberg-Marquardt method with 200 cycles was used for teaching the networks. In Fig. 1 we show an example of the network teaching in the Matlab environment.



Training: Levenberg-Marquardt (trainlm)
Performance: Mean Squared Error (mse)
Derivative: Default (defaultderiv)

Fig. 1. An example of a three-layer artificial neural network teaching with the Levenberg-Marquardt method

The result of the classification was represented on the output layer in the form of a real number. We accepted that output values from 0 to 0.17 represent the lack of hypertension, values from 0.17 to 0.5 represent the 1st degree hypertension, values from 0.5 to 0.83 represent 2nd degree hypertension, and values above 0.83 represent the 3rd degree hypertension. In experiments we tested four models of the network with different input values:

- model 1: we accepted 3 inputs: the Body Mass Index (BMI), the Waist Circumference (WC) and the Age. On the output of the network we received the real number representing the result of the classification;
- model 2: we accepted 3 inputs: the Body Mass Index (BMI), the Waist Circumference normalized in relation to the BMI (WCBMI) and the Age. On the output of the network we received the real number representing the result of the classification;
- model 3: we accepted 4 inputs: the Body Mass Index (BMI), the Waist Circumference (WC), the Sex and the Age. On the output of the network we received the real number representing the result of the classification;
- model 4: we accepted 4 inputs: the Body Mass Index (BMI), the Waist Circumference normalized in relation to the BMI (WCBMI), the Sex and the Age. On the output

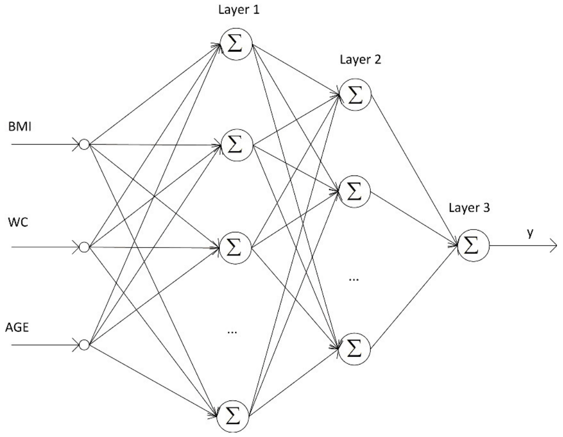

Fig. 2. Artificial Neural Network Architecture

TABLE I
THE RESULTS OBTAINED BY EACH MODEL OF NEURAL NETWORK (THE AVERAGE NUMBER OF INCORRECTLY RECOGNIZED CASES IN PERCENTAGES)

| | HT 0 | HT 1 | HT 2 | HT 3 |
|---|---|---|---|---|
| model 1 | 7.96 | 10.42 | 17.76 | 21.18 |
| model 2 | 6.68 | 11.94 | 16.6 | 17.3 |
| model 3 | 6.52 | 9.82 | 15.18 | 14.86 |
| model 4 | 7.00 | 11.92 | 16.9 | 19.92 |

of the network we received the real number representing the result of the classification.

In models 3 and 4, a non-numerical attribute (Sex) was used. The value of this attribute was converted into number: 0 for women and 1 for men.

In Fig. 2 we present the Architecture of Artificial Neural Network.

## IV. Experimental results

For the test we used all four proposed models of ANNs. Every network was run five times, embracing the learning process, and then, the test of the efficiency of the classification. The obtained result is the average from all five runs. The results obtained by each neural network are collected in table 1. The values in the table are in percent ages and represent the average number of incorrectly recognized cases with the lack of hypertension (HT0), hypertension of the first stage (HT1), hypertension of the second stage (HT2) and hypertension of the third stage (HT3). During the experiments, we used only the results of anthropometrical measurement and systaltic (SBP) and diastolic (DBP) blood pressure. The other factors, such as medicines, family conditionings and other, were not taken into account.

The comparison of model 1 and model 2, let on to check which input value (WC or WCBMI) better determines the results of the classification. The graph in Fig. 3 illustrat the differences in the average number of incorrectly diagnosed cases by neural networks with the use of models 1 and 2.

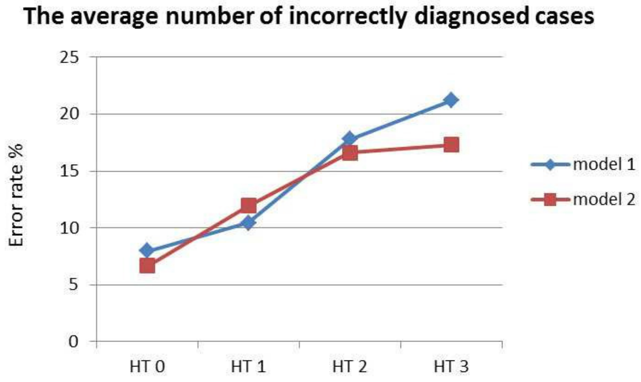

Fig. 3. Differences in the average number of incorrectly diagnosed cases by neural networks with the use of models 1 and 2.

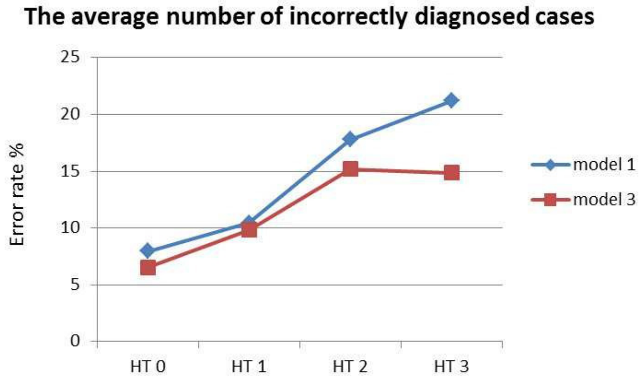

Fig. 4. Differences in the average number of incorrectly diagnosed cases by neural networks with the use of models 1 and 3.

The graph in Fig. 4 illustrates differences in the average number of incorrectly diagnosed cases by neural networks with the use of models 1 and 3.

Models 3 and 4 let on to check if the additional parameter (Sex) will improve exactitude of the classification and how it influences the value of the hypertension. The graph in Fig. 5 illustrates the average number of incorrectly diagnosed cases by neural networks with the use of all four models.

## V. Conclusions

Overweight and obesity leading to arterial hypertension are a serious problem of the population of Poland and other countries around the world. Artificial Neural Networks, basing on anthropometrical factors, which are easy to measure at home, let on to make diagnostic reconnaissances towards the risk of arterial hypertension.

The neural network in which we used the Waist Circumference normalized in relation to the BMI (WCBMI), as the input (model 1) obtained a greater accuracy than the network in which we used the Waist Circumference without normalization (model 2).

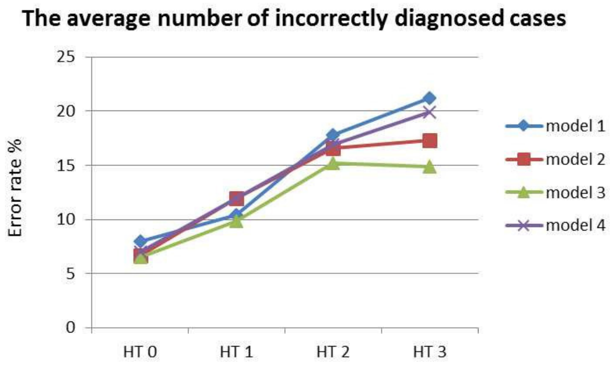

Fig. 5. Average number of incorrectly diagnosed cases by neural networks with the use of all four models.

The introduction of the additional input parameter to the network (the Sex), brought about the enlargement of the accuracy of the network. The greatest difference can be observed in the third stage of hypertension, though in the test set in this category the least cases appeared.

The results of our study may be a starting point for the construction of a more complex ANN system for the assessment of global arterial hypertension risk. Taking into account the growing scale of overweight and obesity epidemic around the world, the Neural Networks systems should be more widely used for diagnosis of this problem.

***Abstract*—We perform a short survey of image thresholding methods for very specific task, and assess their performance comparison. We analyse performance of adaptive thresholding methods concerning segmentation of immunonegative cells of follicular lymphoma tissue samples stained with 3,3'-Diaminobenzidine&Haematoxylin. We use artificial images based on experimental images that greatly simulates real samples and simplifies process of evaluation. We chose 8 methods of adaptive threshold segmentation, with different approach. They were applied to 6 different monochromatic images derived from original RGB images, by splitting layers, conversion to Lab colour space and colour deconvolution. Evaluation of the results was performed with basic statistical measures as sensitivity and specificity along with Jaccard's coefficient. We identify the thresholding algorithms with superior performance. Collected results will be used to design the new better method based on this approach.**

## I. Introduction

TISSUE samples stained immunohistochemically are commonly used by pathologists to distinguish various types of cancer [1]. One of them is follicular lymphoma which is the second most common form of non-Hodgkin's lymphoma [2]. Nowadays, pathologist doesn't have to evaluate samples via microscope but it can be done by examination of digital images of samples. Unfortunately, even with this aid the human evaluation is irreproducible and prone to error [3]. Moreover, it tends to change from one expert to another, as well as in time for one expert. As analysis is mostly based on counting of immunopositive and immunonegative cells, computer evaluation would give many advantages, like acceleration and reproducibility of the process. Unfortunately, segmentation of such images is not an easy task. Most computer-based procedures for immunohistochemistry image analysis [4]–[7] have limited applicability due to numerous drawbacks.

For test images in this study we decided to use simulated (artificial) images based on experimental images of follicular lymphoma tissue sections stained with 3,3-diaminobenzidine (DAB) and contra-stained with haematoxylin (H). The main reason for this decision was having 'gold standard' reference image that can be used to evaluate results of segmentation methods.

Experimental as well as artificial images consist of brown objects among blue ones with bright background that sometimes has slight blue tint. Most of the objects have minor but visible texture. Unfortunately, each and every sample differs in many characteristics. There is a huge variability of shape (from round to elongated), size and colour of objects of interest as well as in the image generally; in colour intensity, range of colour and tone throughout image plane.

For this survey we chose 8 methods of adaptive threshold segmentation to test and evaluate their ability to segment immunonegative cells. We decided to apply segmentation algorithms to 6 different monochromatic images derived from original RGB images. Apart from simple dividing images into single layer images of separate RGB layers we used conversion to Lab colour space, as it was proved to be useful during segmentation in other applications [8]. Since b axis of Lab colour space represents yellow and blue at two ends of the axis, it could be very useful to find proper threshold value to segment blue objects of interest. Also we try to use L (luminescence) layer of Lab colour space as the objects should have contrasting value from the background. Another method we applied in this research is colour deconvolution [9]. We use Haematoxylin layer obtained with predefined colour vector in colour deconvolution algorithm. In summary, we compare results of segmentation performed on: (1) red layer of RGB; (2) green layer of RGB; (3) blue layer of RGB; (4) L layer of Lab colour space; (5) b layer of Lab colour space; (6) Haematoxylin layer after colour deconvolution.

To sum up, in this investigation, we present preliminary study concerning segmentation of immunonegative cells of follicular lymphoma tissue stained with DAB&H. It will lead to development of improved method of segmentation. In cooperation with our previous research [10] on segmentation of immunopositive cells we hope to achieve fully capable software to analyse digitized samples of follicular lymphoma tissue sections.

We acknowledge the financial support of the Polish National Science Centre grant, PRELUDIUM, 2013/11/N/ST7/02797.

## II. Methods

For this study, we decided to use previously created artificial images. Thus, we obtain the 'gold standard' images to evaluate the results. To process the images we have used previously tested methods with changed parameters appropriately for the new type of segmentation (presented in Table I). Evaluation of the results was performed with basic statistical measures as sensitivity, specificity along with Jaccard's coefficient. All necessary computations were performed in MATLAB.

### A. *Artificial images synthesis*

The process of creating and the usefulness confirmation of the artificial images is fully described in our previous work [10]. In short, it is done using the adjusted version of SIMCEP software [11], [12] and Camera Raw 4.1 module of Photoshop CS5. Lehmussola and co-workers developed SIMCEP to synthesize the full colour fluorescent microscopic images of nuclei or cells' culture. With our modification it creates images of transmission light microscopy.

Our artificial images were created based on the model images experimentally collected in Hospital Verge de la Cinta in Tortosa, Spain. They were created to resemble their experimental counterparts as much as possible. The number of cells, their size, shape and distribution have been adjusted. We tried to simulate signal degradation, typical for the microscope and camera technical limitations, such as noise, vinietting and blurring.

The great advantage of this technique is that along with the artificial image we obtain the reference image of 'true' objects of interest. This lets us not only compare number of segmented objects and their approximate position but properly evaluate every pixel of the image.

### B. *Methods of segmentation*

Since samples tend to show wide range of characteristics like colour, tone and intensity as well as contrast fluctuations, the locally adaptive thresholding methods seems to be most appropriate. Local threshold is calculated for every pixel with sliding window image processing. Threshold value is based on the intensity of the analysed pixel and its neighbourhood. All methods used in this study are chosen based on the survey [13], and are fully described in previous publication [10], therefore in the following part we present them briefly. All values of parameters used in segmentation algorithms are chosen experimentally and are presented in Table I.

Niblack [14] is the most basic adaptive threshold method; based on local variance.

Sauvola [15] is another local variance method and can be treated as modified version of Niblack's method.

Bernsen [16] is based on local contrast. Threshold value is calculated as a mean of the minimum and maximum value in neighbourhood of the analysed pixel if the contrast value was high enough.

White [17], basically, if the pixel is considerably (depending on the bias value parameter) darker than its surrounding, it is considered as an object.

Palumbo [18] is using centre-surround scheme. The treated area is divided into near neighbourhood and 4 diagonal windows are far neighbourhood. The tested pixel is supposed to be treated as object when the central window contains the foreground object and the neighbouring windows are filled with background.

Yasuda [19] is local contrast method and consists of four steps. First two are preprocessing; increasing dynamic range in the image, followed by nonlinear smoothing. Then primary thresholding is done, with course marking of background based on local contrast. Finally, precise segmentation to classify rest of the pixels is performed.

Hybrids of Niblack and Sauvola methods are described in previous publication [10]. As the basic methods seemed unsatisfactory in terms of sensitivity and specificity we modified them by adding the contrast condition.

TABLE I
Values of parameters used in segmentation methods

| | $w$ | $k$ | $R$ | $bias$ | $T_c$ | $T_1$ | $T_2$ | $T_3$ | $T_4$ |
|---|---|---|---|---|---|---|---|---|---|
| Niblack | 51 | -0.2 | | | | | | | |
| Hyb.Nib. | 51 | -0.2 | | | 40 | | | | |
| Sauvola | 51 | 0.5 | 128 | | | | | | |
| Hyb.Sau. | 51 | 0.5 | 128 | | 40 | | | | |
| White | 51 | | | 1.05 | | | | | |
| Bernsen | 51 | | | | 40 | | | | |
| Palumbo | 21 | | | | | 100 | 0.85 | | |
| Yasauda | 51 | | | | | 0.19 | 0.39 | 0.8 | 0.05 |

### C. *Methods of evaluation*

To perform proper evaluation exact position of every object should be known. Fortunately, while we use artificial images we can use the black and white reference image of 'true' objects of interest as the 'gold standard'. Taking into account the result of each segmentation method and 'gold standard' image, following measurements are possible: true positive (TP), true negative (TN), false positive (FP), false negative (FN). Based on these parameters, statistical measurement of the performance of segmentation methods can be calculated, such as sensitivity, specificity, and Jaccard's coefficient.

## III. Results

Segmentation was performed on 6 different layers derived from one image. We tried performing segmentation on all of RGB layers. We also tested performance on the Haematoxylin layer acquired by applying colour deconvolution. Additionally, we transformed images from RGB to Lab colour space, and performed segmentation on layers $L$ and $b$.

Performing segmentation on RGB layers is computationally most simple approach that does not involve any transformations. The mean values of sensitivity and specificity for every segmentation method on all images are presented in Table II. Comparing mean results of RGB channels only red and green layers give tolerable results. Segmentation of blue channel cannot give good results as values of object and background

TABLE II
MEAN VALUES OF SENSITIVITY AND SPECIFICITY FOR ALL IMAGES APPLIED TO 6 DIFFERENT MONOCHROMATIC IMAGES DERIVED FROM THE ORIGINAL RGB IMAGES

| layer | sensitivity | specificity |
|---|---|---|
| R (RGB) | $0.895 \pm 0.043$ | $0.914 \pm 0.044$ |
| G (RGB) | $0.827 \pm 0.097$ | $0.912 \pm 0.048$ |
| B (RGB) | $0.501 \pm 0.219$ | $0.878 \pm 0.080$ |
| H (deconv.) | $0.919 \pm 0.047$ | $0.929 \pm 0.050$ |
| L (Lab) | $0.804 \pm 0.129$ | $0.915 \pm 0.049$ |
| b (Lab) | $0.839 \pm 0.071$ | $0.930 \pm 0.079$ |

are very similar for that layer, as can be seen in Figure 1. Hence, we discard blue channel from further analysis. The best of those three channels is segmentation of red channel. Transformation from RGB to Lab colour space is complex computational task but it may become helpful as results of segmentation on $L$ and $b$ layers are better in comparison to those of RGB layers. Objects of interest (blue immunonegative cells) in Luminescence layer ($L$) are significantly contrasted from the background. Unfortunately, so are other objects (brown immunopositive cells). Better results are achieved for $b$ layer of Lab colour space. It seems that blue and brown objects can be well separated in this layer since the representation of $b$ axis is yellow-blue. It is understandable because model brown colour consist only of red and green values (in RGB) as well as yellow which has the same components, while on the other end of the axis is blue colour. Mean value of sensitivity for these four layers is between 0.804 and 0.895 while specificity is between 0.912 and 0.930. Haematoxylin layer acquired by colour deconvolution algorithm stands out as best for performing segmentation. It has mean value of sensitivity $0.919 \pm 0.047$ and $0.915 \pm 0.049$ specificity, what is better than any other tested layer.

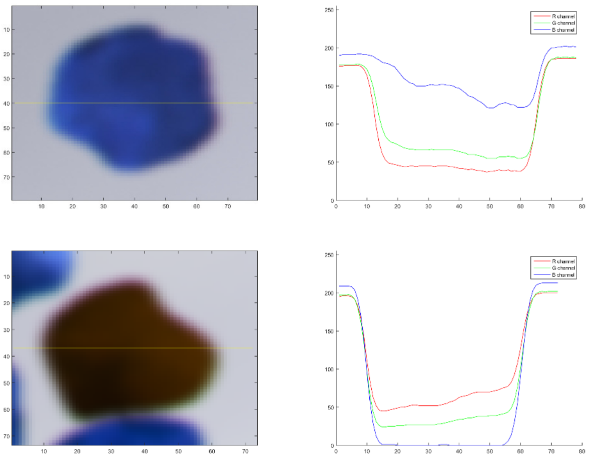

Fig. 1. Comparison of blue and brown objects in RGB colour space. Magnified blue object from artificial image (top-left) and its line profile (top-right); brown object (bottom-left) and its line profile (bottom-right).

In Table III are presented values of sensitivity, specificity, and Jaccard's coefficient for all tested methods on all proposed layers (channels) as mean performance on all test images.

As we stated before segmentation of red channel gives better results than green or blue channel. This also is confirmed while analysing separate methods instead of their mean value. For red channel best sensitivity is achieved by Sauvola method which has also worst specificity value. Contradictory is Palumbo method with best specificity and lowest sensitivity. White method has best value of Jaccad's coefficient and quite good sensitivity and specificity values, both above 0.90. Another to consider is Bernsen method with second highest Jaccard's coefficient and values of sensitivity and specificity above 0.91.

Layer $L$ from Lab colour space presents information about Luminescence in the image. For this layer Sauvola and Palumbo methods have similar results as for red channel. Highest sensitivity and lowest specificity by Sauvola; highest specificity and lowest sensitivity by Palumbo. Best value of Jaccard's coefficient is achieved by HybridSauvola method but it has lower value than for red channel of RGB.

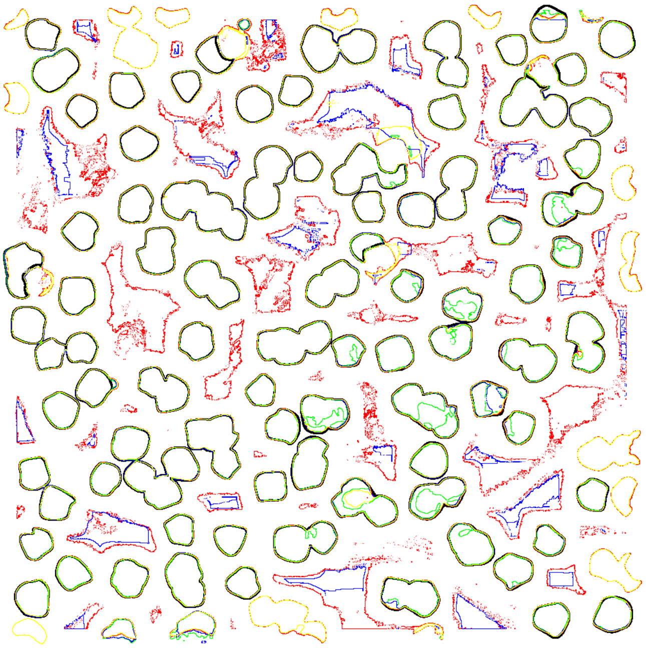

Fig. 2. Comparison of 4 methods performance on Haematoxylin layer. Sauvola—red; Palumbo—green; Bernsen—blue; White—yellow.

Layer $b$ from Lab colour space shows slightly different results. Best value of sensitivity has once again Sauvola method, and also worst specificity. HybridSauvola method seems to increase the specificity of Sauvola method to satisfactory level (0.937) but unfortunately simultaneously lowers the sensitivity value. White method has highest value of specificity but also lowest sensitivity. Palumbo method has acceptable results of sensitivity and specificity, 0.886 and 0.970 respectively, with best value of Jaccard's coefficient.

Last and possibly most interesting tested layer was Haematoxylin created with colour deconvolution. As it was for other

| Yasuda | 0.7356 | 0.9655 | 0.6849 | | 0.7652 | 0.9276 | 0.6524 | | 0.8959 | 0.9434 | 0.7911 |

where: $r_J$ - Jaccard's coefficient; deconv. - colour deconvolution.

layers Sauvola has highest sensitivity and lowest specificity, while Palumbo has highest specificity and lowest sensitivity. The best results according to Jaccard's coefficient are achieved by White method, and it has relatively good results of sensitivity and specificity, 0.930 and 0.964 respectively. Other methods worth considering using on this layer are Bernsen and HybridNiblack with second and third best values of Jaccard's coefficient. Figure 2 shows comparison of 4 most efficient methods that perform segmentation on Haematoxylin layer. Black thick outline of 'gold standard' objects is covered with 4 colour overlays representing 4 methods of segmentation; Sauvola—red, Palumbo—green, Bernsen—blue, White—yellow.

Overall, best results are achieved for *b* layer of Lab colour space and Haematoxylin layer of colour deconvolution. Slightly higher values of specificity can be observed as results of segmentation *b* layer of Lab colour space. Also, slightly higher values of sensitivity are achieved for Haematoxylin layer. On the whole, according to Jaccard's coefficient best of all methods is White method segmentation performed on Haematoxylin layer.

## IV. DISCUSSION AND CONCLUSION

The main aim of this investigation is to analyse performance of adaptive thresholding methods and to gather knowledge how to design the new better method based on this approach. We evaluated performance of 8 methods of segmentation applied to: separate channels of RGB, L and b layer of Lab colour space, and Haematoxylin layer after colour deconvolution. Best results were achieved for b layer of Lab colour space and Haematoxylin layer of colour deconvolution, so only these two should be taken into further consideration. Comparing results of all 8 methods, we concluded that only 4 have future potential: Sauvola, Palumbo, Bernsen, and White. Hybrid methods are also worth mentioning, they tend to have better overall results than their unmodified counterparts based on the Jaccard's coefficient.

Sauvola has best overall sensitivity, what means that there are not many false negative pixels, so there are least pixels representing 'true' objects not included into segmented image. The area of segmented objects of interest seems to be properly segmented; it does not change shape of segmented objects significantly. This method has problem with vast areas of clear background as there are less intensity variations. The extra segmented objects could be discarded from the results during validation phase or if compared to other segmentation method.

Quite the opposite, Palumbo in general has best specificity. The false positive pixels are minimal for this method. Unfortunately it does not segment full area of objects of interest and they have holes as a result. The main advantage of this method is that there are very little extra segmented pixels.

Bernsen has moderate results. It does not affect object size and the error in area detection is regularly located on border part of object. With too large window the method works slow and tends to misclassify small objects with low contrast, especially when they are located near objects with better contrast.

White method decreases the size of segmented objects. The local threshold level in the White method is dependent on bias which increase intensity of analysed pixel causes that the method perform well in images with high contrast between objects and background. Furthermore, in this investigation we adjusted the window size and values of the parameters especially for the tested images. The idea is to find criteria for automatic adjustment of parameters to fit to processed image. We should consider developing appropriate preprocessing phase that could equalize images [20] before they are segmented as it may improve results and make it easier to adjust parameter values.

As a result of this investigation we believe that there are three ways to improve segmentation of tested methods. First, globally, results of different methods could be merged using logical operands and probability analysis. For example, the results of the most accurate in object localization method could be used as seed points for the other methods with precise local area selection. Regrettably, the computational cost and time of computation could be quite high. Second, it seems object oriented analysis could give good results. Separate objects segmented by the best method could be evaluated by shape or colour features. Unfortunately, the immunonegative cells have wide range of these features, shape form round to elongated and colour from light blue to very dark. Also background has often blue tint that could distort the evaluation. Third, development of new method that would merge advantages of best tested methods. Since all four best methods are based on different factors, combining the benefits of variance method, centre-surround scheme, contrast based method, and bias method would not be easy but should give best results. This methodology could be most efficient regarding time and computation cost. As sliding window operations of adaptive thresholding methods tend to be slow it would be best to limit the number of whole image processing as much as possible.

### A. Future works

In future work, we plan to apply tested methods of segmentation to experimental images. If the results will not be satisfactory we plan to develop new method of segmentation based on the advantages of best of tested methods.

## Acknowledgment

We would like to thank Molecular Biology and Research Section, Hospital de Tortosa Verge de la Cinta, Institut dInvestigaci Sanitria Pere Virgili (IISPV), URV, Spain and Pathology Department of the same hospital for their cooperation and generous sharing of samples.

*Abstract*—**This contribution demonstrates how to apply concepts of social network analysis on educational data. The main aim of this approach is to provide a deeper insight into the structure of courses and/or other learning units that belong to a given curriculum in order to improve the learning process.**

**The presented work can help us discover communities of similar study disciplines (based on the similarity measures of textual descriptions of their contents), as well as identify important courses strongly linked to others, and also find more independent and less important parts of the curriculum using centrality measures arising from the graph theory and social network analysis.**

## I. Introduction

NOWADAYS, the process of improving educational curricula requires more sophisticated analyses of relevant datasets than in previous decades. Using various powerful virtual learning environments (see [7], [9], [14], [10], [5]) authorial teams consisting of curriculum designers and guarantors are able to construct a detailed description of each lecture, seminar and practice. The current curricula usually represent a huge amount of data records (thousands of standard pages in total), which cover all necessary requirements on the graduates based on a predefined structure in an online environment including formal and semantic verification. The main objective of this paper is to present an innovative approach of exploring the (medical) curricula in a transparent way. This approach is based on a proven concept of social network analysis (SNA), since SNA provides a natural way of dealing with graph notions such as centrality, and with various models of importance. The primary motivation for these investigations is to create a suitable tool/methodology for anyone who is involved in the complicated process of curriculum design at institutions of higher education. The research can help us when answering – among others – the following questions:

- Are there any content overlaps and/or gaps in the curriculum? (The overlaps might be desirable in some cases and undesirable in others).
- Which disciplines/courses/learning units are similar in terms of contents? And which are "self-standing"?
- Are there some significant communities (clusters) of disciplines/courses/learning units (such that a change of one may influence others)?
- Which disciplines/courses/learning units are probably the "central" parts of the curriculum?

The results of our analysis are intended to be used by the (human) experts responsible for the development and further evaluation of the curricula and institutional management, nevertheless they could also be interesting for students who want to study efficiently and focus mainly on the important parts of the study plan. We are going to introduce a methodology/data mining process that is fully compatible with the process of standardised knowledge discovery in databases (KDD). The data mining process was inspired by Trigo and Brazdil's works [16] and [2].

Our basic requirement on the selected approach is the simplicity and re-usability in practice. We use only a commonly available and free software (R), during the modelling stage, so the process can be repeated without any notable expenses. The possibility of straightforward visualisation is one of the advantages of this approach: we are able to show these content-based relations among textual descriptions of medical education (namely disciplines), not only the formal or organisational relations. Such visualisation can provide a quick and smart overview of a study plan and provide comprehensive information for the subsequent global in-depth curriculum inspection, which could be used for the future planning and changes in the curricula.

## II. Methodology

Data exploration was done in accordance with a proven KDD background, namely the standardised methodology CRISP-DM (CRoss-Industry Standard Process for Data Mining) [1]. This process is entirely independent of selected modeling tools and consists of a cycle that involves six stages (Fig. 1). Each stage represents an independent issue which must be completed in order to move forward. This methodology is used in a wide range of applications including biosciences, industry, even finance [12]. All of the CRISP-DM steps are described below for our setting.

We have already proposed a complex curriculum planning model supporting the outcome-based paradigm [8], which promotes a clear communication between the involved stakeholders (teachers, guarantors, curriculum designers, supervisors and faculty management) [11]. Based on a robust web-oriented

978-83-60810-66-8/$25.00©2015, IEEE

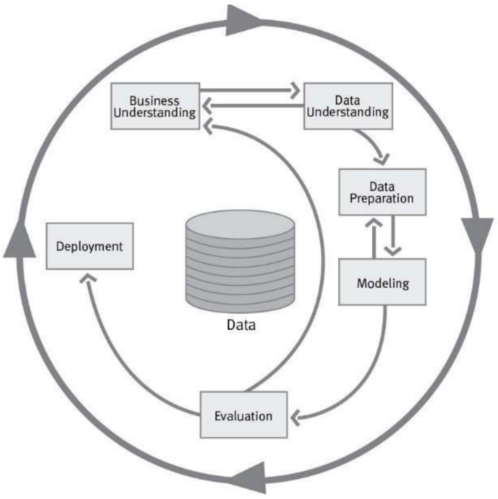

Fig. 1. Diagram of CRISP-DM.

platform for complex curriculum management which provides an effective tools for creating, transparent browsing, and reviewing the curriculum, a correctly compiled and balanced description of the General Medicine study field was defined by the authorial team consisting of 384 guarantors and teachers of the Faculty of Medicine at Masaryk University. It has covered more than 1300 learning units and 7100 learning outcomes, i.e. approximately 2500 standard pages of text. With respect to human cognition abilities, it is not possible to carefully read and verify the content of all learning units with all their linkages and co-dependencies. We have decided to apply the CRISP-DM methodology as a general framework to obtain a deeper knowledge from the medical educational data.

### A. Business understanding

Business understanding is an initial stage, which is focused on understanding the objectives and the problem definition – in our case, in terms of the in-depth exploration of medical curriculum in-depth exploration. The proposed goal is to detect outlying and overlapping areas in the General Medicine study field as well as investigate the mutual similarities of the courses involved. The whole study field is split into four individual modules (Diagnostic Sciences and Neurosciences, Internal Medicine, Surgical Sciences and Theoretical Sciences). These modules consist of 44 medical disciplines (such as Anatomy, Stomatology, Neurology, etc.). In total 144 courses are assigned to one or more disciplines are grouped together on a level of these disciplines for the purpose of this analysis. In this way, each discipline is generated from content-related courses across the entire study field (e.g. the discipline of Anatomy contains the following courses: Anatomy I – lecture, Anatomy I – seminar, Anatomy II – lecture, Anatomy II – practice).

### B. Data understanding

The follow-up stage – called data understanding – begins with the initial collection of data. Each course is described by a set of learning units using textual parameters and descriptors (see Table I). In our particular case, we have detected a set of descriptive attributes related to the learning outcomes, which were defined in accordance with the Bloom's taxonomy [13]. The Bloom's scheme provides a standardised classification of educational objectives that gives a commonly understood meaning to objectives classified in one of six main categories and many subcategories, thereby enhancing communication and achievement of more complex skills and abilities.

TABLE I
SELECTED ATTRIBUTES OF A LEARNING UNIT.

| Attribute | Type |
|---|---|
| learning_unit | varchar (255) |
| total_range | int (10) |
| meaning | text |
| annotation | text |
| mesh_keyword | varchar (255) |
| significant_term | varchar (255) |
| learning_outcome | varchar (500) |
| grouped_outcome | varchar (500) |
| primary_index | varchar (500) |
| secondary_index | varchar (500) |
| assessment_form | varchar (200) |

We have identified several attributes of learning outcomes mined from our curriculum management system, which can provide complete information about the coverage among various medical disciplines. All text data that we used was in English due to easier preprocessing steps.

*Teaser of textual data to be processed:*

```
Section:
-----
Surgical Sciences

Medical discipline:
-------------
Surgery

Group outcome:
---------
Abdominal aorta and its branches
Primary index: Arterial diseases
Secondary index: Closure, stenosis

Learning outcomes:
------------
- Student masters anatomy of arterial system.
- Student describes injuries to the abdominal aorta
and its branches.
- Student lists anatomy of abdominal aorta
and its branches.
```

### C. Data preparation

The stage of data preparation is a necessary prerequisite before applying any mathods of data mining and/or SNA. It consists of a sequence of procedures to create the final dataset from the initial raw data.

Each discipline was represented by a single plaintext file that contains merged contents of several fields from Table I, namely learning_outcome, grouped_outcome, primary_index, secondary_index.

The collection of these plaintext files was loaded as a corpus into the `R` system extended by a couple of packages `tm` and `lsa` – standard packages for text mining and latent semantic analysis. After tokenization at this stage, several standard preprocessing issues were performed – in the following sequence:

- transformation to lowercase,
- stemming (using Snowball),
- punctuation removal,
- numbers removal,
- stopwords removal,
- whitespace stripping.

Similarly to the work by [16] we have chosen a bag-of-words representation of the documents in the corpus and a document-term-matrix was generated. (*tf-idf* weighting [6] was used). Consequently, dissimilarity matrices were computed on the basis of cosine similarity. Values were rounded to two decimal digits and values lower than a certain threshold were replaced by zeros, since extremely low similarities were considered as irrelevant.

### *D. Modeling*

Generaly, various modeling techniques are selected and applied at this stage – SNA methods were applied in our case. Since some of the algorithms involved have several parameters, this stage also contains experiments with different values of these parameters.

*Application of social network analysis – centrality concepts on the similarity graph:* The dissimilarity matrix can be viewed as an adjacency matrix of a similarity graph – undirected graph with weighted edges. On this graph we are going to perform several calculations of centrality measures. Obviously, these values should be interpreted differently – with respect to the roles of disciplines/courses/learning units in the educational framework. We are going to deal with the following centrality measures:

*Closeness* – The closeness centrality of a node $v$ in a graph $G$ is defined by the inverse of the sum of the lengths of the shortest paths to/from all the other nodes in the graph $G$, i. e.:

$$c(v) = \frac{1}{\sum_{i \in V(G), i \neq v} d(i, v)},$$

where $d(i, v)$ is the length of the shortest path from node $i$ to node $v$ and $V(G)$ is the set of all vertices of the graph $G$.

If there is no path between a couple of nodes then the total number of nodes of the graph is used instead of the path length. By the mentioned calculation we obtain the so-called *raw closeness* of the node. To get normalised closeness of the node $v$, we multiply the raw closeness by $n - 1$, where $|V(G)| = n$: we are going to use this normalised version. Nodes (disciplines) with low value of closeness are those disciplines with their content distant from other ones, thus, roughly speaking, they are independent on the others.

*Betweenness centrality* – In the simplest case (without edge weighting), the raw betweenness centrality of a node $v$ corresponds with the number of shortest paths from all nodes to all others that go through a considered node, i. e.:

$$b(v) = \sum\nolimits_{i,j,v \in V(G), i \neq j, i \neq v, j \neq v} \frac{g_{ivj}}{g_{ij}},$$

where $g_{ij}$ is the total number of shortest paths going from node $i$ to $j$ and $g_{ivj}$ is the total number of all shortest from node $i$ to node $j$ going through $v$. To get normalized betweenness $b_n(v)$ of the node $v$, we calculate $b_n(v) = \frac{2b(v)}{(n-1)(n-2)}$, where again, $|V(G)| = n$.

This definition can be extended for weighted networks. Nodes (disciplines) with a high betweennes centrality are those that are the best for joining the students' knowledge from different collections of disciplines.

*Eigenvector centrality* – One of the methods of computing of approximate importance of a given node. The idea behind this measure is that centrality of each node is the sum of the centrality values of its neighbour nodes. More precisely, the eigenvector centrality values correspond to the values of the first eigenvector of the adjacency matrix. The eigenvector centrality in our case models identification of important disciplines of the curriculum.

All these computations are done using the `igraph` package [3] that contains several built-in functions covering the area of SNA. The values of these measures were normalised in a relevant way. According to our goal, our intention of this stage is to find out nodes (disciplines) with high values of proposed measures to identify the core and important parts of the curriculum and, in contrary, also the nodes (disciplines) with lowest values of centrality measures to identify those that are relatively independent of others.

Extremely low values of these attributes can also indicate a non-proper description of the discipline (e.g. missing important parts of the description). Disciplines with the most interesting results (means highest values of centrality measures attributes) are presented below.

*Ten disciplines with the highest betweeness centrality:*

1) Pathological physiology (0.265),
2) Physiology (0.164),
3) Surgery III (0.140),
4) Pathology (0.111),
5) Clinical examination in neurology (0.104),
6) Neuroscience (0.083),
7) Immunology (0.070),
8) Intensive care medicine (0.065),
9) Biology (0.065),
10) Preventive medicine (0.063).

*Ten disciplines with the highest closeness centrality:*

1) Pathological physiology (0.106),
2) Pathology (0.105),
3) Clinical examination in neurology (0.105),
4) Immunology (0.105),
5) Biology (0.105),
6) Surgery III (0.105),
7) Internal medicine – part 4 – Gastroenterology and haematology (0.105),
8) Intensive care medicine (0.105),
9) Clinical oncology (0.105),
10) Histology and embryology (0.105).

*Ten disciplines with the highest eigenvector centrality:*

1) Pediatrics II (1.000),
2) Pediatrics III (0.904),
3) Clinical oncology (0.867),
4) Surgery I-II (0.842),
5) Surgery III (0.819),
6) Pathology (0.782),
7) Internal medicine – part 4 – Gastroenterology and haematology (0.522),
8) Clinical examination in surgery (0.406),
9) Dermatovenerology (0.375),
10) Pathological physiology (0.358).

On the oposite side there are disciplines with low values.

*Disciplines with zero betweenness centrality:*

- Anatomy II,
- Basic medical terminology I,
- Clinical examination in internal medicine,
- Communication and selfexperience,
- Community medicine,
- Diagnostic imaging methods,
- Family medicine and geriatrics,
- Gynecology and obstetrics,
- Internal medicine – part 2 – Cardiology and angiology,
- Internal medicine – part 6 – Occupational medicine,
- Medical ethics I,
- Medical ethics II,
- Medical chemistry,
- Medical microbiology II,
- Medical psychology,
- Nursing,
- Ophthalmology,
- Orthopaedics,
- Pediatrics II,
- Pharmacology I,
- Stomatology.

*Ten disciplines with the lowest closeness centrality:*

1) Anatomy II (0.098),
2) Medical ethics I (0.017),
3) Medical ethics II (0.017),
4) Basic medical terminology I (0.017),
5) Communication and selfexperience (0.017),
6) Diagnostic imaging methods (0.017),
7) Family medicine and geriatrics (0.017),
8) Nursing (0.017),
9) Ophthalmology (0.017)
10) Stomatology (0.017).

*Ten disciplines with the lowest eigenvector centrality:*

1) Medical microbiology II (0.013),
2) Clinical examination in internal medicine (0.009),
3) Pharmacology II (0.006),
4) Medical psychology (0.004),
5) Anatomy III (0.004),
6) Anatomy II (0.001),
7) Pharmacology I (0.001),
8) Anatomy I (0.001),
9) Medical ethics II (0.000),
10) Medical ethics I (0.000).

*Interpretation:* In general, we show medical disciplines with extreme (the highest/the lowest) values of selected centrality measures. The achieved results represent novel and hopefully useful information about the structure of the General Medicine study field created in the curricula. For instance, Pathological physiology and Pathology appear in all top-ten lists in all centrality measures, Surgery III, Clinical examination in neurology, Immunology, Biology, Internal medicine – part 4 – Gastroenterology and haematology, Clinical oncology in two of them. It may indicate that these disciplines belong purposely to an essential part of the curriculum or, on the contrary, it may reveal an undesirable preference of mentioned disciplines, which in fact cannot be identified by a visual human inspection. So, logically the final interpretation has to be done under the supervision of responsible curriculum designers and senior guarantors, who are familiar with optimal composition and intersections of individual disciplines, courses and learning units.

*Application of social network analysis – community detection on the similarity graph:* The community detection is a common task when dealing with social networks. Communities, i.e. densely connected subgraphs have also an importance for exploring the curricula: communities correspond with subsets of mutually close disciplines (with respect to content similarity). In contrast to hard clustering we do not insist on the rule that each item (discipline) is contained in just one cluster (community).

For detecting communities, the Walktrap algorithm [15] was used. The main idea of this algorithm is that short random walks tend to stay in the same community, see [3]. The implementation of this algorithm is also contained within the `igraph` package in `R`, and for our purposes it was executed with a parameter of length of the random walk set to $k = 4$.

Fig. 2 provides a basic overview of communities that were found. The thickness of the edges corresponds with the similarity between nodes (disciplines). Communities are bounded shapes with a grey background color. As we can see, we have several "singleton" communities along with some bigger ones that establish the core of the curriculum.

Fig. 2. Overview of the curriculum with marked communities.

- Examples of larger communities: {Preventive medicine, Health care and policy, Community medicine, Biophysics, Internal medicine – part 6 – Occupational medicine, Epidemiology of infectious diseases}, {Medical chemistry, Biochemistry I, Biochemistry II }, . . .
- Examples of independent communities: {Nursing}, {Diagnostic-Imaging methods}, {Communication and self experience}, . . .

A detail of a community within the entire graph is shown in Fig. 3. There are also communities connecting just disciplines divided into two parts, such as Medical ethics I and Medical ethics II, Pharmacology I and II, etc. These results surely are not coincidental; quite the opposite, they confirm the reasonability of the method.

### *E. Evaluation and Deployment*

A checking procedure is performed in this stage in order to find the right meaning of analytical outputs. The obtained results were verified by representatives of the faculty management, in order to confirm the final interpretation. It may indicate either balanced or unbalanced representation of compulsory and optional courses intended for graduation to obtain professional qualification for employment as a physician. The curriculum visualisation based on the location of individual disciplines and their coloured marking is useful with regard to the possibility of a comprehensive evaluation of the curriculum structure. It makes it possible to identify weak points and shortcomings in terms of inconvenient interdisciplinary relations, as well as remote disciplines with hardly any relations to other disciplines. Additionally, the visualisation can very easily confirm the consistency of individual specialised disciplines, which leads to the idea of correctly specified requirements on the acquired knowledge and skills of future physicians. Currently, the final process of deployment is still ongoing. In the end, presented visualisation will be integrated directly into the curriculum management platform as an additional overview module.

## III. Conclusion and Future Work

In this work we have introduced a novel method for exploring general curricula that uses several concepts of social network analysis. The presented use-case provides an easy-to-understand visualisations of the entire medical curriculum and centrality models involved disciplines. The entire process of obtaining the knowledge is done according to an industrial standard in data mining (CRISP-DM). Our plans for further work are described below.

*1) Improving the similarity graph:* In this experimental stage, only a part of the accessible data was used

(learning_outcome, grouped_outcome, primary_index, secondary_index). Further development of this approach will be based on incorporating data such as the MeSH [4] terms. There is also an opportunity to experiment with weights: terms contained in certain controlled vocabularies, thesauri, ontologies etc. can be taken with boosted weights. The "NLP" stage will be improved in several ways, for example dealing with synonyms, hypernyms etc.

*2) Enriching the visualisation:* At this stage, we have only focused on the structure of the similarity graph and visualisation of obtained communities – that is, in fact, the core of the original work. Hence we have only used a small amount of attributes of the produced graph, i. e. the thickness of the edges (and vertices grouping). The remaining parameters of the visualisation can therefore carry additional formal, organisational or empirical data:

- The size of a node should correspond with the total number of teaching hours per discipline.
- The color of a concrete node can be chosen accordingly to a given classification of the discipline.
- The opacity should correspond with the importance of the node – the eigenvector centrality (or some other attribute of the discipline (for example, the ratio of students that fail the exams).
- Textual labels of the nodes can be used for information about the number of students attending the discipline.
- Edges on another layer (represented in a different color) can link a discipline having the same lecturers.

Both of these activities might lead to more information-rich visualisations that would provide a better insight to the specific curriculum which will be evaluated manually by experts in the near future.

## Acknowledgment

We would like to express our special thanks to the management of the Faculty of Medicine at Masaryk University, represented by Prof. Jaroslav Štěrba (Vice-Dean for Education in Clinical Branches) and Prof. Jiří Mayer (Dean of the Faculty of Medicine), and also to the Institute of Biostatistics and Analyses at Masaryk University represented by Assoc. Prof. Ladislav Dušek.

***Abstract*—Statistical analysis of medical data plays significant role in medical diagnostics development. However in many cases the statistics is not effective enough. In the paper we consider combining statistical inference with clustering in the preprocessing phase of data analysis. The proposed methodology is checked on cardiovascular data and used for developing methods of early diagnosis of hypertension in children. Experiments, conducted on the real data, have demonstrated that the proposed hybrid approach allowed to discover relationships which have not been identified by using only the statistical methods. We have observed approximately 30% growth in the number of correlations between diagnosed attributes. Moreover all the obtained statistically significant dependencies were stronger in clusters rather than in the whole datasets.**

## I. Introduction

IN RECENT years medical progress as well as the equipment development make possible collecting the increasing amount of data. One can expect that their analysis will help medical practitioners in improving patient care, proposing new therapies or developing the existing ones. However, statistical analysis, which is commonly used to support medical diagnosis, in many cases, turns out to be not effective enough. Such situation takes place, when the correlations between parameters, which seem to be useful for medical inference, are not possible to obtain. For example, it might happen, when standard deviation in the dataset takes on the large value [1].

To improve the performance of statistical models, we propose the new approach, which consists in including clustering in the preprocessing phase. Both of the techniques have already been broadly investigated in medical applications, but their combination has not been examined as supporting tools for medical diagnosis so far. The presented approach enables to identify groups of similar instances, for which statistical models can be built effectively. Special attention is drawn to feature selection process. We assume that the set of attributes used in clustering and statistical analysis phases should be different, not correlated and consistent with the process of medical diagnosis as well as the state of art of the approaches to statistical analysis of the medical data (see [2] for example).

In the paper we focus on cardiovascular diseases, which are the leading causes of death in the majority of countries [3]. The research aims at developing methods for early diagnosis of hypertension (high blood pressure) in children. The proposed methodology was verified by experiments done on three different sets of real children cases. Experiment results showed that application of the cluster analysis effectively supports statistical inference for the diagnosis in the considered cardiovascular problem.

The remainder of the paper is organized as follows. In Section II relevant work is presented. Next, the medical issues of hypertension problems in cardiovascular diagnosis are introduced, then the proposed methodology is described. In the following section, the experiments conducted on real data are depicted. Finally, the results are discussed and some concluding remarks are presented.

## II. Related Work

In medicine most of the rules for diagnosis and treatment are based on statistical analysis. However, new challenges connected with medical data analysis impose application of more sophisticated methods such as data mining techniques which ensure the process improvement. Application of data mining techniques in biomedical and healthcare fields was discussed by Yoo et al. [4]. The authors stated that descriptive and predictive power of data mining could be widely used in these areas.

Cluster analysis has already been integrated with statistical methods for medical data in the research of Haldar [5]. However the goal of the study was not do discover new dependencies, but to define the phenotypes of clinical asthma. The research was proposed against other models of asthma classification and according to authors it might have played a supporting role for different phenotypes of heterogeneous asthma population. A survey of data mining methods that has been applied to traditional Chinese medicine (TCM) clinical data systems was provided by [6]. Cluster analysis, association rules, a latent structure model and a topic model were considered in the context of Chinese medicine.

In [1] different clinical decision support systems for heart disease prediction and diagnosis were compared. These systems were based on such data mining techniques as: a multiplayer perceptron, genetic algorithms, fuzzy rules, decision trees and Bayesian networks. As the result of investigations the authors stated that the considered techniques are not satisfactory and finally there is still lack of a solution for the

978-83-60810-66-8/$25.00©2015, IEEE

identification of treatment options for the patients with heart diseases.

In [7] a statistical inference of heart rate and blood pressure was examined. The authors considered three different approaches. The first one was based on examining correlation between raw data. Then since the measurements could be corrupted by noise, a filtration procedure was performed on data before correlating the signals. In the last approach least squares approximation was applied. The results of all of the techniques were similar. The obtained correlation coefficients seemed to be an unpredictable random numbers.

Meng et al. [8] compared the performance of logistic regression, artificial neural networks and decision tree models for predicting diabetes or prediabetes using common risk factors. The research proved the advantages of decision tree model comparing to the other considered techniques. The authors of [9] examined the performance of the alternate classification methods, such as bootstrap aggregation, boosting, random forests and support vector machines with conventional classification trees to classify patients with heart failure. Bashir et al. [10] proposed combination of three classifiers for intelligent heart disease diagnosis. Broad review of data mining techniques applied in this area was presented in [11].

## III. Hypertension Problems in Cardiovascular Diagnosis

Hypertension is the cardiovascular disease, which may have their onset in the young [12]. Hence arterial hypertension is a significant problem in pediatric practice. It is estimated that this pathology affects 3-5% of the total children population, while for teenagers the percentage of hypertension cases increases up to 10%. Therefore finding effective methods which support early diagnosis of hypertension and thus help in implementing an appropriate management to prevent the disease is currently the matter of interests of many researchers.

Hypertension is mainly defined on the basis of blood pressure measurements. However the initial cardiac data can be characterized by over 50 attributes. All patients undergo physical examination, manual arterial blood pressure measurements (RR SBP, RR DBP), ambulatory blood pressure monitoring (ABPM-S, ABPM-D), echocardiographic examination to evaluate cardiac function using standard parameters (ejection fraction, shortening fraction and myocardial performance index) and tissue Doppler examination (systolic mitral annular velocity profile and regional function parameters: velocity, strain, strain rate). A selection of attributes, which cardiologists use to diagnose arterial hypertension (see [13], [14] and [15]) is shown in Table I. The first two columns of the table contain names and descriptions of selected parameters, the third one presents ranges of attribute values.

To improve early detection of hypertension in children, the researchers look for new factors, which may indicate the high blood pressure appearance [16]. Medical data analysis helps in evaluating the characteristics of the variables in the data sets of healthy and diagnosed children and discovering the relationships between all the parameters. The detailed medical descriptions and statistical analysis of these issues were subjects of the research presented in [13], [14] and [15]. The authors stated that the high value of standard deviation in the dataset disabled obtaining some of the correlations between parameters, which could have been useful for medical inference. That fact motivated us to build methodology described in the presented paper.

TABLE I
The selection of parameters collected for arterial hypertension evaluation

| **Name** | **Description** | **Range** |
|---|---|---|
| HA | Arterial hypertension presence | Nom. (Yes/No) |
| BMI | Body mass index | 11.9 - 31.6 |
| BWT | Body weight | 14.6 - 88.0 |
| BSA | Body surface area | 1.4 - 2.2 |
| HC | Head circumference | 29.0 - 36.0 |
| PI | Ponderal index | 14.58 - 26.20 |
| RR SBP | Manual measurement of systolic blood pressure | 86 - 150 |
| RR DBP | Manual measurement of diastolic blood pressure | 44 - 87 |
| ABPM-S | Ambulatory systolic blood pressure monitoring | 19 - 87 |
| ABPM-D | Ambulatory diastolic blood pressure monitoring | 4 - 78 |
| IVSd | Interventricular septum | 5 - 14 |
| PWDs | Posterior wall thickness | 11 - 19 |
| TG | Triglyceride Level | 24 - 236 |
| E/A | Ratio of the early to the late mitral inflow velocities | 1.15 - 1.77 |
| DecT | Deceleration time - time interval of peak E-wave velocity to its extrapolation to the baseline | 126 - 325 |
| AEF | Atrial ejection force | 4570 - 9158 |

## IV. Materials and Methods

In medical research, an analysis of the results of observations plays the crucial role, as its effects are expected to be implemented into practical applications. The process of medical research is usually supported by statistical analysis but very often it is not effective enough. In many cases, dissimilarities or inconsistency within the data sets appear due to incorrect measurements or distortions. The presence of such deviations may lead to the rejection of true hypothesis in the case of small data sets. The use of clustering before conducting a statistical analysis allows to identify groups of similar cases, and thus to better evaluate respective parameters.

The proposed methodology of improving medical inference process from a medical data set consists of three main steps:

- feature selection, which enables choosing the set of attributes for building clusters,
- clustering based on the parameters indicated by the previous step to distinguish groups of similar characteristics,

- statistical analysis performed in clusters to find new dependencies between all the collected parameters.

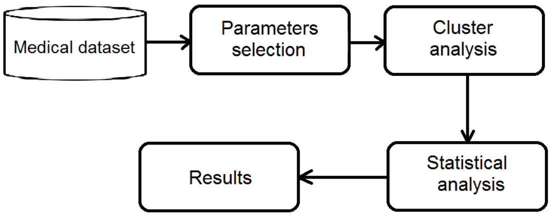

Fig. 1. System architecture for improved knowledge discovery using clustering techniques.

The general structure of our approach is shown on Fig. 1. We assume that clustering and statistical analysis are applied on the preprocessed and transformed data, and are preceded by feature selection process. The description of each step is presented in the following subsections.

### A. Feature Selection

Feature selection is a technique of choosing an appropriate subset of the available attributes, which ensures building the model with high classification accuracy. In medical data analysis there exist two main feature selection approaches: using of automatic feature selection mechanisms or selecting parameters as a result arising from the process of medical diagnosis. The first one was considered in [17]. The authors tried to provide a generic introduction to variable elimination, which can be applied to a wide range of machine learning problems. They considered filter, wrapper and embedded methods. However, they found out that comparison of feature selection methods can only be done on the data of the same characteristics.

Cheng, in turn, stated that in the case of cardiovascular diseases the feature subsets selected in the process of medical diagnosis improve the sensitivity of the analysis [18]. Such approach will be used in the proposed methodology, to obtain a set of attributes for further analysis.

### B. Clustering

Cluster analysis is one of the most commonly used data mining techniques, as it may be applied to classify complex data of many variables and many dimensions. Unlike discriminant analysis, no classification variables are inserted to divide the original data. What is more, in many cases, when the groups are detected, it is necessary to use other methods to discover the meaning of clustering [19]. Therefore, combination of cluster analysis and statistical inference seems to be the effective tool supporting medical diagnosis.

During investigations of the effectiveness of the proposed methodology, two different clustering approaches: deterministic and probabilistic were considered. As the presented technique aims at supporting physicians in making medical diagnosis, there were chosen simple comprehensible algorithms, because doctors should understand the tools they use. In the first group, k-means algorithm has been considered. In the case of medical data, this technique gives higher accuracy and lower root mean square error (RMSE) in comparison with other clustering methods, such as fuzzy C-means clustering, mountain clustering or subtractive clustering [20]. As the probabilistic method, expectation-maximization (EM) algorithm has been investigated. EM uses the finite Gaussian mixtures model to generate probabilistic descriptions of clusters in terms of means and standard deviations [19].

*1) The K-Means Algorithm:* The k-means algorithm is one of the most popular clustering method. The clusters in data set are defined by minimizing a distance (dissimilarity) function. In most of the cases Euclidean metric is considered as distance function [2],[21].

Let us consider the set of n data $X = \{x_i; i = 1, ..., n\}$ and the set $C$ of $k$ cluster centers $C = \{c_j; j = 1, ..., k\}$. For a given $k$, the goal of clustering is to find $C$ for which the function determined by (1) achieves its minimum.

$$min_j \left( \sum_{i=1}^{n} \|x_i - c_j\| \right) \tag{1}$$

The algorithm for k-means can be described as follows [21]:

1) Randomly choose $k$ data points from $X$ as the initial set $C$ of cluster centers. Denote them by $c_j, j = 1, ..., k$.
2) Reassign all $x_i \in X$ to the closest cluster mean $c_j$
3) Update all $c_j \in C$ as means of the points assigned to the corresponding clusters.
4) Repeat steps 2 and 3 until cluster assignments do not change.

Choosing $k$ initial centers at random, does not guarantee finding optimal clusters. To increase the chance of finding a global minimum in (1), it is usually suggested to run the algorithm several times with different initial choices and pick out the best final result - the one with the smallest total squared distance [21].

*2) The EM Algorithm:* The expectation - maximization (EM) algorithm is an iterative algorithm used to calculate maximum likelihood estimates in parametric models in the presence of missing data [22].

The goal of statistical models is to find the most likely set of clusters on the basis of training data and prior expectations. Expectation- Maximization algorithm (EM) uses the finite Gaussian mixtures model to generate probabilistic descriptions of clusters in terms of means and standard deviations [19]. The big advantage of EM algorithm is a possibility to select a number of clusters by cross validation techniques, what allows to obtain its optimal value [21]. That feature allows not to determine the number of clusters at the beginning. Similarly to k-means method, parameters are recomputed until the desired convergence value is achieved.

*3) Optimal Number of Clusters:* One of the most important issue connected with clustering is an identification of the optimal number of clusters. There exist different approaches to solve this problem.

In the case of k-means algorithm, the technique called elbow criterion has been considered. The elbow criterion says that one should choose a number of clusters, such that adding the next one does not increase quantity of information sufficiently [23]. When a graph for a validation measure calculated in the clusters is plotted against the number of clusters, at first amount of information is increasing, but at some point the gain starts decreasing, giving an angle in the graph, that is called the elbow.

In some cases, elbows cannot be unambiguously identified. Therefore it may be helpful to use another validation method for finding optimal number of clusters. As in the case of EM algorithm the optimal number of clusters can be determined by cross validation technique [21], the number of clusters indicated by elbow criterion can be confirmed by EM clustering.

It is worth mentioning that in medicine the number of clusters is very often equal to two as there exists common intention to split the whole data set into two groups [20]. Besides, when the number of considered instances is small, what very often takes place in medical applications, the bigger number of clusters would decrease the group sizes and as a consequence would make the medical inference less reliable as it is difficult to obtain sufficiently high power of statistical tests [2],[24].

### C. Statistical Analysis

Statistical data analysis usually begins with an assessment of measures of descriptive statistics, which allows to detect errors that were not identified during data preparation phase. The basic descriptors, for which the evaluation is indicated, include measures of central tendency (arithmetic mean, median and modal), measures of dispersion (range and standard deviation). Next statistical inference using a suitable test is carried out. The selection of the test is made on the basis of the type and the structure of the analyzed data. It depends on attribute types, scale type, number of experimental groups and their dependency, as well as the test power. The test selection should be done in accordance with the requirements of the USMLE (The United States Medical Licensing Examination). In the current research, we will consider the tests commonly used in medical diagnosis problems [1]:

- Kolmogorov-Smirnov test, which is used to test for normality of distribution of the attributes,
- Unpaired two-sample Student's *t*-test for the significance of a difference between two normally distributed values of attributes,
- Mann-Whitney U test, which is a non-parametric test for significant differences determination, where attributes were in nominal scales.

The impact of one variable measured in an interval or ratio scale to another variable in the same scale can be expressed using the Pearson's correlation coefficient $r_P(x, y)$. In the case where one or both of the variables are measured with an ordinal scale, or variables are expressed as an interval scale, but the relationship is not a linear one, the Spearman's correlation $r_S(x, y)$ test is used.

## V. Experimental Analysis and Results

The main objective of the experiments was to examine the performance of the proposed approach by comparing the results derived from statistical analysis carried out on clusters with the ones obtained for the whole datasets. The experiments were conducted on the real datasets, which were gathered for early diagnosis of arterial hypertension in children.

### A. Data Description

There have been considered three different datasets ("HEART", "ECHO", "IUGR") collected from children hospitalized in the University Hospital No 4, Department of Cardiology and Rheumatology, Medical University of Lodz. Each of the dataset was examined for the particular cardiovascular problem:

- "HEART" - to discover dependencies between arterial hypertension and left ventricle systolic functions,
- "ECHO" - to evaluate correlations between arterial hypertension and myocardial functions using tissue Doppler echocardiography,
- "IUGR" - to discover dependencies between abnormal blood pressure and being born as small for gestational age.

The "HEART" dataset consisted of 30 cases, the "ECHO" dataset of 66 instances and the "IUGR" dataset contained 50 specimens. There were no missing values within attributes.

### B. Cluster Analysis

In the first step of the experiments, the clusters for diagnosed children were created by using two clustering algorithms: k-means and EM implemented by WEKA Open Source software [21].

Clusters were built taking into account attributes according to feature selection method consistent with the process of medical diagnosis (see [2]). In the case of arterial hypertension, diagnosis performed by medical expert is mainly based on the blood pressure measurements (either manual or ambulatory monitored). The rest of the attributes are usually supportive for medical staff as each of them separately cannot indicate the disease and multivariate analysis is difficult to perform without any computer support. Therefore for "HEART" and "ECHO" datasets we considered 4 attributes: RR SBP, RR DBP, ABPM-S and ABPM-D in accordance with hypertension diagnosis (see Table I). In the case of "IUGR" dataset we used 3 attributes: birth weight, head circumference and ponderal index as consistent with the diagnosis of intrauterine growth restriction (being born as small for gestational age), and included 16 risk factors (i.a. hypertension in relatives, smoking during pregnancy) in a feature selection subset, which may have an impact on intrauterine growth restriction [28].

To choose the best number of clusters the elbow criterion has been applied. As validation measure, within cluster sum of squares has been considered. As the result, the charts for validation measures plotted against number of clusters indicated elbow points c=2 for "HEART" and "ECHO" datasets and c=3 for "IUGR" dataset (see Fig. 2).

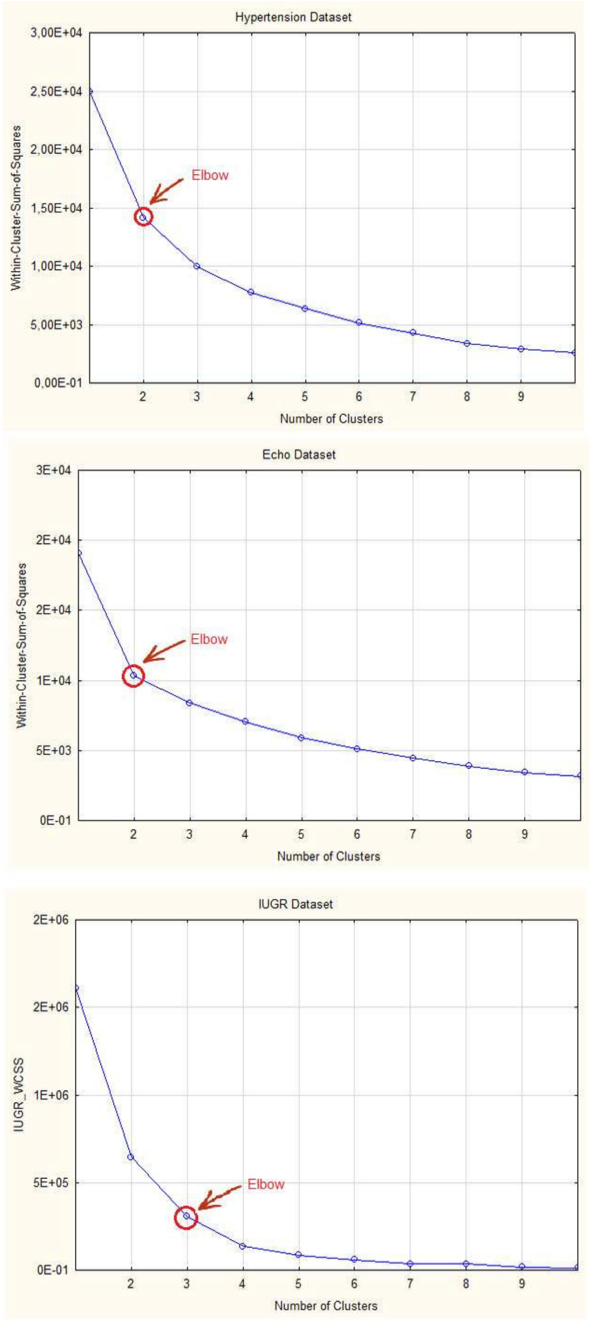

Fig. 2. Elbow charts for number of clusters determination.

Additionally to elbow criterion, EM algorithm which automatically generated number of clusters by using cross-validation [21] was implemented. The obtained results (c=2 for "HEART" and "ECHO" datasets and c=3 for "IUGR" dataset) confirmed the proper choice of the number of clusters.

It is worth mentioning that during clustering process, the subgroup characterized by higher mean values of parameters concerning arterial hypertension and lower standard deviations of those attributes or ,in the case of "IUGR" dataset, lower mean values of parameters concerning birth weight and size, was distinguished. In the case of "HEART" that subgroup consisted of 22 cases for k-means algorithm and 23 for EM method, "ECHO" subset included 44 and 35 instances respectively, "IUGR" subgroup contained 19 specimens for k-means algorithm and 25 for EM method. Sizes of the clusters for all the datasets are presented in Table II.

TABLE II
SIZES OF THE CLUSTERS

| Dataset | Numbers of instances in clusters | |
|---|---|---|
| | k-means clustering | EM clustering |
| HEART | 8, 22 | 7, 23 |
| ECHO | 22, 44 | 31, 35 |
| IUGR | 19, 14, 14 | 25, 15, 7 |

### C. Statistical Analysis

Analysis of correlations among datasets, in order to support medical knowledge acquisition and decision making, is still one of the most popular techniques in medical research [25]. Therefore next step of the experiments concerned indication of the attributes, which are not significantly correlated with the ones used for building clusters, and thus can be used in statistical analysis process. By insignificant correlation we mean values with correlation coefficient r<0.3 and p-value>0.05 ([26], [27]). Tables III, IV, V and Fig. 3 present correlation values of the features used in clustering and the ones indicated for statistical analysis.

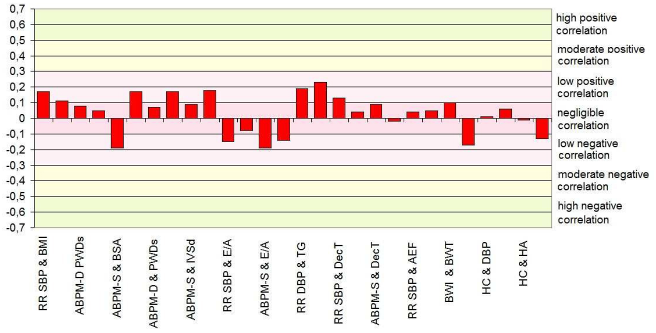

Fig. 3. Values of correlation coefficient between attributes used for clustering and statistical analysis.

Correlation values obtained for the clusters were compared to the ones got for the whole group of diagnosed children. Comparison of results confirmed effectiveness of the proposed methodology. For each dataset we obtained greater number of statistically significant correlations which may lead to improved medical diagnosis in the future. By significant correlations we mean values with correlation coefficient r>=0.3 and p-value<=0.05 ([26], [27]). The results of detected correlations are presented in Table VI, where the column (3) presents the numbers of discovered dependencies in clusters and the

TABLE III
VALUES OF CORRELATIONS BETWEEN FEATURES USED FOR CLUSTERING AND STATISTICAL ANALYSIS FOR "HEART" DATASET

| Attribute 1 | Attribute 2 | Corr. coeff. | p-value |
|---|---|---|---|
| RR SBP | BMI | 0.17 | 0.38 |
| ABPM-S | BMI | 0.11 | 0.55 |
| ABPM-D | BMI | 0.08 | 0.67 |
| RR DBP | BSA | 0.05 | 0.77 |
| ABPM-S | BSA | -0.19 | 0.31 |
| RR DBP | PWDs | 0.17 | 0.36 |
| ABPM-D | PWDs | 0.07 | 0.67 |
| RR SBP | IVSd | 0.22 | 0.23 |

Concluding, the results of the experiments have shown that the proposed approach, which consists of supporting statistical inference by clustering, significantly improved the effectiveness of the medical data analysis for all the considered datasets.

## VI. CONCLUSIONS

Typically, during the process of computer-aided clinical and epidemiological studies only one of selected data analysis method is involved. In spite of the mostly used statistical analysis, in the paper, a hybrid methodology of medical data analysis has been proposed. The presented method consists of combination of clustering and statistical inference, where the first technique is used as a data preprocessing tool for the second one. The investigations have shown that supporting statistical analysis by clustering provides significant benefits. Experiments conducted on the real data have demonstrated that

TABLE VII
SAMPLE VALUES OF CORRELATIONS DETECTED WITH AND WITHOUT CLUSTERING

| **Dataset name (1)** | **Correlation type (2)** | **Correlation coefficient (3)** | **Significance (p-value) (4)** |
|---|---|---|---|
| Whole dataset | | | |
| HEART | BSA & PWDs | 0.35 | 0.05 |
| | BWT & IVSd | -0.35 | 0.05 |
| | BMI & PWDs | 0.46 | 0.01 |
| ECHO | TG & E/A | -0.26 | 0.03 |
| | BMI & DecT | 0.29 | 0.02 |
| | SBP & AEF | 0.29 | 0.02 |
| IUGR | BWT & DBP | -0.36 | 0.01 |
| | HA & BWT | -0.24 | 0.08 |
| Clustering method: k-means | | | |
| HEART | BSA & PWDs | 0.55 | 0.01 |
| | BWT & IVSd | -0.47 | 0.03 |
| | BMI & PWDs | 0.62 | <0.01 |
| ECHO | TG & E/A | -0.45 | 0.03 |
| | BMI & DecT | 0.38 | 0.01 |
| | SBP & AEF | 0.59 | <0.01 |
| IUGR | BWT & DBP | -0.38 | 0.01 |
| | HA & BWT | -0.54 | 0.04 |
| Clustering method: EM | | | |
| HEART | BSA & PWDs | 0.51 | 0.01 |
| | BWT & IVSd | -0.45 | 0.03 |
| | BMI & PWDs | 0.61 | <0.01 |
| ECHO | TG & E/A | -0.44 | 0.01 |
| | BMI & DecT | 0.35 | 0.05 |
| | SBP & AEF | 0.46 | 0.01 |
| IUGR | BWT & DBP | -0.58 | 0.01 |
| | HA & BWT | -0.26 | 0.05 |

the proposed hybrid method allowed to discover relationships which have not been identified previously.

Depending on the dataset, the growth of 10% - 100 % in the number of correlations between diagnosed attributes was obtained. Moreover all the calculated statistically significant dependencies were stronger in clusters rather than in the whole datasets.

The results of the presented investigations can be further implemented in practical diagnostic applications and can constitute the basis for improved medical inference described in [13], [14] and [15].

Future research will consist in developing the proposed methodology by considering some additional problems connected with medical data analysis including data gathering, data quality assurance, feature selection and outliers detection. The last one is especially worth considering as statistical analysis results are deviation sensitive. Therefore, the data need to be checked for outlier instances before proceeding with the analysis. The problem of handling outliers can be considered separately, or can be included as part of clustering process, but in such a case cluster analysis algorithm which deals with outliers should be implemented - random sample consensus (RANSAC) algorithm is regarded as giving satisfactory results [29].

Feature selection plays the crucial role in classification analysis. Although the choice of clustering attributes was carefully examined by medical experts and was consistent with the research presented in [1], we cannot exclude the possibility that considering other attributes may produce new meaningful conclusions. Therefore in future investigations we intend to verify this approach with different automatic feature selection methods, including genetic algorithms [30].

The analysis carried out as part of the current study involved data from laboratory tests, medical observations and their interpretations. However, the data for the analysis can be acquired by imaging studies. For the specified cardiac system the future analysis will concern SPECT images, ECG and EEG signals. Additional further studies will focus on efficient mining in medical imaging data and binding them with any other numerical and text data.

*Abstract*—**Data mining (DM) is a collection of algorithms that are used to find some novel, useful and interesting knowledge in databases. DM algorithms are based on applied fields of mathematics and informatics, such as mathematical statistics, probability theory, information theory, neural networks. Some methods of these fields can be used to find hidden relation between data, what can be used to create models that predict some behavior or describe some common properties of analyzed objects. In this paper, we combine methods of DM with tools of reliability analysis to investigate importance of individual database attributes. Results of such investigation can be used in database optimization because it allows identifying attributes that are not important for purposes for which the database is used. Our approach is based on some coincidence between the key terms of DM and reliability analysis.**

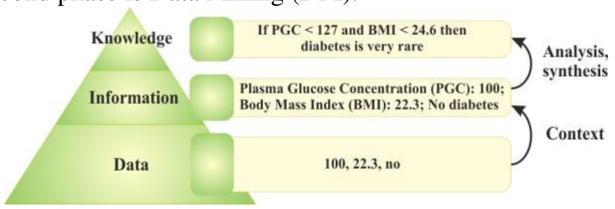
## I. Introduction

ONE of the current problems of modern medicine is processing and analysis of a huge amount of data that are generated by medical systems. This calls for design of automatic or semi-automatic process that could be used to find useful and understandable knowledge from data. This process is known as a Knowledge Discovery in Databases (KDDs) and it involves an (semi-)automatic, exploratory analysis and modeling of large data repositories to identify valid, novel, useful, and understandable patterns from large and complex datasets [1].

The main idea of a KDD is to transform a huge amount of row data into useful information and knowledge that can be very easy interpreted. In general, data represent basic facts and statistics without any context. As an example, let us consider numbers “100” or “22.3” or simple value “no”. When we add a context to the data, then we get information. For example, a patient with plasma glucose concentration at 2 hours in an oral glucose tolerance test of 100 and body mass index (patient’s body mass in kg divided by the square of its height in m) of 22.3 does not suffer diabetes. So, the basic difference between data and information is in its information value, i.e. data have no information value themselves in compare to information.

If we have enough information from some domain, then it can be possible to identify some general facts that characterize the domain. These general facts are known as knowledge. For example, let us consider the example of relation between plasma glucose concentration, body mass index and diabetes of a patient. If we have such information about many patients, then, for example, we can derive that there is a little probability that patients with plasma glucose concentration under 127 and body mass index under 24.6 suffer diabetes. This knowledge can be identified in dataset [2] that contains 768 records about the diabetes incidence in the Pima Indian population living near Phoenix in Arizona.

The relation between data, information and knowledge is very often described by the knowledge pyramid (Fig. 1). It expresses that a huge amount of data can be transformed into information by adding a context and, then, analysis and aggregation of information can lead in the discovery of general patterns in data that represent knowledge about the studied domain. One of the most popular terms for the second phase is Data Mining (DM).



Knowledge
If PGC < 127 and BMI < 24.6 then diabetes is very rare
Analysis, synthesis
Information
Plasma Glucose Concentration (PGC): 100; Body Mass Index (BMI): 22.3; No diabetes
Context
Data
100, 22.3, no

Fig. 1 Knowledge pyramid

## II. Knowledge Discovery Process and Data Mining

In general, DM is a collection of methods focused on building model and finding patterns or trends in data. When DM is used in a process in which their outcome is evaluated, so that we can think about the product as being a new package of information, then we speak about a knowledge discovery process [3].

A knowledge discovery process or KDD is a very complex non-linear process that involves not only data analysis but also its preparation as well as knowledge interpretation and using the discovered knowledge. A KDD involves six important steps that are [3], [4]: understanding the problem domain, understanding the data, preparation of the data, data mining, evaluation of the discovered knowledge and using the knowledge. The term non-linear means that, in any step, there can be identified some problems that cause need to return to some of the previous steps and repeat the whole process from that step.

A KDD is not a one-pass process [3], and its every iteration gives a different view on the data. For example, in the preprocessing phase, we can identify quite a lot of missing data, so their prediction could become the goal of the first iteration of the KDD. In the second iteration, we can focus on the creation of a model that could be used to predict patient's diagnosis from that data (predictive DM) or to identify patients with similar relations between their symptoms and diagnosis (descriptive DM).

### A. *Understanding the Medical Problem Domain*

At the beginning of a KDD, we need to identify what type of knowledge should be found in the data. This requires understanding the problem domain. In case of medical data, the domain comes from medical area and, therefore, the main goals of this phase are [3]:

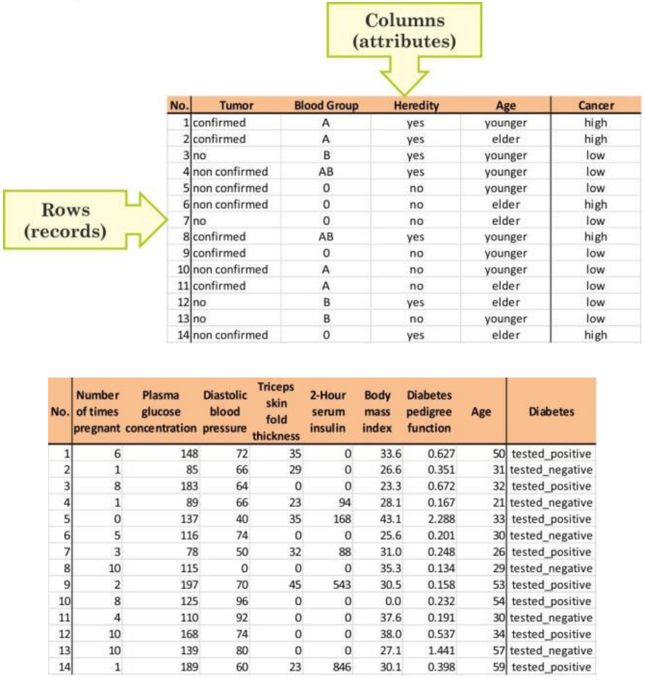
a) translation of medical goals into DM ones, and
b) determination of success criteria from the medical and DM point of view.

### B. *Understanding the Data*

When we understand the medical problem domain, then the data that are available should be analyzed. This analysis identifies which data will be used, and which additional information will be needed. The main goal of this step is to create a dataset for the next steps of KDD.

The result of this step can be very often interpreted as a table with rows and columns. The columns represent individual attributes of analyzed data while rows agree with individual records (instances/patients). Examples of two datasets are in Fig. 2. The first one contains 5 attributes related to cancer and it stores information about 14 patients. The second table is a sample of dataset focused on the diabetes incidence in the Pima Indian population [2]. It has 9 attributes and 14 records (the all dataset has 768 rows).

In Fig. 2, we can see that two different types of attributes exist – categorical and numerical [5] (Fig. 3). Categorical attributes are non-numerical and, usually, they have several possible values. They are also known as qualitative because they describe an object from qualitative point of view. The categorical attributes can be split into two separate groups: nominal and ordinal. The basic difference between them is that nominal attributes contain data that cannot be ordered, i.e. there is define no relation such as "greater/better than" or "lower/worse than", while ordinal ones are defined on data that can be ordered in some way. As an example, let us consider blood groups (A, B, AB, 0) and pain degree (severe, mild, none). There is no reason to assume that blood group A is better than 0 but, in case of pain degree, it is clear that no pain is better than severe one.

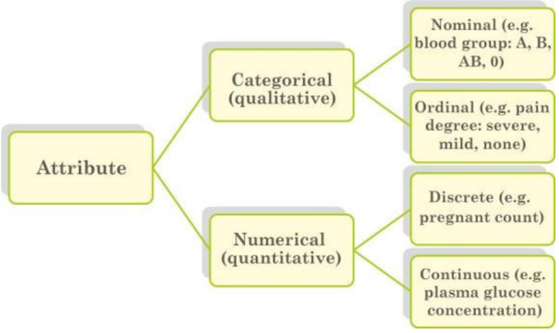


Columns (attributes)
Rows (records)

| No. | Tumor | Blood Group | Heredity | Age | Cancer |
|---|---|---|---|---|---|
| 1 | confirmed | A | yes | younger | high |
| 2 | confirmed | A | yes | elder | high |
| 3 | no | B | yes | younger | low |
| 4 | non confirmed | AB | yes | younger | low |
| 5 | non confirmed | 0 | no | younger | low |
| 6 | non confirmed | 0 | no | elder | high |
| 7 | no | 0 | no | elder | low |
| 8 | confirmed | AB | yes | younger | high |
| 9 | confirmed | 0 | no | younger | low |
| 10 | non confirmed | A | no | younger | low |
| 11 | confirmed | A | no | elder | low |
| 12 | no | B | yes | elder | low |
| 13 | no | B | no | younger | low |
| 14 | non confirmed | 0 | yes | elder | high |

| No. | Number of times pregnant | Plasma glucose concentration | Diastolic blood pressure | Triceps skin fold thickness | 2-Hour serum insulin | Body mass index | Diabetes pedigree function | Age | Diabetes |
|---|---|---|---|---|---|---|---|---|---|
| 1 | 6 | 148 | 72 | 35 | 0 | 33.6 | 0.627 | 50 | tested_positive |
| 2 | 1 | 85 | 66 | 29 | 0 | 26.6 | 0.351 | 31 | tested_negative |
| 3 | 8 | 183 | 64 | 0 | 0 | 23.3 | 0.672 | 32 | tested_positive |
| 4 | 1 | 89 | 66 | 23 | 94 | 28.1 | 0.167 | 21 | tested_negative |
| 5 | 0 | 137 | 40 | 35 | 168 | 43.1 | 2.288 | 33 | tested_positive |
| 6 | 5 | 116 | 74 | 0 | 0 | 25.6 | 0.201 | 30 | tested_negative |
| 7 | 3 | 78 | 50 | 32 | 88 | 31.0 | 0.248 | 26 | tested_positive |
| 8 | 10 | 115 | 0 | 0 | 0 | 35.3 | 0.134 | 29 | tested_negative |
| 9 | 2 | 197 | 70 | 45 | 543 | 30.5 | 0.158 | 53 | tested_positive |
| 10 | 8 | 125 | 96 | 0 | 0 | 0.0 | 0.232 | 54 | tested_positive |
| 11 | 4 | 110 | 92 | 0 | 0 | 37.6 | 0.191 | 30 | tested_negative |
| 12 | 10 | 168 | 74 | 0 | 0 | 38.0 | 0.537 | 34 | tested_positive |
| 13 | 10 | 139 | 80 | 0 | 0 | 27.1 | 1.441 | 57 | tested_negative |
| 14 | 1 | 189 | 60 | 23 | 846 | 30.1 | 0.398 | 59 | tested_positive |

Fig. 2 Examples of medical datasets



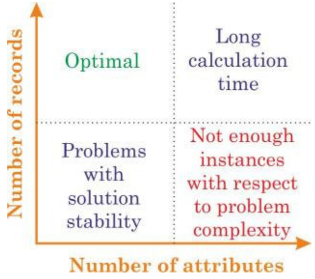
Attribute
Categorical (qualitative)
Numerical (quantitative)
Nominal (e.g. blood group: A, B, AB, 0)
Ordinal (e.g. pain degree: severe, mild, none)
Discrete (e.g. pregnant count)
Continuous (e.g. plasma glucose concentration)

Fig. 3 Types of attributes

Numerical attributes are another class. They are expressed in the form of numbers. These attributes define object properties from quantitative point of view and, therefore, they are also known as quantitative attributes. They can be subdivided into two groups: discrete and continuous. Discrete attributes are often defined on a set of some whole numerical values and very often count numbers of some events. As an example, let us consider the number of times when a woman has been pregnant or the birth year of a patient. When the attribute is continuous, then it means there is no limitation (except the lower and upper limits) on the values that can be taken. Typical examples are patient's height, weight or plasma glucose concentration.

One of the typical problems of KDD that is related to data is how much data is optimal for DM algorithms (Fig. 4).

There exists no definitive answer but, in general, more records are better because we can avoid the problems of underfitting, when the created model is too simple to analyze data that do not come from the original dataset. Similarly, datasets with less attributes are better than ones with many because the discovered knowledge can be interpreted easier.



Optimal
Long calculation time
Problems with solution stability
Not enough instances with respect to problem complexity
Number of records
Number of attributes

Fig. 4 Problems of DM related to the number of attributes and records

### C. Preparation of the Data

When we understand the medical problem domain and the data on which KDD will be performed, we can prepare them for DM algorithms. This is one of the most important and the most time consuming steps of KDD [3]. It consists of two phases: data cleansing and data transformation.

The quality of data is the most important factor on which the success of KDD depends. Real databases contain a lot of data. However, these data can include incorrect or missing values. If there are a lot of such values, then the result of a DM algorithm will be a model that is unusable in practice. Therefore, data cleansing is very important step. Its main task is to enhance data reliability. There exist a lot of methods that can be used for this purpose. The simplest ones are based on the assumption that most of the data are correct and, therefore, incorrect data can be handled simply by its removing. More sophisticated methods involve some statistical methods to identify and replace incorrect or missing values and the most complex ones use supervised DM algorithms to predict the correct value of an attribute.

When the data have required quality, then we can prepare them for DM algorithms. This phase involves production of new attributes (when given attributes are not very appropriate for DM) and reduction of attribute count (models created from huge amount of attributes are usually very complicated, which results in problems with interpretation of gained knowledge; also, such models are usually very accurate for data from which they have been produced, but inaccurate for new data and, therefore, their deployment can be very problematic).

New attributes can be produced from one or more existing attributes. Therefore, we distinguish between one-attribute and multi-attribute transformations. Typical examples of one-attribute transformations are: normalization (mapping continuous data to values in interval <0, 1>), percentages (values are related to a specified base value), scores (transformation of ordinal data to discrete ones), etc. Examples of multi-attribute transformations are ratios (quotient of two attributes, e.g. using body mass index instead of weight and height), rates (number of event occurrences divided by time, e.g. number of cigarettes per day), and other linear and nonlinear combinations.

There exist several approaches for reducing the number of attributes. Very often, medical expert knowledge can be sufficient to solve this problem. Another alternative is to use some methods of mathematical statistic such as principal component analysis, kernel principal component analysis, independent component analysis [6], etc.

### D. Data Mining

At the beginning of this phase, the appropriate DM task has to be chosen (Fig. 5). There exist two different goals, for which DM can be used: description and prediction [7].

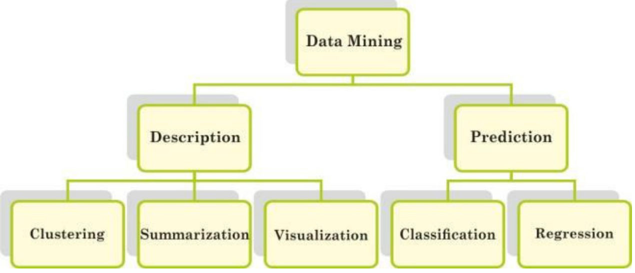


Fig. 5 Basic data mining models

Descriptive methods create models that are used for better understanding of given dataset. Typical examples are clustering, summarization and visualization [3]. The main idea of clustering is to find natural clusters of objects in a dataset. Objects are grouped together if they are similar to one another and dissimilar from objects in other clusters. Summarization is focused on data aggregation that is useful if we want to find some global characteristics of the entire dataset. The global characteristics allow describing data without necessity of knowing exact values of attributes of individual objects in dataset. So, they reduce the dataset size in terms of attributes or records count. Visualization includes techniques that aim is to simplify data understanding.

Predictive methods are used when the attributes can be subdivided into two groups: input and output attributes. In this case, DM can be used to discover the relationship between inputs and output attribute. (For example, the second dataset in Fig. 2 contains 8 input attributes, which more or less relates to diabetes, and 1 output attribute that identifies whether the patient suffer diabetes or not.) Based on the possible values of the output attribute, two types of prediction can be recognized: classification and regression [7]. The former maps the input space into predefined classes or, in general, into a discrete-valued domain, i.e. the output attribute is categorical or discrete numerical (Fig. 3). Typical algorithms of classification include neural networks (existing dataset is used to create and train a neural network that will be used to classify new records), decision trees (existing dataset is used to create a decision tree that will be capable to correct classify new records), instance based learning (every new record is classified according to its similarity with records that have already been classified), etc. Regression models transform the space of input attributes into a real-valued domain, i.e. the output attribute is continuous numerical according to Fig. 3, and the typical examples are linear and non-linear regression.

When we identify the appropriate DM task, then we have to choose and employ DM algorithm that will be used to achieve the goal, e.g. for clustering, we can select from statistical methods, support vector clustering, *k*-means clustering, hierarchical clustering, etc. Every algorithm has some parameters that have to be set correct to get satisfied result, e.g. how many clusters do we want to create, what is the minimal size of a cluster. These parameters are usually obtained by running the algorithm more times with different values of parameters and analyzing the obtained results.

### *E. Evaluation of the Discovered Knowledge*

The result of DM phase is a model that can be used to describe given data or to predict values of some attributes. When we want to interpret the model, then we have to understand the results that are described by it. This means that we have to be able to interpret the results from the medical point of view. This allows us to understand the discovered knowledge and identify whether it is novel and interesting. If the obtained knowledge is novel, then we can check its impact on the medical goal determined at the beginning of the KDD and recognize its usefulness in medical environment.

### *F. Using the Discovered Knowledge*

Finally, when the model is evaluated, then it should be incorporated into another system that will use the knowledge represented by the model. The success of this step determines the effectiveness of the entire KDD because the KDD has been unnecessary without further use of the discovered knowledge. According to [7], there are many challenges in this step, such as losing the “laboratory conditions” under which the model has been created. This means that the model has been produced from a certain static dataset, but the data become dynamic after the model deployment.

The result of KDD is knowledge that can be used for description purposes or for prediction. In case of predictive model that is created from a dataset containing only categorical attributes, the discovered knowledge can be represented as a table that enumerates all combinations of values of input attributes and defines value of the output for each of them. Such kind of table is used also in reliability analysis, and it is known as the structure function. This indicates that some tools of reliability analysis could be used in the analysis of the discovered knowledge.

## III. Reliability Analysis

Reliability is an important characteristic of systems. Every system consists of one or more components (basic parts of the system that are assumed to be indivisible into smaller elements). One of the principal tasks of reliability analysis is investigation of influence of individual system components on system activity and identification of components that are most important for system proper work. This investigation is known as importance analysis.

### *A. Binary- and Multi-State Systems*

Before the importance analysis can be performed, a model of the system has to be created. As a rule two types of models are used in reliability analysis. The first one is known as a Binary-State System (BSS). This model is based on the assumption that the system and all its components can be in one of only two possible states – functioning (labelled by number 1) and failure (represented by number 0). The dependency between states of individual system components and system state is expressed by a special relation that is known as structure function. The structure function of a BSS has the following form [8], [9]:

$$\phi(x_1,...,x_n) = \phi(\boldsymbol{x}) : \{0,1\}^n \to \{0,1\}, \tag{1}$$

where $n$ is a number of system components, $x_i$ is a variable denoting state of the $i$-th component and $\boldsymbol{x} = (x_1,\ldots, x_n)$ is a vector of states of system components (state vector). The structure function of a BSS can be viewed as a Boolean function and, therefore, some approaches related to analysis of Boolean functions can be used in the analysis of BSSs [9].

BSSs have been widely used in reliability analysis, especially in the analysis of systems in which any deviation from perfect functioning results in failure of the system, e.g. nuclear power plants [10], aviation systems [11]. However, these models are not very appropriate for systems that can operate at different performance levels, i.e. systems that can meet their mission also when they are not perfectly functioning, e.g. distribution networks [12] or healthcare systems [13]. Therefore, models that allow defining more than two states in system/components performance are used in the analysis of such systems. These models are known as Multi-State Systems (MSSs).

A general MSS permits defining different number of states for the system and for its components. If we assume that the system has $m$ possible states and its $i$-th component, for $i = 1,\ldots, n$, can be in one of $m_i$ states, then the structure function of the MSS corresponds to the next map [14]–[16]:

$$\begin{gathered}\phi(x_1,...,x_n) = \phi(\boldsymbol{x}) : \\ \{0,...,m_1 - 1\} \times \ldots \times \{0,...,m_n - 1\} \to \{0,...,m-1\},\end{gathered} \tag{2}$$

where 0 corresponds to completely failure of the system/ component while $m$ -1 ($m_i$ -1) means that the system (the $i$-th component) is perfectly functioning.

A special type of MSSs is a homogenous system, in which $m_1 = \ldots = m_n = m$. The structure function of such system can be interpreted as a Multiple-Valued Logic (MVL) function. This fact allows us to use some methods of MVL logic in reliability analysis of MSSs [16].

The mathematical model of structure function used in reliability analysis can be combined with methods of DM to perform analysis of medical databases. This analysis can be used to identify database attributes that carry no important information from the point of view of database purpose.

For example, let us consider the example of database for the analysis of the breast cancer diagnosis from [17]. In this example 4 categorical input attributes are used (Table I): $A_1$ (*Gynecological history*), $A_2$ (*Tumor*), $A_3$ (*Heredity*), and $A_4$ (*Age*). Each combination of values of the input attributes is connected to output attribute B (*Breast Cancer Possibility*). Let the attributes have the next values: $A_1 = \{A_{1,1}, A_{1,2}, A_{1,3}\}$, $A_2 = \{A_{2,1}, A_{2,2}, A_{2,3}\}$, $A_3 = \{A_{3,1}, A_{3,2}\}$, $A_4 = \{A_{4,1}, A_{4,2}\}$, and $B = \{B_1, B_2, B_3\}$ assuming that these values has the meaning presented in Table I.

TABLE I.
ATTRIBUTES VALUES

| Attribute | Attribute Values | Description of Attribute Values |
|---|---|---|
| $A_1$ | $A_{1,1}$ | Gynecological history with high risk |
| | $A_{1,2}$ | Gynecological history with medium risk |
| | $A_{1,3}$ | Gynecological history with low risk |
| $A_2$ | $A_{2,1}$ | Yes and confirmed by medical examination |
| | $A_{2,2}$ | Yes and non-confirmed |
| | $A_{2,3}$ | No |
| $A_3$ | $A_{3,1}$ | Yes |
| | $A_{3,2}$ | No |
| $A_4$ | $A_{4,1}$ | Younger than 40 years |
| | $A_{4,2}$ | 40 years or more |
| B | $B_1$ | High Possibility of Breast Cancer |
| | $B_2$ | Medium Possibility of Breast Cancer |
| | $B_3$ | Low Possibility of Breast Cancer |

In [17], an association rule for breast cancer diagnosis was inducted based on the methods of DM. This rule includes 4 input attributes and one output attribute (Table II). From reliability point of view, the input attributes can be interpreted as system components and the output attribute is considered to be the system state. This implies that the table representing the discovered knowledge can be interpreted as the structure function of a MSS that depends on 4 variables: the 1-st and 2-nd variable has 3 possible values and the 3-rd and 4-th have two values. This structure function is defined based on all possible values of the input attributes and the output attribute is calculated according to the association rule derived in [17].

In section IV, we will use some approaches of reliability analysis to identify input attributes that have the greatest influence on the value of the output attribute. These results can be used to perform some database optimization since we can find attributes that have very little influence on the output attribute and, therefore, it might not be necessary to store them in the database.

### B. Coherent and Noncoherent Systems

Based on the properties of the structure function, two different classes of systems can be recognized – coherent and noncoherent. A system is coherent if a failure/degradation of any system component can result only in system failure/ degradation. This means that the structure function of coherent systems is monotonic (non-decreasing) [8], [14].

TABLE II.
STRUCTURE FUNCTION FOR DATABASE OF BREAST CANCER DIAGNOSIS

| Variables<br>$x_1$ $x_2$ $x_3$ $x_4$ | $\phi(\boldsymbol{x})$ | Variables<br>$x_1$ $x_2$ $x_3$ $x_4$ | $\phi(\boldsymbol{x})$ |
|---|---|---|---|
| 0 0 0 0 | 1 | 1 1 1 1 | 2 |
| 0 0 0 1 | 1 | 1 2 0 0 | 0 |
| 0 0 1 0 | 1 | 1 2 0 0 | 2 |
| 0 0 1 1 | 1 | 1 2 0 1 | 2 |
| 0 1 0 0 | 2 | 1 2 1 0 | 2 |
| 0 1 0 1 | 0 | 1 2 1 1 | 2 |
| 0 1 1 0 | 2 | 2 0 0 0 | 2 |
| 0 1 1 1 | 0 | 2 0 0 1 | 2 |
| 0 2 0 0 | 2 | 2 0 1 0 | 2 |
| 0 2 0 1 | 2 | 2 0 1 1 | 2 |
| 0 2 1 0 | 2 | 2 1 0 0 | 2 |
| 0 2 1 1 | 2 | 2 1 0 1 | 2 |
| 1 0 0 0 | 1 | 2 1 1 1 | 2 |
| 1 0 0 1 | 1 | 2 2 0 0 | 2 |
| 1 0 1 0 | 1 | 2 2 0 0 | 2 |
| 1 0 1 1 | 1 | 2 2 0 1 | 2 |
| 1 1 0 0 | 2 | 2 2 1 0 | 2 |
| 1 1 0 1 | 0 | 2 2 1 1 | 2 |

A system is noncoherent if its structure function is not monotonic. This implies that a noncoherent system admits situations in which component failure/degradation can cause system repair/improvement [18].

The coherency is a typical property of most systems studied in reliability engineering. This indicates that many tools of reliability analysis are based on the assumption that the structure function is monotonic. However, there also exist some systems whose structure function cannot be monotone, e.g. logic networks [19] or *k*-to-*l*-out-of-*n* systems, which are functioning if at least *k* but not more than *l* components are working [20]. The analysis of such systems is more complicated than the analysis of coherent systems and, therefore, it has to be done more carefully.

### C. Availability

The structure function defines system topology, and it carries no information about reliability of individual system components. Therefore, if we want to analyze not only topological properties of the system but also some probabilistic characteristics (e.g. system availability or unavailability, mean time to failure), the probabilities of states of individual system components have to be known:

$$p_{i,s} = \Pr\{x_i = s\}, \quad s \in \{0, \ldots, m_i - 1\}, \quad i \in \{1, \ldots, n\}, \qquad (3)$$

where $m_i = 2$ for BSSs. Please note that in case of BSSs, $p_{i,0}$ is known as unavailability of the *i*-th system component and $p_{i,1}$ as its availability.

Knowledge of system structure function and probabilities (3) can be used to compute three important characteristics of the system – the probability that the system is in state *j* (for *j* = 0,…, *m* -1), the system availability, which is defined with regard to system state *j* as follows [14], [15]:

$$A^{\geq j} = \Pr\{\phi(\boldsymbol{x}) \geq j\}, \quad j \in \{1,\ldots,m-1\}, \tag{4}$$

and the system unavailability, which is defined with regard to system state $j$ as the probability that the system cannot fulfill a requirement that requires at least level $j$ of system performance [14], [15]:

$$U^{\geq j} = \Pr\{\phi(\boldsymbol{x}) < j\} = 1 - A^{\geq j}, \quad j \in \{1,\ldots,m-1\}. \tag{5}$$

Please note, in case of BSSs ($m = 2$ in definitions (4) and (5)), the system availability is defined as the probability that the system is in state 1 while the unavailability agrees with the probability of system 0-state. Therefore, terms “system availability (unavailability)” and “the probability that the system is in state 1 (0)” can be used as synonyms in case of BSSs. However, this is not true for MSSs, in which these two terms represent two different concepts.

System availability and unavailability are very important in reliability analysis. They can be used to estimate mean time to system failure or mean time to system repair. However, they do not allow identifying components that have the greatest influence on system activity. This is very important task because its results can be used to optimize system reliability or to plan system maintenance.

### D. *Importance Analysis*

Importance analysis is a part of reliability engineering. It is used to quantify situations in which a change of component state results in a change of system state. For this purpose, Importance Measures (IMs) are used. There exist a lot of IMs [21]. However, in what follows, we will consider only two of them – the Structural Importance (SI) and the Birnbaum’s Importance (BI).

The SI and BI have originally been developed for the analysis of coherent systems. In [22], the SI of component $i$ has been defined as a relative number of situations in which the component is critical for system failure/functioning, i.e. as a proportion of cases when a failure (repair) of the $i$-th system component results in system failure (repair). In the same paper, the BI has been introduced as the probability that the component failure (repair) causes system failure (repair). These definitions imply that the main difference between the SI and BI is that the former analyzes only the system structure while the latter takes into account not only the structure function but also availabilities (unavailabilities) of system components. Therefore, the SI is primarily used to analyze topological properties of the system.

The considered IMs have been generalized for coherent MSSs in [16], [23]–[25]. These works have introduced several types of the SI and BI depending on whether we are interested in:

a) identification of component states that are the most important for a given system state/ availability [16], [23], [25],
b) identifying component states that have the most influence on the whole system (not only on a specific system state/availability) [24],
c) finding components that are the most important for a given system state/availability,
d) revealing the total importance of individual components for the whole system [25].

Finally, works [18], [26] have introduced definitions of the SI and BI for noncoherent BSSs. These versions of the SI and BI allow quantifying:

a) dependency of system failure (repair) on a failure (repair) of a given component,
b) dependency of system repair (failure) on a failure (repair) of a given component,
c) the total influence of a given component on the system activity.

According to our knowledge, no generalizations of the considered IMs have been proposed for importance analysis of noncoherent MSSs. This can be caused by the fact that these models are used in reliability analysis very rarely.

### E. *Logical Differential Calculus*

Logical differential calculus is a tool used to investigate dynamic properties of Boolean and MVL functions [27]. The central term of this tool is a Boolean/MVL derivative. There exist several types of this derivative. For our purposes, the most important is Direct Partial Logic Derivative (DPLD).

A DPLD of a Boolean function $f(\boldsymbol{x})$ with respect to variable $x_i$ can be defined in the following way [27]:

$$\partial f(j \to \bar{j}) / \partial x_i(s \to \bar{s}) = \\ = \begin{cases} 1, \text{ if } f(s_i, \boldsymbol{x}) = j \text{ and } f(\bar{s}_i, \boldsymbol{x}) = \bar{j} \\ 0, \text{ other} \end{cases}, \tag{6}$$

where $f(a_i, \boldsymbol{x}) = f(x_1,\ldots, x_{i-1}, a, x_{i+1},\ldots, x_n)$ for $a \in \{s, \bar{s}\}$ and $s, j \in \{0, 1\}$. According to this definition, the DPLD of a Boolean function reveals situations in which change of Boolean variable $x_i$ from value $s$ to $\bar{s}$ causes that the Boolean function value changes from $j$ to $\bar{j}$.

In the similar way, a DPLD of a MVL function $f_m(\boldsymbol{x})$ with respect to variable $x_i$ is defined as follows [27]:

$$\partial f_m(j \to h) / \partial x_i(s \to r) = \\ = \begin{cases} 1, \text{ if } f_m(s_i, \boldsymbol{x}) = j \text{ and } f_m(r_i, \boldsymbol{x}) = h \\ 0, \text{ other} \end{cases}, \tag{7}$$

where $f_m(a_i, \boldsymbol{x}) = f_m(x_1,\ldots, x_{i-1}, a, x_{i+1},\ldots, x_n)$ for $a \in \{s, r\}$; $s, r, j, h \in \{0,\ldots, m\text{ -}1\}$, $s \neq r$, and $j \neq h$. Clearly, this derivative models consequence of change of the MVL variable from value $s$ to $r$ on the value of the considered MVL function and, therefore, it can be used to detect situations in which the investigated change of the MVL variable results in the change of the function value from $j$ to $h$.

Since the structure function of a BSS can be interpreted as a Boolean function and the structure function of a homogenous MSS as a MVL function, DPLDs can also be used in reliability analysis of such systems [9], [16]. Moreover, the next little modification of definition (6) also allows applying them to non-homogenous MSSs:

$$\partial\phi(j \to h)/\partial x_i(s \to r) = \\ = \begin{cases} 1, \text{ if } \phi(s_i, \boldsymbol{x}) = j \text{ and } \phi(r_i, \boldsymbol{x}) = h \\ 0, \text{ other} \end{cases}, \tag{8}$$

where $s,\ r \in \{0,\ldots, m_i\text{-}1\}$, $s \neq r$ and $j,\ h \in \{0,\ldots, m\text{-}1\}$, $j \neq h$. Please note that this definition is the most general definition of a DPLD from which definitions (6) and (7) can be obtained simply using the assumption that $s,\ r,\ j,\ h \in \{0,1\}$ or $s, r, j, h \in \{0,\ldots, m\text{-}1\}$ respectively. Therefore, in what follows, we will primarily use this definition.

In terms of reliability analysis, DPLDs are used to identify situations in which a given change of state of the *i*-th system component results in the investigated change of the system state. These derivatives can be split into four groups:

A. $j > h$ and $s > r$ – these derivatives identify situations in which component failure/degradation results in system failure/degradation,

B. $j < h$ and $s < r$ – these DPLDs detect situations in which component repair/improvement causes a repair/improvement of system activity,

C. $j > h$ and $s < r$ – these derivatives can be used to find coincidence between component repair/improvement and system failure/degradation,

D. $j < h$ and $s > r$ – these DPLDs investigate situations in which system repair/improvement is caused by failure/degradation of the considered component.

Based on the definition of a coherent system, only DPLDs from groups A and B are relevant in the analysis of such systems. However, this is not true for noncoherent systems, for which the derivatives from all groups can be nonzero.

### *F. Importance Measures based on Direct Partial Logic Derivatives*

The SI and BI are used to quantify coincidence between component state change and change of system state. Based on the previous paragraphs, this coincidence can be identified based on DPLDs. Therefore, these derivatives can also be used to compute the SI and BI [9], [13], [16].

Firstly, let us consider a coherent BSS. The structure function of this system is monotone, therefore, only DPLDs $\partial\phi(1 \to 0)/\partial x_i(1 \to 0)$ and $\partial\phi(0 \to 1)/\partial x_i(0 \to 1)$ can be nonzero for this type of systems. The former identifies situations in which a failure of component *i* results in system failure, and the latter detects state vectors at which a repair of the component causes that the system begins work. Since the SI of component *i* is defined as a relative number of situations in which a failure (repair) of component *i* results in system failure (repair), this IM can be computed using DPLDs in the following manner [9]:

$$\begin{aligned} \mathrm{SI}_i &= \mathrm{TD}\big(\partial\phi(1 \to 0)/\partial x_i(1 \to 0)\big) \\ &= \mathrm{TD}\big(\partial\phi(0 \to 1)/\partial x_i(0 \to 1)\big), \end{aligned} \tag{9}$$

where TD(.) denotes truth density of the argument interpreted as a function with Boolean-valued output, i.e. a proportion of situations in which the argument takes value 1.

The BI of component *i* can be calculated using DPLDs in the similar way [9]:

$$\begin{aligned} \mathrm{BI}_i &= \Pr\{\partial\phi(1 \to 0)/\partial x_i(1 \to 0) = 1\} \\ &= \Pr\{\partial\phi(0 \to 1)/\partial x_i(0 \to 1) = 1\} \end{aligned} \tag{10}$$

since it is defined as the probability that a failure (repair) of the component causes system failure (repair).

Secondly, let us consider a noncoherent BSS. In this case all four DPLDs that can be defined are relevant because all of them can contain nonzero elements, i.e. DPLDs $\partial\phi(1 \to 0)/\partial x_i(1 \to 0)$, $\partial\phi(1 \to 0)/\partial x_i(0 \to 1)$ can be used to find correlation between system failure and change of state of component *i* while derivatives $\partial\phi(0 \to 1)/\partial x_i(0 \to 1)$, $\partial\phi(0 \to 1)/\partial x_i(1 \to 0)$ identify situations in which a change of component state results in system repair.

It has been proposed in [18] that importance analysis of noncoherent BSSs should be performed in three steps. Firstly, we should quantify influence of component failure on system failure (repair). Secondly, impact of component repair on system failure (repair) should be quantified. Finally, the total influence of the considered component on system failure (repair) can be estimated as the sum of the results obtained in the previous two steps. This implies that several IMs of one type can be defined for one component. For example, in case of the SI, the next four measures can be calculated:

$$\begin{aligned} \mathrm{SI}_{i\downarrow}^{\downarrow} &= \mathrm{TD}\big(\partial\phi(1 \to 0)/\partial x_i(1 \to 0)\big), \\ \mathrm{SI}_{i\uparrow}^{\uparrow} &= \mathrm{TD}\big(\partial\phi(0 \to 1)/\partial x_i(0 \to 1)\big), \\ \mathrm{SI}_{i\downarrow}^{\uparrow} &= \mathrm{TD}\big(\partial\phi(0 \to 1)/\partial x_i(1 \to 0)\big), \\ \mathrm{SI}_{i\uparrow}^{\downarrow} &= \mathrm{TD}\big(\partial\phi(1 \to 0)/\partial x_i(0 \to 1)\big). \end{aligned} \tag{11}$$

The first two SI measures are used to quantify coincidence between component failure (repair) and system failure (repair). The remaining SI measures estimates topological correlation between component failure (repair) and repair (failure) of the system. The total topological influence of component *i* on system failure is computed in the following manner [26]:

$$\begin{aligned} \mathrm{SI}_i^{\downarrow} &= \mathrm{SI}_{i\downarrow}^{\downarrow} + \mathrm{SI}_{i\uparrow}^{\downarrow} \\ &= \mathrm{TD}\big(\partial\phi(1 \to 0)/\partial x_i(1 \to 0)\big) \\ &\quad + \mathrm{TD}\big(\partial\phi(1 \to 0)/\partial x_i(0 \to 1)\big), \end{aligned} \tag{12}$$

and on system repair in the following way:

$$\begin{aligned} \mathrm{SI}_i^{\uparrow} &= \mathrm{SI}_{i\uparrow}^{\uparrow} + \mathrm{SI}_{i\downarrow}^{\uparrow} \\ &= \mathrm{TD}\big(\partial\phi(0 \to 1)/\partial x_i(0 \to 1)\big) \\ &\quad + \mathrm{TD}\big(\partial\phi(0 \to 1)/\partial x_i(1 \to 0)\big). \end{aligned} \tag{13}$$

It is clear that

$$\mathrm{SI}_{i\downarrow}^{\downarrow} = \mathrm{SI}_{i\uparrow}^{\uparrow},\ \mathrm{SI}_{i\uparrow}^{\downarrow} = \mathrm{SI}_{i\downarrow}^{\uparrow},\ \mathrm{SI}_{i}^{\downarrow} = \mathrm{SI}_{i}^{\uparrow} \qquad (14)$$

and, therefore, $\mathrm{SI}_{i\downarrow}^{\downarrow}$, $\mathrm{SI}_{i\uparrow}^{\downarrow}$, and $\mathrm{SI}_{i}^{\downarrow}$ can be used not only in the investigation of system failure but also in the analysis of system repair.

Please note that the same results can also be obtained for the BI of noncoherent BSSs by replacement of the truth densities in equations (11) – (13) with the probabilities that the DPLDs take value 1.

Thirdly, let us focus on coherent MSSs. In this case, we can quantify several dependencies between component state and system state. For simplicity, we will consider only situations in which component degradation coincide with system degradation, i.e. we will not introduce the IMs for component improvement. Furthermore, we will assume that system components can degrade only one state. Using these assumptions, we can calculate the SI of state *s* of component *i* for system state *j* as follows [16]:

$$\mathrm{SI}_{i,s\downarrow}^{j\downarrow} = \sum_{h=0}^{j-1} \mathrm{TD}\big(\partial\phi(j \to h)/\partial x_i(s \to s-1)\big), \qquad (15)$$

for $i \in \{1,\dots,n\}$, $s \in \{1,\dots,m_i\text{-}1\}$, $j \in \{1,\dots,m\text{-}1\}$.

Based on the meaning of DPLDs, this IM corresponds to the relative number of situations in which a minor degradation (i.e. degradation by one state) of state *s* of component *i* results in degradation of system state *j*. Using the ideas presented in [24], [25], this SI can also be used to compute the relative number of situations in which a minor degradation of state *s* of component *i* results in system degradation:

$$\begin{aligned}\mathrm{SI}_{i,s\downarrow}^{\downarrow} &= \sum_{j=1}^{m-1} \mathrm{SI}_{i,s\downarrow}^{j\downarrow} \\ &= \sum_{j=1}^{m-1}\sum_{h=0}^{j-1} \mathrm{TD}\big(\partial\phi(j \to h)/\partial x_i(s \to s-1)\big),\end{aligned} \qquad (16)$$

or the relative number of situations in which a minor degradation of component *i* causes degradation of system state *j*:

$$\begin{aligned}\mathrm{SI}_{i\downarrow}^{j\downarrow} &= \frac{1}{m_i-1}\sum_{s=1}^{m_i-1} \mathrm{SI}_{i,s\downarrow}^{j\downarrow} \\ &= \frac{1}{m_i-1}\sum_{s=1}^{m_i-1}\sum_{h=0}^{j-1} \mathrm{TD}\big(\partial\phi(j \to h)/\partial x_i(s \to s-1)\big),\end{aligned} \qquad (17)$$

or the proportion of state vectors at which a minor degradation of component *i* results in system degradation:

$$\mathrm{SI}_{i\downarrow}^{\downarrow} = \frac{1}{m_i-1}\sum_{s=1}^{m_i-1} \mathrm{SI}_{i,s\downarrow}^{\downarrow}. \qquad (18)$$

Equation (16) can be used to quantify topological influence of state *s* of component *i* on the whole system. Similarly, equations (17) allows us to investigate the total influence of component *i* on system state *j* and formula (18) the total influence on the whole system. In the similar way, the BI for a minor degradation of component state for a coherent MSS can be defined. The only difference is that the truth densities in (15) – (17) have to be replaced with the probabilities that the considered DPLDs are nonzero.

## IV. Use of Importance Analysis in Investigation of Medical Databases

As we mentioned in section III.A, a complete medical database can be obtained from a medical dataset using some tools of DM. The complete database containing only qualitative (categorical) attributes can be viewed as a MSS whose structure function agrees with the relation (discovered knowledge) between the input attributes and the output attribute. However, the main problem is that the database has to be interpreted as the structure function of a noncoherent MSS because it can contain situations in which a decrease in value of input attribute can result in increase of value of the output attribute. For example, in Table II, change of variable $x_2$, which corresponds to value of attribute $A_2$, from value 1 to 0 causes that the value of the structure function of the considered database changes from value 0 to 1 if $x_1 = 0$, $x_3 = 0$, and $x_4 = 1$. This fact requires proposing some generalizations of the SI for noncoherent MSSs if we want to use this measure to find input attributes that have the greatest influence on the output attribute.

In noncoherent systems, not only component degradation but also component improvement can result in system degradation. This implies that we also need to detect situations in which component improvement results in system degradation. DPLDs $\partial\phi(j \to h)/\partial x_i(s \to s+1)$ in which $j > h$ can be used for this purpose. Based on these DPLDs, topological influence of a minor improvement of state *s* of component *i* on degradation of system state *j* can be estimated using the next version of SI:

$$\mathrm{SI}_{i,s\uparrow}^{j\downarrow} = \sum_{h=0}^{j-1} \mathrm{TD}\big(\partial\phi(j \to h)/\partial x_i(s \to s+1)\big), \qquad (19)$$

for $i \in \{1,\dots,n\}$, $s \in \{0,\dots,m_i\text{-}2\}$, $j \in \{1,\dots,m\text{-}1\}$.

In case of noncoherent BSSs, the total influence of a given component on system failure is computed as the sum of SI measures analyzing consequences of the component failure and repair. Therefore, in case of MSSs, the total importance of state *s* of component *i* for degradation of system state *j* can be computed simply using the next SI:

$$\mathrm{SI}_{i,s}^{j\downarrow} = \begin{cases} \mathrm{SI}_{i,s\uparrow}^{j\downarrow} & \text{if } s = 0, \\ \mathrm{SI}_{i,s\downarrow}^{j\downarrow} & \text{if } s = m_i - 1, \\ \mathrm{SI}_{i,s\downarrow}^{j\downarrow} + \mathrm{SI}_{i,s\uparrow}^{j\downarrow} & \text{else,} \end{cases} \qquad (20)$$

where $\mathrm{SI}_{i,s\downarrow}^{j\downarrow}$ is computed based on formula (15).

SI measures (15), (19), and (20) are useful for evaluation of influence of a given component state on degradation of a given system state. However, they do not allow identifying importance of the whole component on degradation of a given system state or importance of a given component state on the entire system (regardless of a concrete system state). For these purposes, other versions of the SI have to be defined. This can be done in the similar way as in the case of coherent MSSs, i.e. the total importance of a given component state on system activity can be computed as follows:

$$\mathrm{SI}_{i,s}^{\downarrow}=\sum_{j=1}^{m-1}\mathrm{SI}_{i,s}^{j\downarrow}=\begin{cases}\mathrm{SI}_{i,s\uparrow}^{\downarrow} & \text{if } s=0,\\ \mathrm{SI}_{i,s\downarrow}^{\downarrow} & \text{if } s=m_i-1,\\ \mathrm{SI}_{i,s\downarrow}^{\downarrow}+\mathrm{SI}_{i,s\uparrow}^{\downarrow} & \text{else,}\end{cases}\qquad(21)$$

where $\mathrm{SI}_{i,s\downarrow}^{\downarrow}$ (definition (16)) quantifies consequences of deterioration of state $s$ of the $i$-th system component on system activity, and $\mathrm{SI}_{i,s\uparrow}^{\downarrow}$ calculates results of improvement of state $s$ of component $i$ on system degradation. Please note that $\mathrm{SI}_{i,s\uparrow}^{\downarrow}$ is computed similarly as $\mathrm{SI}_{i,s\downarrow}^{\downarrow}$, i.e.:

$$\begin{aligned}\mathrm{SI}_{i,s\uparrow}^{\downarrow}&=\sum_{j=1}^{m-1}\mathrm{SI}_{i,s\uparrow}^{j\downarrow}\\&=\sum_{j=1}^{m-1}\sum_{h=0}^{j-1}\mathrm{TD}\big(\partial\phi(j\to h)/\partial x_i(s\to s+1)\big).\end{aligned}\qquad(22)$$

The total topological influence of component $i$ on a given system state can be calculated based on the next formula:

$$\mathrm{SI}_i^{j\downarrow}=\frac{1}{m_i-1}\sum_{s=0}^{m_i-1}\mathrm{SI}_{i,s}^{j\downarrow}=\mathrm{SI}_{i\downarrow}^{j\downarrow}+\mathrm{SI}_{i\uparrow}^{j\downarrow},\qquad(23)$$

where $\mathrm{SI}_{i\downarrow}^{j\downarrow}$ (definition (17)) quantifies results of degradation of the $i$-th system component on degradation of system state $j$, and $\mathrm{SI}_{i\uparrow}^{j\downarrow}$ evaluating consequences of improvement of the $i$-th component on degradation of system state $j$ is computed using the following formula:

$$\begin{aligned}\mathrm{SI}_{i\uparrow}^{j\downarrow}&=\frac{1}{m_i-1}\sum_{s=0}^{m_i-2}\mathrm{SI}_{i,s\uparrow}^{j\downarrow}\\&=\frac{1}{m_i-1}\sum_{s=0}^{m_i-2}\sum_{h=0}^{j-1}\mathrm{TD}\big(\partial\phi(j\to h)/\partial x_i(s\to s+1)\big).\end{aligned}\qquad(24)$$

Based on the meaning of DPLDs, it can be shown simply that SI (21) agrees with the relative number of state vectors at which a minor change (i.e. a change by one state) of state $s$ of component $i$ results in system degradation, SI (22) identifies the relative count of state vectors at which a minor improvement of state $s$ of component $i$ results in system degradation, SI (23) corresponds to the relative number of situations in which a degradation or improvement of component $i$ causes decrease in state $j$ of the system, and SI (24) agrees with the proportion of state vectors at which an improvement of component $i$ causes deterioration of state $j$ of the system

Finally, the total topological importance of a given component on system activity can be defined as the relative number of state vectors at which a change of component state results in system deterioration and, therefore, it can be computed as follows:

$$\mathrm{SI}_i^{\downarrow}=\mathrm{SI}_{i\downarrow}^{\downarrow}+\mathrm{SI}_{i\uparrow}^{\downarrow},\qquad(25)$$

where $\mathrm{SI}_{i\downarrow}^{\downarrow}$ (definition (18)) quantifies results of degradation of the $i$-th system component on system degradation, and $\mathrm{SI}_{i\uparrow}^{\downarrow}$ computed based on the next formula:

$$\mathrm{SI}_{i\uparrow}^{\downarrow}=\frac{1}{m_i-1}\sum_{s=0}^{m_i-2}\mathrm{SI}_{i,s\uparrow}^{\downarrow}\qquad(26)$$

evaluates consequences of improvement of the considered component on system degradation.

In this section, we have proposed a lot of SI measures that can be used in the investigation of topological properties of noncoherent MSSs. For clarity, we summarize them in Table III. The similar formulae could also be proposed for BI measures. The only difference is that the probabilities that the DPLDs are nonzero have to be used in formulae (15) – (26) instead of the truth densities.

TABLE III.
STRUCTURAL IMPORTANCE MEASURES FOR NONCOHERENT MULTI-STATE SYSTEMS

| SI | Coherent Part (Influence of Component Degradation) | Noncoherent Part (Influence of Component Improvement) |
|---|---|---|
| $\mathrm{SI}_{i,s}^{j\downarrow}$ | $\mathrm{SI}_{i,s\downarrow}^{j\downarrow}=\sum_{h=0}^{j-1}\mathrm{TD}\left(\frac{\partial\phi(j\to h)}{\partial x_i(s\to s-1)}\right)$ | $\mathrm{SI}_{i,s\uparrow}^{j\downarrow}=\sum_{h=0}^{j-1}\mathrm{TD}\left(\frac{\partial\phi(j\to h)}{\partial x_i(s\to s+1)}\right)$ |
| $\mathrm{SI}_{i,s}^{\downarrow}$ | $\mathrm{SI}_{i,s\downarrow}^{\downarrow}=\sum_{j=1}^{m-1}\mathrm{SI}_{i,s\downarrow}^{j\downarrow}$ for $s>0$ | $\mathrm{SI}_{i,s\uparrow}^{\downarrow}=\sum_{j=1}^{m-1}\mathrm{SI}_{i,s\uparrow}^{j\downarrow}$ for $s<m_i-1$ |
| $\mathrm{SI}_i^{j\downarrow}$ | $\mathrm{SI}_{i\downarrow}^{j\downarrow}=\frac{1}{m_i-1}\sum_{s=1}^{m_i-1}\mathrm{SI}_{i,s\downarrow}^{j\downarrow}$ | $\mathrm{SI}_{i\uparrow}^{j\downarrow}=\frac{1}{m_i-1}\sum_{s=0}^{m_i-2}\mathrm{SI}_{i,s\uparrow}^{j\downarrow}$ |
| $\mathrm{SI}_i^{\downarrow}$ | $\mathrm{SI}_{i\downarrow}^{\downarrow}=\frac{1}{m_i-1}\sum_{s=1}^{m_i-1}\mathrm{SI}_{i,s\downarrow}^{\downarrow}$ | $\mathrm{SI}_{i\uparrow}^{\downarrow}=\frac{1}{m_i-1}\sum_{s=0}^{m_i-2}\mathrm{SI}_{i,s\uparrow}^{\downarrow}$ |

Based on the relation between medical database and the structure function of a noncoherent MSS, the proposed SI measures can be used to analyze importance of individual input attributes on the value of the output attribute. For illustration, let us consider the medical database defined by Table II. The total topological importance of individual input attributes is computed based on formula (25) in Table IV. Based on the data presented in this table, the input attribute that has the greatest influence on the output attribute is $\mathrm{A}_2$. On the other hand, value of attribute $\mathrm{A}_3$ has no influence on attribute B. This implies that attribute $\mathrm{A}_3$ is not important for tasks for which the table is used (i.e. decision whether the breast cancer has high possibility or not) and, therefore, it is not necessary to store its values in the database.

## V. CONCLUSION

This paper focuses on correlation between some key terms of KDD (or DM) and reliability analysis. We illustrated that KDD is a very complex process whose main part is DM. DM is used to discover some new information (knowledge) in a database (predictive DM) or for better understanding of data stored in a database (descriptive DM). In case of predictive DM used on databases containing only categorical attributes, the discovered knowledge can be interpreted as a table that can be viewed as the structure function of a MSS. This allows us to use some methods of reliability analysis in investigation of database properties. One of them is importance analysis, which identifies influence of system components on the system activity.

TABLE IV.
IMPORTANCE OF INDIVIDUAL INPUT ATTRIBUTES FOR THE OUTPUT ATTRIBUTE

| Input Attribute | $\mathrm{SI}_i^{\downarrow}$ |
|---|---|
| A1 | 0.25 |
| A2 | 0.50 |
| A3 | 0 |
| A4 | 0.22 |

In this paper, we considered use of importance analysis in investigation of coincidence between change of input attributes and change of the output attribute of a table representing the discovered knowledge. This required extending some measures used in importance analysis on noncoherent MSSs. The extension was done using logical differential calculus. The presented approach can be used to optimize number of attributes occurring in the table. Furthermore, it can also be used to decide which attributes have to be measured with the most accuracy to ensure that the prediction based on the table representing the discovered knowledge will be correct.

# 5th International Workshop on Advances in Semantic Information Retrieval

RECENT advances in semantic technologies form a solid basis for a variety of methods and instruments that support multimedia information retrieval, knowledge representation, discovery and analysis. They influence the way and form of representing documents in the memory of computers, approaches to analyze documents, techniques to mine and retrieve knowledge. The abundance of video, voice and speech data also raises new challenging problems to multimedia information retrieval systems.

We believe that our workshop will facilitate discussions of new research results in this area, and will serve as a meeting place for researchers from all over the world. Our aim is to create an atmosphere of friendship and cooperation for everyone, interested in computational linguistics and semantic information retrieval. The ASIR'15 workshop will continue to maintain high standards of quality and organization, set in the previous years. We welcome all the researchers, interested in semantic information retrieval, to join our event.

## Topics

The workshop addresses semantic information retrieval theory and important matters, related to practical Web tools. The topics and areas include but not limited to:

- Domain-specific semantic applications.
- Evaluation methodologies for semantic search and retrieval.
- Models for document representation.
- Natural language semantic processing.
- Ontology for semantic information retrieval.
- Ontology alignment, mapping and merging.
- Query interfaces.
- Searching and ranking.
- Semantic multimedia retrieval.
- Visualization of retrieved results.

***Abstract*—The paper is devoted to classification of MEDLINE abstracts into categories that correspond to types of medical interventions - types of patient treatments. This set of categories was extracted from Clinicaltrials.gov web site. Few classification algorithms were tested including Multinomial Naive Bayes, Multinomial Logistic Regression, and Linear SVM implementations from sklearn machine learning library. Document marking was based on the consideration of abstracts containing links to the Clinicaltrials.gov Web site. As the result of an automatical marking 3534 abstracts were marked for training and testing the set of algorithms metioned above. Best result of multinomial classification was achieved by Linear SVM with macro evaluation precision 70.06%, recall 55.62% and F-measure 62.01%, and micro evaluation precision 64.91%, recall 79.13% and F-measure 71.32%.**

## I. Introduction

AT THE moment an evidence-based medicine approach is actively developing in medical practice. This approach requires an expert to choose a method of patient treatment based on available evidences of safety and efficiency of the method. Complexity of evidence-based medicine application in practice involves not only control over saving new research results, but also assessment of the quality and reliability of existing ones. To solve this problem in evidence-based medicine a grading scale for ranking studies by level of evidence is used. For example, in the USA the National Guideline Clearinghouse[1] recommends to follow levels of evidence and grades (table I, table II).

TABLE I
Levels of Evidence

| | |
|---|---|
| I A | Evidence from meta-analysis of randomized controlled trials (RCTs) |
| I B | Evidence from at least one randomized controlled trial |
| II A | Evidence from at least one controlled study without randomization |
| II B | Evidence from at least one other type of quasi-experimental study |
| III | Evidence from non-experimental descriptive studies, such as comparative studies, correlation studies, and case-control studies |
| IV | Evidence from expert committee reports or opinions or clinical experience of respected authorities, or both |

TABLE II
Grades of Recommendations

| | |
|---|---|
| A | Directly based on Level I evidence |
| B | Directly based on Level II evidence or extrapolated recommendations from Level I evidence |
| C | Directly based on Level III evidence or extrapolated recommendations from Level I or II evidence |
| D | Directly based on Level IV evidence or extrapolated recommendations from Level I, II, or III evidence |

However, in some cases studies corresponding to the first level of evidence may contain errors in the correctness of randomized controlled trials (RCTs). More detailed description of some examples with errors in studies with the first level of evidence is reviewed in [1]. Solution of the problem is the Grading of Recommendations Assessment, Development and Evaluation (GRADE) system. This system evaluates level of evidence for different studies and ranks them by recommendation significance with due consideration of additional criteria for evaluation. Additional criteria for GRADE are presented in table III and described in more detail in [2]. GRADE considers only two classes of recommendations: strong or low-level recommendations. The quality level of evidence is presented in 4 levels. Thus, using additional GRADE factors it becomes possible to rise or lower the value of research.

Another actively developing research trend is information retrieval application in the field of medicine based directly on the use of MEDLINE[2] database. For example, in [3] MEDIE search engine developed for MEDLINE database, that executes semantic search, keyword search and generalized concordance lists (GCL) search is described. In [4] the Hierarchical Hidden

Markov Models algorithm for retrieving information about protein and its location from the MEDLINE abstract database is considered. Study [5] considers a method of automatic term extraction developed specifically for indexing documents from large medical collections. Computational experiments are conducted on a set of documents from MEDLINE database. In [6] an unsupervised clustering technique called SOPHIA is presented, that is evaluated on the MEDLINE testing set collection. Study [7] describes an experiment that changes the ranking strategy using the term-graph data structure for assessing the importance of a document to a user's query to the MEDLINE database. In [8] existent question-answering system based on principles of evidence based medicine is presented. Study [11] describes a fuzzy VIKOR framework for ranking internet health information providers.

Based on the relevance and demand for joint studies in the field of medicine and information retrieval, it was decided to start a development of a search engine for the MEDLINE database on the basis of the Saint-Petersburg State University with the support of Pavlov First Saint-Petersburg State Medical University and Tashkent Institute of Postgraduate Medical Education. The main goal of the project is to develop a new ranking method for search results, which takes account for a level of evidence and GRADE criteria.

## II. Problem Statement

The object of analysis of this work are documents containing abstracts of articles from the MEDLINE international database of medical research. The goal is to group abstracts according to subtypes of medical interventions. Subtypes of medical interventions correspond to various methods for patient treatment and prophylaxis. Examples of medical intervention subtypes were taken from the Clinicaltrials.gov[3] Internet resource:

1). Drug;
2). Biological;
3). Device;
4). Dietary Supplement;
5). Procedure;
6). Radiation;
7). Behavioral;
8). Genetic;
9). Other.

This website is a public register approved by the US International Committee of Medical Journal Editors. It provides relevant structured information about conducting clinical studies for a wide range of diseases.

The assigned task falls within the domain of machine learning and requires an implementation of the following auxiliary problems:

1). Development of a method for automatic markup of abstracts from a training and test set by medical intervention subtypes, based on the existence of a link between documents that represent paper abstracts from MEDLINE database and contents of registered clinical trials on Clinicaltrials.gov. The link is presented by reference to Clinicaltrials.gov Web resource.

2). Training methods for multinomial classification by means of selected set of classical algorithms such as Multinomial Naive Bayes, Multinomial Logistic Regression, and Linear SVM from the sklearn[4] library for further evaluation and selection of a more effective algorithm.

First it was decided to evaluate linear multinomial classification algorithms for an obtained marked sample of MEDLINE abstracts. Therefore, the following linear algorithms were chosen: Multinomial Naive Bayes, Multinomial Logistic Regression, and Linear SVM. In the future it is planned to choose a set of nonlinear multinomial classification algorithms and conduct experiments with the same marked sample of MEDLINE abstracts.

## III. Methods for abstracts markup

At the first stage of handling the problem 90 paper abstracts of the year 2011 taken from MEDLINE database and

[3] https://clinicaltrials.gov/

[4] http://scikit-learn.org/

which contained links to the Clinicaltrials.gov Web site were examined. To simplify abstract processing, an abstracts.xml document was created which has the following structure (per entry). Document structure (1):

```
<document>
   <doc_id></doc_id>
   <date></date>
   <title></title>
   <body></body>
   <topics></topics>
   <place></place>
   <author></author>
   <type></type>
</document>
```

where: <document> is a document container; <doc_id> is a paper identifier; <date> – publication date of the article; <title> – title of the article; <body> – body of the abstract; <topics> – article keywords; <place> – journal where the article was published; <author> – paper authors; <type> – a subtype of medical intervention. All abstracts were transfered into this structure. Every record in abstracts.xml satisfies the structure listed above.

These 90 documents were marked manually based on the search for links between abstracts and Clinicaltrials.gov Web resource. Linkage was performed by finding in abstract a reference (eg., NCT00893711). Such a reference meant that the study was indexed at Clinicaltrials.gov. The sequence of manual markup was as follows:

1) A link to Clinicaltrials.gov site was retrieved from an abstract.

2) With the help of Clinicaltrials.gov internal search engine a search was performed in order to find studies corresponding to the reference given in the abstract. An example of using internal search engine is presented in Fig. 1.

3) After the search, a found subtype of medical intervention was manually added to the document structure in the <type> </type> field. It was proposed to impose a restriction on the Clinicaltrials.gov web-resource search results: if the study was represented by two subtypes of medical intervention as it is shown in Fig. 1, it was suggested to use the first subtype because it contains the main information about the study.

As a result of manual marking it was possible to group 60 out of 90 abstracts into the following subtypes: Behavioral, Biological, Device, Dietary_Supplement, Drug, Other, and Procedure. The remaining 30 abstracts were divided into 4 groups:

1) no link to clinicaltrials.gov;

2) contains a link, but no information about the subtype of medical intervention;

3) contains a link but studies are of observational type;

4) contains a link with an error (eg., ISRCTN51481987).

It was further decided to consider corpus containing 2000000 abstracts for years 2006 to 2013 and automate the process of markup. An automation has been implemented with the help of an application developed in python that performs a search for links in abstracts (eg. NCT00893711) as a regular expression and a web-crawler that searches through links http://clinicaltrials.gov/show/NCT00776256?resultsxml=true replacing the part (NCT00893711) with the one found in the abstract and extracting data from the xml page contained in the <intervention_type> field. Results extracted from <intervention_type> field were then added to the <type> </ type> field of document structure (1) using the developed software application. The result of parsing xml pages also imposes restrictions: in case of two fields <intervention_type> is marked by the first field.

As a result of an automatic marking of 2000000 abstracts, 3534 abstracts were marked. Remaining abstracts were divided into groups:

1) no link to clinicaltrials.gov;

2) contained a link, but when referring to web-crawler on corresponding page an error appeared "404 - page not found";

3) contained a link but corresponding studies were of observational type;

4) contained a link with an error (eg., CTNO1481987).

As a result of marking, every subtype of medical intervention aggregated the following number of the abstracts: Behavioral – 585, Biological – 242, Device – 238, Dietary Supplement – 191, Drug – 1619, Other – 333, Procedure – 300, Radiation – 18, and Genetic – 8. After that, 3534 abstracts were divided into training set and testing set for performing training and testing of the following classifiers: Multinomial Naive Bayes, Multinomial Logistic Regression, and Linear SVM using the sklearn library. Also, experiments with changing parameters of classifiers were performed in order to determine the most efficient algorithm for classification.

## IV. Experimental part

This section presents experiment results for multinomial classification of automatically marked 3534 MEDLINE abstracts by subtypes of medical interventions. Such algorithms as Multinomial Naive Bayes, Multinomial Logistic Regression, and Linear SVM were used (names of algorithms in sklearn library: MultinomialNB, LinearSVC, LogisticRegression). Marked abstracts were divided into training set and testing set in ascending order by date of publication as follows:

- For training:
  - 2651 abstracts from 2006 till 2012 year containing the following number of classes with abstracts: Behavioral - 450, Biological - 174, Device- 189, Dietary Supplement - 145, Drug - 1198, Other - 266, Procedure - 209, Radiation - 12, Genetic - 8.
- For testing:
  - 883 abstracts from 2012 till 2013 year containing the following number of classes with abstracts: Behavioral - 135, Biological - 68, Device - 49, Dietary Supplement - 46, Drug - 421 Other - 67, Procedure - 91, Radiation - 6.

As a partition result, testing set contained the following sub-types of medical interventions: Behavioral, Biological,

Dietary Supplement, Drug, Other, Procedure, and Radiation. To evaluate classification result for the testing set for each subtype of medical intervention such measures as precision, recall and F-measure were used:

$$Precision = \frac{TP}{TP + FP},$$

$$Recall = \frac{TP}{TP + FN},$$

$$F\text{-}measure = 2 * \frac{Precision * Recall}{Precision + Recall},$$

where $TP$ – true positive classification value, i.e. the classifier identified an element of the testing set correctly. $FP$ – false positive value, i.e. the classifier referred an element to the class falsely. $FN$ – false negative elements, i.e. the classifier falsely did not refer an element to the class. To assess different multinomial classification algorithms, macro and micro precision and recall values, as well as F-measure were calculated using the following formulas:
Macro:

$$precision = \frac{\sum_{n=1}^{m} Precision_n}{m},$$

$$recall = \frac{\sum_{n=1}^{m} Recall_n}{m},$$

$$F\text{-}measure = 2 * \frac{precision * recall}{precision + recall}.$$

Micro:

$$precision = \frac{\sum_{n=1}^{m} TP_n}{\sum_{n=1}^{m} TP_n + \sum_{n=1}^{m} FP_n},$$

$$recall = \frac{\sum_{n=1}^{m} TP_n}{\sum_{n=1}^{m} TP_n + \sum_{n=1}^{m} FN_n},$$

$$F\text{-}measure = 2 * \frac{(precision) * (recall)}{(precision) + (recall)},$$

where $m$ is the number of classes. Calculation of micro precision and recall was performed by summing up all true positive, false positive and false negative results of classification for each class.

In this experiment we use the «bag of words» model [9]. For vector of features we use vector of terms from the dictionary, composed of all annotations from corpora. In process of forming dictionary no stemming was used. With the help of $tf\text{-}idf$ metric, weight for every term was assessed.

$$tf\text{-}idf(t, d) = tf(t, d) * idf(t),$$

where $tf$ – term frequency:

$$tf(t, d) = \frac{n_{t,d}}{|d|},$$

$t$ – term, $d$ – document, $n_{t,d}$ – entry of $t$ term occurence in $d$ document, $|d|$ – total number of terms in $d$ document; $idf$ – inverse document frequency:

$$idf(t) = \log \frac{N}{df(t)},$$

where $N$ – number of documents in corpora; $df$ – number of documents, in which term $t$ occures.

During the experiments, the optimal parameters of classifiers were selected for the case with the removal of stop words, as well as for the case with no stop words removing from the dictionary. More detailed options of the algorithms and their values are given in the documentation for the library

sklearn. Below the optimum parameters of the algorithms are presented.

The following algorithm parameters were used for the classification of documents from the test set with no account for stop words:

MultinomialNB: alpha = 1.0, fit_prior = True;

LinearSVC: penalty = 'l2', loss = 'squared_hingle', multi_class = 'ovr', C = 1.0;

LogisticRegression: penalty = 'l2', multi_class = 'ovr', C = 1.0, solver = 'liblinear';

Results are presented in tables IV, V.

The following algorithm parameters were used for the classification of the testing set with stop words in the dictionary:

MultinomialNB: alpha = 2.0, fit_prior = True;

LinearSVC: penalty = 'l1', loss = 'hingle', multi_class = 'crammer_singer', C = 0.8;

LogisticRegression: penalty = 'l1', multi_class = 'multinomial', C = 0.8, solver = 'newton-cg'.

Corresponding results are presented in tables VI, VII.

Based on the results of computational experiments, the best results were obtained without accounting for stop words in the dictionary and when using LinearSVC with the following parameters: penalty = 'l2', loss = 'squared_hingle', multi_class = 'ovr', C = 1.0.

Corresponding results for macro evaluation: precision= 70.06%; recall = 55.62%; F-measure = 62.01%. Results of micro evaluation: precision = 64.91%; recall= 79.13%; F-measure = 71.32%.

## V. Discussion

Relatively low classification quality rates are associated with the fact, that documents for classification describe medical studies, which were performed during patients treatment. Some differences in documents from various classes are related only to subtypes of medical treatments, that were considered in the studies, and can describe patients suffering from the same disease. The result that was recieved can be compared with results from the research [10],where maximum F-measure value of 80% has been achieved by using linear SVM during the classification of abstracts on RCTs and on non RCTs. In our case maximum value of macro F-measure = 62.01% and micro F-measure = 71.32% has been also retrieved when using linear SVM, with multiclassification of abstracts by subtypes of medical interventions.

## VI. Conclusion

This article describes methods that allow to automate grouping MEDLINE abstracts by subtypes of medical interventions. Computational experiments were carried out using the following algorithms: Multinomial Naive Bayes, Multinomial Logistic Regression, and Linear SVM from the sklearn library. Linear SVM algorithm showed the best result of multinomial classification.

For further research it is planned to perform the following tasks:

- chose the set of nonlinear multinomial classifier algorithms and examine 3534 MEDLINE abstracts using these algorithms;
- classify the remaining 1996466 unmarked abstracts using Linear SVM algorithm;
- extract facts from the marked abstracts about a specific subtype of a medical intervention described in the study;
- group abstracts by subtypes of medical intervention using a catalog of natural science subjects MESH[5] and contents of the <topics> field from the document structure (1).

***Abstract*—The paper contributes to the problem solving in semantic browsing and analysis of scientific articles. With reference to presented visual interface, four – the most popular methods of mapping including own approach - MDS with spherical topology, have been compared. For a comparison quantitative measures were applied which allowed to select the most appropriate mapping way with an accurate reflection of the dynamics of data. For the quantitative analysis the authors used machine learning and pattern recognition algorithms and described: clusterization degree, fractal dimension and lacunarity. Local density differences, clusterization, homogeneity, and gappiness were measured to show the most acceptable layout for an analysis, perception and exploration processes. Visual interface for analysis how computer science evolved through the two last decades is presented on website. Results of both quantitative and qualitative analysis have revealed good convergence.***

## I. Introduction

Nonlinear growth of scientific writing imposes a new forms of academic databases management. The latter includes the both retrieval and analytical exploration. Analysts, science of science professionals, science policy makers need various computing, statistical and visualization tools to monitor how science or scientific domains evolved.

Authors designed and described in a series of papers [1], [2] the visual interface for analysis of dynamics of computer science through the two last decades[1]. Screenshot of spherical application is shown on Figure 1. Users can interact, manipulate and browse the data and see how graphical pattern change in time. The nodes represent scientific articles from digital library and the colour – appropriate thematic category. Similarity metrics was based on semantic relations between documents [2]. In order to generate 3D layout, multidimensional scaling (MDS) technique was applied and enriched by Morse potential [1].

Overlapping spots show where the categories mutually integrate that means an articles at that location are semantically similar. Visualization of classified documents reveals both organization of digital library content as well as allows users to track how it changes over time. This paper presents further study on visualization maps. Authors decided to test this prototype regarding to mapping algorithms. Four mapping methods were compared in terms of dynamics and analytical possibility of output visualization. The next chapter shows the outline of VxOrd, MDS, VOS, SOM as the most popular methods.

## II. Mapping preview

How we, as analysts, perceive and understand the connections between data, depends on graphical layout. Thus, the final structure of visualized knowledge can be drawn either by spatial arrangement (2D or 3D) of analysis units or by the relationship between nodes in graph or combination of these two.

One of the basic ordination algorithm - VxOrd extends a traditional force-directed approach [3]. VxOrd determines the both number and size of clusters automatically based on the data. Popular software for data mapping and visualization - Gephi[2] uses this technique. Due to Gephi users can analyse large networks consisting of even millions of nodes. The most popular technique for dimension reduction is MDS, which involves minimizing the difference between Euclidean and graph-theoretic distances. MDS has been widely applied for constructing knowledge maps of authors, articles, journals, and keywords [3]-[5]. The same satisfactory representation of knowledge can be produced by use of new mapping technique VOS introduced in series of works by Van Eck and Waltman [6],[7]. The idea of VOS is to minimize a weighted sum of the squared distances between all pairs of items.

Dimension reduction can be also achieved in self organized maps – the kind of unsupervised neural network which aimed to project high-dimensional data into a lower-dimensional space [4]. The nodes (input vectors) form two dimensional regular grid; node's neighbourhood is defined to be all connected nodes. During training process similar input vectors stimulate adjacent neurons and therefore output SOM map shows semantic relationships between data, where similar items are mapped close together. Comparing MDS and VOS,

researchers concluded that maps constructed using VOS approach provide a more satisfactory representation of the underlying dataset [8]. MDS-VOS tests revealed the first one is distance preserving while the second - topology preserving technique [9],[10].

## III. Methodology

The complex structure of large graphs commonly is measured by modularity. According to Fortunato [11], modularity can be defined as the function which evaluates the goodness of partitions of graph and is defined by ties between vertices, vertices and hubs. Structure described by linked objects does not match with character of present data. Authors analyse the visualization of classified documents. Primary categories are taken from library classification. All relationships between collected classes and documents were predefined by specialists permanently working on computer science taxonomy. Visualized articles are assumed to reveal semantics while keeping their thematic similarity. These new correlations (down-top) between data allow to rich independence of the original organization of items (top-down). As every rigid scheme, it is characterized by adequacy and disjointedness of subclasses. Therefore, evaluation metrics can be based on spatial configuration of visual layout instead of links outline. To analyze the final nodes distribution, image processing methods were applied. Then evaluation of graphical pattern should be carried out taking into account the accuracy, topology (space filling and capacity) and perception abilities of users.

The authors present alternative approach: a sphere surface has been selected as a target mapping space. There are some arguments for a sphere surface: it “has no edges and therefore it is possible to represent not only local similarities but also large-scale ones regarding the whole space. The benefit of a curved surface in comparison to a plane one is a more capacious exploration space” [1,10]. 3D visualization is a popular but also challenging method in large dataset mapping and modelling.

### A. Assumptions

By implication, evaluation process will touch how to fit interface to the requirements of analysts and domain experts. The study is based on the following assumptions.

1. A given visualization layout might serve as a graphical interface for the exploration and semantic retrieval of scientific articles. From this point of view the most important is configuration on the bottom level (documents) – then can be evaluated the spatial distribution of nodes.
2. Current modifications by editors of the original classification are aiming at its improvement. The classification reflects the most of current changes in computer science. Quickly developing categories will form dense clusters and overlap each other. These tendencies must be visible on visualization maps generated for different time periods.
3. In the construction of the ergonomic user interface, such features as capacity, homogeneous distribution and edgelessness must be taken into consideration.

Short movie[3] shows how three dimensional configuration allows the user to analyze semantic distribution of articles and its behavior in time.

### B. Evaluation steps

On Figure 2 we can see the elements of evaluation process. Continuity characteristics is crucial for present study. For this purposes clusterization potential was validated by machine learning and image recognition algorithms. Structural complexity can be evaluated by fractals analysis. Quantitative measures are different for several maps and the changes tendency are essential too.

All dimension reduction methods determine the arrangement of classes and subclasses nodes. Documents distribution was calculated by using geometrical rules in 2D or 3D space [10]. Obtained pattern became the basic material for comparison and further study.

If we plan to involve users to scientific domain analysis, visualization interface must be user-friendly and carry good navigational features. Another usefulness of such application is retrieval of semantically similar documents. Precision in this case will be an appropriate measure of this visual searching system.

### C. Research material

Visualization maps were obtained by using the same data but distinct in terms of data configuration (like matrixes versus data pairs), mapping algorithms and space topology. The series of every ten-year layouts show the changes of pattern and thus the evolution of the ACM classification and computer science knowledge (see Appendix). An insight into the differences in graphical patterns could reveal the most and the least complex structures due to human perception. The system of human perception is able to recognize a natural tex

[3] www.wizulizacjainformacji.pl/unas/interface.avi

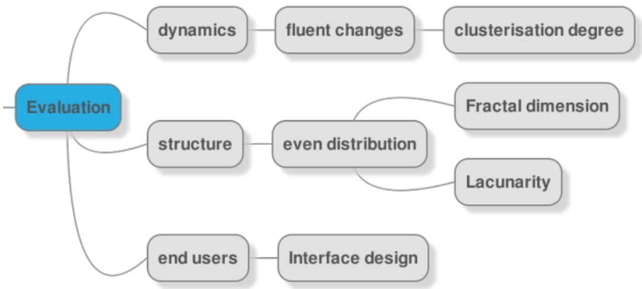

Fig. 2 Decision map of visualization evaluation steps

ture appearing in nature as a result of evolutionary adaptation. The human vision allows determining approximately whether the perceived structure differs one from another in terms of complexity[12].

For example, the first series of maps is characterized by a relative even distribution while VxOrd by data grouping on edges and bends. Furthermore, VxOrd and VOS distributions are highly limited to the output geometry [10]. The result may be a non-effective space for navigation in those cases. But human perception cannot be one of the main criteria for comparison and estimation of visual layouts, although useful in the final conclusions. Quantitative approach requires that the authors analyze local density differences and quantify clusterization, rarefaction, homogeneity and porosity.

Output maps can be described by both density and colour of nodes. If information about the main thematic category assignment is excluded (i.e. the colour), the clusters can be identified by density only. Consequently, clusterization and its changes can deliver information on how knowledge advances and how knowledge organization changes throughout two decades, independently of the primary (original) classification.

## IV. Quantitative Analysis of Maps

### A. Clusterization and its dynamics

To identify clusters on given maps we used the most popular partition technique, based on distances between points and/or points to centroids – k-means clustering [11]. Algorithm aims to minimize the within-cluster sum of squares:

$$\sum_{i=1}^{k}\sum_{x_j\in S_i}\|x_j-c_i\|^2 \qquad (1)$$

where $S_i$ indicates the subset of points in the $i$-cluster, $c_i$ – the centroid of cluster.

The disadvantage of this algorithm in our assignment is the requirement to know the number of clusters. To find optimal number of classes we modeled the data by a set of Gaussian distributions [13].

The number of components can be estimated by the Bayesian Information Criterion [14] (BIC), which is based on a penalization of the observed log-likelihood – the function of $x$, $\theta$. The preffered model is the one with the lowest value of BIC which decides about the number of clusters. Thus the 6 clusters are recognized for the MDS –sphere (authors method) and SOM and 8 for both VxOrd and VOS. These new clusters reorqanize initial data assignment to the 11 main initial categories, coded by colour. By k-means clustering the centroids of clusters are found, demonstrated on Figure 3 according to the the MDS –sphere map.

Dynamical characteristics of clustering are crucial for a final evaluation of the presented approaches in terms of structural analysis. In any sequence of maps it is possible to find the one with a highly developed clusterization just intuitively.

To evaluate clustering and its dynamics, a misclassification rate offered by the standard k nearest neighbour (k-NN) rule was used as a criterion. That error rate was estimated by the leave-one-out method [15],[16]. The k-NN rule assigns the classified object to the class most heavily represented from among its nearest objects in the training set (i.e. nearest neighbours). The reference set, also called a training set, is a set of objects with a known class membership and in a certain sense it defines the considered classes. The leave-one-out method consists in the classification of each object from the reference set by the decision rule obtained from the training set decreased by the currently classified object. The ratio of the number of misclassified objects to a numerical force of the reference set estimates the above mentioned error rate used as the clustering quality criterion.

The low error rate value denotes that the considered classes (or clusters) differentiate easily, but high values of the error rate mean that the classes overlap. The leave one out method is very convenient in the case of classifiers based on the k-NN rule since no training is required. This property of the k-NN classifiers was intesively used for creating a fuzzy k-NN rule proposed by one of the authors of the present work [17] and for introducing the more sophisticated pair-wise k-NN classifier [18].

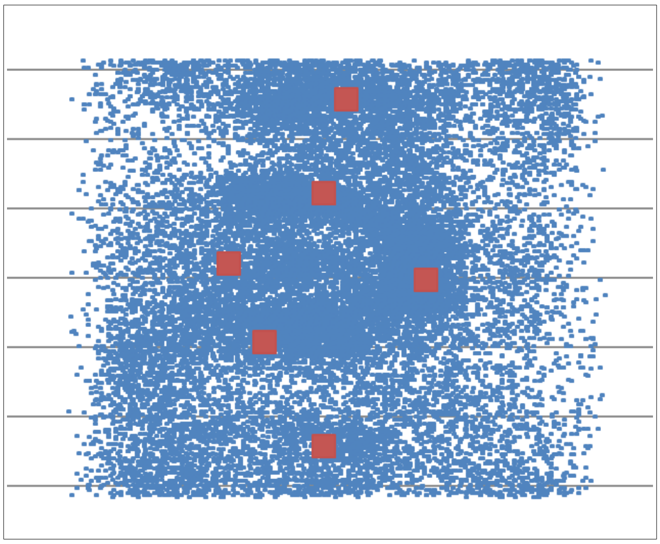

Fig. 3 Data distribution with six clusters centroids (along “horseshoe” shape).

TABLE I.EVALUATION OF CLUSTERIZATION BY K-NEAREST NEIGBOURS METHOD FOR EACH VISUALIZATION MAP BASED ON ERROR RATES.

| **Phase** | **Training** | | | **Testing** | | |
|---|---|---|---|---|---|---|
| | **1988** | **1998** | **2009** | **1988** | **1998** | **2009** |
| Authors' method | 0.0140 | 0.0115 | **0.0074** | 0.8890 | 0.8300 | **-** |
| VOS | 0.0119 | **0.0078** | 0.0110 | 0.9011 | **-** | 0.8710 |
| VxOrd | 0.0084 | 0.0107 | **0.0045** | 0.8707 | 0.7898 | **-** |
| SOM | 0.0143 | **0.0121** | 0.0128 | 0.8480 | | 0.8090 |

In every series of visualizations it is possible to point at the map with the clearest clustering structure – model map. The other, as it can be assumed, develops towards clustering pattern. If the algorithm for pattern (points) clustering of model map is trained, other ones can be tested by using the nearest neighbour method. Which one serves as a training set and which one as a testing set can be found first by evaluation of the standard k-NN classifier. The lower error rate means a better clustering structure (bold numbers in *Training* part of Table 1).

The results of training allow selecting an apropriate dataset (bold) for testing. During the testing phase (*Testing* part) the clusterization quality can be tracked on the basis of error rate changes. It is worth noting that comparison must be made along rows, not columns, because of the use of different methods to generate patterns.

The data in Table 1 show that the clusterization increases in one case – the first row, which characterizes the authors' approach. It proves continuous changes of CCS towards overlapping categories and reorganization needs.

### B. Even distribution, FD and Lacunarity

The authors' study of visualization maps relates to visual interface: which method of mapping can deliver the best way to explore a complex dataset of scientific articles?

Restrained homogenous distribution on a sphere surface can be estimated by the volume of empty places. The more holes in the pattern, the more heterogeneous it is. The appropriate parameter is *Lacunarity* - the degree of holes distribution having the lowest value for indeterminate structure. Lacunarity is often used in medical imaging for detection of structural changes in bone texture on radiographs [19].

Visualization maps can be considered as flat textures associated with the patterns of documents nodes distribution. Lacunarity $\lambda$ is defined as:

$$\lambda_{\epsilon,g} = CV^2_{\epsilon,g} = \left(\frac{\sigma}{\mu}\right)^2_{\epsilon,g} \qquad (2)$$

where $\sigma$ is the standard deviation and $\mu$ is the mean for pixel per box at this size $\varepsilon$, in a box at this orientation $g$. Lacunarity pertains to both gaps and heterogeneity. To simplify, the more *gappiness* in the image (i.e. sparsely occupied maps), the higher lacunarity. Some recent research has shown that there is a correlation between lacunarity and *fractal dimension*, FD [20],[21].

The FD is a complexity indicator with a non-integer value. The fractal dimension could be characterized as a scale of transition to homogeneity and is therefore very practical in the dynamics study case. Because the maps were generated by three different mapping algorithms they present distinct homogeneity, what is according to our assumption, one of the criteria of the ergonomic visual interface.

The values of lacunarity and the FD for every map are shown in Table 2. The highest value in each row (bold numbers in the first part of Table 2) indicates a map with the large porosity (gappiness). Bold FD values in the second part of the same table means the best formed structure (implicitly clear clusterization). The first row data presents a continuous growth of complexity degree with simultaneously dense occupation (high FD and lowest lacunarity values). Other (VOS, SOM and VxOrd) demonstrate oscillations are difficult to interpret. Consequently, the dynamics of each index across time for every method was evaluated. Lacunarities of every method should not be compared because of different spanning geometry.

If should be taken into consideration that the fractal dimension for random (or pseudo-random) distribution equals 2.77, the more does the FD tend to this value, the pattern is more homogeneous [22]. And inversely, the low FD (bold numbers in Table 2) means the distribution resembles linear. A stable structural change (in contrary of step change) in time is proved by the authors' method.

## V. DISCUSSION

According to authors' conception, in order to measure dynamics of graphical patterns we need to focus on how complexity evolves. Therefore clustering resolution has been tested by use of machine learning and pattern recognition algorithms.

TABLE II. LACUNARITY AND FD FOR EACH VISUALIZATION MAP.

| **Method** | **Lacunarity** | | | **Fractal Dimension** | | |
|---|---|---|---|---|---|---|
| | **1988** | **1998** | **2009** | **1988** | **1998** | **2009** |
| Authors' method | 0.0185 | 0.0155 | **0.0147** | 2.34 | 2.39 | **2.50** |
| VOS | **0.0035** | 0.0144 | 0.0067 | 2.23 | 2.15 | **2.40** |
| VxOrd | **0.0247** | 0.054 | 0.0421 | 2.18 | 2.15 | **2.23** |
| SOM | 0.3340 | **0.305** | 0.319 | 1.82 | 1.84 | **1.97** |

The authors proposed the qualitative measures for evaluation of structural changes of pattern: FD and lacunarity.

In general, we can conclude: the larger complexity degree, the lower randomness. On the other hand, the complex structure is also can be determined by the clustering level. The current findings confirmed by presented measures (Table 1, Table 2) show that clusters have become more explicit with time at the maps generated by authors' approach and at the same time tend to uniform distribution (lowest lacunarity and FD resembles the value of random distribution). The high lacunarity informs about dense network of holes among others, due to overlapping pattern. Next acceptable technique in the terms of changes continuity is SOM. Qualitative approach to compare visualization maps [10] shows the similar results: both MDS-sphere and SOM reveal consequence in dynamics changes, moreover VOS and VxOrd – inappropriate topology for data exploration [10, Appendix]

How easy users can play with data and analyze their change – show the ergonomic properties of visualization interface. Homogeneous occupation of visual layout, edgeless, continuity in changes should feature good visualization [23]. Several papers described particularly this application from the end-users-analysts point of view [10], [24]. Another practical aspect pertain relevant documents retrieval due to visual representation. This still remains the main direction of current study. After receiving good precision for a small sample, authors intend to repeat experiment with bigger dataset and all presented methods.

Recent research [20],[21] show a strong correlation between the FD and lacunarity. To check this, it is required to have a more representative dataset i.e. be multi-various. To find essential changes including paradigms, the period of analysis must be extended to three or four decades, i.e. until 2017. There basic technological problem has appeared: the ACM has changed the classification and applied it to the collection of 2013. The success to supplement the dataset depends on whether the ACM will standardize the old classification schemes according the new version and adapt it to the whole dataset.

Undoubtedly, a sequential series of three maps is not enough to estimate knowledge evolution dynamics. A more multi-variety dataset to track all changes in fast growing knowledge is needed, but truly objective circumstances concerning data gathering were appeared. However, proposed measures can be considered if we need to select the best data distribution in the terms of interface functionality.

## VI. SUMMARY

Visual interface for analyzing how computer science evolved through the two last decades is briefly presented in current paper. This application includes an interactive 3D map of scientific articles organized by their semantic relationships. The authors proposed the conception how to quantitatively evaluate different visualization maps in respect of possibilities of dynamics analysis. They also characterize topological arrangement in the terms of navigation functionality.

Four methods of mapping including own approach of mapping (MDS with spherical topology) have been compared. Quantitative measures allowed selecting the most appropriate mapping way with an accurate reflection of the current changes of computer science. In the quantitative analysis authors tracked the changes of pattern clusterization over time. Clusterization degree they evaluate using machine learning and pattern recognition algorithms (Table 1). They adopted both lacunarity and the fractal dimension of visualization patterns to find the scale of randomness in dynamics (Table 2). Moreover the local density differences, clusterization, rarefaction, homogeneity, and gappiness were measured to show the most acceptable layout for analysis, perception and exploration processes. 3D MDS maps (authors' approach) and SOM have shown the better properties than VOS and VxOrd. These results have proved the findings and interpretations obtained from qualitative analysis [9]. Given maps have revealed essential changes in computer science literature during the time of the development of the CCS classification compared.

***Abstract*—This paper describes the automatic summarization system developed for the Polish language. The system implements sentence-based extractive summarization technique, which consists in determining most important sentences in document due to their computed salience. A structure of the system is presented, as well as the evaluation method and achieved results. The presented attempt is intended to serve as the baseline for future solutions, as it is the first summarization project evaluated against the Polish Summaries Corpus, the standardized corpus of summaries for the Polish language.**

## I. Introduction

AUTOMATIC text summarization is a very active research field in recent years. Its purpose is to reduce a text document, by extracting its most important parts in order to create more condensed, but still human-readable form, known as summary. The task consists in the creation of an appropriate computer application and a framework for testing and evaluation.

In this paper we focus on sentence-based extractive summarization using machine learning. We implement well-known techniques, improved and merged into a single summarizing system. The system uses a list of features applied in previous projects, supplemented by new ones, introduced by the paper's authors. Polish Summaries Corpus, a resource created by Ogrodniczuk and Kopeć in [1] has been used as the dataset for training machine learning algorithms. No one has ever used this corpus to create a summarizing system before.

Moreover, an evaluation method has been developed. It is based on the ROUGE summarization evaluation package introduced at Document Understanding Conference (DUC) in 2004, by Chin-Yew Lin [2], who proved it to be a correct measure for the task. We propose to use this evaluation method in future automatic summarization solutions for the Polish language for the sake of objective comparison. The present solution could then serve as the baseline for new systems.

The paper is organized as follows: the rest of the current section describes briefly the aim of the summarization task and main methods in the field. Section 2 provides a review of already existing summarization systems for the Polish language. In section 3 Polish Summaries Corpus is described in detail. Section 4 outlines our solution, it's overall framework, as well as the employed set of features. Section 5 introduces the evaluation methodology and presents our experiments and their results. Eventually, section 6 contains some conclusions and the outline for future work.

### A. Aim of summarization

Modern digital technologies, including World Wide Web, result in information excess. Everyday brings vast amount of new on-line information of various type. Processing this continuously growing information databases is not possible by a single human. Automatic summarization is an attempt to confront information processing needs. It is based on the assumption that a computer system can read all data quickly and present its condensed from. Summarization is useful in medicine, law or scientific areas, as well as in everyday life.

Formally, in the area of text summarization, "summary can be defined as a text that is produced from one or more texts, that contains a significant portion of information in the original text(s), and that is no longer than half of the original text(s)" [3].

### B. Methods of summarization

Automatic text summarization may be classified according to program's input or output. As regards input, summarization may concern one document or multiple documents (multi-document summarization). Further, in case of multi-document summarization, input data may be *monolingual* or *multilingual*. As regards output, one may distinguish *extracts* and *abstracts*. Mani (2001) claims that "an extract is a summary consisting entirely of material copied from the input" (which in fact can be paragraphs, sentences, phrases, terms or even single nouns) and "abstract is a summary at least some of whose material is not present in the input". Extractive summaries are obviously easier to obtain. Moreover, summaries may be *indicative* or *informative*, which means they can indicate source text's topics and give a brief idea of what the original text is about, or cover the topics in the source text, respectively [3]. Finally, *generic* and *user-focused* (a.k.a. *query-driven*) summaries may be distinguished. *Generic* summaries try to cover all relevant information from the source text, while *user-focused* ones respond to user's information needs expressed as topic or query [3].

Literature often considers automatic summarization a three-stage process. Lloret (2006) names the following steps of the process:

978-83-60810-66-8/$25.00©2015, IEEE

- *interpretation* of the source text in order to obtain a text representation,
- *transformation* of the text representation into a summary representation,
- *generation* of the summary text from the summary representation.

Methods of text summarization may differ as far as the level of processing is concerned: *surface*, *entity*, or *discourse* levels [4]. It is worth noting that there exist systems, which adopt hybrid-approaches.

*Surface-level* approaches make use of shallow features to analyze information included in a text document. Usually, these features are combined together into a salience function used to extract information. Examples of such features are:

- Thematic features — based on term frequency analysis and statistically salient terms,
- Location features — based on position in text, paragraph or section depth,
- Background features — based on presence of title or headings terms, or a user's query,
- Cue words and phrases — based on presence of special 'bonus' or 'stigma' terms.

*Entity-level* approaches are based on the internal representation of text. They model text entities and their relationships across a document. Examples of such relationships between entities are:

- Similarity — e.g. vocabulary overlap,
- Proximity — distance between text units,
- Co-occurrence — words occurring in common contexts,
- Thesaural relationship among words — e.g. synonymy, hypernymy,
- Coreference — e.g. anaphora, cataphora, noun phrases,
- Logical relations — e.g. agreement, contradiction, entailment, consistency,
- Syntactic relations — e.g. relations based on parse trees,
- Meaning representation-based relations — e.g. predicate-argument relations.

*Discourse-level* approaches model the global structure of text, and its relation to communicative goals. Examples of such structures are:

- Format of the document,
- Threads or topics as they are revealed in the text,
- Rhetorical structure of the text.

## II. Review of experiments on summarization of Polish Texts

This section covers experiments on automatic summarization for the Polish language, resulting in theoretical works, as well as working implementations. All of them apply extractive methods of summarization.

### A. PolSum2 (S. Kulikow)

The first attempt on automatic text summarization for the Polish language was made by Ciura et al. [5] and resulted in the *PolSum* system, which then evolved into *PolSum2*. The system is still available at http://las.aei.polsl.pl/PolSum/. *PolSum2* is an extractive system. It performs various kinds of text analysis (morphological, syntactic, semantic) in order to extract most important sentences from an input document. The system also recognizes anaphora, which results in better coherence between selected sentences.

*PolSum2* performs in three stages of summarizing[5]. The first stage, called 'Calling remote analyzer' is intended to call the remote server, which performs text analysis. The *Linguistic Analysis Server* (LAS) is used for this purpose. This tool, created by the same authors, performs linguistic analysis on the levels of: morphological, syntactic and semantic analysis. The syntactic analysis builds a parse tree on the basis of Syntactic Group Grammar for Polish (SGGP) [6]. The system also performs the analysis of anaphoric relations. The seconds stage of summarization process is 'Selecting the essential sentences'. There is no concrete information on the criteria for sentence weighting. The last stage is called 'linearization'. It is designed to create coherent output. Proper forms of words are generated and placed in proper places in sentence. The system also performs homonyms reduction and anaphora substitution for better result reading.

The papers that describe the system do not provide any information about evaluation results.

### B. Lakon (A. Dudczak)

Adam Dudczak's *Lakon* is another automatic text summarization system created for the Polish language [7]. It is available on-line at http://www.cs.put.poznan.pl/dweiss/research/lakon/. The system was developed as a result of author's Master Thesis, whose one of main goals was to compare effectiveness of some popular extractive methods for the Polish language. Three methods were developed. They were based on the following heuristics:

- $tf \times idf$ and *Bm25 Okapi* — assumes that words occurrence frequency determines sentence's salience
- sentence's position in text — assumes that most important sentences are often at the beginning of paragraphs,
- lexical chain — assumes that relations across sentences determine their salience.

The system was evaluated on the corpus created from 10 manually summarized newspaper articles. 60 volunteers manually created totally 285 summaries of these articles. Evaluation results indicated that the most effective features were words occurrence frequency and sentence's position. The lexical chains method was proved to be worse than the others.

### C. Summarizer (J. Świetlicka)

*Świetlicka's Summarizer* [8] is the latest tool created for Polish. It is available on-line at http://clip.ipipan.waw.pl/Summarizer. This solution is the most similar to the one proposed here. It uses various machine learning methods for training an extractive summarizer based on a set of sentence's features. These features include:

- LLR — *Log Likelihood Ratio*,
- $tf \times idf$,

- Sentence's centrality,
- Occurrence of characteristics phrases — bonus and stigma words, popularity of one or two first words of a sentence,
- Similarity to the title — indicating occurrence of words from the title in a sentence,
- Number of words starting with uppercase — indicating Named Entities,
- Number of tokens that are not proper words — i.e. punctuation or numbers,
- Localization — position of the sentence in paragraphs and position of the sentence in the whole text,
- Length of sentence,
- Length of paragraph,
- Length of text,
- Type of sentence — based on the last token: declarative, interrogative, imperative.

A number of tests were performed on different subsets of these features. The author used about 13 different machine learning algorithms in order to compare their effectiveness. The corpus was created by the author on his own and contains 102 newspaper articles for training and 67 articles for evaluation.

*Świetlicka's Summarizer* also performs simple summary linearization. It consists of three steps. At first, sentences are sorted in the order of their appearance in the document. Secondly, fragments in parentheses are removed in order to make sentences shorter. Lastly, some special words are removed from the beginnings of sentences, such as: therefore, moreover or however.

The discussed work contained the following conclusions:

- localization-based features, particularly sentence position in the paragraph and the whole document, tend to be the most important ones,
- sentence centrality feature is also very effective,
- cue words feature are not so effective,
- machine learning algorithms tend to be an effective solution for automatic summarization. Using a set of features result in better quality than using each separate feature.

## III. Polish Summaries Corpus

Polish Summaries Corpus is a resource created by Ogrodniczuk and Kopeć in 2014 [1]. Its aim is to provide a high quality corpus containing manual summarization examples. The corpus forms a significant facilitation for further researchers, who can build their own summarization tools based on this corpus, as well as evaluate them. Ogrodniczuk and Kopeć notice that previous works on automatic summarization in the Polish language lacked a common corpus and a common evaluation method, therefore their results are not comparable. *Rzeczpospolita corpus* — a collection of articles from the Web archive of a Polish newspaper [9] was used as the base corpus for Polish Summaries Corpus.

Polish Summaries Corpus contains 569 text documents divided into 7 categories: Society and Politics, Sport, Economy, Culture news, Law, National news and Science and Technology. All these texts have been manually summarized by independent annotators. All 569 documents have the extractive summaries and 154 have also the abstractive summaries. For each document in the corpus 5 independent propositions of summarization have been created. Each proposition of summarization contains 3 summaries of a given text of the approximate length of 5%, 10%, 15% of the original, respectively. The summaries are included in one another: 10% summary contains only fragments from previously selected 20% summary and so on. Therefore, the corpus size is 8355 summaries.

## IV. The proposed solution

The solution presented here implements sentence-based extractive summarization. It consists of two main components: linguistic analysis and summarization application. The latter component selects essential sentences and generates the result summary. The summarization component appplies neural networks as a machine learning algorithm. The Open Source implementation — PyBrain[10] was used.

### A. Methodology

The linguistic analysis component performs various kinds of text analysis. The input document is divided into paragraphs, sentences and tokens. Subsequently, lemmatization is performed, parts of speech, named entities and headers are determined. Finally, the internal document model is created and transferred to the summarization component.

The summarization component works as a three-stage process. The first stage computes feature values for each sentence in the document. The second stage is sentence weighting based on the previously trained machine learning model and computed features. In the third stage, the summary is prepared according to the obtained sentences weights. This stage includes the sorting of result sentences, according to their order in the original document.

### B. Description of features

This section describes each feature used in the system. Selection of the features was based on literature [3], [4], [11], [7], [8] as well as a few new ideas. The complete list of used features includes:

- *TfIdf* — sum of *term frequency – inverse document frequency* value for every word in sentence,
- *Centrality* — arithmetic average of sentences similarity to every other sentence in the document. Cosine similarity is used as a similarity measure between two sentences,
- *SentLocPara* — position of a sentence in the paragraph: in the first, second or third of equal parts,
- *ParaLocSection* — position of the paragraph in the document: in the first, second or third of equal parts,
- *SentSpecialSection* — occurrence in a special section like the beginning (introduction) or ending (conclusion) of document,

$$\text{ROUGE-N} = \frac{\sum\limits_{S\in\{ReferenceSummaries\}} \sum\limits_{gram_n \in S} Count_{match}(gram_n)}{\sum\limits_{S\in\{ReferenceSummaries\}} \sum\limits_{gram_n \in S} Count(gram_n)} \tag{1}$$

- *SentInHighestTitle* — number of words from heading or title in the sentence,
- *ParaLength* — paragraph length: short (up to 1 sentence), average (2–5 sentences) or long (more than 5 sentences),
- *SentLength* — sentence length: short (up to 7 words), average (7–14 words) or long (more than 14 words),
- *SentType* — type of the sentences, based on its last punctuation mark: declarative, interrogative or imperative.
- *MetaInfo* — sentences not referring to the document content, i.e.: an information about document's author or photo signatures,
- *AvWordLength* — the average of words lengths in sentences,
- *Verb* — existence of the final verb,
- *Nouns* — number of nouns in sentence,
- *Pronouns* — number of pronouns in sentence,
- *SentInHighestPname* — number of Named Entities in the sentence as found by a naive method, recognizing Named Entity as a word starting with capital letter,
- *NER* — number of Named Entities in the sentence as found by NERf Named Entities Recognition tool [12],
- *NERTf* — sum of every Named Entity frequency in the whole document, occurring in given sentence,
- *PersNameNE* — number of recognized NE of the "person" type,
- *OrgNameNE* — number of recognized NE of the "organization" type,
- *PlaceNameNE* — number of recognized NE of the "place" type,
- *DateNE* — number of recognized NE of the "date" type,
- *GeogNameNE* — number of recognized NE of the "geography" type,
- *TimeNE* — number of recognized NE of the "time" type.

The features applied by authors of this paper, which were not mentioned in the referred works, are: *MetaInfo*, *AvWordLength*, *Verb*, *Nouns*, *Pronouns*, *NER*, *NERTf*, *PersNameNE*, *OrgNameNE*, *PlaceNameNE*, *DateNE*, *GeogNameNE* and *TimeNE*.

## V. Evaluation

### A. Evaluation method ROUGE (DUC conference)

ROUGE stands for Recall-Oriented Understudy for Gisting Evaluation [2]. It was introduced by Chin-Yew Lin at Document Understanding Conference (DUC) in 2004 and since then it has became the standard method for the evaluation of automatic summarization systems. It provides a set of measures to automatically determine the quality of summary in comparison to ideal summaries created by humans. The measures are based on overlapping units such as n-grams, word sequences and word pairs. ROUGE has been proved to be highly correlated with human judgements. This section describes ROUGE-N methods, which were proved to work well in single document summarization tasks.

ROUGE-N is an n-gram recall between a candidate summary and a set of reference summaries [2].

It is computed using the (1) formula, where n stands for the length of the n-gram, $gram_n$, and $Count_{match}(gram_n)$ is the maximum number of n-grams co-occurring in a candidate summary and a set of reference summaries. It is worth noting that the denominator of (1) increases if more than one reference documents are used. Moreover, larger weight is assigned to matching n-grams occurring in multiple references, so if words are shared by more references, ROUGE-N favors them.

### B. Experiments and Results

A number of experiments were performed. Different subsets of features were used in order to achieve the best results in summarization. Every learned model for each features susbset was evaluated with ROUGE-1, ROUGE-2 and ROUGE-3 methods. Random summarization was used as a baseline. Features were divided into subsets, as follows:

- *Sub1* $\in \{TfIdf, ParaLength, Centrality, SentType, SentSpecialSection, SentInHighestTitle, SentLength, SentLocPara, ParaLocSection\}$
- *Sub2* $\in$ *Sub1* $\cup \{Pronouns, MetaInfo, Verb, Nouns, AvWordLength\}$
- *Ner1* $\in \{SentInHighestPname\}$
- *Ner2* $\in \{NER, NERTf\}$
- *Ner3* $\in \{OrgNameNe, GeogNameNe, DateNe, PlaceNameNe, PersNameNe, TimeNe\}$

Evaluation results are placed in Table I. It is clear that almost every subset of features used in experiments gave nearly the same results, which were about 15% better than the baseline, according to the F-1 score. No feature subset performed clearly better than the others. New features, included in *Sub2* raised the score slightly, just as dividing the Named Entities information into categories did (*Ner3*). In fact, using the NER tool, instead of naive methods tends to give slightly better results in summarization. Summing up, the best results in ROUGE-1, ROUGE-2 and ROUGE-3 were achieved using the largest subset of features. The experiments have shown that developing new features may be quite useful, but there is no single feature that separately raises the score significantly.

## VI. Conclusion and Future Work

In this article, we have presented the document summarizing approach for the Polish language. It is based on sentence extraction and applies neural networks as a machine learning

TABLE I
EXPERIMENTS' RESULTS.

| | ROUGE-1 | | | ROUGE-2 | | | ROUGE-3 | | |
|---|---|---|---|---|---|---|---|---|---|
| | Recall | Precision | F-1 | Recall | Precision | F-1 | Recall | Precision | F-1 |
| RANDOM | 0.29 | 0.34 | 0.30 | 0.14 | 0.17 | 0.15 | 0.13 | 0.15 | 0.13 |
| $Sub1$ | 0.45 | **0.45** | 0.44 | 0.34 | **0.33** | 0.33 | 0.33 | **0.32** | 0.32 |
| $Sub2$ | 0.47 | **0.45** | 0.45 | 0.35 | **0.33** | 0.33 | 0.35 | **0.32** | 0.33 |
| $Sub1 \cup Ner1$ | 0.44 | 0.42 | 0.43 | 0.32 | 0.29 | 0.30 | 0.31 | 0.28 | 0.29 |
| $Sub1 \cup Ner2$ | 0.49 | 0.43 | 0.45 | 0.37 | 0.31 | 0.34 | 0.37 | 0.31 | 0.33 |
| $Sub1 \cup Ner3$ | 0.49 | 0.42 | 0.45 | 0.37 | 0.30 | 0.33 | 0.36 | 0.29 | 0.32 |
| $Sub2 \cup Ner1$ | 0.48 | 0.42 | **0.46** | 0.37 | 0.32 | 0.34 | 0.36 | 0.31 | 0.33 |
| $Sub2 \cup Ner2$ | 0.47 | 0.42 | 0.44 | 0.35 | 0.3 | 0.32 | 0.34 | 0.29 | 0.31 |
| $Sub2 \cup Ner3$ | **0.51** | 0.43 | **0.46** | **0.39** | 0.32 | **0.35** | **0.39** | 0.31 | **0.34** |

algorithm. This approach seems to be promising in achieving acceptable summarizing method for the Polish language, however there are some difficulties in choosing the proper features set and tuning machine learning algorithm. We conclude that there is still much work to do in the field. We hope that our approach will serve as a inspiration, as well as a baseline for the future research at the task of automatic summarization for Polish.

***Abstract*—This paper focuses on a generalized approach to providing user interface to a web-based expert system (WBES). We examine MVC and MVP design patterns used traditionally to construct a web application user interface. In order to leverage the strength of the MVC/MVP design patterns we propose a special ontology representing a user communication domain. We describe a self-service networked infrastructure for automatic deployment of command line interface (CLI) applications. We demonstrate how to apply the proposed ontology for the design of a WBES aimed at supporting client software re-execution in clouds. In particular, we address the problems existing in the area of software development for music information retrieval algorithms implementation.**

## I. Introduction

Pervasive nature of modern software is a popular subject of the present-day technology discourse, whether the question concerns computer-assisted education, interface design, usability or elementary forms of programming, which are one of necessary elements of modern information literacy. In particular, service-oriented software and cloud technology significantly transformed the way we use computing and storage capabilities.

There is a constant interest to organizing processes of research software distribution in order to make computational and data resources available for other users. For example, in the domain of information retrieval (IR) many developed approaches are semantic relatedness centered. The focus of such works is on developing algorithms for better semantic relatedness evaluation, semantic classification or clusterization. An obvious way to evaluate an IR algorithm is to use various test collections, while an algorithm itself might be implemented in the form of a computer program. However, those programs often remain unpublished. In some IR domains, particularly, in music information retrieval (MIR), even if a software implementation is reusable, test collections might not be available for a third party researcher either for the reason of their big size or due to the copyright restrictions. That's one of the reasons explaining difficulties of comparing or reproducing results achieved by other researchers. From the study [1] we know some statistics of what MIR researchers are as software developers. The figures are rather discouraging: 82% of researchers did develop software, but only 39% of those took steps to achieve better reproducibility. It is no wonder that only 35% of those developers published any code, whereas 51% said their code had never left their own computer. Often the only way to follow is to believe in the results reported in papers without any possibility to be sure that the reported results came from a research method, and not from bugs in the software. Thus, researchers often re-implement algorithms based on the published descriptions; such re-implementations are not often executed in the same context as it was for the original software.

In [2] the best practices are examined, which are aimed to improve research reproducibility. Among them there are such ones as using collaborative platforms (like *Github*) and resource sharing mechanisms in order to lower the barrier to reproduce the third party work. In [3] a platform for re-executing software in the same context is described. That solution is based on capturing files and environments required for an experiment, and building an archive with subsequent software re-execution on a third party machine.

In [4] the authors took the significant step toward research reusability and reproducibility in the domain of machine learning. They developed and maintain a networked system (OpenML) for sharing and organizing data sets and algorithms solving the typical machine learning tasks. In our work we pay attention to two broader aspects of the reproducibility problem. Firstly, it might not be permitted to distribute the source code, the binary files or the datasets due to the legal issues. Secondly, due to manifold existing supporting tools (such as version control systems, build systems or runtime environments) it is not easy to configure a local environment in a way to be capable to run a third party software not limited by the specific data and task types.

A possible solution addressing both mentioned issues is to distribute both software and datasets as services accessible via a standard client (e.g. a web browser). In such a case neither data copying, nor environment configuration is required. However, distributing algorithms and datasets as services is far

978-83-60810-66-8/$25.00©2015, IEEE

from being a trivial problem. There is a certain similarity with Milne and Witten's consideration on data mining. Researchers who want to use Wikipedia as a knowledge source have two major options: either to base their work on secondary structures, or to build their own algorithms from scratch [5]. There are difficulties to share the algorithms due to lack of supporting platforms. We think that the similar situation exists in the domain of MIR.

Clouds can serve as a platform to share algorithms as services. One significant problem is a relatively high barrier to entry for non-experts. In our earlier work we described sources, advantages and problems of deploying research software in clouds and proposed an architecture of a provisioning service for automatic CLI applications deployment in computing clouds [6]. The proposed solution targets problems of build and run error discovery and handling, with special emphasis on errors conditioned by possible misconfiguration of a virtual platform where client software modules have to be executed.

The remaining text is organized as follows. In section II-A we discuss the process of CLI software deployment and provide a brief survey of existing approaches in order to explain their limitations and constraints (conditioning difficulties of provisioning applications as services). For the reason that we consider using expert systems as one of possible ways to overcome such difficulties, in section II-B we pay attention to a web based expert system (WBES) user interfaces. In section II-C we analyze a state-of-the art example of a web based expert system and evaluate its architecture with reuse and change scenarios. We discover that the modification of a model requires changes in all the model-view-presenter (MVP) architecture components, which, in a sense, goes against the motivation to use MVC/MVP pattern in design. In section III we examine two approaches to define a model interface: a domain *aware* approach and a domain *agnostic* approach. In order to better separate a presenter from a model, we propose to complement a subject domain ontology with a user communication ontology. For the problem of provisioning software in clouds, we define an ontology of software provisioning partially described in section III-A as well as a user communication ontology (section III-B). In section IV we describe a software provisioning self-service networked infrastructure, its architecture and its major components. In section V we demonstrate how the proposed approach helps in developing a web-based expert system for CLI applications deployment in computing clouds. We list some experiments we arranged in order to evaluate the knowledge based approach of using introduced networked infrastructure for provisioning a series of projects developed in the domain of MIR. We compare the knowledge based approach with the other existing implementations (section V-A) and describe a scenario based architecture evaluation process (section V-B).

## II. Related Work

In order to position our work within the framework of the service distribution domain we have to examine three major issues. First, we attempt to have a look at existing systems for deploying CLI applications in clouds with respect to the user expertise necessary to use such systems properly. Second, we analyze existing works on expert system user interface development with special attention paid to WBESs. Third, we analyze an emerging problem of providing a web-based user interface of an expert system to end users: specifically, how to apply MVC or MVP design patterns (widely used in web application architectures) for a WBES.

### A. Deploying a CLI Application in a Cloud

Research software (especially in the MIR domain) is often developed as desktop applications which primarily were not intended to be executed in networked or distributed environments. This aspect causes difficulties of their deployment in clouds without significant changes in software code. For example, an *OpenShift PaaS*[1] provides two ways to deploy an application in a cloud. The first way is to develop a custom cartridge, while the second one is to develop a module for an existing cartridge (e.g. *JavaEE* cartridge, *Python* cartridge, *Ruby-on-Rails* cartridge, etc.). Unfortunately, both approaches seem to be unsuitable for deploying CLI applications having no any networking capabilities. In order to support networking features without modification of an existing application, a proxy component is required [7]. The reality is that a deployer must be provided with the exact configuration describing a runtime environment. If the configuration is not valid (for example, an incorrect *Python* version is selected) users get unrecoverable deployment errors. In order to recover deployment errors automatically we could use such approaches as *AutoBash* [8].

In our earlier work we described how to extend the *AutoBash* approach by applying knowledge engineering formalisms [9]. We designed a proxy architecture which, in turn, is an enhanced *MEDEA*[2] proxy where a knowledge base is leveraged to control deployment and execution processes. In fact, the system described in the following sections of this paper can be considered as a web based expert system helping users to deploy a CLI application both in a cloud and within a desktop environment. Thus, the idea is to make deployment and invocation process as easy as uploading applications and datasets via web forms. Specifically, in the MIR domain the main algorithm experimentation scenarios are the following:

- A researcher wishes to test his/her algorithm by using one of the standard test collections, which might not be publicly available;
- A researcher wishes to compare the algorithm to other algorithms by using the same corpus;
- A researcher wishes to test a third party algorithm by using his/her own test corpus;
- A researcher wishes to test the corpus by running third party algorithms.

In the above mentioned work [9] we analyzed two popular software platforms facilitating the above mentioned scenarios:

[1] http://openshift.redhat.com

[2] MEDEA – Message, Enqueue, Dequeue, Execute, Access

one used in MIR, while the second used as a software deployment infrastructure.

*NEMA*[3] [10] provides access to the MIR software and data sets through the Internet. The environment was developed in 2008–2010, just about the period when the very first cloud service commercial implementations appeared. In fact, the *NEMA* provides a platform as a service (PaaS) and allows provisioning client software as a service (SaaS). The NEMA uses a set of preconfigured virtual machine images; each image provides a platform (e.g. *Python*, *Java*, etc.), which is completely configured to be used by the *NEMA* flow service. Storing a large set of custom images is expensive, moreover, any image modification has to be done manually; that's why using *NEMA* in public clouds is not easy.

The *MEDEA*[4] [7] infrastructure enables the deployment of an arbitrary CLI application on an arbitrary cloud platform. The *MEDEA* uses standard virtual machine images provided by a cloud and uploads a special wrapper (a task worker, in *MEDEA* terms) to the running virtual machine. The wrapper initializes the respective execution environment (*Python* or *Java*, for example) and then executes a client application. If we consider *MEDEA* as a self-service platform (within the context of MIR), there are two issues to be observed. Firstly, MIR applications often have dependencies on third party components and libraries, therefore, a wrapper might not initialize the environment properly. Sometimes researchers are unable to upload these libraries due to certain license restrictions; sometimes they don't know how to create an application package containing all the required dependencies. Secondly, there are MIR test collections which are not publicly available, so the code executed against those collections shall be considered to be "unsafe", and shall be executed in managed way in order to avoid dataset leaking. Let us mention that within the framework of the proposed architecture we address both issues by introducing a deployment manager that includes a wrapper component as it is described in the following sections.

The special case is *MIREX*[5], which is not a platform but an organization providing a service for testing algorithms delivered by its creators. In addition to the published test collections, some "secret" test collections are also used, and the evaluation process is arranged in the form of an annual contest. Thus, researchers have to wait for the results till the next competition, hence, this is not a way for everyday use.

### B. Expert System User Interfaces

As mentioned in [11], "Expert systems is a branch of Artificial Intelligence that makes extensive use of specialized knowledge to solve problems at the level of a human expert." As a result of Internet evolution and telecommunication tools development a new type of expert systems appeared: Web Based Expert Systems (WBES)[12]. In our work we pay attention to one important aspect of WBES design, i.e. user communication with WBES.

The focus of the majority of current works on expert system user interfaces is on the functional requirements (e.g. on capabilities the UI does provide and the reasons for them). Examples of such requirements are listed in [11]. We also found research works focused on a particular expert system development containing some screenshots of an expert system user interface and a discussion on the system architecture (see [13] for instance). Fewer works are focused on WBES development process [14]. We only found few works discussing a level of workload separation between a server and a client of an expert system [15]. The same is true for architectural issues of providing a user interface for a generic expert system [16], [17].

In [18] the authors realized that existing approaches to evaluate an expert system are connected mostly with the rules evaluation, paying less attention to user interaction issues. Some researchers complain about "a lack of a general methodology for developing web-based expert systems" [12] and notice that "web sites that enclose an expert system have been developing ad hoc and their developers do not follow any systematic method or process" [19].

### C. A Case Study: Web Based Expert Systems and Design Patterns

In order to better understand WBES user communication issues, we studied one of the rare state-of-the-art examples of the WBES where there is a discussion on WBES architecture and WBES-related design patterns.

For an end user, a WBES is presented as a web application. As we can see from many works (see [20], [21] for example) a common way to implement web applications is to use a model-view-controller (MVC) pattern [22] or its generalization known as a model-view-presenter (MVP) pattern [23]. However, using MVP might present a problem if we evaluate an architecture by using any scenario-based method (for example, *SAAM* [24]).

Let us think, for instance, of an MVC-based solution for an automatic price negotiation proposed in [25]. The authors suggest we use a production knowledge base with an inference engine as a *Model*, while the generated HTML pages are *Views* and a mediator component is a *Controller* (see Figure 1). As it is well known, if we follow an MVC pattern we expect to have such an advantage that each of the three structural components (e.g. a *Model*, a *View* and a *Controller*) can be modified independently. It allows to improve such software quality properties as reusability, modifiability and reduce a ripple effect appearing if one of the components changes significantly [23]. Let's evaluate this statement with the following scenarios:

1) *Reusability*: we can change an expert system domain from price negotiation to CLI application execution. If we consider this rather substantial change, we have to modify the *Model* (despite keeping the inference engine,

[3] NEMA – Networked Environment for Music Analysis: www.music-ir.org/?q-nema/overview

[4] MEDEA – Message, Enqueue, Dequeue, Execute, Access

[5] MIREX – Music Information Retrieval Evaluation eXchange: http://www.music-ir.org/mirex/

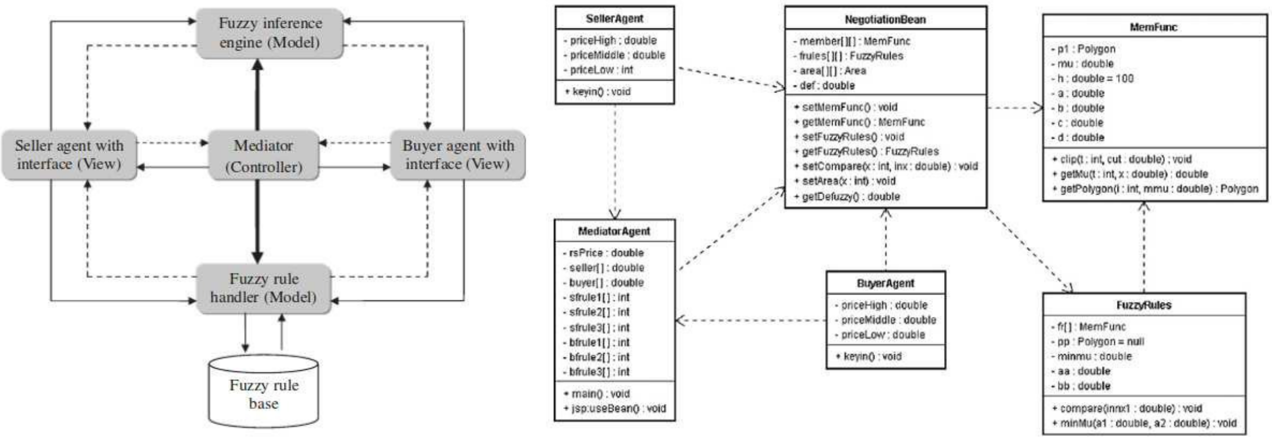

Fig. 1. The MVC design pattern and the price negotiation system class diagram [25]

we still have to change the knowledge base), the *View* (in order to be compatible with another ontology serving us as a dictionary of concepts used for production rules) as well as the *Controller* (since the model interface has to be updated in order to be compatible with that new ontology).

2) *Changeability*: during the evolution the price negotiation domain description changes significantly: temporal aspects are added to the price negotiation rules similar to "if a seller decreased the price on a small value followed by decreasing the price on a medium value then ...". If we consider this change, we have to modify the *View* (in order to make it compatible with another set of concepts) as well as the *Model* and the *Controller* (for the similar reasons as those in the reusability scenario description).

Thus, the above scenarios require changes in all the three MVC major components.

Applying methods of formal architecture evaluation allows to evaluate component relations and discover whether a system follows a loosely coupled design strategy [26]. Let us note that using component interfaces doesn't guarantee system loose coupling since a scenario might affect changes in an interface, which, in turn, leads to the changes in all the components depending on this interface.

Both of the above mentioned scenarios require an ontology to be changed (e.g. the dictionaries used in production rules). This is a key factor since other two components (e.g. the *View* and the *Presenter/Controller*) directly depend on the domain ontology.

We think that the problem is that an interface is strongly connected to the subject domain. If we succeed to remove the subject domain related information from the interface, we are able to construct a user friendly GUI without having to redesign an expert system architecture in order to fit every change in the expert system subject domain.

Following [23], there are two major problems to be resolved while developing a GUI application:

- *UI*: How does the user interact with my data?
- *Data Management*: How do I manage my data?

Each problem falls into three more concrete questions (see Figure 2). In our work we only address the following questions: *What is my data?* (see Section III-A), *How do I change my data?* (see Section IV-C1), and partially the question *How do I display my data?* (see Section IV-C2). In MVC terms the questions are: *What is the interface of my model for the view?* and *What is the interface of my model for the controller?*.

## III. Introducing the Model

After the analysis of a series of existing expert system implementations, we realized that there are two basic approaches to define a *Model* interface:

1) **Expert system domain aware model interface:** There are interface methods directly connected to the subject domain as it is implemented in work [25] (e.g. *setPriceHigh* in the example of automated price negotiation on the web). Figure 5 (1) illustrates this issue.
2) **Domain agnostic model interface:** A user interface communicates directly with the inference engine interface as it is implemented in works [27], [28]. It means that there are methods like *assertFact(fact: Fact)* (see Figure 5 (2)).

If we follow the first approach, we have to change the *Model* interface in order to respond to subject domain changes. If we rely on the second one, we are able to keep the *Model*–presenter interaction interface, but changes in the subject domain still require changes both in the *Model* (the knowledge base rules) and in the *Presenter* (since the latter should be able to assert new facts to the knowledge base). Thus, both approaches are not aimed at using the MVP pattern in the best way.

In order to separate the *Presenter* and the *Model* we propose to complement an expert system subject domain ontology (e.g. automatic price negotiation or CLI application deployment) with a user communication subject domain ontology (*UserComm*, see Figure 5 (3)). As far as a problem of user

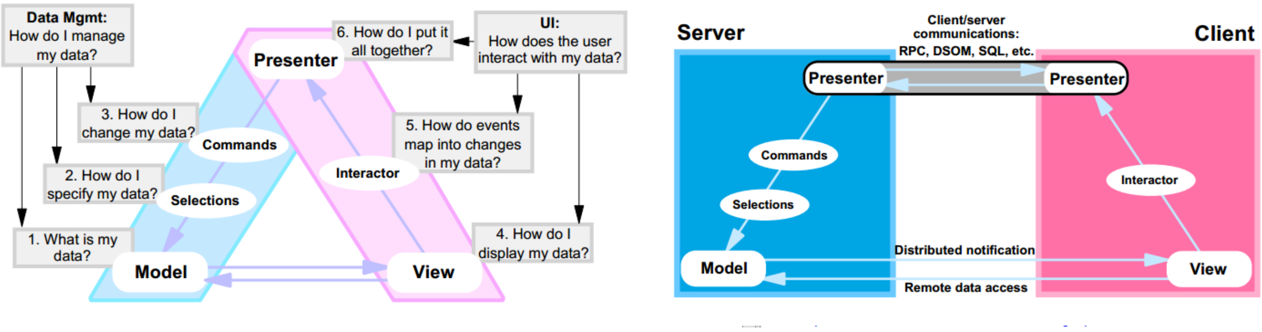

Fig. 2. The MVP design pattern [23]

communication can be described with no connection to the subject domain problems, a user communication model can be developed once and then reused oftentimes as long as its interface is well designed and doesn't change. Therefore, as a *Model*, we propose to use a knowledge base (with rules description and its working memory), but an interface of the model for other components includes only the concepts from the *UserComm* domain.

### A. Introducing a Request-Activity and Related Facts Core Ontology

In order to formalize both software provisioning and execution error description, as well as the relationships between an error and an error resolution procedure, knowledge engineering formalisms are required. In [29] and [9] we proposed and argued for a *Software Provisioning Ontology* that describes processes of software code building and execution with much attention paid to represent build and execution errors as well as the actions required to fix the recognized errors. In the earlier mentioned works we also demonstrated how ontologies of specific tasks can be defined by extending the core ontology base entities.

Hereinafter we only introduce basic entities of the above mentioned software provisioning ontology aimed at describing and resolving the problems of CLI software provisioning to a virtual platform. Let us mention again that we focus on deployment problems in relation to the special software class – *research software implementing the MIR algorithms*. The authors of such programs are usually able to implement an algorithm in the form of CLI-based console application, which transforms the input data to the output according to the data formats required by a certain algorithm evaluation system. However, it is common that a developer might not be experienced enough to resolve runtime environment failures or to guarantee that virtual platform requirements are satisfied.

The major concepts of this ontology are *Activities* and activity *Requests* (see Figure 3). An *Activity* is a sequence of *Actions* aimed at achieving an activity goal, while a *Request* can be considered as a new goal setting. An activity might aggregate requests (being subrequests, in a sense), while a request might consist of activities: if an activity fails, an error has to be identified and fixed, then the activity for the same request has to be restarted. If the activity failure can not be fixed, the request is considered failed.

In order to describe activity results, we introduce a concept of an *Activity status*, which is twofold: there may be an *Activity runtime status* and an *Activity completion status*. The *Activity runtime status* instances are an *Activity being executed* and an *Activity suspended*. The *Activity completion status* instances are an *Activity succeeded* and an *Activity failed*. We assume that an activity is completed successfully if the activity goal is reached (for example, for the activity *Unpacking* the artifact has been successfully unpacked). Otherwise the activity is failed (for example, some file artifact has not been unpacked for the reason that the required archiving utility has not been found in the system).

The *Request* features a necessary and appropriate condition that there starts an activity of a particular type. Similar to an activity concept, a *Request* might also have its status, which is also twofold: there are a *Request runtime status* and a *Request completion status*. The *Request runtime status* instances are a *Request being executed* and a *Request suspended*, while the *Request completion status* instances are a *Request succeeded* and a *Request failed*. If at least one activity for the request is completed successfully, the request is considered to be completed successfully too. By contrast, if all the activities associated with the given request failed, the request is considered to be failed.

Subject domain ontologies are rarely used in expert systems directly: they are usually too common to describe the subject domain-related specific tasks. However, we are able to define an ontology of specific tasks by extending the base entities of the core ontology, and in so doing to follow an *extendibility* principle of the ontology design: "an ontology should be designed so as to allow to use shared vocabularies and to support monotonic ontology extension or/and specialization (i.e. new terms might be introduced without revising existing definitions)" [30].

Let us note that in the earlier mentioned work [9] we also demonstrated how to construct the knowledge base production rules in order to manage processes of client application building and execution with detecting respective errors while using some building tool (e.g. *maven*) as a kind of specific building system.

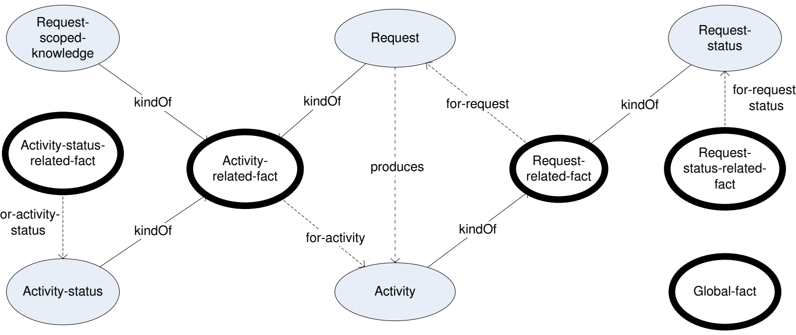

Fig. 3. Activities and requests are main ontology concepts

### B. User Communication Ontology

The user communication ontology (that we refer to as *UserComm*) is based on *Request-RequestStatus* and *Related-Facts* concepts of the core ontology mentioned in the previous section.

The *UserComm* ontology provides the following concepts (see Figure 4) which represent users' requests:

- A **user request** extends a *Request* concept and represents a request generated by a user. Associated *request related facts* provide more details on the user request
- An **ordered argument** extends a *request related fact* and represents a part of the user request in the form of an *integer-value*, where a value is an arbitrary string.
- A **key-value argument** extends a *request related fact* concept and represents a part of the user request in the form of *key-value* where *key* and *value* are strings.
- A **key-(multivalue argument)** extends a *request related fact* concept and represents a part of the user request in the form of *key-(array of values)*, where *key* and each *value* are strings.
- A **named artifact** extends a *request related fact* concept and represents a part of the user request in the form of a *name-(binary file)*, where *name* is a string
- An **unnamed artifact** extends a *request related fact* concept and represents a part of the user request in the form of *binary file*. At most one unnamed artifact may be associated with a request.

The *UserComm* domain description serves as an abstraction layer used by both the *Presenter* and the *Model* allowing to hide real expert system's domain from the *Presenter* as shown in Figure 5 (3). UML diagram presenting the *Model* interface to be used by a *Presenter*, a *Controller* or a *View* is shown in Figure 6. In the following sections we describe how the *Presenter* and the *View* use the *Model* interface, and how the expert system domain rules communicate with a user via the *UserComm* ontology abstraction layer.

## IV. Software Provisioning Self-Service Networked Infrastructure: An Architecture and Major Components

An architecture of a system for automated experiments with algorithms developed in MIR is shown in Figure 7 (see also [6]). It includes the following components:

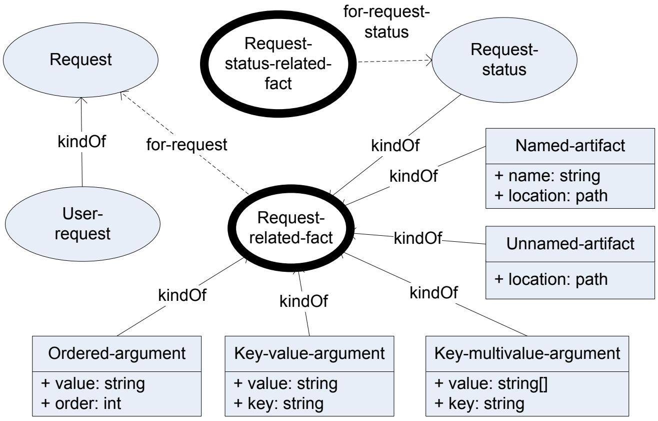

Fig. 4. *UserComm* domain ontology

- User interface
- Submitted applications repository
- Virtual machine images repository
- Deployment knowledge base
- Deployment manager
- Input provider service
- Result collecting service
- Statistics service
- Authentication and authorization service
- Client virtual machines
- Cloud manager
- Cloud administrator console

Some of the listed components (e.g. a cloud administrator console, authentication and authorization services, etc.) are provided by a cloud infrastructure.

Provisioning client applications to a cloud is supported by two major components of a virtual platform: a *cloud broker* and a *deployment manager* (see Figure 8). The latter is a composition of a *deployment manager agent* and a *configuration manager*. A *knowledge base* (KB), an *inference engine* and its *working memory* are components of an expert system controlling the provisioning process.

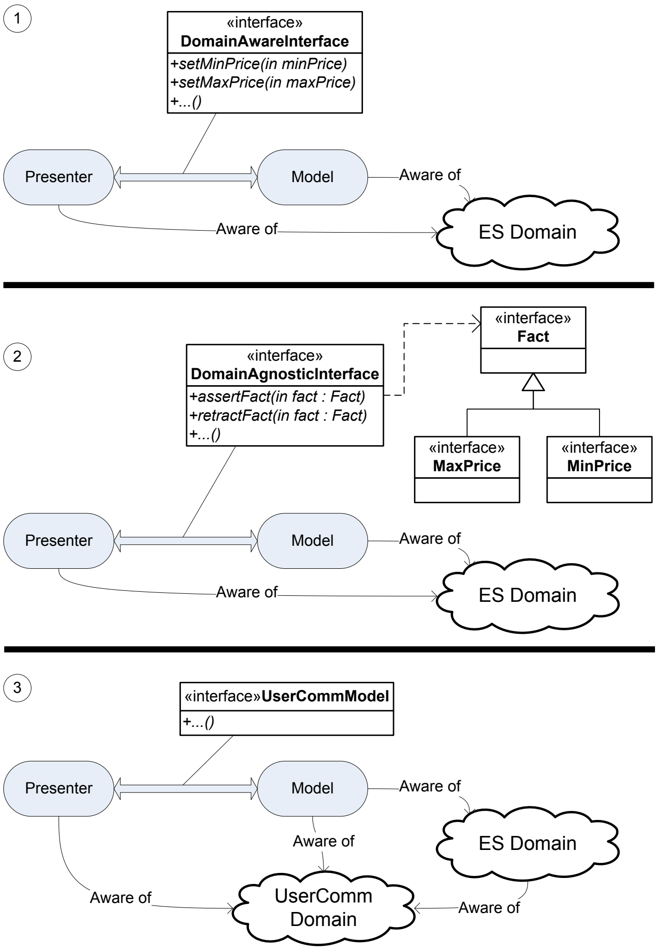

Fig. 5. Model interface for a presenter: (1) expert system domain aware; (2) expert system domain agnostic; (3) user communication domain aware

Fig. 6. Model interface

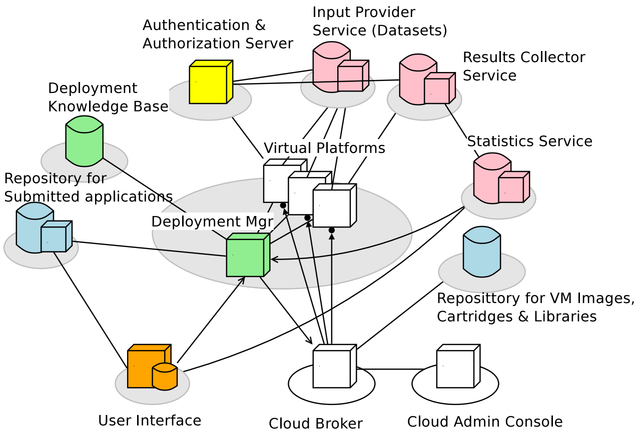

Fig. 7. CLI software provisioning service architecture

### A. Deployment Manager

Similar to the *MEDEA* approach, a wrapper is uploaded to a virtual machine deployed in a cloud. The wrapper provides an HTTP interface and executes a client CLI application in response to user inputs provided via an HTTP proxy interface. Normally the wrapper consists of two components: a *proxy* and an *executor*, where the proxy invokes the executor directly according to HTTP commands received via an HTTP interface. In our implementation, in contrast to a traditional approach, the proxy and the executor never interact directly but via indirect communications using a knowledge base. In terms of the MVP design pattern the *Proxy* is a *Presenter*, the *Knowledge Base* is a *Model*. while the *View* could be either a client side web browser, or a server side HTML code generator component.

Let us note that an expert system often communicates not only with a user but with other components of the system. For instance, for the purpose of CLI application deployment an expert system might need executing a command (a communication with the executor) or changing a platform configuration (a communication with the configuration manager). The problem is how to define an interface that doesn't need to be changed if an expert system domain changes. This problem is similar to the problem of interface definition between a *View* and a *Model*, as well as between a *Presenter* and a *Model* in MVP pattern. Hence, we can use the same approach. We can define an ontology (*ActionExecution* ontology or *ConfigManagement* ontology) used for communication between an expert system and any external component.

### B. Deployment Manager Agent

The deployment manager agent gathers runtime information about the client application and about the environment state and uses the knowledge base in order to resolve deployment and execution errors such as absence of required components or libraries, improper runtime environment version, etc. The agent interacts with the configuration manager by using the *ConfigManagement* ontology (including high-level commands like "need Python3") in order to reconfigure the platform properly. In turn, the configuration manager interacts with the cloud broker (which is a component provided by a cloud itself) by using low-level commands (e.g. "change VM image"). In so doing, the configuration manager controls the installation of the external components (such as language runtimes, necessary middleware or databases) to the platform. It also controls virtual machines recreation if required.

### C. Proxy

The proxy component is responsible for providing a capability to access the expert system by supporting two routines:

1) Asserting user requests to the knowledge base;
2) Retrieving the execution status.

In a sense, the proxy acts as an adapter transforming the data representation from one form (HTTP) to another (*UserComm* facts) and vice versa. The *UserCommModel* interface (see Figure 6) is used for interaction with the knowledge base. Request related facts for a request generated by the proxy

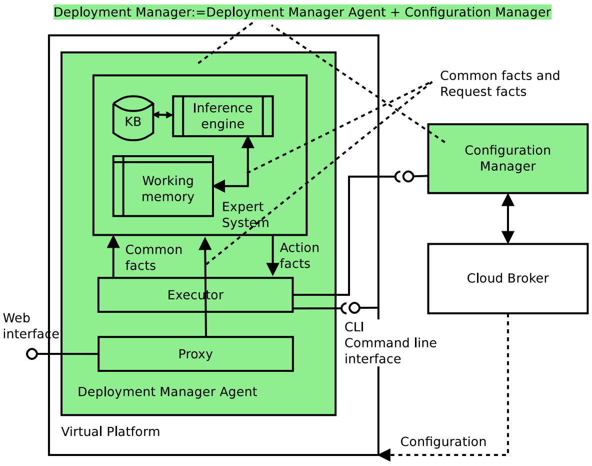

Fig. 8. Managing application deployment in a cloud

should be only concepts from the set of concepts defined by the *UserComm* ontology. In order to interact with a user the REST-like HTTP interface is provided (as defined in Table I).

Two major procedures for HTTP requests processing are described in the following subsections.

*1) Proxy: Processing POST Requests:* In this section we describe a method for an arbitrary HTTP request transformation to a knowledge base facts representation with use of a fixed set of *UserComm* ontology concepts. The method consists of five major steps:

1) Parse an HTTP request (according to RFC 2616).
2) Map parts of the HTTP request to ontology facts according to the rules defined in Table II.
3) Obtain a $ContextHandler$[6] object from the HTTP request URL.
4) Obtain a $RequestHandler$ object by invoking $createNewRequest$ method (see Figure 6) with a $ContextHandler$ parameter obtained in the previous step. In fact, this invocation asserts new $UserRequest$ object to the knowledge base of the model.
5) Assert all the $RequestRelatedFacts$ by invoking $addRequestRelatedFact$ method with a $RequestHandler$ parameter obtained in the previous step.

*2) Proxy: Processing GET Requests:* In this section we describe a method for querying a $RequestResult$ with an HTTP request. The method consists of six major steps:

1) Parse an HTTP request according to RFC 2616.
2) Extract $RequestHandler$ object from the request URL.
3) Get a $RequestStatus$ for a $RequestHandler$ by invoking $getRequestStatus$ method (see Figure 6) with a $RequestHandler$ parameter obtained in the previous step.
4) Get a $RequestStatusRelatedFacts$ for a $RequestHandler$ by invoking $getRequestStatusRelatedFacts$ method (see Figure 6).
5) Decide on view layout on the base of the $RequestStatus$ properties (including runtime type information) and a variety of $RequestStatusRelatedFacts$ (or use some default layout).
6) Draw each object with its own widget being a part of the layout.

### D. Execution Process

As we described in our earlier work [6], we extended the *MEDEA* and *NEMA* execution model by adding the second phase of the execution process. During the first phase (command execution) some debugging information can be written to *stdout*/*stderr*, to the environment logs and so on. These execution results are represented as facts and asserted into the working memory. During the second phase the results are analyzed. As soon as the expert system determines the execution failure and the error cause is determined, the expert system issues appropriate reconfiguration command. This command is handled by the executor, which either performs the necessary operations by itself or delegates them to the configuration manager.

An *executor* is a platform-specific component. It observes a working memory for the presence of action facts. We use a deferred action execution model: as soon as the inference engine does not have any active rules, the executor performs the required actions described in the form of action facts stored in the working memory. Such an approach is tolerant to action facts addition, deletion or modification up until the moment when the agent performs the action.

### E. Configuration Manager

The configuration manager interacts with the cloud broker in order to provide the required configuration, i.e. to install/uninstall necessary/unnecessary system components, (frameworks, applications). As soon as the reconfiguration process is completed, the configuration manager asserts new environment configuration facts. As a result, this assertion might activate the rules asserting actions in order to execute the failed command again or to notify the user about an unrecoverable failure detected.

## V. Evaluation

First, let us demonstrate how to apply the proposed system architecture to develop a web-based expert system for CLI applications deployment in a cloud. We consider only user communication aspect of the system in this example.

The *Proxy* component provides an API as described in Table I. We extended the proxy interface with a GET method for all URLs supporting POST requests. The response to the GET request to such a URL returns a simple HTML page that a user can use to upload an artifact (zip archive, for example)

[6] According to Section III-A a context for a *Request* is an *Activity*. By convention a top-level activity may represent a user and a context for all top-level requests. For a subrequest its context is represented by the request's parent *Activity*

TABLE I
REST INTERFACE OF THE PROXY COMPONENT

| URL | HTTP method | Description |
|---|---|---|
| /action/<contextHandler>/<relative path>?<query string> | POST | Submit a user request within the context $contextHandler$. The request is executed according to the procedure described in section IV-C1. |
| /status/<requestHandler> | GET | Get execution result for a request identified by $requestHandler$. The request is executed according to the procedure described in section IV-C2. |

TABLE II
HTTP REQUEST TO *UserComm* CONCEPTS TRANSFORMATION RULES

| HTTP message part | Ontology concept | Description |
|---|---|---|
| Segment(*) of <relative path> | OrderedArgument(segNo, segValue) | The segment is represented by its value *segValue* (path segment name as it appears in the URL) and its order *segNo*(i.e. number of '/' signs in the URL before the segment) |
| Parameter(**) from <query string><br>('key=value') | KeyValueArgument(key, value) | The query string parameter is represented by its *key* and *value*. |
| Parameter from <query string><br>('key' or 'key=values[]') | KeyMultivalueArgument(key, value[]) | The query string parameter is represented by its *key* and *value[]* (zero or several, but not exactly one value). |
| HTML form input field<br>(input field type is not 'file') | KeyValueArgument(fieldId, value) | The form input field is represented by its id *fieldId* as it appears in HTML code or in multipart HTTP message and *value* (the contents of the field or the entity value in multipart HTTP message) |
| HTML form input field<br>(input field type is 'file') | NamedArtifact(fieldId, fileContentsPath) | The file input field is represented by its id *fieldId* as it appears in HTML code or in multipart HTTP message and a path *fileContentsPath* to a local copy of the binary file received from a user |
| HTTP named entity<br>(not HTML form) | NamedArtifact(entityName, fileContentsPath) | Named entity is represented by its id *entityName* as it appears in multipart HTTP message and a path *fileContentsPath* to a local copy of the binary file received from a user |
| HTTP default entity | UnamedArtifact(fileContentsPath) | Default entity is represented by a path *fileContentsPath* to a local copy of the binary file received from a user |

(*) According to RFC 3986 path of a URL consists of zero or more segments separated by slash ('/') character.
(**) RFC 3986 doesn't set any restrictions on a query string format. In practice Web developers use ampersand ('&') separated 'key=value', 'key=values[]' or 'key' format as defined in RFC 1866.

to the server. Selecting a file to upload followed by clicking on "Submit" button causes the form to be uploaded to the same URL that is used to download the form. In our system the GET URL path is "/action/user/deploy/" so the POST URL path is also "/action/user/deploy/".

According to the algorithm described in Section IV-C1, the proxy parses an HTTP message in the following way: a *contextHandler* is string "user", a relative path consists of one segment "deploy". Hence an input field with an artifact is transformed to $NamedArtifact(\text{“}artifact'', \text{“}/local/file/path'')$ and URL path is transformed to $OrderedArgument(1, \text{“}deploy'')$. The proxy invokes $createNewRequest$ method (see Figure 6) of the model and receives a $RequestHandler$ that is used to assert all other facts via $addRequestRelatedFact$ method and returns the $RequestHandler$ to the user's browser. The latter redirects the response to URL "/status/RequestHandler".

In the knowledge base we can construct a rule translating a *UserComm* domain to an expert system domain as follows:

```
RULE 'Deploy an artifact'
IF
  ctx : Context('user')
  req : UserRequest(ctx)
  exists OrderedArgument( order==1
                    AND value=='deploy'
                    AND request==req)
  artifact : NamedArtifact(name=='artifact'
                     AND request==req)
THEN
  assert(Expert system domain facts)
END RULE
```

Similarly, we are able to define the rules to translate the expert system domain back to the *UserComm* domain.

Redirection to "/status/RequestHandler" URL enables users to monitor execution process. In the simplest case the request result might be described as a status string, e.g. "in progress", "completed" and so on.

### A. Expert System Evaluation: Preview

Currently we tested the approach by implementing a prototype system that was successfully used for automatic deployment of two *Java* projects (built with *maven*) selected among the projects submitted to the *MIREX 2013* contest[7]. During the deployment there were several configuration errors. For each error we provided the knowledge base rule in order to detect and fix configuration errors. Table III lists the examples of build and run errors discovered during our experiments.

### B. Scenario Based System Architecture Evaluation

*1) Reuse Scenario: Domain That Changes:* Let's revisit the case study investigated in Section II-C: the change of the *Model* provoked changes in both the *View* and the *Controller*. As we discovered in Section II-C, these changes are conditioned by the fact that the *Model* provides a domain-specific interface for data modification. If we use the described architecture (which includes two domains: the communication domain (*UserComm*) and the expert system domain), changing the expert system domain doesn't lead us to the communication domain changes. Thus, the *Model* interface can be preserved, and the *Presenter* remains unchanged. The *View* might need to be updated in order to support new *RequestStatusRelatedFacts* introduced by the changed expert system domain. The communication interface between a *View* and a *Model* (as well as between a *View* and a *Presenter*) remains unchanged. To sum up, updating the *Model* component leads to changes in the *View* only because this new domain has new concepts to be visualized.

*2) Change Scenario: Model That Changes:* The *Model* change can be handled the same way as the domain change (see section V-B1). Updating the *Model* might lead to changes in the *View* if this new model has new concepts to be visualized.

*3) Change Scenario: Managed and Unmanaged Execution Modes:* As we described in [6], the architecture with isolated proxy and executor components allows implementing different execution modes (e.g. system behavior) without modifications of neither the proxy, nor the executor. In practical cases, at least two execution modes are useful: *managed mode* and *unmanaged mode*. Regardless of the current mode, the knowledge base is able to detect and fix recoverable errors in order to support client software automatic deployment.

In the *managed mode* we have a predefined client code invocation command, as well as we use strict validation of the input and output data. Validated output data are automatically published as request status related facts. Especially in case of MIR, in the managed mode it is possible to keep private music collections safe while providing access to these collections for processing by third party algorithms.

In the *unmanaged mode* the invocation command, as well as its input and output data are defined in an HTTP request. The framework doesn't check input and output data, but it still detects and fixes recoverable execution errors.

While these modes differ significantly in behavior, they are implemented entirely at the knowledge base level. It means that in order to support managed or unmanaged modes, only changes in the knowledge base component (i.e. in the *Model*) are required.

*4) Change Scenario: Deploying a CLI application in IaaS or PaaS clouds:* The basic idea of this evaluation scenario is to check whether the expert system is able to deploy a CLI application to *PaaS* and *IaaS* clouds. The platform configuration can be handled in three different ways:

1) In *PaaS* clouds the configuration manager can delegate all operations to the cloud broker (as in *OpenShift*). Necessary components can be installed as cartridges developed by the communities (e.g. *Python* or *Ruby* cartridges). This approach is the easiest to implement, but it requires support from the cloud as Figure 9 (left) illustrates.
2) In *PaaS* and *IaaS* clouds the configuration manager is able to install all the required software itself. Software installation can be implemented using the same interfaces that end users have. Indeed, within the context of deployment there is no big difference whether the deployment manager deploys a particular version of a build system (e.g. *maven*), or a MIR research application. This approach is illustrated in Figure 9 (middle).
3) In *IaaS* clouds it is possible to have a set of preconfigured virtual machines, hence configuring means switching of virtual machine images as shown in Figure 9 (right). This way might be resource consuming but in some cases there is no other choice. For instance, it is useful to have two images: one with **nix* OS and the other one with *Windows* OS, because there is no way to install *Windows* applications to **nix* or vice versa with no virtual machines usage.

In its pure forms neither *PaaS* nor *IaaS* fits the task of MIR research software automatic deployment and execution. For example, using the only *PaaS* it is often impossible to implement access to big local data. If we consider an example of *MSD* (Million Songs Dataset [31]) with its size of about 240 GB, we immediately face two problems: 1) a virtual platform is usually limited by only several GBs of disk space, 2) for a virtual platform it is usually not allowed to mount new partitions, volumes or remote file systems. Our subject domain restrictions make it almost impossible to force client software developers to use some network file system similar to *webdav*.

In turn, an *IaaS* does support mounting new partitions. However, installing and configuring, say, a *Python* environment requires installing the *Python* interpreter from the repositories and its additional configuration by using scripts, i.e. the process not trivial for non-experts. On the contrary, in a *PaaS* the same effect may be achieved by only one command for installing the respective cartridge (of course, if the required cartridge exists, and the latter observation is true for a great majority of practical cases and *PaaS* platforms). Therefore we propose to use a hybrid approach *IaaS+PaaS*, where a *PaaS* may be deployed within an *IaaS* cloud.

TABLE III
EXAMPLES OF ERRORS DISCOVERED DURING EXPERIMENTS WITH MIREX 2013 PROJECTS

| Error | Component | Detection method | Recovery action |
|---|---|---|---|
| Incorrect encoding of source file | javac | Pattern matching. Look for “error: unmappable character for encoding” in javac log | Add appropriate javac/maven flag to specify encoding. Encoding can be detected automatically or provided by user |
| copy-maven-plugin runtime exception | maven | Pattern matching. Look for “copy-maven-plugin:0.2.5:copy” and “java.lang.NoClassDefFoundError: Lorg/sonatype/aether/RepositorySystem;” in maven log | Downgrade maven to version 3.0.5 |
| X11 server required | JVM/AWT | Pattern matching. Look for “java.awt.HeadlessException” in JVM classloader log(*) | Install X11 server (we use Xvfb virtual server) |

(*)This exception is especially interesting for two reasons: 1) nobody expected AWT exception in CLI application and 2) This exception is caught in client code, but it is not handled properly (it is ignored). The only way to detect that the exception was thrown is to analyze the classloader log.

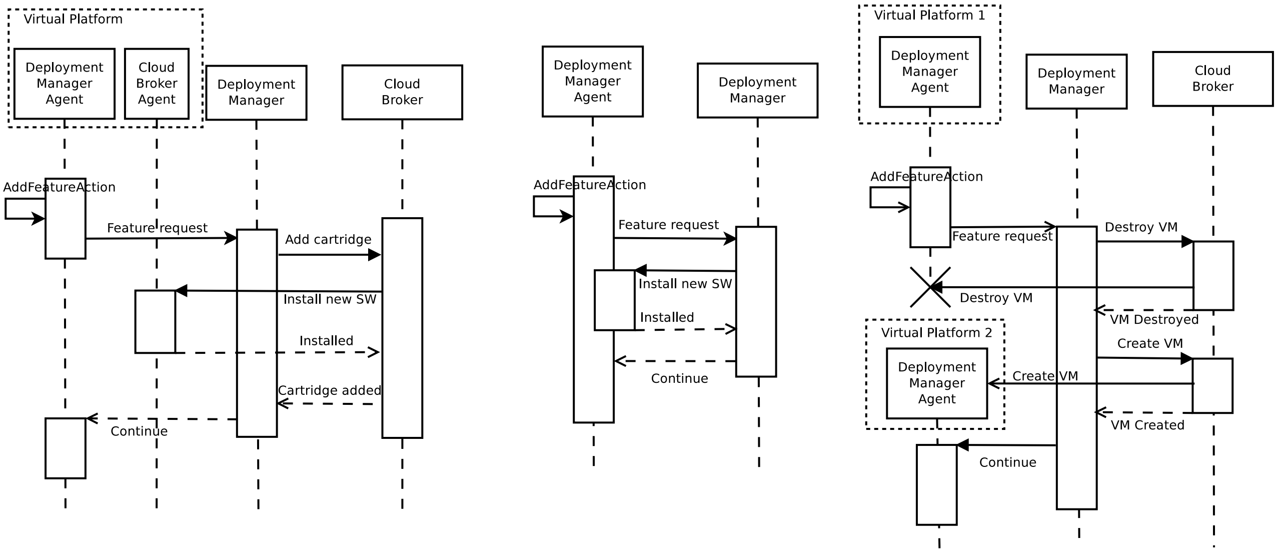

Fig. 9. PaaS/IaaS reconfiguration: (Left) New cartridge installation; (Middle) New software installation; (Right) Virtual machine recreation.

## VI. CONCLUSION

In this paper we have examined the problem of CLI application provisioning in clouds. Being a web application interacting with a cloud broker in order to manage cloud resources and their configuration, the proposed infrastructure provides a *PaaS* platform to deploy CLI applications as *SaaS* services. In contrast to existing solutions we have proposed an architecture where a proxy component and an executor don’t interact directly. Instead of invoking each other, they assert or retract facts in/from an expert system working memory. Thus, the approach draws on the knowledge engineering formalisms used not only for configuration errors recovery, but also for decision making on how to handle requests in order to protect intellectual property (in regards to MIR one can talk about music collections, software implementations, etc.). Although in this research we experimented mostly with automatic deployment of *Java+maven* applications, we are working on knowledge base extensions that allow deploying native *Windows*, *Python*, *MatLab* and *Vamp*[8] applications.

The proposed architecture addresses some of the most complex tasks of client virtual machine automatic reconfiguration, including the following:

1) Installing operating systems on a virtual machine;
2) Installing and configuring a build environment;
3) Installing and configuring a required version of a runtime environment;
4) Installing third party libraries during building;
5) Installing third party runtime libraries;
6) Providing access to machine learning and test data;
7) Providing access to a storage for execution results;
8) Providing user-side access to a client virtual machine.

We have investigated MVC and MVP design patterns as well as the major difficulties of their application to implementing a user interface for a web-based expert system. By introducing a special ontology representing user communication concepts, we have attempted to achieve an MVP-based implementation of an expert system with respect to the loose coupling design requirements, which, in turn, are strongly connected to improving such software quality properties as reusability and changeability. With regards to the demands of scientific communities, we believe that the introduced approach is in good direction to reproducibility, which is

[8] http://www.vamp-plugins.org/

"not an afterthought – it is something that must be designed into a project" [32]. Let us conclude with sharing the idea that research reproducibility might add an overhead (that we attempted to avoid in our approach). However, even "some reproducible practices are better than none – it does not have to be perfect to be a huge improvement" [2].

## Acknowledgment

We would like to express our great appreciation to Nina Popova and Michael Tramontano for the very valuable suggestions. The authors would like to thank Prof. Franck Leprevost for the invitation to present this research within the framework of the 2014 Eastern Europe–Luxembourg Workshop on Cloud Computing, Communications, Security and Services in conjunction with the International Conference on Cloud Networking. An opportunity to have a preliminary discussion of this work has significantly improved our current contribution.

# Concepts extraction from unstructured Polish texts: a rule based approach

Piotr Szwed
AGH University of Science and Technology
E-mail: pszwed@agh.edu.pl

***Abstract*—We present recently developed solution allowing extraction of concepts from unstructured Polish texts with special focus on correct morphological forms of obtained concept names. As Polish is a highly inflected language, detected names need to be transformed following Polish grammar rules. We propose a user-friendly method for specification of transformation patterns, which is based on a simple annotations language. Annotations prepared by a user are compiled into transformation rules. During the concept extraction process the input document is split into sentences and the rules are applied to sequences of words comprised in sentences. Recognized strings forming concept names are aggregated at various levels and assigned with scores. We report also results of initial experiments performed on a medical text.**

***Index Terms*—NLP, Text Mining, concept extraction, unstructured text, inflection, rules**

## I. Introduction

IN THIS PAPER we investigate the problem of concepts extraction from unstructured Polish texts. The term concept is defined here as a sequence of words (an n-gram) occurring frequently in analyzed documents. However, as primary function of concepts is to represent objects, ideas, events or activities, extracted names should comprise words belonging to specific parts of speech classes (usually nouns or verbal nouns with complements) and also satisfy certain syntactical restrictions stemming from language conventions.

Concepts retrieved from unstructured textual data have several applications. Their usage improves relevance of documents returned by search queries due to more accurate indexing and clustering. They may help to assure data privacy by identifying sensitive information and removing it from published texts (documents anonymization). Models based on concepts can be used to express and structure knowledge existing within an organization, which is often distributed between large number of documents of various types: e-mails, reports or internal regulations.

The goal of our work was to develop a tool allowing to extract referenced concepts from documents in Polish language. The key assumption made was that concept names should have correct morphological forms according to Polish grammar rules. Such feature was selected due to aesthetic reasons (in various applications concept names are presented to end users), as well as the expectation that in many situations using the correct form may improve sense disambiguation. Hence, the designed solution, apart from identifying concepts, should provide automatic translation of n-grams representing concepts to their nominative form. This task is particularly challenging for the Polish language, which is characterized by the high degree of inflection.

We decided to apply a rule based approach to perform transformation of concept names. The rule language, inspired by Petri nets, allows to define patterns of input tokens and required transformations. For this purpose part of speech (POS) information is used. Considering the complexity of POS tags, specification of rules may be a complicated and tedious task. We build the translation rules fully automatically by defining samples of translation patterns (annotations) and compiling them to rules.

The paper is organized as follows: next Section II discusses the problem of concept extraction, as well as several tools dedicated to Polish language processing. It is followed by Section III, which presents general features of our approach. Next Section IV describes shortly Morfologik, a dictionary and POS tagging/lemmatizing library. In Section V we discuss models, algorithms and other details of the solution. Results of initial experiments are given in Section VI. Last Section VII provides concluding remarks.

## II. Related works

Ontology learning is a process of building ontologies from various data representations. It includes such tasks as identification of concepts, their relations and attributes, arranging into hierarchies. Such task is apparently easier in the case of structured or semi-structured data. A challenging problem, however, is building ontologies (usually taxonomies) comprising concepts extracted from unstructured text documents [14]. For this purpose various text mining techniques can be used: syntactical analysis, Formal Concept Analysis [4] and clustering [7].

Concepts (sometimes also referred as compound terms or phrases) are important features used in Text Mining [23]. Compound terms processing is a technique aiming at improving accuracy of search engines by indexing documents according to compound terms, i.e. combinations of 2 or more single words. During query execution searched compound terms are also extracted form queries (which can be phrases in natural language) and then matched with compound terms attributed to documents. A good example can be a compound term “table wine”. A document referencing it is more likely to discuss wines, than pieces of furniture. Such approach outperforms solutions that use in queries keywords combined

978-83-60810-66-8/$25.00©2015, IEEE

with boolean operators. The idea of statistical compound terms processing was proposed and commercialized by Concept Search company [5]. On the other hand, a syntactical technique based on rules defining patterns for various European languages was developed within CLAMOUR project (see reports at http://webarchive.nationalarchives.gov.uk/20040117000117/ http://statistics.gov.uk/methods_quality/clamour/default.asp).

In [9] Dalvi, Kumar et al. from Yahoo Labs. coined an idea of a *web of concepts*. They claimed that the current model of the web in form hyperlinked pages represented by bags of words should be augmented by extracting concepts and creating a new rich view of all available resources for each concept instance. The paper discussed several use cases enabled by the new approach, including: more accurate web search, browsing optimization, session optimization and advertising. The paper also indicated several challenges, related mainly to information extraction, potential uncertainty and changing data. An algorithm for concept extraction following this idea was proposed in [20].

Blake and Pratt [2] used automatically retrieved concepts to build searchable representations of medical texts. In [3] authors also extracted ontologies from medical texts and showed that using concepts improves search results.

Osinski and Weiss described Lingo, a concept driven document clustering algorithm [19]. Concepts (frequent sequences of terms), were used to label clusters in a document-term matrix.

An important task in NLP language classification is *tagging*, i.e. assigning part of speech (POS) information to inflected forms of words. This is a challenging task for a highly inflected languages like Polish. According to [1] words in English language can be described with about 200 tags whereas for Polish their number ranges at 1000.

In our work we used Morfologik stemming library [17], which is discussed in detail in Section IV. The software and the dictionary was used in several projects including Language tool [18], carrot search [19], PSI toolkit [10], PELCRA [21] and Smyrna [11]. Morfologik dictionary was integrated as a part of PoliMorf [27].

Language tool [18], [16] is a proofreading program supporting a number of languages including Polish. It allows to define text correction rules referring to explicit token values, lemmatized words and part of speech tags. Rules can be specified either in XML format or written directly as Java classes. The tool provides also a visual rule editor, which allows to construct a rule in an interactive manner. As the rules yield suggestions, their core functionality is somehow similar to the concepts extraction rules described in this paper.

## III. Towards Polish concepts extraction

Concepts are terms denoting sets of objects sharing common properties. The most general concepts are represented in texts as single nouns (referring to tangible or abstract objects) and verbal nouns describing actions. Examples of both types can be a *car* (a tangible object) or *driving* (an action). Subclasses of general concepts are usually represented by various complements, e.g. a *green car* (a car having the green color) or *car driving* (an action performed on a specific type of vehicle).

Hence, concepts in texts are represented by n-grams (sequences of tokens), whose elements satisfy grammar rules related to correct words ordering and their morphological forms. The rules are language specific; this in particular applies to the Polish language, in which the complements can be declined depending on the noun case, e.g. for the green car: *zielony samochód* (Nominative), *zielonego samochodu* (Accusative), *zielonemu samochodowi* (Dative), etc.

Table I gives examples of several sentences and concepts identified in a supervised manner. Underlined words indicate parts of concept names denoting their superclasses, e.g. *szybki samochód* $\sqsubset$ *samochód*. (The English equivalent is: *FastCar* $\sqsubset$ *Car*).

The concepts listed in Table I constitute typical parts of speech combinations: adjective+noun (*szybki samochód*, *słone jezioro*, *mały ludzik*), nount+noun (*architektura systemu*, *hurtownia danych*) or verbal noun+noun (*leczenie pacjenta*, *zbieranie informacji*). They appear in source sentences as sequences of tokens that after identifying them should be transformed into appropriate nominative forms following the language grammar rules, especially, as regards noun complements. In most cases concepts occur in distinct parts of sentences, however sometimes they may overlap, e.g three concepts can be selected for the entry 6 in the table. Similarly, for the entry 10 showing two adjectives separated by a coma and a noun, three concepts forming a small taxonomy are possible:

- *mały ludzik* $\sqsubset$ *ludzik*
- *zielony ludzik* $\sqsubset$ *ludzik*
- *mały zielony ludzik* $\sqsubset$ *mały ludzik* $\sqcap$ *zielony ludzik*

### A. Rule based approach

The proposed approach to concept extraction consists in defining rules that search for selected patterns in an input text, then apply appropriate morphological transformations to matched words in order to obtain correct forms of concepts.

This is shown in Fig. 1. A window having the length equal to size of a rule input pattern slides through the input text. Sentences are the natural boundaries for the analysis, i.e. the window stops at the sentence end.

If the rule is applicable for a current n-gram appearing in the window, a set of output sequences of tokens is produced. They constitute candidates for concepts, that can be further analyzed and aggregated according to various attributes: sentences, where they occurred, frequency in the whole document, weights describing confidence, etc.

### B. Specification of rules - learn by example

Selection of the language used to specify extraction rules is an important decision, as the language capabilities have strong impact on both on the process on rules definition and obtained results. In our approach we decided to define rules in a semi-formal way, by giving samples of expected translations rather

TABLE I
IDENTIFICATION OF CONCEPTS IN SENTENECES AND EXAMPLES OF ANNOTATIONS.

| # | Sentence | Concept | Annotation | Function |
|---|---|---|---|---|
| 1. | Jeżdżę *szybkim samochodem.* | szybki samochód | @(szybki samochód = szybki @samochód) | extract noun + verb |
| 2. | Morze Kaspijskie jest *jeziorem słonym.* | słone jezioro | @(jeziorem słonym = słone @jezioro) | inversion + Instrumental → Nominative |
| 3. | *Leczenie pacjenta* przebiegało bardzo wolno. | leczenie pacjenta | @(leczenie pacjenta = @leczenie pacjenta) | extract verbal noun + complement |
| 4. | Opracowałem *architekturę systemu.* | architektura systemu | @(architekturę systemu = @architektura systemu) | Accusative → Nominative |
| 5. | *Rozwojowi rolnictwa* towarzyszyło *zanikanie lasów.* | rozwój rolnictwa<br>zanikanie lasów | @(rozwojowi rolnictwa = @rozwój rolnictwa)<br>@(zanikanie lasów = @zanikanie lasów) | Dative → Nominative<br>extract verbal noun + complement in plural form |
| 6. | Następnie poświęcił się *zbieraniu informacji* o *losach misjonarza.* | zbieranie informacji<br>los misjonarza | @(zbieraniu informacji = @zbieranie informacji)<br>@(losach misjonarza = @los misjonarza) | Dative → Nominative<br>Locative plural → Nominative sing. |
| 6. | Obecnie coraz częściej stosowane są *zwinne metodyki zarządzania projektami informatycznymi.* | zwinna metodyka<br>metodyka zarządzania<br>zarządzanie projektami informatycznymi | @(zwinne metodyki = zwinna @metodyka )<br>@(metodyki zarządzania = @metodyka zarządzania)<br>@(zarządzania projektami informatycznymi = @zarządzanie projektami informatycznymi) | Nominative plural → Nominative sing.<br>Nominative plural → Nominative sing.<br>Accusative → Nominative |
| 8. | *Hurtownie danych* stanowią osobną klasę *systemów informatycznych.* | hurtownia danych<br>system informatyczny | @(hurtownie danych = @hurtownia danych)<br>@(systemów informatycznych = @system informatyczny) | Nominative plural → Nominative sing.<br>Genitive plural → Nominative sing. |
| 9. | Małe, *zielone ludziki* rozłożyły się u *podnóża dębu.* | zielony ludzik<br>podnóże dębu | @(zielone ludziki = zielony @ludzik)<br>@(podnóża dębu = @podnóże dębu) | Nominative plural → Nominative sing.<br>Locative → Nominative |
| 10. | *Małe, zielone ludziki* rozłożyły się u podnóża dębu. | mały ludzik, zielony ludzik, mały zielony ludzik | @(małe $, zielone ludziki = mały @ludzik \| zielony @ludzik \| mały zielony @ludzik) | Nominative plural → Nominative sing. |

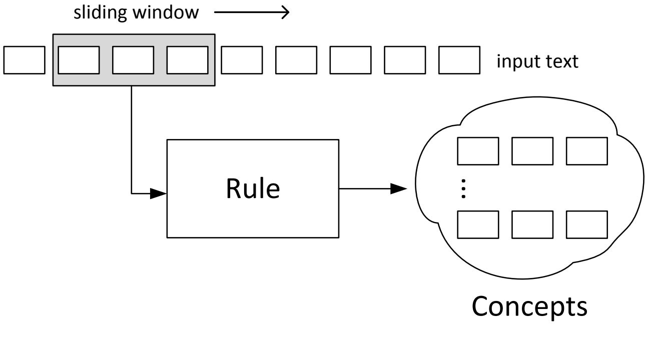

Fig. 1. General rule design

than using formally defined rules. The translation patterns are defined using special, relatively simple textual annotations that can be embedded in a source text or placed in a separate file.

The third column of Table I gives examples of annotation matching the identified concepts. Each annotation starts with '@' (at sign) followed by the annotation body put between two parentheses. The '=' sign separates the input pattern and a list of output sequences, whereas '|' is the output sequence separator. Optional '@' sign within an output sequence identifies a key, i.e. a possible concept superclass.

The last column of Table I specifies the expected function for each annotation example. Usually, annotations define transformations of declination cases and plural forms, which according to Polish grammar rules should be applied both to nouns and their complements. However, they may be used to specify extraction patterns only, not accompanied by morphological transformation. Examples are given in rows 1, 3 and 5.

It should be remarked that, basically, annotations do not specify exact matches of words (for an exact match the dollar sign is used as in row 10). The intent of annotations is to specify indirectly rules applicable to classes of tokens. For example a rule derived from the annotation `@(zwinne metodyki = zwinna @metodyka )` (agile methodologies → agile methodology) in row 6 of Table I applies to feminine nouns in plural form with an adjective. Hence, it should match also the pair of words, which are tagged with the same POS information, e.g. *długie wstążki* (long ribbons), and properly convert it to the singular form *długa wstążka*.

An advantage of the proposed indirect method of rules specification is its simplicity: translation patterns can be defined very quickly, moreover, specifications are not bounded to a particular rule language or execution engine. Depending on a compiler used, rulsets in various rule languages can be obtained.

In many cases defined translation patterns may result in conflicting rules. Let us consider the following annotations:

1) `@(hurtowniom danych=@hurtownia danych)`
2) `@(grubościom pokryw=@grubość pokrywy)`

The first translation results in a noun having a complement in plural form, whereas int the second case the complement is singular. However, they both represent valid transformations. To tackle with such problems the language used to represent rules should allow to attribute results with weights representing likelihood of concept occurrence.

### C. Process of concept extraction

The outline of the process of concept extraction is presented in Fig. 2. A text file containing manually prepared annotations is compiled yielding a set of rules stored in an XML file. The input text is split into sentences and then the rule set is executed for each sentence giving candidate concepts. Finally, the concept occurrences are aggregated and sorted. As different rules may return identical results, the aggregation is at first performed at the sentence level, then for the whole document.

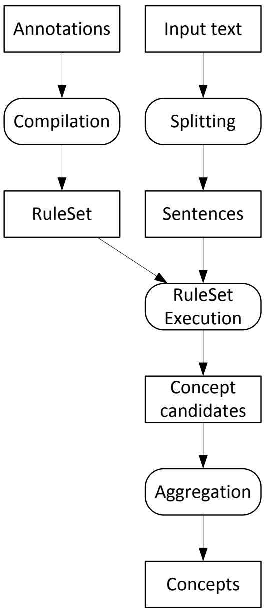

Fig. 2. Process of concept extraction

## IV. Morfologik

During annotations processing and rules execution input words are checked for specific part of speech properties and undergo morphological transformations. This function is provided by the Morfologik.

Morfologik is both a a comprehensive dictionary of Polish inflected forms and a software library written in Java accompanied by a number of utility tools. The main function offered by the Morfologik is *stemming* (lemmatization) of Polish words, i.e. finding a stem (lemma) accompanied by grammar information for an inflected form. Examples of inflected forms and corresponding stems can be: *psu* – *pies* (noun: dog), *czystego* – *czysty* (adjective: clean) or *pisaniu* – *pisać* (verbal noun writing and verb: to write).

Morfologik dictionary can be seen as a relation

$$D \subset IF \times S \times \mathcal{P}, \tag{1}$$

where $IF$ is a set of inflected forms, $S$ is a set of stems, $S \subset IF$, and $\mathcal{P}$ is a set of POS tags defining properties of inflected forms (part of speech, gender, singular vs. plural, declination case, etc.)

A few entries from the Morfologik dictionary are shown in Table II. It can be observed that several stems may be found for an inflected form, e.g. *czarnym* – *czarna*, *czarny*. Moreover, pairs of inflected forms and stems can be attributed with multiple tags (separated with '+' sign).

A tag is a string of symbols (usually abbreviations) separated by colon signs. Examples in the table show typical tag elements: *subst* – noun, *adj*-adjective, *ger*–verbal noun, *sg*–singular, *pl* –plural, *nom*, *gen*, *dat*, *acc*, *inst*, *loc* – declination cases. For a given part of speech class, tag components appear in the same order. In some cases multiple symbols separated by dot sign may occur, e.g. "m1.m2" - various classes of masculine forms.

Based on the Morfologik dictionary scheme two functions can be defined: $stem$ (2) and $synth$ (3). The first takes as input an inflected form and returns a set of stems with accompanying tags, the second synthesizes inflected forms from an input stem and tag.

$$stem \colon IF \to 2^{S \times \mathcal{P}} \tag{2}$$

$$synth \colon S \times \mathcal{P} \to 2^{IF} \tag{3}$$

Morfologik fully supports stemming. The library uses internally an efficient dictionary representation based on Finite State Machine (FSM) model, which is characterized by compact data size and short access times [8]. The current Morfologik dictionary for the Polish language (version 2.0) constitutes a large 317 MB text file, whereas the same data compiled to FSM are stored in 2.7 MB binary file. The precompiled dictionary is a part of Morfologik distribution, however, the library offers also a number of awk scripts to preprocess the dictionary data, as well as tools allowing to compile it into FSM.

Unfortunately, the synthesizing function is not provided directly by the library, although the documentation suggests that it is possible to rebuild (revert) the dictionary and recompile to FSM form. As the guidelines for implementing an FSM

TABLE II
SAMPLE ENTRIES FROM THE MORFOLOGIK DICTIONARY.

| $IF$ - inflected form | $S$ – stem (lemma) | $\mathcal{P}$ - part of speech tags |
|---|---|---|
| czarnym | czarna | subst:pl:dat:f |
| | czarny | adj:pl:dat:m1.m2.m3.f.n1.n2.p1.p2.p3:pos<br>+adj:sg:inst:m1.m2.m3.n1.n2:pos<br>+adj:sg:loc:m1.m2.m3.n1.n2:pos<br>+subst:pl:dat:m1+subst:sg:inst:m1+subst:sg:loc:m1 |
| czystego | czysty | adj:sg:acc:m1.m2:pos+adj:sg:gen:m1.m2.m3.n1.n2:pos |
| psu | pies | subst:sg:dat:m1+subst:sg:dat:m2 |
| pisaniu | pisać | ger:sg:dat.loc:n2:imperf:aff:refl.nonrefl |
| | pisanie | subst:sg:dat:n2+subst:sg:loc:n2 |

based synthesizer seemed quite difficult to follow, we left this possibility for further improvements. Instead, we developed a synthesizing function, which uses the dictionary data stored in a local PostgreSQL database. It was populated with 288657 stems, 1173 tags broken on plus (+) signs and 7410145 triples comprising inflected forms, stems and tags.

The implemented $synth(s, p)$ function comprises two steps:

1) A query to the database is made to select a set of triples matching the stem $s$. As the query result set $IFT = \{(if, s', p') \in D \colon s' = s\}$ is returned. The set is usually small, in most cases it contains up to 30 entries.
2) From the triples in $IFT$ a set of inflected forms $IF = \{if \colon (if, s', p') \in IFT \wedge match(p, p')\}$ is selected, whose tags $p'$ match $p$. The $match(t, t')$ function takes into account order of symbols appearing in tags, as well as alternate properties indicated by the dot separator.

The time efficiency of the implemented $synth$ function is obviously inferior to the $stem$ function offered by Morfologik. Single call to $stem$ (based on FSM representation) takes about 0.085 ms, whereas $synth$ (based on database queries) ranges to 0.75 ms. It should be remarked that we have also implemented an ORM version of $synth$ . In this case the execution time is about 1.25 ms.

## V. METHODS

The language used to define rules is based on Petri nets. Each rule comprises ordered sets of input and output places, which are linked by transitions.

Fig. 3 gives an example of the rule comprising three input places, three output places and four transitions. Multiple transitions, here *t1* and *t2* may link a pair of input and output places. The net layout shows also, how inversion of tokens can be achieved.

Each rule transition is assigned with two sets of tags: input $itag$ and output $otag$. Input tags are used as guards, they allow check if the transition applies to a word tagged with part of speech information. Output tags are used to synthesize target inflected form from a word stem (lemma). Additionally, each transition has assigned weight, that can be used to differentiate less and more likely translation schema.

Below we give a formal definition of the language used to define rules.

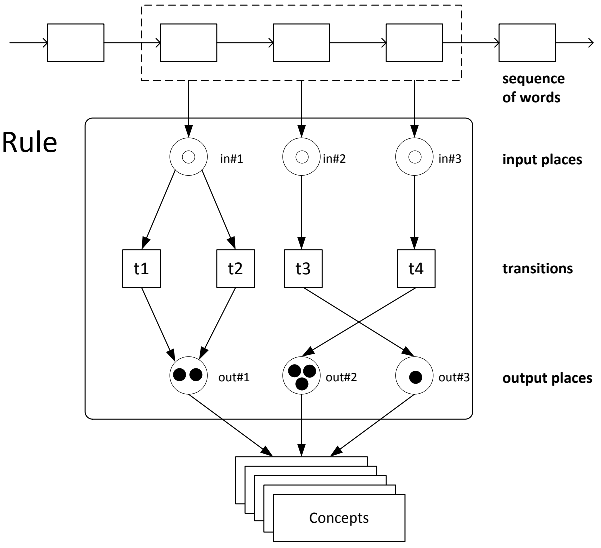

Fig. 3. Detailed rule design

**Definition 1.** Concept extraction rule is a tuple $R = (\mathcal{P}, I, O, T, itag, otag, itoken, \mu)$, where:

- $\mathcal{P}$ is a set of tags
- $I = \{i_1, i_2, \ldots, i_n\}$ is an ordered set of input places,
- $O = \{o_1, o_2, \ldots, o_m\}$ is an ordered set of output places,
- $T \subset I \times (O \cup \{nil\})$ is a set of transitions,
- $itag \colon T \to 2^{\mathcal{P}}$ is a function assigning to a transition a set of *input tags*,
- $otag \colon T \to 2^{\mathcal{P}}$ is a function assigning to a transition a set of *output tags*,
- $itoken \colon I \to \mathcal{A}$ is a function assigning to an input place an exact (possible empty) string form $\mathcal{A}$
- $\mu \colon T \to [0, 1]$ is a transition weight function

The symbol $nil$ used in transition definition denotes a fake output place. It is used when a transition serves as a guard allowing to check if an input place contains a word appertaining to a particular class without translating it. The $itoken$ function is used to assign particular token values to input places. They result from compilation of '\$'-token specifications in input annotations (see Table I row 10).

### *A. Compiling annotations to rules*

An annotation defining multiple outputs $@(\sigma = \pi_1|\pi_2|\dots|\pi_k)$ is split into $k$ rules corresponding to annotations $@(\sigma = \pi_1)$, $@(\sigma = \pi_2)$,..., $@(\sigma = \pi_k)$. (Symbols $\sigma$ and $\pi$ stand here for input and output sequences of words.

For an annotation $@(\sigma = \pi)$, $n$ input places and $m$ output places are created, where $n$ and $m$ denote the lengths of $\sigma$ and $\pi$ respectively.

Then each word in sequences $\sigma$ and $\pi$ is stemmed and transitions between input and output places are derived based on stem matching.

Fig. 4 illustrates this process on an example of annotation `@(informacji przetwarzaniu = @przetwarzanie informacji)`. The equivalent English term is *information processing*. The annotation defines a translation pattern that includes inversion and changing the case of the whole expression from Dative to Nominative form.

Rounded rectangles depict words appearing in the input sequence $\sigma$ (above) and output sequence $\pi$ (below). For each word in the sequence the stemming information is determined with Morfologik $stem$ function. It consists of a stem (lemma) and a set of tags. The word *informacji* is classified as the noun *informacja* tagged as singular or plural form with various declination cases (see the first transition in Fig. 5 for details). The stemming information for *przetwarzanie(u)* gives two options: it is either a noun *przetwarzanie* (Eng. *processing*) or a verbal noun (tagged by Morfologik as *ger*) derived from the verb *przetwarzać* (Eng. *to process*).

Hence, by performing stem/tags matching three transitions are created (indicated by arrows in Fig. 4): one for places corresponding to the mapping *informacji* → *informacji* and two for *przetwarzaniu* → *przetwarzanie*. XML code for the resulting rule is presented in Fig. 5.

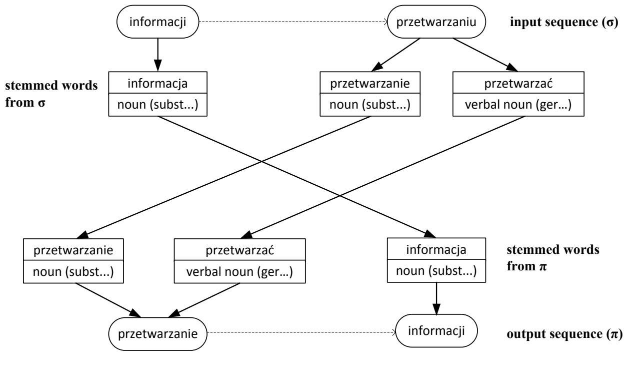

Fig. 4. Translation of annotation `@(informacji przetwarzaniu = @przetwarzanie informacji)`

It is expected that rules obtained as results of the annotations compilation satisfy the following conditions:

- Each output place is a target of a transition: $\forall o \in I . \exists t = (i_s, o_e) \in T \colon o = e_e$
- All transitions leaving an input place must target the same output place: $\forall t_1 = (i_1, o_1), t_2 = (i_2, o_2) \in T . i_1 = i_2 \rightarrow o_1 = o_2$

If the compilation returns a rule, which does not satisfy the above conditions, the source annotation is reported as ambiguous. Obviously, with the presented translation algorithm it is not possible to compile such annotation as `@(danym danym = dane @dane)` although it can be quite easily interpreted as *given data*.

To our consolation, statistical translation functions of Google Translate (as of 2015) also have problems in this case: *danym danym* is translated to *given the*, wheras *dane dane* to *data data*. However, after specifying the input n-gram explicitly, i.e entering *“dane dane”* the correct form *given data* is returned.

Fig. 5. A rule in XML format

### *B. Execution of rules*

As the described rules (see Definition 1) follow the Petri net approach, to define their execution such notions as tokens and marking are necessary. The set of tokens $TK$ is defined as $TK = IF \times S \times \mathcal{P} \times \mathbb{R}^{0+}$. (See also formula 1.) Components of a token tuple $(if, s, p, w) \in TK$ are the following: $if$ denotes an inflected form, $s$ is a stem, $p$ is a part of speech tag and $w$ is a non-negative weight.

**Definition 2** (Marking)**.** *Marking* for a rule $R = (\mathcal{P}, I, O, T, itag, otag, itoken, \mu)$ is defined as a function that assigns sets of tokens to places $M : I \cup O \rightarrow 2^{TO}$

Before executing rules, each word in an input sequence $\pi = (\pi_i)$ is submitted to Morfologik $stem$ function (see formula 2) and corresponding sequence of stemming information is obtained $\rho = (\rho_i)$, where $\rho_i \in 2^{S \times \mathcal{P}}$. Hence, $\pi_i$ is an input inflected form of a word and $\rho_i$ a set of possible stem–tag combinations for $\pi_i$.

Execution of a rule comprises the following steps:

1) Input places are filled with tokens starting from position $b$ in sequences $\pi$ and $\rho$ ($b$ defines the beginning of the sliding window). Each $k$-th input place receives tokens from $\pi_{b+k}$ and $\rho_{b+k}$. Its marking is gets: $M(I_k) \leftarrow \{\pi_{b+k}\} \times \rho_{b+k} \times \{0\}$.
2) For each input place $I_k \in I$ it is checked, if there exists at least one enabled transition (or exact word matching, if specified). Hence, for each transition $t \in T(I_k)$ and each token $tk = (if, s, p, w) \in M(I_k)$ it is checked, if the sets of transition input tags $itag(t)$ and token tags $p$ match. The matching function compares tags in both sets, splitting them into smaller parts where needed. A pair $(t, tk)$, such that the transition $t$ is enabled is called an enabled binding.
3) Finally, transitions are executed for all enabled bindings $(t, tk)$. If $O_i$ is the output place for the transition $t$, and $tk = (if, s, p, w)$, then the marking for $O_i$ is modified according to (4):

$$M(O_i) \leftarrow M(O_i) \cup synth(s, otag(t)) \times \{s\} \times \\ \times (p \cap otag(t)) \times weight(t, tk) \quad (4)$$

Interpretation of the formula (4) is the following: a stem (lemma) together with output tags are submitted to the $synth$ function, which returns a set of inflected forms. In consequence, for an input word $if_{in}$ the chain of translations is accomplished:

$$if_{in} \xrightarrow{p_i n \cap itag(t)} \{s\} \xrightarrow{p \cap otag(t)} \{if_{out}\}$$

In the first step $if_{in}$ is converted into a set of stems $\{s\}$. In the second stems are converted back to altered inflected forms $\{if_{out}\}$ according to the set of output tags assigned to the transition.

The $weight(t, tk)$ function is used to assign weight value to tokens. It calculates the Jaccard index of two sets: token tags $p$ and transition input tags $itag(t)$ and then multiplies it by the transition weight $\mu(t)$.

$$weight(t, tk) = \frac{|p \cap itag(t)|}{|p \cup itag(t)|} \cdot \mu(t) \quad (5)$$

Weight calculation according to formula (5) is based on a certain intuition: the Jaccard index allows assessing the similarity between a prototype word appearing in the annotation, from which the rule originates and the input term.

After executing a rule, its output places may contain several tokens. Such situation is shown in Fig 3, where the place *out#1* contains two tokens, the place *out#2* three and the place *out#3* one. For the presented example six separate strings representing concept candidates, each of them having different content and weights are obtained.

### C. Aggregation

Aggregation of results constitutes the final stage of text processing and concepts extraction. Actually, it is rather a chain of aggregations performed at subsequent levels (see Fig. 6). All data processed within the chain are attributed with numerical weights (scores). At each step, apart from data conversions (e.g. combining tokens into strings) the assigned weights are summarized using various norms: $sum$,$min$, $max$, etc.

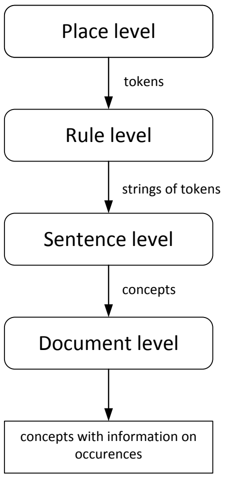

Fig. 6. The chain of aggregations

- During the aggregation occurring at the *place level* identical tokens assigned to an output places combined into one. The default norm is $sum$.
- Aggregation at the *rule level* aims at creating strings from sets of tokens residing in output places. In the same time weights tokens are aggregated and obtained values are assigned to strings. The default norm is $min$.
- Various rules may return identical concepts. At present there are no measures implemented that would allow to manage the ruleset, and in particular remove redundant rules [13]. Aggregation at the *sentence level* combines multiple strings using the selected norm (default is $max$).
- Finally, aggregation at the *document level* keeps track of occurrences of concepts in sentences, counts them and aggregates the weights. (The default norm is $sum$).

### D. Implementation

The software implementing the discussed approach was implemented in Java language, what enables integration with Morfologik stemming libraries and Jena for OWL output handling. It includes the following modules:

- A tool allowing to load the Morfologik dictionary into PostgreSQL database (see Section IV)

- Synthesizer shortly described in Section IV
- Annotations compilation tool, which create rules and serializes them with JAXB libraries
- Sentence scanner allowing to split the input text into sentences and perform additional preprocessing
- Rule execution modules
- Configurable aggregation modules, e.g. it is possible to select various aggregation norms
- Output modules that renders results in various formats including CSV and OWL

## VI. Experiments and results

In this section we present initial results of concept extraction from a large text file specifying medical guidelines for asthma treatment. The file is a Polish translation of a document issued by Global Initiative for Asthma (GINA) in 2011. The file size is 308KB it contains about 40000 words and 2000 sentences.

We selected this document, as it was used in previous works aiming at building ontologies of medical guidelines and performing fuzzy reasoning based on ontological models [24]. Moreover, the presented here solution was intended to be an improvement of a prototype tool (unpublished) that used internally FSM to extract concepts from texts. Both tools were tested on the same file and we wanted to compare the results of the described method and the previous one (available at http://home.agh.edu.pl/~pszwed/en/doku.php?id=ontologies#in_polishgina_guidelines_glossary). The main difference with respect to the previous solution is the focus on correct morphological form of concept names and different approach to evaluation of the accuracy of extracted concepts .

The ruleset used during the experiment resulted from compilation of an annotations file comprising translation patterns for single words and pairs of words only. Single word translations were limited to nouns and verbal nouns, 2-grams included variations comprising nouns, verbal nouns and adjectives in various cases. The resulting ruleset contained 223 rules.

The average processing time (concepts extraction without rules compilation) was about 36.785 seconds (executed on Intel Core i7-2675QM laptop at 2.20 GHz, 8GB memory under Windows 7). The extraction process returned 5151 concepts.

Table III shows selected results ordered by the weight values. It comprises top 20 results, 10 concepts from the middle and 10 concepts with the lowest weights. The word in capital letter indicates the key, i.e. the part of the concept name referring to a prospective superclass. Improperly identified concepts are underlined.

In the whole table the entry 2495 is apparently incorrect according to syntactical rules. The correct form should be: *EKONOMIKA_wdrażania*. Other underlined entries are formed correctly according to grammar rules, however their semantics does not match the document content. Position 18 WIEKO (Eng. lid) should be replaced by WIEK (Eng. age). The word NIEODPOWIEDNI (Eng. inaccurate) is rather an adjective. However, according to Morfologik it can be classified both as adjective and noun. The word SŁUŻĄCY can be interpreted as “a servant” and “serving to”. In this context rather the second meaning was used over the document.

TABLE III
Extracted concepts from the Polish translation of asthma treatment medical guideline

| Pos | Concept | Count | weight |
|---|---|---|---|
| 1 | DROGI_oddechowe | 161 | 644.00 |

| 5151 | BETA | 1 | 0.01 |

Fig. 7 shows extracted concepts related to the term *ryzyko* (Eng. risk) arranged into a small hierarchy. The term repeated quite frequently over the document. It can be seen that in two cases 3-grams would be more adequate, because some complements are missing, e.g. *RYZYKO_utraty* (Eng. risk of loosing).

The presented software is still in development phase, hence only preliminary results of concept extraction can be given. During future experiments several parameters controlling the execution should be tuned to provide high accuracy ratio.

The configurable parameters include norms used at various stages of aggregation (see Section V-C), as well as weights assigned to rules and individual transitions. Taking into account the complexity of rule definitions (see Fig. 5) and the number of rules, weights tuning must be performed in an automated way.

We already started to implement such mechanisms. During the experiment described in Section VI rules with single word transformation patterns were attributed with smaller weights (0.3). This value was selected quite arbitrarily.

Another example is related to handling a situation described as *tag conflict*. Quite often Morfologik identifies a word a member of two various part of speech classes, e.g. an adjective vs. a noun or a verbal noun vs. a noun. In this case, while compiling the annotations, we attribute higher weights to transitions derived from adjectives and verbal nouns (0.9), than nouns (0.1).

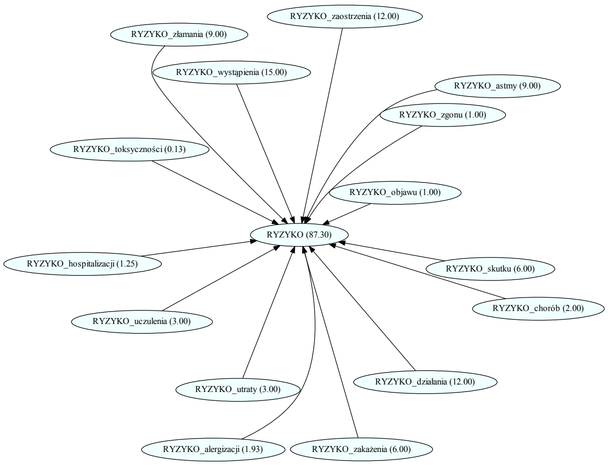

Fig. 7. Concepts related to the term *ryzyko* (risk)

## VII. Conclusions

In this paper we present a solution for concept extraction from Polish texts with special focus on correct morphological forms of obtained concept names. As Polish is a highly inflected language, detected names need to be transformed following Polish grammar rules. We propose a user-friendly method for specification of transformation patterns, which is based on a simple annotations language. Annotations prepared by a user are compiled into transformation rules. During the concept extraction process the input document is split into sentences and the rules are applied to sequences of words comprised in sentences. Recognized strings forming concept names are aggregated as various levels. Although the annotation language is simple, it is flexible enough to specify various translation patterns, for example it is possible to apply inversion or to omit such tokens appearing in the input sequence as commas or prepositions.

The design of rules follow the language of Petri nets, combining elements of colored [12] and fuzzy [6] Petri nets. Rules comprise input places (filled with elements of analyzed n-grams), output places, where results are collected, and transitions linking them. Similarly to colored Petri nets, tokens are tuples – in this case they represent words and part of speech information. Tokens are also equipped with fuzzy weights. The internal behavior exhibited during rules execution borrows from fuzzy Petri nets (i.e. there is no conflict between transitions that may fire simultaneously and produce multiple tokens in output places). A similar approach was used in our previous works related to semantic event recognition and it turned out to be very efficient [26], [25].

Although we did not provide the formalization in the flavor of fuzzy rules and Fuzzy Inference Systems and fuzzy rules [22], [15], the discussed approach follows this direction. A token put in an input place receives a weight based on a kind of membership function (see Section V-B, step 3). This step resembles the fuzzification stage in fuzzy inference systems. Further, after a rule is executed, weights of output token are combined using configurable aggregation norms. This in turn corresponds to defuzzification step. Nevertheless, the transformation rules are not semantic, they are not prepared by experts and do not reference linguistic terms in the sense of fuzzy logic.

The rules are obtained fully automatically. This point also differs the presented approach from the Language tool [18] discussed in Section. II.

The developed software is tightly coupled with the Morfologik dictionary for the Polish language and accompanying library API. However, the proposed approach is quite general and can be applied to texts in other languages, provided that a language specific dictionary, as well as a software supporting lemmatization and synthesizing are available.

There are several avenues for future work. We plan to define 3-gram translation patterns and patterns comprising verbs, .e.g. *he* reads a book → book reading. Further improvement to the extraction accuracy can be achieved by tuning several parameters: rule and transition weights and norms. Another direction may be related to rule management, removing redundant rules, refactoring (e.g. splitting transitions) and purging tag sets assigned to transitions.

# AAIA'15 Data Mining Competition: Tagging Firefighter Activities at a Fire Scene

AAIA'15 Data Mining Competition: Tagging Firefighter Activities at a Fire Scene is a continuation of the last year's competition organized within the framework of International Symposium on Advances in Artificial Intelligence and Applications (AAIA'15, https://fedcsis.org/aaia). It is also an integral part of the 2nd Complex Events and Information Modelling workshop (CEIM'15 https://fedcsis.org/ceim) devoted to the fire protection engeneering. This time, the task is related to the problem of recognizing activities carried out by firefighters based on streams of information from body sensor networks. Prizes worth over 4,000 PLN will be awarded to the most successful teams. The contest is sponsored by Polish Information Processing Society (http://www.pti.org.pl/), with a support from University of Warsaw (http://www.mimuw.edu.pl/) and ICRA project (http://icra-project.org/).

## Introduction

A fire ground is considered to be one of the most challenging decision taking environment. In dynamically changing situations, such as those occurring at a fire scene, all decisions need to be taken in a very short time. Since wrong decisions might have severe consequences, a commander of the response team is forced to act under a huge psychological pressure. This fact, combined with incomplete or inaccurate information about the current situation, sometimes leads to committing serious mistakes [1].

There are several initiatives that investigate this complex problem. One of them is The National Near Miss program in the USA (www.nationalnearmiss.org/). It gathers and analyzes reports describing real-life dangerous situations, and tries to draw some conclusions regarding their causes. Based on several thousand of carefully analyzed reports, experts identified the “lack of situational awareness” as the main factor associated with major accidents among firefighters [2]. This observation is in accordance with the results of the previous edition of our data mining competition [3]. The situational awareness corresponds to the cautiousness of a commander and his understanding of the actual state of the environment. Conditions affecting the situational awareness can be broken down into three groups: a lack of information, a lack of knowledge and a lack of cognition [4]. In this context, it seems that an increase in the situational awareness of commanders would result in taking better decision and thus increasing the safety of firefighters. Studies on the causes for mortal accidents during the actions of firefighters were also conducted by the Department of Homeland Security of the United States [5]. One conclusion of their research is that over 43% of deaths at a fire scene was caused by the stress or overexertion. Therefore, another critical way of increasing the firefighter safety is by monitoring their kinematics and psychophysical condition during the course of fire & rescue actions.

Our research team works on those problems within a frame of ICRA project (www.icra-project.org/). One of prototype tools developed as a result of this project is, so called, a "smart jacket". This device is a wearable set of body sensors that allows to automatically track a firefighter at a fire scene. It also enables real-time screening of firefighter’s vital functions and monitoring of ongoing activities at the scene. The later of those two tasks is the main scope of this year’s AAIA Data Mining Competition. We would like to ask participants to come up with efficient algorithms for labelling activities conducted by firefighters during their training exercises, based on provided data sets from our body sensor network. More details regarding the data and their acquisition process can be found in Task description section. Moreover, a good starting point for research on the problem of activity recognition based on body sensor data was described in [6]. We hope that your expertise and innovative ideas will become a valuable contribution in our effort to increase the safety of brave men and women serving in Polish State Fire Service.

## Special session at CEIM'15

As in the previous year, a special session devoted to the competition will be held at 2nd Complex Events and Information Modelling workshop (CEIM'15 https://fedcsis.org/ceim) which is a part of 10th International Symposium on Advances in Artificial Intelligence and Applications (AAIA'15, https://fedcsis.org/aaia). We will invite authors of selected reports to extend them for publication in the conference proceedings (after reviews by Organizing Committee members) and presentation at the conference. The publications will be treated as regular papers (including indexation in the Thomson Reuters Web of Science, DBLP, Scopus and other portals). The invited teams will be chosen based on their final rank, innovativeness of their approach and quality of the submitted report.

## Awards

Authors of the top ranked solutions (based on the final evaluation scores) will be awarded with prizes:

- First Prize: 3000 PLN + one free FedCSIS'15 conference registration,
- Second Prize: 1000 PLN + one free FedCSIS'15 conference registration,
- Third Prize: one free FedCSIS'15 conference registration.

The award ceremony will take place during the FedCSIS'15 conference (September 13 - 16, Łódź). Traditionally, invited authors who decide to attend the conference will receive a diploma and a competition T-shirt.

## Contest Organizing Committee

**Andrzej Janusz,** University of Warsaw.
**Michał Meina,** University of Warsaw
**Adam Krasuski,** Main School of Fire Service
**Krzysztof Rykaczewski,** University of Warsaw
**Bartosz Celmer,** Main School of Fire Service
**Dominik Ślęzak,** University of Warsaw & Infobright Inc.

***Abstract*—In this paper, we summarize AAIA'15 data mining competition: Tagging Firefighter Activities at a Fire Scene, which was held between March 9 and July 6, 2015. We describe the scope and background of the competition. We also reveal details regarding the data set used in the competition, which was collected and tagged specifically for the purpose of this data challenge. We explain the data acquisition process which involved using a body sensor network system consisting of several inertial measurement units and a physiological data sensor. Finally, we briefly discuss submitted results with respect to their possible real-life application in our decision support system.**

## I. Introduction

The emergency scene is considered to be one of the most dangerous and stressful working environments [3]. Each year the numbers of firefighters die or are injured during the fire & rescue operations. There are many contributing factors which lead to the unsafe events. Those factors are investigated by special commissions and according to [10] 25% of accidents are caused by bad decision making, 29% by bad situational awareness and 10% by bad communication.

The key aspect (regardless of the type of the Incident Management System) comes down to modelling of perception and evaluation of the emergency scene by the Incident Commander (IC) [5], [9], [6]. The relevant incident assessment methodology increases the safety of the rescuers and the chances for success. Information plays a pivotal role in the perception and evaluation. Therefore, there is a strong demand on increasing the sensor density in order to provide more information to the IC. The information reported to the IC must satisfy the *information triangle* rule [5]. It means that it should be *relevant, accurate* and *timely*. All of those aspects — in dynamically changing environment such as a fire incident is — is difficult to satisfy.

During emergency firefighters are mostly concentrated on their principal activities. For the safety reasons they are not able to share in real-time with the IC the information about the current conditions. Paradoxically, as described above, activities currently performed by the firefighters, their physical condition as well as temporal and spatial relation to the fire are crucial for the IC in order to ensure safety operating of the firefighters.

Since the information at the emergency scene is crucial for the operating safety and the personal real-time reporting from firefighters are hampered, the new ways of indirect communication and information sharing are needed. The computer-based systems for human activity recognition may help to reduce the unsafe events, improving the communication and increasing the efficacy of the incident management. Moreover, due to the dangerous environment for human, it could be expected that in the future more and more robot will be involved in operating at the emergency scene. The human activity recognition system may create a bridge for human robot cooperation at the scene.

Human activity recognition using Body Sensor Networks (BSN) is a non-invasive system that is able to deliver information about person locomotion patterns, current posture and specific action performed. In the system that is considered in this paper, a network of inertial measurement units are used. They are able to gather kinematic (motion) data from different parts of the body. This information is then processed using classification techniques [16] (by the body-worn computation unit) in order to estimate activity and passed via radio link to the IC. In such systems like described training data needs to be prepared beforehand and classification procedure needs to take into account power consumption on mobile processing unit and low-radio link throughput.

This paper describes a data mining competition which was organized at the Knowledge Pit platform [14]. Special dataset collected during training exercises of firefighters cadets using custom-built BSN was prepared and made available publicly to encourage a research community to work on new methods and classification models in this particular application. The competition was a part of a broader research addressing a sensory data acquisition at the incident place. The submitted

The research was partially supported by the Polish National Science Centre - grant 2012/05/B/ST6/03215 and by the Polish National Centre for Research and Development (NCBiR) — grant No. O ROB/0010/03/001 in the frame of Defence and Security Programmes and Projects: "Modern engineering tools for decision support for commanders of the State Fire Service of Poland during Fire&Rescue operations in the buildings".

results forms very valuable input into the field and forms a comparable platform for future research.

The paper starts from a detailed discussion of the data acquisition process, including our hardware setup, collection of the data and the process of tagging. The third section describes the preprocessing of the data set for the competition and the evaluation scenario of solutions submitted by competitors. This section also includes a brief summary of the competition results. The paper ends with concluding remarks and a draft of our plans for future work.

## II. Data Acquisition

This section describes data acquisition part of the competition. In the first paragraph we will discuss our hardware design and processing challenges connected with on-line processing the data. Second paragraph will summarize recording sessions and the final paragraph will cover process of annotating the data set.

### A. Hardware setup

The data acquisition hardware is consisted of sensors (seven IMUs and physiological data sensor) and Data Acquisition Unit (DAU). In order to overcome clock synchronization issues all IMUs are connected via physical link to real-time embedded system that streams the data to DAU. Physiological sensor has it own clock synchronization system, therefore information can be streamed via Bluetooth. Moreover, DAU provides simple web interface (accessible via Wi-Fi connection) to control recording trials (starting, stopping and monitoring data collection process).

In our setup we use:

- 7×IMU (Polulu AltIMU-9 rev-4) — 3-axis accelerometer ($\pm 16\,g$ dynamic range) and gyroscope ($\pm 2000\,°/s$ maximum angular rate) with 16 bit signed integer resolution, two IMUs for legs, two for hands and arms and one for back,
- Real-time system embedded — based on Arduino Micro prototype platform, connected via USB interface to DAU,
- Data Acquisition Unit — based on Odroid-U3+ with external battery, additional Bluetooth and Wi-Fi module,
- Physiological data sensor — Equivital EQ02 SEM,
- Communication nodes — XBee-PRO® 868.

In a low level point of view, IMU are two different sensors, one for measuring accelerations one for angular rates. Both, accelerometer and gyroscope provide 16 bit signed integer for each axis (horizontal, vertical and altitudinal), and communicate via $I^2C$ bus. In order to provide the data with zero-time offset between different IMUs, we used real time system (microcontroller) and we have prepared parallel communication version of $I^2C$ library. The library enables us to read the sensor readings from all IMUs at the same time with 1000 samples per second. We decided, however, to gather the data with the frequency about 200 Hz which is a sufficient for classification purposes, while providing low noise and enough accuracy for the most of the sudden movements.

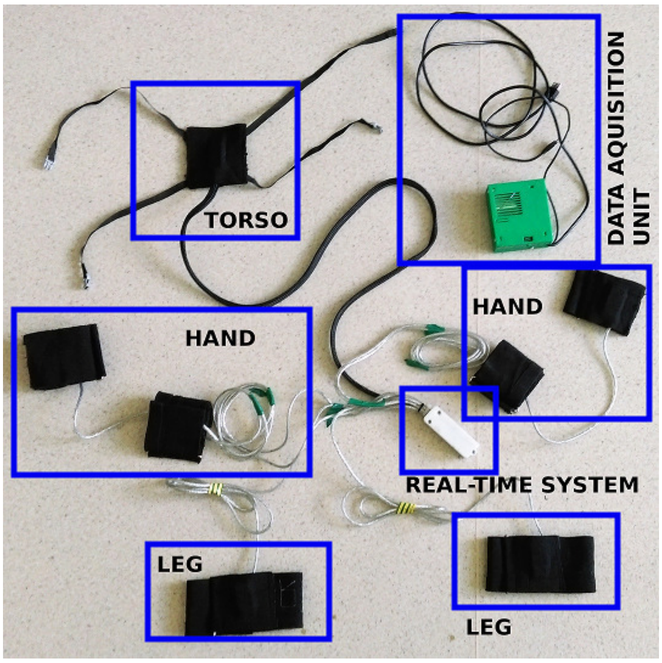

Fig. 1. Hardware setup that is able to gather motion data from different parts of the body. IMUs are kept in a custom 3D printed casing and mounted to the body using elastic bands.

Physiological data (ECG waveform, heart rate, breathing rate and skin temperature) was recorded by Equivital[1] on internal storage and redundantly sent via Bluetooth to DAU.

During recording session the raw data was stored on DAU using binary format. Single sample, consist of readings from all sensor which sums up to 680 bits ($16$ bit $\cdot\ 2{\cdot}7$ sensors $\cdot\ 3$ axis $+\ 8$ bit time stamp). In the real application, however, the minimum required bandwidth for the data transmission is higher because of network maintaining routines overhead, so final minimal bandwidth was more than $49.8\,kB/s$ for each subject. Reliable transmission of the raw data through radio for longer distances (1–2 km) while maintaining reasonable power consumption is very challenging or almost impossible task. LTE or Wi-Fi connections enables us to stream such amount of data, but while using these technologies problems with the power consumption arise (see [13], [7]). Although low frequency radios have low bandwidth, the power consumption is sufficient — this setup, however, imposes the need of processing the data locally and transmission partially preprocessed data.

Most intuitive and robust design is that the data is processed on DAU and only the classification result should are sent to remote server. On the other hand there is no implementation of more sophisticated classification system dedicated to work on embedded system (due to floating point precision and lack of processing power). Therefore, we have used Odroid-U3+ platform based on quad-core Cortex-A9. This platform has a two scaling frequencies options and possibility of choosing the

[1] http://www.equivital.co.uk/

number of cores being used. This setup gives us ability to scale power consumption depending on classification algorithm.

### B. Training session recording

Recording sessions took place from January till February 2015 at the Main School of Fire Service in Warsaw. Sixteen cadets were recorded during a training session of fire incident. There were two scenarios of the trial and each of them was repeated three times. However, we did not use breathing apparatus and real-life obstacles which changes significantly kinematics of a subject in real incidents.

Recording procedure was as follows: before session each sensor was calibrated on-place and checked for errors using gravitational force measurements in different sensor orientations. Two cadets participated in each session, whereas only one of them was wearing the sensors. Second cadet was later responsible for maintaining equipment on field. Those preparations lasted for 30 minutes. Each session was recorder using two cameras. Quality of the kinematic recordings was monitored with respect to throughput of the data using mobile device. At the beginning of each trial subject was asked to jump for three times to estimate precise time shift between video and kinematic data. Cadet performed two significantly different scenarios in three trials (each of them lasted 3–5 minutes), after that wearable sensor was transferred to the second cadet. At the end of the trial, the sensor on-body mounting was checked for displacement and the data was archived.

Recording of two cadets usually lasts for three hours and it requires commitment of three additional persons. After manual examination and verification of data quality we have chosen only eight out of fifteen sets of recordings. In the most of cases the reason for the elimination of a recording was either a sensor malfunction or a displacement of the sensor during the recorded training session.

### C. Tagging the data set

Tagging was prepared using video material on which acceleration from torso sensor was overlaid with precise time synchronization using marker (three jumps that was very easily observable in sensory data). Time series was divided into episodes of actions and there was always left a small gap between episodes in order not to introduce noisy transition phases (for example, deceleration from running to walking).

We decided to prepare two set of labels (tags), namely:

- **posture** which included: crawling, crouching, jumping, movement, standing, stooping,
- **activity** — few tags specifying short and specific actions. It included: carrying, carrying_hammer, carrying_nozzle, carrying_hose, hammer_striking, hose_throwing, ladder_down, ladder_up, manipulating, mounting_hose, nozzle_usage, running, searching, signal_hose_pullback, signal_water_first, signal_water_main, stairs_down_fast, stairs_up, stairs_up_fast, standing_up, starting, step, stopping, taking_equipment, taking_hammer, waiting, walking.

TABLE I. OCCURRENCES OF POSTURE TAG IN FINAL DATA SET.

| Posture | Number of occurrences | Total time [s] |
|---|---|---|
| crawling | 27 | 461.75 |
| crouching | 125 | 1109.0 |
| jumping | 96 | 242.75 |
| movement | 613 | 3083.0 |
| standing | 423 | 1524.25 |
| stooping | 267 | 645.0 |

TABLE II. MOS POPULAR TAGS IN SECOND GROUP.

| Activity | Number of occurrences | Total time [s] |
|---|---|---|
| ladder_down | 24 | 230.5 |
| ladder_up | 23 | 237.5 |
| manipulating | 482 | 1787.75 |
| no_action | 51 | 122.5 |
| nozzle_usage | 48 | 715.5 |
| running | 337 | 1800.25 |
| searching | 25 | 439.0 |
| signal_hose_pullback | 2 | 4.25 |
| signal_water_first | 33 | 63.0 |
| signal_water_main | 30 | 51.25 |
| signal_water_stop | 4 | 9.75 |
| stairs_down | 32 | 175.0 |
| stairs_up | 69 | 294.0 |
| starting | 49 | 119.5 |
| stopping | 47 | 123.25 |
| striking | 68 | 339.75 |
| taking_hammer | 47 | 68.75 |
| throwing_hose | 84 | 208.5 |
| walking | 94 | 273.25 |

However, not all of these tags were fully independent. For example, carrying always occurs after one of carrying_hammer, carrying_nozzle, carrying_hose. Therefore, not all combinations exist.

First tag in the activity labels specifies main action and other introduce detailed activities. The idea behind this was to show hierarchy of events.

### D. The acquired collection of data

The data set consist of 16 recording session (one for each cadet), while only 8 is most suitable for analysis. Each session is composed from kinematic data divided into six trials (three trials for two scenarios) accelerometer and gyroscope in three axes from seven mounting points described before (see Fig. 2 as example of such session). There are 3 065 664 records as a whole summing up to 4.25 h of data.

TABLE III. EIGHTEEN MOST POPULAR COMBINATION OF TAGS.

| Posture | Activities | Total time [s] |
|---|---|---|
| movement | running | 727.25 |
| movement | running carrying_hose carrying | 537.50 |
| crawling | searching | 439.00 |
| movement | running carrying_hammer carrying | 436.00 |
| crouching | nozzle_usage | 432.25 |
| crouching | manipulating | 389.00 |
| stooping | manipulating | 350.00 |
| standing | striking | 339.75 |
| crouching | manipulating mounting_hose | 261.75 |
| standing | nozzle_usage | 260.00 |
| standing | manipulating carrying_nozzle carrying | 252.50 |
| standing | manipulating | 248.50 |
| movement | ladder_up carrying_nozzle carrying | 237.50 |
| movement | ladder_down carrying_nozzle carrying | 197.75 |
| movement | stairs_down | 168.50 |
| stooping | throwing_hose | 158.75 |
| movement | stairs_up carrying_nozzle carrying | 137.25 |
| movement | stairs_up carrying_hammer carrying | 132.75 |

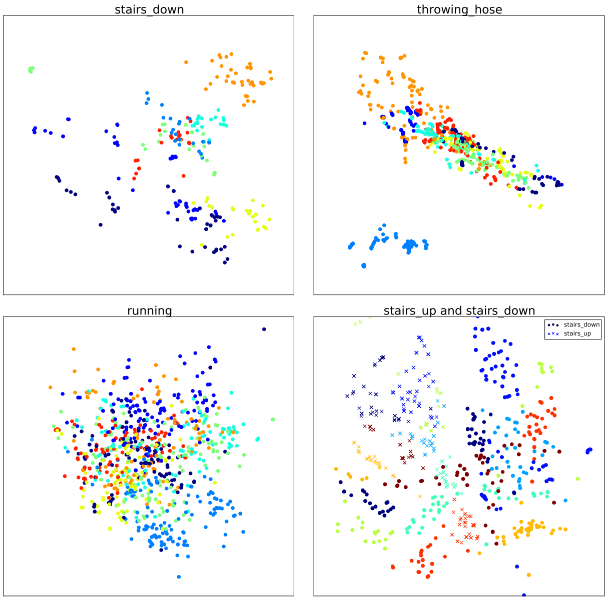

Fig. 3. MDS embedding for selected activities (colours denotes different test subjects). Notice that in the last figure dots denotes stairs_down tag, whereas crosses stairs_up.

Physiological data is composed from ECG waveforms from two leads filtered using proprietary algorithm. From this time series heart rate (estimated in the periods of 5 seconds) and R-R intervals are computed and enclosed into the data set. Additionally, breathing rate was estimated using elastic band and skin temperature are enclosed.

The main challenge for classification scenario in this particular data set is to generalize the same activities between different subjects. Certain physical activities can be performed in a very different way — this problem arises from number of reasons: starting from handedness, physical disposition, weight and height, etc. Those differences could be even so significant that they can be used for biometric authentication [8]. Moreover, sensor placement can be slightly different between session (although we put extra effort to ensure the same mounting places).

In Fig. 3 we depicted similarities of randomly selected $\sim 2\,s$ sequences of data. To be more precise, we see there multidimensional scaling on the set of features of the data, i.e. solution to the following minimization problem

$$\min_{x_1,\ldots,x_N\in\mathbb{R}^2} \sum_{1\leq i<j\leq N} \left(\|x_i - x_j\| - \|f_i - f_j\|\right)^2, \qquad (1)$$

where $f_i \in \mathbb{R}^K$ denotes feature vector of the $i$th window. The feature vector is composed using statistics commonly used in solutions described in section III-D.

The bottom-right plot of Fig. 3 illustrates that the certain activity can be more similar to different activity than the same activity of different subject. Of course this strictly depends on classification model but, all in all, this shows that physical activity classification needs to be performed with respect to subject identification. Another problem is illustrated on top-right plot of the same figure. In the dataset there was left-handed subject and certain activities (for example throwing_hose) was performed in very distinctive way.

## III. AAIA'15 Data Mining Competition

AAIA'15 Data Mining Competition took place between March 9, 2015 and June 5, 2015 at Knowledge Pit on-line platform. It was a continuation of the contest initiated during the previous edition of the data challenge associated with International Symposium on Advances in Artificial Intelligence and Applications (the AAIA conference series) [14]. This year's topic was related to real-time screening of firefighters' vital functions and monitoring of ongoing physical activities at the incident scene.

### A. *The task description*

The objective in this competition was to devise efficient methods for automatic labelling of short series of the sensory data with basic activities of a firefighter. On the one hand, this task was very challenging due to a fact that different people tend to perform the same activities in different ways. On the other hand, automatically generated and accurate activity labels would facilitate monitoring of firefighters' safety and contribute to development of efficient command supporting systems [13], [14].

For the purpose of the competition we provided the acquired data in a tabular format as two separate sets. The training data set contained 20,000 rows and 17,242 columns. Each row corresponded to a short time series (approximately $1.8\,s$ long) of sensory readings. Such a short time period was dictated by the applicability requirements and the available hardware setup (see Section II-A)

The first 42 columns represented aggregations of data from sensors monitoring firefighter's vital functions. The remaining columns were divided into 400 chunks that represented consecutive readings from the sets of kinetic sensors attached to firefighter's torso, hands, arms and legs (see the more detailed description in Section II). Therefore, a single chunk of columns consisted of 43 numeric values, from which the first one was time from the beginning of the series and the following 42 values represented the readings from the accelerometers (measured in $m/s^2$) and gyroscopes (measured in $deg/s$).

An average time difference between consecutive sensory readings in the data was $4.5\,ms$. Labels for the training data were provided in a separate file. Each row in this file contained two labels for a corresponding row in the training data. The first label described a posture of a firefighter and the second described his current activity. In the original dataset the activity was described by 1 to 4 tags. For the competition we have provided only the main activity. Test data file was in the same format as the training data set, however, the labels for the test series were hidden from participants.

It is important to note that the training and test data sets consisted of recordings which were obtained from different groups of firefighters. Each of the sets contained the data acquired from only four persons and the scenario of the training exercises which they conducted was slightly different. There were no firefighter identifiers available in the data. By hiding this information from participants we wanted to promote

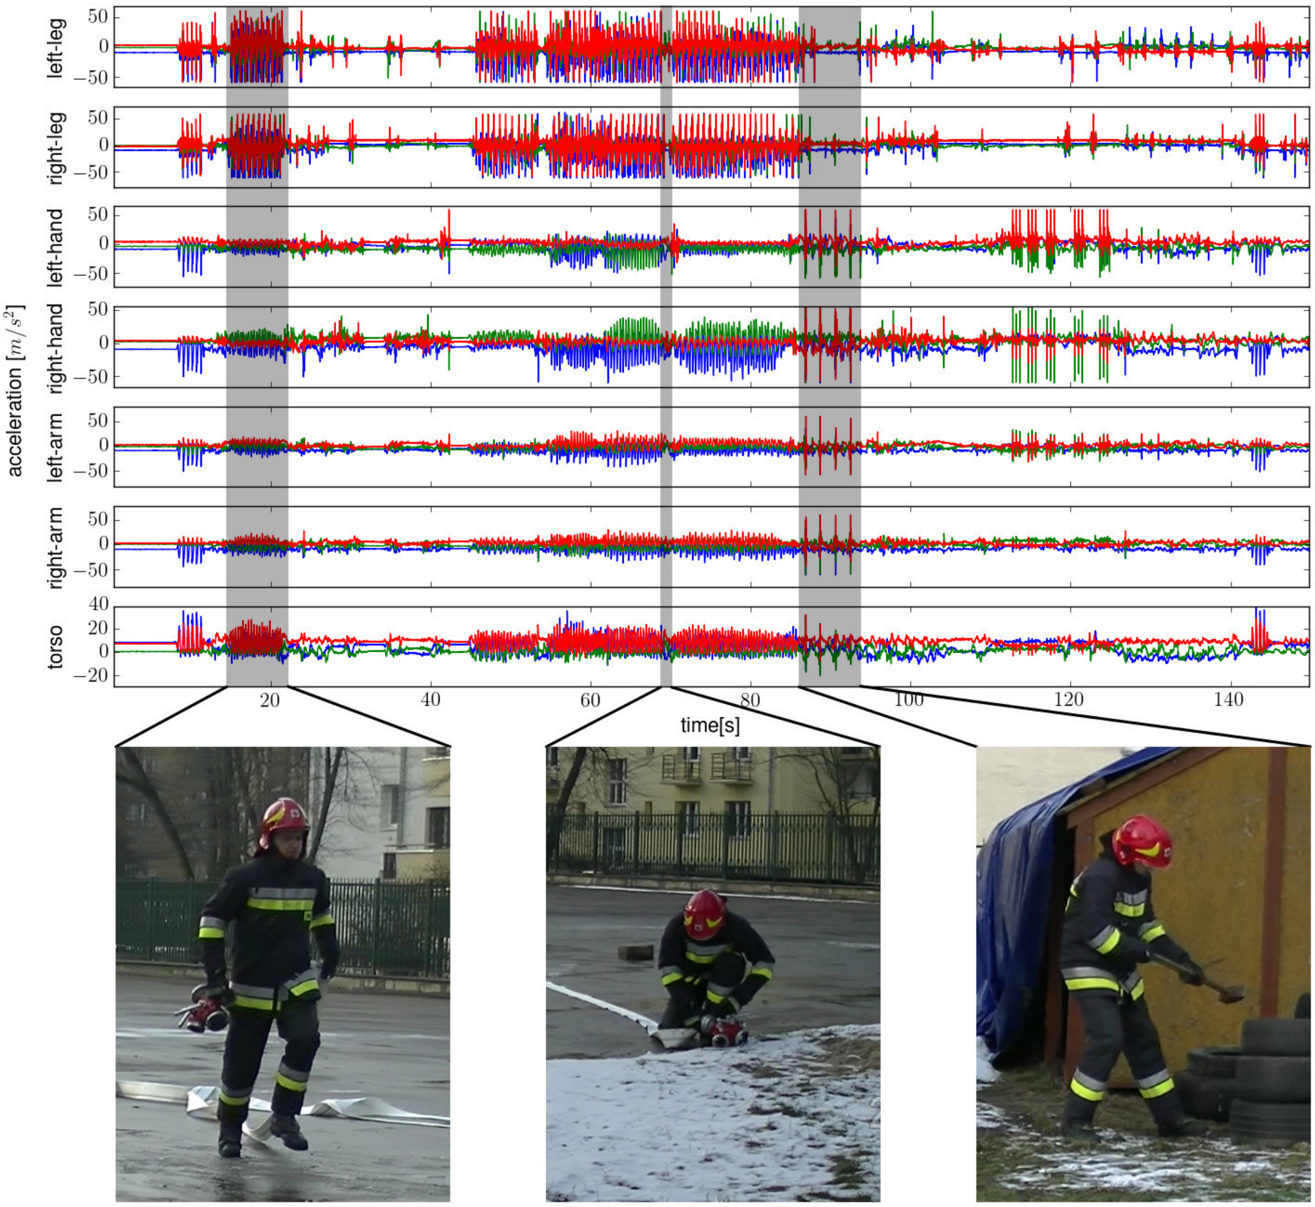

Fig. 2. Accelerations from BSN. Three actions were selected and marked.

solutions which are insensitive to individual characteristics of particular firefighters and are able to cope with disturbances of the data. Those prerequisites were the main reason for the unbalanced distribution of decision labels and had a huge impact on the shape of the most successful solutions.

### B. Evaluation procedure

The quality criterion in the competition was devised so that it reflected the specific requirements for the task. Since this task involved labelling sequences with tags that could take many different values with unbalanced representation in the data, the quality of submitted solutions was assessed using the balanced accuracy measure. This particular criterion had been already used in several others data mining competitions, e.g. [18]. It is insensitive to skewed distribution of decisions and thus promotes classifiers which are able to robustly identify labels of cases from minority classes.

The balanced accuracy (BAC) is typically defined as an average accuracy within all decision classes. In particular, if we denote a vector with predictions returned by a classifier by $preds$ and a vector of true decision labels by $labels$, we may define BAC as:

$$ACC_i(preds, labels) = \frac{|\{j : preds_j = labels_j = i\}|}{|\{j : labels_j = i\}|}, \quad (2)$$

$$BAC(preds, labels) = \frac{1}{l}\sum_{i=1}^{l} ACC_i(preds, labels), \quad (3)$$

where $l$ is the total number of possible labels. In our compe-

TABLE IV. THE FINAL AND PRELIMINARY RESULTS OF THE TOP-RANKED TEAMS.

| Rank | Team name | Preliminary | Final score |
|---|---|---|---|
| 1 | jan | 0.85768 | 0.83912 |
| 2 | zagorecki | 0.85184 | 0.82985 |
| 3 | nitekna | 0.85015 | 0.8261 |
| 4 | mathurin | 0.82523 | 0.80408 |
| 5 | lp319499 | 0.80318 | 0.79137 |
| ... | ... | ... | ... |
| 38 | baseline | 0.61414 | 0.60361 |

tition, a value of BAC measure was separately computed for the two decision attributes (the posture and activity). Due to the fact that the decision attributes considerably differed in the number of possible values, we decided to assign them different weights which would compensate for the increased difficulty of predicting the activity label. As a result, the BAC values for the posture and activity attributes had a different impact on the evaluation score. If we denote the BAC value for the posture as $BACp$ and the value for the activity as $BACa$, we can determine the evaluation score of a solution $s$ as:

$$score(s) = \frac{BACp(s) + 2 \cdot BACa(s)}{3}. \tag{4}$$

The evaluation procedure in the competition was two-fold. During the course of the contest an on-line evaluation system was providing a constant feedback for the participants in a form of a publicly available leaderboard — a dynamic ranking of participant's best results. However, the scores displayed on the leaderboard were only a preliminary assessment of the solution's quality. They were computed using only $10\,\%$ of available test data. After completion of the competition there were the second evaluation round. It was available only for those teams which had provided a description of their solution in a form of a short competition report. The final evaluation was carried out independently from the preliminary one, using the remaining part of the test data.

### C. Summary of the competition results

AAIA'15 Data Mining Competition attracted skilled data mining practitioners from around the world. Comparing to the previous year's edition of the challenge there were noticeably more registered teams (152 in total, an increase by 36 teams), from which 79 actively participated in the challenge by submitting at least one solution (an increase by 22 teams). We received 1,840 correctly formatted solutions (an increase by $42\,\%$) and the top-ranked participants have beaten the baseline solution by nearly 24 percentage points. Additionally, 50 teams provided a brief report describing their approach. Table IV shows scores obtained by the top-ranked teams.

The solutions submitted by participants proved to be a valuable source knowledge. They not only provided an insightful view on the state-of-the-art in multidimensional time series analysis but also contained inspiring new ideas, design specifically for the considered problem. The most interesting of these ideas are described by their authors in separate papers submitted for the competition track of AAIA'15 conference [2], [11], [15], [17], [19], [20].

### D. Summary of the most successful submissions

The top-ranked participants of AAIA'15 Data Mining Competition managed to test effectiveness of a wide range of approaches to classification of high dimensional sensory data. However, nearly all of the successful solutions had a common denominator. They all utilized some sort of attribute engineering or feature extraction methods [12] in order to represent the time series data by a new set of attributes. In all cases, the main purpose of this data transformation was to define an attribute space which on the one hand was insensitive to differences in movement patterns between different firefighters and on the other hand, was characterized by a much lower dimensionality in comparison to the tabular representation of the competition data.

Among the new features used in the top solutions a large share corresponded to summary statistics, commonly used to describe sample distributions. These characteristics include typical location statistics (i.e. mean, centiles, time window minimum and maximum), shape statistics (i.e. skewness, kurtosis) and dispersion statistics (i.e. standard deviation, energy, range and difference between centiles). Several solutions also made use of characteristics measuring the dynamics of data, such as the mean, minimum and maximum difference between values of consecutive sensor readings. Finally, the two best solutions in the competition were using features derived from the Fast Fourier Transform of the data.

Having defined a suitable representation of data, the participants were employing standard machine learning algorithms to perform the classification. Among the most popular classifiers were the Random Forest [4] and Support Vector Machines [1]. The best results were obtained by teams which carefully tuned parameters of their learning algorithm. Interestingly, the top-ranked participants were using different approaches to tackle the problem of two decision attributes in the data. Some of the teams constructed two independent classifiers, whereas the others merged the two class labels into a single one and trained a single model for a multi-class prediction problem. However, the best performing classification model was firstly trained to predict the first label (the posture) and then, the obtained prediction was used as a new feature for prediction of the second label [15].

## IV. CONCLUSION

Physical activity classification based on inertial data from body sensor networks is a very challenging task. The main difficulty that needs to be addressed when solving this problem is the fact, that same activity can be performed in very different ways by different subjects. Moreover, due to severe hardware limitations, any classification scenario in a real-life application needs to find a trade-off between a classification accuracy and power efficiency. So far very little work has been done to address this issue and devise new methods that would be suitable for mobile, long-running platforms.

In this paper we described a data set that can be used in future studies on this important subject. We also summarized a data mining competition which we had organized in order to draw attention of data mining community and stimulate research in this type of application areas. In particular, solutions submitted by participants of the competition constitute a valuable insight regarding the state-of-the-art in the on-line activity recognition field.

***Abstract*—Multi-sensor based classification of professionals' activities plays a key role in ensuring the success of an his/her goals. In this paper we present the winning solution to the *AAIA'15 Tagging Firefighter Activities at a Fire Scene* data mining competition. The approach is based on a Random Forest classifier trained on an input data set with almost 5000 features describing the underlying time series of sensory data.**

## I. Introduction

HUMAN activity recognition based on sensor inputs, cf., e.g., [1], [7], [14], is essential in many practical applications. In particular, a fire scene constitutes a dynamic environment in which valid, precise, and fast human decisions play a key role. Here, the aim is to achieve success in an emergency rescue mission, having in mind safety of the involved firemen [4] and his/her ability to save other peoples' lives and – in the second place – property, wealth, etc. It is worth noting that an automated decision support system may be used to increase the widely-conceived quality of an agents' behavior. One of its most fundamental components relies on a proper detection of an action a fireman is actually performing at a given moment. The topic of *AAIA 2015 Data Mining Competition: Tagging firefighters' activities at a fire scene* [8] aimed to deliver accurate model for recognising firefighters movements and activities based on multi-sensor data. In consecutive sections we explain the winning approach in very detail. The proposed solution was implemented in the `R` environment for statistical computing [11]. The solution is available on–line as a Git repository at https://github.com/janekl/AAIA15_Data_Mining_Contest.

The paper is organized as follows. In the section to follow, we describe the analyzed data set and define the evaluation metric used. In Section III we discuss main challenges that the data set brought. In Section IV we present the winning solution in detail and indicate its advantages, limitations, and possible extensions for future work. Finally, Section V concludes the paper.

## II. Problem Statement

The main purpose here is to design a model for a classification problem with two class attributes. The first class denotes the main activity of a firefighter. This class is referred to as *posture* class and it has 5 distinct labels (`crawling`, `crouching`, `moving`, `standing` and `stooping`). The second class, called *action* class denotes a particular activity of a firefighter and consists of 16 labels (4 labels associated with movement along ladder or stairs: `ladder_down`, `ladder_up`, `stairs_down`, `stairs_up`, 2 labels regarding forward movement: `walking` and `running`, labels describing firefighters' operational movements: `manipulating`, `nozzle_usage`, `signal_hose_pullback`, `signal_water_first`, `signal_water_main`, `signal_water_stop`, `striking` and `throwing_hose` and a `no_action` label).

The evaluation metric employed in the competition is the weighted average of *balanced accuracy* for the two classes. Below we recall the definition of this measure. For each label $l_i$ within a class attribute we define *classification accuracy* as

$$\mathrm{acc}(l_i) = \frac{|\{j : l(x_j) = l_i \wedge p(x_j) = l_i\}|}{|\{j : l(x_j) = l_i\}|},$$

where $l(x_j) = l_i$ denotes the true label for instance $x_j$ and $p(x_j)$ denotes the label assigned by a classifier. If a class attribute $C$ assumes $L$ possible labels, then the balanced accuracy score for that class is defined as

$$\mathrm{BAC}(C) = \frac{1}{L}\sum_{i=1}^{L}\mathrm{acc}(l_i).$$

Now, we may consider the weighted average of balanced accuracy scores for *posture* and *action* classes, which is given by

$$\mathrm{EvaluationMetric} = \frac{1}{3}\mathrm{BAC}(\mathtt{posture}) + \frac{2}{3}\mathrm{BAC}(\mathtt{action}).$$

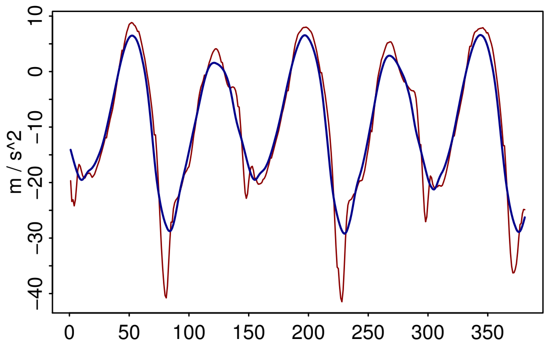

Fig. 1. Plot of the raw series (red) along $x$-axis of the accelerometer recordings at right hand for pair of labels (moving, running) and the smoothed series with 20-moving average filter (blue).

During the competition, the solutions were evaluated against approximately 10% of test data. An evaluation metric is the essence of a contest for both its organizers and participants. Through design of an evaluation metric, the organizers define their goal that they want to achieve. On the other hand, the participants need to tailor their models to optimize a given evaluation metric.

To train a statistical model, a training set consisting of 20.000 instances, each tagged with a pair of labels for *posture* and *action* class, was used. Each instance consists of basic statistics on the vital functions of a firefighter and a set of 42 time series which came from x/y/z–axis recordings from gyroscopes and accelerometers attached at 7 points on the body of a firefighter (left hand, right hand, left arm, right arm, left leg, right leg, torso). Each time series consists of 400 recordings (every 4-5 ms) over ca. 2 seconds. Test set consists of 20.000 instances as well. The goal was to develop a model for tagging instances in the test set with a pair of labels for the two class attributes. Both the training and test data set are of size approximately 2.4 GB (uncompressed *csv* files).

## III. Main challenges

### A. The same action, different results

Among one of the many challenges we find that the data set was inherently noisy. Moreover, the samples of activities in the training and test sets were due to activities of different firefighters. We observed that this had a significant impact on the classifier's score: our scores in terms of the evaluation metric were as high as 98% on a hold-out validation set. This is a considerably high score bearing in mind that the given classification problem is presumably not an easy task. However, in related studies as high accuracy scores were reported [10], [5]. The scores on the official leader-board were significantly lower – with the best scores being equal to ca. 85% during preliminary evaluation. The fact that an instance may come from different source is a great challenge in any application domain.

### B. Imbalance of labels distribution

Another problem which required proper handling was related to the imbalance of labels proportion within each class attribute. Table I presents the pair of labels within *action* and *posture* for the test set.

Since the evaluation metric in the competition was the discussed balanced accuracy score, no label was distinguished and misclassification rate has equal weight for every label within each class. This metric treats each label within a class as being equally important (equal weights), regardless of its *a priori* distribution in the data. This distribution of labels varied significantly on the training set. For example, only about 0.5% of all instances constitute for the `signal_hose_pullback` label while about 32% for the `manipulating` label within the *action* class. This means that we are given over 60 times more instances having the former label. Such an uneven distribution of labels requires proper handling by a model. To overcome the problem of imbalanced label distribution, we trained individual classifiers in an ensemble (to be precise, using the below-discussed Random Forest method) based on a stratified subsamples of training set in which each label was represented in an equal amount. The proper balancing of the training set enabled to tailor a model for the evaluation metric employed in the competition.

## IV. The winning solution

Let us describe the implemented approach towards feature extraction and model building for activity tagging problem. The model used was based on the Random Forest classifier which is an ensemble of decision trees. It is observed that in practical situations it often yields high accuracy scores [2], [6]. Another advantage of the Random Forest classifier is that it is a fast method: its training and prediction phase can be parallelized. Is is also relatively easy to handle (i.e., its parameter setup) as compared to other advanced ensemble methods. Both the described below feature extraction and the final model training procedures (included in the GitHub repository) can be performed on a single machine within a couple of hours. In our computations we used a 4–core 2.0 GHz CPU 16 GB RAM machine. The described parameter optimization steps were performed on a cluster of 10 8–core 3.40 GHz CPU 16 GB RAM machines to speed up the computations.

### A. Feature extraction

Our approach was particularly focused on the phase dealing with features' extraction. The extracted features were based on literature [5], [9], [10] as well as the authors' experimental ideas. The processed training/test dataset is of size about 1.4 GB. For each activity we derived over 4700 features describing a particular activity. First of all, we filtered the data with a moving average window of size 20, see Figure 1. Since the sensor recordings were gathered at a 4.5 ms. resolution, this roughly corresponds to averaging the arriving over a window of 0.1 second. This step was not crucial for the model performance, however, it allowed to filter out the noise slightly.

TABLE I
COUNTS FOR PAIRS OF LABELS FOR THE TWO CLASSES – TRAINING SET.

| | crawling | crouching | moving | standing | stooping |
|---|---|---|---|---|---|
| ladder_down | 0 | 0 | 465 | 0 | 0 |
| ladder_up | 0 | 0 | 476 | 0 | 0 |
| manipulating | 0 | 1764 | 331 | 2356 | 1898 |
| no_action | 0 | 87 | 0 | 491 | 0 |
| nozzle_usage | 0 | 492 | 0 | 443 | 0 |
| running | 0 | 0 | 4324 | 0 | 0 |
| searching | 459 | 0 | 0 | 0 | 0 |
| signal_hose_pullback | 0 | 0 | 0 | 98 | 0 |
| signal_water_first | 0 | 0 | 41 | 496 | 0 |
| signal_water_main | 0 | 46 | 0 | 405 | 0 |
| signal_water_stop | 0 | 0 | 0 | 277 | 0 |
| stairs_down | 0 | 0 | 644 | 0 | 0 |
| stairs_up | 0 | 0 | 1157 | 0 | 0 |
| striking | 0 | 0 | 0 | 1022 | 0 |
| throwing_hose | 0 | 0 | 0 | 234 | 930 |
| walking | 0 | 0 | 1064 | 0 | 0 |

Next, for each of the time series, we derived basic summary statistics: quantiles (denoted with qx in Tables III and IV for x $\in \{0.01, 0.05, 0.1, 0.2, \ldots, 0.9, 0.95, 0.99\}$), standard deviation (sd), skewness, kurtosis, amplitude (defined as the difference between 0.99-quantile and 0.01-quantile of the series), the signal energy (ener; defined as the sum of squares of consecutive recordings), the ratio between its maximal absolute value and the median and minimal and maximal of the first differences of a series (deriv1min and deriv1max). We extracted a set of quantiles and standard deviations on the time series processed by the Fast Fourier Transform, to its real, imaginary and modulus (ModFFT) parts independently. Additionally, we recorded first 5 Fourier coefficients of the real and imaginary part of the transformed series. We also extracted quantiles and standard deviation of the periodogram (Period) of each time series. Further, for each pair of time series we computed the linear correlation coefficients (cor).

We also extracted several experimental features for counting the number of peaks in the series based on their sub-chunks in which they exceeded the mean by one or two standard deviations. We imposed a constraint that the minimal length of a sub-chunk is 5 (for the filtered series). Finally, we counted the number of times a given series crosses 0 and its mean.

Another property of Random Forest model is that it has an inherent method of evaluation of feature relevance. Tables III and IV present the 50 most important features for two individual classification tasks for the two class attributes. The criterion of our choice according to which features are evaluated is the mean decrease in Gini Impurity Index for classification (column M.D.Gini). As far as the vital functions are concerned, median respiratory rate reading med.rr is present in the top 50 list for *action* classification problem.

Let us note that the number of features derived is large and some of them do not posses a clear interpretation. However, due to Random Forest model described in the next section – which includes an inherent method of selecting relevant attributes – we were able to handle and select relevant content from this rich set of features.

### B. Classification model

For the purpose of tagging the activities we used the balanced Random Forest [2]. By the balanced Random Forest classifier we mean an ensemble of trees that are trained on subsamples of training set in which every label within a given class is represented in an equal amount. This model was used in a stepwise approach. In the first step, we trained the model which aimed to recognize the *posture* of a firefighter. In the second one, we trained the model to recognise the main *action* of a fireman, given *posture* class attribute. This approach is analogous to the classifier chaining method in multilabel classification tasks [12]. In the tagging phase for new data we plug the predicted *posture* labels by the first model as an input for the model for the *action* class. The combined predictions complete the tagging phase for test set.

The idea behind such a chaining method was driven by the fact that some combinations of activities and posture labels are mutually exclusive. For example, the posture cannot be equal to standing when the main activity is equal to ladder_up. When individual classifiers were trained, such inconsistencies were very common. We managed to reduce them by employing the mentioned stepwise approach. However, we did not succeed in eliminating them at all: our final submission still contained some fraction of prediction labels that were mutually exclusive. By mutually exclusive pairs of labels we mean such a combination of pairs of labels that were not observed in the training set (see Table II; these pairs are given in bold). Another way of reducing conflicts was to aggregate different submissions by, e.g., majority voting. We observed that aggregating individual submissions often produced a new submission with a higher preliminary evaluation score than each of the individual ones. This serves as a method for providing more stable and accurate predictions since, e.g., they are based on a larger number of trees.

We also experimented with one-vs-all and single class (i.e., a single class was obtained by mapping each pair of labels within (*posture*, *action*) classes to an individual class) versions of the model. However, the best results were achieved by

TABLE II
COUNTS FOR PAIRS OF PREDICTED LABELS FOR THE TWO CLASSES – TEST SET.

| | `crawling` | `crouching` | `moving` | `standing` | `stooping` |
|---:|---:|---:|---:|---:|---:|
| `ladder_down` | 0 | **1** | 459 | **209** | 0 |
| `ladder_up` | 0 | **2** | 452 | **118** | 0 |
| `manipulating` | 0 | 1576 | 12 | 1639 | 2438 |
| `no_action` | 0 | 71 | 0 | 467 | **31** |
| `nozzle_usage` | 0 | 454 | 0 | 1060 | 0 |
| `running` | 0 | **13** | 3974 | 0 | **2** |
| `searching` | 513 | **42** | 0 | 0 | 0 |
| `signal_hose_pullback` | 0 | 0 | 0 | 96 | 0 |
| `signal_water_first` | 0 | **3** | 10 | 580 | 0 |
| `signal_water_main` | 0 | 55 | 0 | 174 | 0 |
| `stairs_down` | 0 | 0 | 533 | 0 | 0 |
| `stairs_up` | 0 | 0 | 1442 | 0 | 0 |
| `striking` | 0 | **13** | **7** | 1026 | **49** |
| `throwing_hose` | 0 | 0 | 0 | 196 | 982 |
| `walking` | 0 | **2** | 1251 | **46** | **2** |

the described chaining method.

### C. Parameter tuning

Due to the discussed issue of performing activities by different people, the model's parameter tuning process poses a real challenge. We were primarily interested in the parameters responsible for balancing the classifier (parameter `sampsize` in `R`'s `randomForest` package), the minimal number of instances in the leafs (parameter `nodesize`) and the number of sampled features to perform a test split (parameter `mtry`). In our methodology we experimentally set parameters by monitoring out–of–bag error accuracy estimates for each of the classes. Additionally, we run 3–fold cross validation for different pairs of parameters (`mtry`, `nodesize`). Our conclusions was that the parameter `nodesize` should be set to 1, i.e., the trees should be grown to maximal depth. Moreover, given `nodesize = 1`, setting parameter `mtry` to a couple of hundreds already provided stable and high accuracy scores. Finally, to balance training sets, in our initial trials we sampled more instances of most represented labels, i.e., `moving` within *posture* class and `manipulating` and `running` within *action* class as indicated by lower out–of–bag error estimates for those labels. However, significantly better preliminary scores were obtained just by sampling each of the labels in an equal amount. Although choosing parameter values based on leader–board score is quite a dangerous way of tuning them, we took this risk for those parameters as the test set instances differ significantly from the training set ones. In any case, sampling each of the labels equally appears to be a reasonable setup. The described sampling procedure was a crucial step of achieving high evaluation scores. Another advantage of this methodology is that the models are training using fewer instances from the training set. This may in turn prove useful to a reduce overfitting of the model to the training data. The number of trees in the forest was set to 700, i.e., a relatively large number accounting for the computation time of the model.

### D. Final submission

During the competition, we submitted over 100 proposals, which were based on different ideas and changes in model parameters and enrichment of the training data with new features. Most of them relied on experiments with different setup of Random Forest model, but we also tried the Gradient Boosting Machine (GBM) model (tree-based) [3], [13]. However, the performance of a less complex Random Forest model was satisfactory and we devoted more time for optimising this model. Moreover, we primarily focused on the feature extraction step.

The best performing model consists of 700 trees, it has the number of attributes for performing test split equal to 300, stratified over class attribute with sample size of 400 for each *posture* and 90 for *action* label. The final submission was derived by majority voting of three classifiers (in fact, two–stage classifiers) with weights 1.5 (to avoid ties), 1, 1 respectively:

1) Random forest model with the minimum size a leaf in a single tree equal to 1 (attribute `nodesize = 1`)
2) Random forest model with `nodesize = 3` and
3) Random forest model with `nodesize = 1` trained on the dataset with exclusion of features associated with left arm of sensory data and a subset of quantiles $(0.01, 0.05, 0.2, 0.4, 0.6, 0.8, 0.95, 0.99)$.

The preliminary evaluation scores were 0.858, 0.8573, and 0.8567 for consecutive models. The averaging step was aimed to reduce the variance of a single model as well as to resolve the mentioned conflicts due to contradictory labels. We used this method as we concluded by our previous experimentation with averaging that it yields higher evaluation scores. However, in case of our final submission, it yielded a not significantly lower preliminary evaluation score than the best one used for aggregating. In any case, we believed that it would produce more stable and accurate predictions on the whole test set. The third model was trained on a subset of attributes since we observed that some recordings in the test set have constant values of these which we interpret as missing values. We also excluded a part of quantiles with the aim to reduce overfitting of the model to the training sample (however, this appeared not to be of help in this case). The final submission yielded score of $0.8577$ during preliminary evaluation and $0.8391$ on the whole test set – it was ranked the first among 79 submitted proposals.

### *E. Unsolved puzzles a.k.a. future work*

By the end of the challenge, we were still left with some unsolved problems that became evident after the solutions were submitted.

First of all, our final submission still contained some mutually exclusive pairs of labels e.g. `ladder_down` and `standing` or `walking` and `standing`. This problem was limited to some extent by the two–stage classification as well as submissions averaging.

The other problem with our submissions was that our model never predicted the activity `signal_water_stop`. Perhaps feeding the classifier with more instances with this particular label could resolve this issue. This could also possibly apply to `signal_hose_pullback` label within *action* class as there where merely 98 instances tagged with this activity. Finally, as we already mentioned, our preliminary evaluation scores based on out–of–bag predictions from the Random Forest model were overly optimistic: the scores on training data were about $98\%$ of the evaluation metric while the evaluation of our solution on the whole training data yielded much lower score of about $84\%$. This issue could be addressed by, e.g., performing evaluation and optimisation of a model via cross-validation, where the validation folds would contain activities performed by different firefighters. However, this could not be performed as the information on, e.g., firefighters identifiers performing a given action was not made available to the participants. Another possibility would be to derive more robust features with better generalisation properties for different people performing the same activities.

## V. Conclusions

The *AAIA'15 Data Mining Competition: Tagging Firefighter Activities at a Fire Scene* contest was a very interesting and absorbing event. Taking part in such competitions requires some persistence as only few tested ideas prove to give an improvement for the classification score. It is enough to mention that our winning solution was submitted within 24 hours of the competition's deadline.

In our approach, we employed Random Forest classifier and spend much more time on pre-processing data and engineering new features. We believe that the key to success were good data. Using a more sophisticated model may constitute for improvement in classification, however, as in this competition raw time series data needed to be processed, we regarded feature engineering as a more important step. Moreover, proper balancing of training sample provided major gains in the evaluation metric employed in this competition.

The code for our submission is available at GitHub. Further enhancements of the proposed solution are possible. We hope that it will serve as a benchmark for even better performing models for the task of tagging activities at a fire scene.

***Abstract*—Collecting data at regular time nowadays is ubiquitous. The most widely used type of data that is being collected and analyzed is financial data and sensor readings. Various businesses have realized that financial time series analysis is a powerful analytical tool that can lead to competitive advantages. Likewise, sensor networks generate time series and if they are properly analyzed can give a better understanding of the processes that are being monitored. In this paper we propose a novel generic histogram-based method for feature engineering of time series data. The preprocessing phase consists of several steps: deseansonalyzing the time series data, modeling the speed of change with first derivatives, and finally calculating histograms. By doing all of those steps the goal is three-fold: achieve invariance to different factors, good modeling of the data and preform significant feature reduction. This method was applied to the AAIA Data Mining Competition 2015, which was concerned with recognition of activities carried out by firefighters by analyzing body sensor network readings. By doing that we were able to score the third place with predictive accuracy of about 83%, which was about 1% worse than the winning solution.**

***Keywords*—feature engineering, feature reduction, time series classification, temporal data mining***

## I. Introduction

THE introduction of lightweight and low-cost sensors has increased the potential for real time measurements of different activities. The advancements in microelectronics, wireless communications and other scientific areas has introduced the possibility of placing tiny sensor nodes on specific places of the body in order to monitor the health of patients or human body activities in general [1]. These sensors generate large amounts of data that need to be processed often in real-time. Most of the data, like temperature, accelerometer readings, GPS locations, etc can be presented as a time series data and processed as such. Time series data analysis allows detection of patterns in the data and making assumptions about the current activities or even predict future activities based on the past data. The operations that can be performed based on the time series data are mainly directed towards pattern discovery, clustering, classification and rule discovery [2]. Due to the density of the available data that can be collected by the sensors and the nature of the time series data, there are three main tasks that need to be defined so that the previously mentioned operations can be performed [3]: Dimensionality reduction and Data representation, Distance measurement and Indexing.

Dimensionality reduction and Data representation is one of the most important tasks that need to be performed when analyzing the time series data. This process is taken for granted when we use our sensory organs to obtain the data and then our brain processes it so we can make conclusions. The time series data is usually noisy and too large to be processed by a computer in an acceptable time frame. The human brain processes have learned to ignore the noisy data when generating conclusions. This is why a good representation and dimensionality reduction is crucial before we can continue with the decision making based on the given or obtained data when using a machine learning method. The representation must consider the assumption that time series data is not always aligned properly [4], that it is noisy and that it should comply to the constraints of time and space for its processing. By choosing the right data representation we are able to engineer good features for any given dataset.

The distance measurement is one of the main things that need to be defined in order to make a successful distinction between different time series and be able to correctly classify or identify similar patterns in the data. There are several well known distance measurements that can be used to identify difference between time series. The distance measurement must be invariant to many transformations of the time series data such as amplitude or time shifting, uniform amplification, additive noise, time scaling, etc [3]. For this reason many types of distance measurements have been proposed in the literature and each have their advantages and drawbacks. They can be divided in several groups. There are distance measurements based on the time series shape that use the direct signal properties to give the distance between two series. Then, there are measurements based on the operations needed to make the signals similar with each-other. Also there are measurements based on features extracted from the signal and finally there are measurements based on finding some higher level structure so the series can be compared.

The Indexing problem is related to improving the retrieval speed for a given series when searching trough a database of time series data.

In this paper we propose a histogram-based method for feature engineering for time series data. We use Support Vector Machine to generate the classification model for the data and present the obtained results.

978-83-60810-66-8/$25.00©2015, IEEE

The paper is organized as follows. In section II we describe the problem that is addressed by this paper. Then, in section III we give overview of the process used to generate the features and the needed transformations of the data. Next, in section IV we address the machine learning method for generating classification models based on the obtained features. Thereupon, in section V we present the obtained results after applying the proposed methods on the competition dataset. Finally, in section VI we discuss the findings of this research and make some conclusions about the applicability of the proposed methods for feature engineering of time series in general.

## II. Problem description

The topic of the AAIA'15 Data Mining Competition [5] was Tagging Firefighter Activities at a Fire Scene. In particular, the task is related to the problem of recognizing activities carried out by firefighters based on streams of information from body sensor networks. A fire ground is considered to be one of the most challenging decision taking environment. In dynamically changing situations, such as those occurring at a fire scene, all decisions need to be taken in a very short time [6]. Several initiatives and research projects analyze various aspect of this complex problem [6, 7, 8]. The lack of situational awareness is listed there as the main factor associated with major accidents among firefighters. The research presented in these papers aims to increase the firefighter safety by monitoring their kinematics and psychophysical condition during the course of fire and rescue actions. The following paragraph is extracted from the competition website [5] and describes the task in more detail.

During the course of the ICRA project [9], a so called "smart jacket" have been developed. This device is a wearable set of body sensors that allows to automatically track a firefighter at a fire scene. It also enables real-time screening of firefighter's vital functions and monitoring of ongoing activities at the scene. The later of those two tasks is the main scope of this AAIA'15 Data Mining Competition. The goal was participants to come up with efficient algorithms for labeling activities conducted by firefighters during their training exercises, based on provided data sets from a body sensor network. The data were obtained during training exercises conducted by a group of eight firefighters from The Main School of Fire Service. The sensors were registering firefighter's vital functions (i.e. ECG, heart rate, respiration rate, skin temperature) and movement (i.e. seven sets of accelerometers and gyroscopes placed on torso, hands, arms and legs). Each exercise session was also captured on video and the recordings were synchronized with time series representing the sensor readings. All this data were presented to experts who manually labeled it with activities. The objective in this competition is to devise efficient methods for automatic labeling of short series of the sensory data with basic activities of a firefighter. On the one hand, this task is very challenging due to a fact that different people tend to perform the same activities in different ways. On the other hand, however, automatically generated and accurate activity labels would facilitate monitoring of firefighter's safety and contribute to development of efficient command support systems.

The submitted solutions were evaluated on-line and the preliminary results were published on the competition leaderboard. The preliminary score was computed on a random subset of the test set, fixed for all participants. It corresponded to approximately 10% (about 2000 instances) of the test data. The final evaluation was performed after completion of the competition using the remaining part of the test data (about 18000 instances). Those results was also published on-line. The assessment of solutions was done using the balanced accuracy measure which is defined as an average accuracy within all decision classes. It was computed separately for the labels describing the posture and main activities of firefighters. The final score in the competition was a weighted average of balanced accuracies computed for those two sets of labels. Namely, for a vector of predictions *preds* and a vector of true labels *labels*, the balanced accuracy is defined with eq. (1) and (2). Here $BAC_p$ is the balanced accuracy for labels describing the posture, and $BAC_a$ is the balanced accuracy for labels describing the main activity.

$$ACC_i(preds, labels) = \frac{|j : preds_j = labels_j = i|}{|j : labels_j = i|} \tag{1}$$

$$BAC(preds, labels) = \left( \sum_{i=1}^{l} ACC_i(preds, labels) \right) / l \tag{2}$$

The final score in the competition for a solution $s$ was be computed with eq. (3):

$$score(s) = \frac{BAC_p(s) + 2 \times BAC_a(s)}{3} \tag{3}$$

The instances of the available training and test datasets are comprised mostly of sensor readings as time series and 42 values representing some aggregations of data from sensors monitoring firefighter's vital functions. There are totally 7 sensor locations and 2 sensor types, and each sensor is providing readings for the 3 axes, so the total number of time series is $7 \times 2 \times 3 = 42$. Each of those 42 time series has 400 samples, and one additional series of the timestamps of the readings relative to the start of the series. Each instance is labeled with two labels: one representing the posture of the body, and one representing the main activity of the firefighter. After analyzing the datasets, it is evident that there are 4 classes of the first label and 16 classes of the second label, while there are totally 24 different class combinations of the first and second label. Table I displays the classes for each of the two labels and their distribution in the training set.

Obviously the first challenge in this task is the feature engineering of the time series, so that they can be powerful predictors in relation to the labels, but also to be invariant to several things:

- Invariant to the range of values of the sensor readings because different firefighters can perform the same actions differently.
- Invariant to the alignment of the interval represented by the time series. In the current case, let us consider an action that is being performed longer the duration of the intervals. For example, the firefighter might be running for 20 seconds. From those 20 seconds we

TABLE I. DISTRIBUTION OF CLASSES PER LABEL

| Label 1 | Label 2 | Training Instances | Distribution (%) |
|---:|---:|---:|---:|
| crawling | searching | 459 | 2.3 |
| crouching | manipulating | 1764 | 8.8 |
| crouching | no_action | 87 | 0.4 |
| crouching | nozzle_usage | 492 | 2.5 |
| crouching | signal_water_main | 46 | 0.2 |
| moving | ladder_down | 465 | 2.3 |
| moving | ladder_up | 476 | 2.4 |
| moving | manipulating | 331 | 1.7 |
| moving | running | 4324 | 21.6 |
| moving | signal_water_first | 41 | 0.2 |
| moving | stairs_down | 644 | 3.2 |
| moving | stairs_up | 1157 | 5.8 |
| moving | walking | 1064 | 5.3 |
| standing | manipulating | 2356 | 11.8 |
| standing | no_action | 491 | 2.5 |
| standing | nozzle_usage | 443 | 2.2 |
| standing | signal_hose_pullback | 98 | 0.5 |
| standing | signal_water_first | 496 | 2.5 |
| standing | signal_water_main | 405 | 2.0 |
| standing | signal_water_stop | 277 | 1.4 |
| standing | striking | 1022 | 5.1 |
| standing | throwing_hose | 234 | 1.2 |
| stooping | manipulating | 1898 | 9.5 |
| stooping | throwing_hose | 930 | 4.6 |

could extract thousands of different 1.8s subintervals that represent the action running. Ideally, the feature representation should describe all of those subintervals with almost the same feature vector.

- Invariant of the actions that precede the action that is currently being predicted. To put it differently, the feature descriptor should be invariant to Markov properties of the time series. Firefighter actions have these characteristics so they should be properly modeled. From the actions listed in table I, it seems highly unlikely that the firefighter can perform all pairs of actions (i.e. states) in sequence with the same probability. On the contrary, some state transitions seem very unlikely.

After the features are engineered and the dataset is processed, the next challenge is how to perform feature selection. This is essential because there is significant amount of features that can have negative impact on the used classification algorithms.

Finally, the last challenge is how to build classification models for the different labels given the training dataset. Table I reveals another significant challenge - the number of labels is large and their distribution is highly unbalanced. In the following sections we describe how we have coped with the above challenges and which results were obtained using different techniques. Even though at this point we have mentioned specific numbers like the number of time series or the number of samples in a time series, the approach is generic and in the remaining of the paper we use parameters for them.

## III. FEATURE ENGINEERING

In order to address the feature engineering for any problem, first we need to understand the nature of the time series data. Time series data can have different time sampling intervals and different scales of the values, however, most of the data can be useful when building a classification model. In the following subsections we describe which methods were used to address different types of challenges in modeling the time series.

### A. *Capturing the sensitivity to change with first derivatives*

By definition first derivatives are used to capture the speed of changes of some function. When instead of a continuous function we have a discrete sample, like a time series, finding an analytic solution is difficult. Nevertheless, we can estimate them. For a time series with $K$ readings that are collected at times $t[i], 0 \leq i < K$, we can calculate $K-1$ first derivatives. In this case $K = 400$, but we also have the timestamps of the readings which show that usually the interval between readings is 4.5ms. Nevertheless, we decided to use the original time stamp in order to calculate the first derivatives more accurately. Eq. 4 shows how the first derivative $fd$ of time series $j$ and at time $t(i), 0 < i \leq N$ can be estimated.

$$fd_j(i) = \frac{reading_j(i) - reading_j(i-1)}{t(i) - t(i-1)} \tag{4}$$

### B. *Modeling seasonality*

Often in time series there are seasonal components that can consist of periodic, repetitive, and generally regular and predictable patterns in the levels of its values. This is especially evident in business data where things like the holidays, days of week, months, quarters have impact on the values in a business time series (e.g. sales, profit, etc). Seasonal effects can conceal both the true underlying movement in the series, as well as certain non-seasonal characteristics which may be of interest to analysts. There are several main reasons for studying seasonal variation:

- Describing the seasonal effect can provide a better understanding of its impact on a time series.
- Eliminating the seasonal component from time series can aid studying other components such as cyclical and irregular variations.
- Use it to build better models for forecasting and prediction of future seasonal trends.

Keeping in mind that many body movements are also periodic, it occurred to us that maybe we should try to discover and model the seasonality in the current problem. We believe that seasonality in this domain should capture the individual characteristics and style of a particular firefighter and/or the context when some action is performed. By context we mean whether the firefighter is rested (e.g. at the beginning of an exercise), tired (after some time performing various actions), etc.

Before continuing to describing methods for modeling seasonality, some components need to be defined:

- The irregular component (sometimes also known as the residual) is what remains after the seasonal and trend components of a time series have been estimated and removed. It results from short term fluctuations in the series which are neither systematic nor predictable. In a highly irregular series, these fluctuations can dominate movements, which will mask the trend and seasonality.
- The trend is defined as the long term movement in a time series without irregular effects (like calendar related effects in business data), and is a reflection of

the underlying level. In financial data it is the result of influences such as population growth, price inflation and general economic changes.

To model a seasonal component, as described in [10], the following methods are usually used:

1) In an additive time-series model, the seasonal component is estimated as defined with eq. (5). There $S$ stands for the seasonal values, $Y$ is for actual data values of the time-series, $T$ is for trend values, $C$ is for cyclical values and $I$ is for irregular values.
$$S = Y - (T + C + I) \tag{5}$$
2) In a multiplicative time-series model, the seasonal component is expressed in terms of ratio and optionally with percentage as in eq. (6):
$$S = \frac{T \times S \times C \times I}{T \times C \times I} \times 100 = \frac{Y}{T \times C \times I} \times 100 \tag{6}$$
3) The deseasonalized time-series data will have only trend ($T$) cyclical($C$) and irregular ($I$) components and is expressed with eq. (7) and (8), respectively:
$$Y - S = (T + S + C + I) - S = T + C + I \tag{7}$$
$$\frac{Y}{S} \times 100 = \frac{T \times S \times C \times I}{S} 100 = (T \times C \times I) \times 100 \tag{8}$$

Additionally there is a pseudo-additive model that can be used, but as it was not explored in this research we do not provide more information about it.

The main challenge is discovering the seasonal index that describes the seasonality. Some of the methods for measuring it are: methods of simple averages, ratio to trend, and ratio to moving average. In order to apply them we would have needed experimentation about the length of the sliding window, for which we did not have time, so we decided to do something simpler. Namely, we have opted to use the additive model because we believed that it will correspond to the nature of the data. In particular, although there are difference between the same actions performed by different individuals, they are only linearly shifted values.

Next, we assumed that the seasonal component for each of the $N$ time series ($N = 42$ in the case-study) in one sample can be modeled with the mean value of the $K$ values ($K = 400$ in the case-study). In like manner, we calculated the deseasonalized values (refereed to as deltas in the remaining of the paper) in each training and test instance as defined with eq. (9), where $0 \leq i < 42$ and $0 \leq j < 400$.
$$Delta_i(j) = reading_i(j) - \frac{1}{K} \sum_{j=0}^{K-1} reading_i(j), \tag{9}$$

The motivation behind this approach came from the competition problem. Namely, the observation that some movements should have higher amplitudes than other (e.g. acceleration during running compared to acceleration during walking or standing). With this approach we hope to capture the characteristics of each movement in a more invariant way. Namely, the logic is that if some firefighter performs the same action with higher amplitudes than another, the actual sensor readings for the two series would differ more then the delta values (see eq. (9)).

After we have modeled the characteristics of each movement and posture with the first derivatives and the deltas, as explained in section III the set of available features in the datasets is comprised of:

- 42 values representing the vital functions (specific only to the current problem).
- $N \times K$ which corresponds to the number of series times the number of samples in the series. In this case, this is $42 \times 400 = 16800$ values for the deltas, which represent the original readings from the sensors. Although we are not including the original time series in the model, we calculate some statistics based on them, as described in the following paragraph.
- $N \times (K - 1)$ which corresponds to the number of series times the number of first derivatives in the series. In this case this is $42 \times 399 = 16758$ values for the first derivatives.
- $N \times K$ which corresponds to the number of series times the number of samples in the series. In this case this is $42 \times 400 = 16800$ values for the deltas.

To summarize, after modeling the sensitivity to change with first derivatives as described in subsection III-A, and modeling the seasonality described in the current section, there are 3 time series: the original sensor readings, the series of first derivatives and the time series of deltas. For each of them we can calculate the minimum, maximum, mean and standard deviation, a total of 4 metrics, which results in $N \times 3 \times 4$ values (504 in this case). With this the total number of available features adds up to $N \times K + N \times (K - 1) + N \times 3 \times 4$. In general, we could enrich the feature set by adding other statistics like first quartile, median, third quartile, interquartile range, skewness, kurtosis, etc, but in this research we have not explored this.

The first obvious problem is the number of features, which is way to high for most machine learning algorithms. More importantly, these features are dependent on the start and alignment of the time series. In section V we discuss how these considerations apply to the competition dataset. In the next subsection III-C we propose a robust method that can address these issues.

### C. Histogram-based modeling of time series

In order to address the issues with the features that are available after modeling the sensitivity to change of the time series and modeling the seasonality, it is evident that we need to perform some transformation. Discrete Fourier Transformation (DFT) [11] converts a finite list of equally spaced samples of a function into the list of coefficients of a finite combination of complex sinusoids that has those same sample values. It is usually used to transform the sampled function from its time to the frequency domain. The obtained list of coefficients would be used as a descriptor for the time series, however, we needed a simpler approach that would be more useful for real time applications.

Nevertheless, DFT lead us to the idea to discretize the values in the time series and then to compute histograms based on it. There are multiple ways in which we can discretize the data, but we decided to apply the simplest one, which is uniform discretization. In order to do that, we needed the minimum and maximum values of series and the number of discretization intervals (referred to as bins in the remaining of the paper). Namely, after calculating the minimum and maximum values of each of the $N$ series of first derivatives and deltas, we only needed to decide how many discretization bins to use. In this case we have $N = 42$ series of first derivatives and $N = 42$ series of deltas. Using more bins means results in more values in the histograms and finer grained granularity, but yields more features. In our tests we have tried using 30, 50 and 100 bins. Somewhat surprisingly, the number of bins did not have a significant impact on the classification results. Our analysis showed that with proper classification model one can achieve good performance using a reasonably small number of bins. We provide more details regarding the influence of the number of discretization bins on the classification performance in section V.

To better explain how the histogram-based approach works let us consider only one time series instance with $N$ values. The following steps should be performed prior applying the transformation:

- Determine the minimum and maximum values of each time series. We need them in order to find on which interval the discretization should be performed.
- Determine the step between discreet values $ds$ based on the number of discretization bins $B$ and the $min$ and $max$ values for the particular time series. This can be calculated with eq. (10)

$$ds = \frac{max - min}{B} \tag{10}$$

After the discretization step, $ds$, is calculated for a particular time series, all training and test instances can then be discretized. For each original value $V$ we can calculate the discrete value $DV$ with eq. (11).

$$DV = -|min| + round(\frac{|min| + V}{ds}, 0) \times ds \tag{11}$$

The next step is to calculate the histogram for the time series. If we use $B$ bins, then the histogram for a particular training instance will have $B$ values. By doing this, from a time series with $N$ values we obtain a histogram of $B$ values, where $N > B$. The $B$ values represent the transformed features which are robust, but are also a significantly reduced representation of the original time series.

To illustrate the transformation let us consider the exemplary time series shown at Fig. 1. Let us assume that we want to discretize the values of this time series (red line) to $B = 7$ bins on the interval $[-3, 3]$. After we calculate the discretization step according to eq. (10) we determine the discrete values according to (11). Using the discrete values (blue line) we can calculate the histogram displayed on Fig. 2. Consequently starting from a time series with 20 values, a histogram of 7 values is obtained.

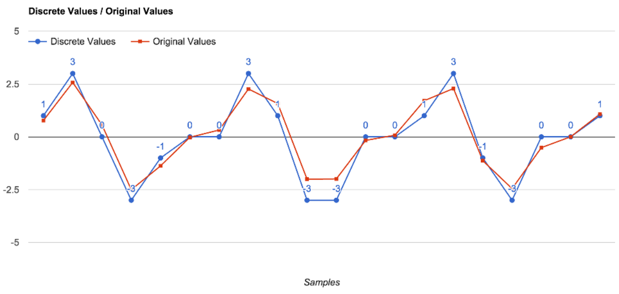

Fig. 1. Original and discrete values of an exemplary time series

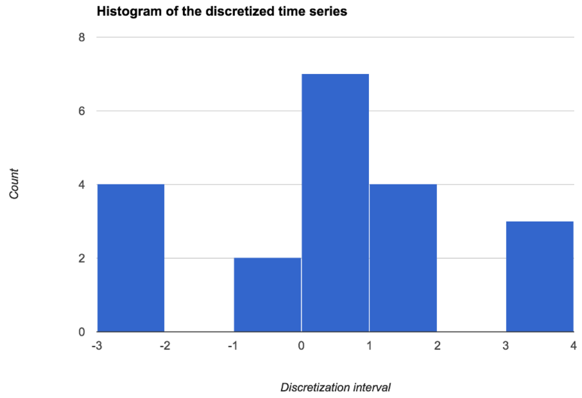

Fig. 2. Histogram of the discrete values of an exemplary time series

After applying the histogram transformation of the time series described above, when using $B$ discretization bins, the following dataset is obtained:

- 42 values representing the vital functions (specific to this case only).
- $2 \times N \times B$ for the first derivatives and the deltas. In this case $N = 42$, so $Hist = 2 \times 1260$ for $B = 30$, $Hist = 2 \times 2100$ for $B = 50$, and $Hist = 2 \times 4200$ for $B = 100$.
- $N \times 3 \times 4$ for the 4 aggregated values of the 3 types of series, which in this case is 504 additional features.

To summarize, after performing the histogram transformation, the total number of features in the dataset of the current problem was 3066, 4746 and 8946 when using 30, 50 and 100 bins, respectively.

### D. Feature selection

After inspection of the transformed dataset it was evident that for some features almost all training instances had the same value. In order to address this, we calculated the variance of each feature in the training set. Using the variance for discarding non-informative features is a simple baseline approach to feature selection. It removes all features whose variance does not meet some threshold. If a feature has the same value in all training samples, then its variance is 0.

When discarding the features with different thresholds for the variance, we have obtained the results in the following table. It can be noted that using a threshold greater than 0.05 does not significantly reduce the number of features. On the contrary, the cross validation results showed decline in performance. Table II shows the number of retained features per discretization bins and variance threshold on the competition datasets.

TABLE II. RETAINED FEATURES PER DISCRETIZATION BINS AND VARIANCE THRESHOLD

| Discretization bins | Features | Variance threshold | Retained features |
|---:|---:|---:|---:|
| 30 | 3066 | 0.05 | 1780 |
| 50 | 4746 | 0.001 | 3196 |
| 50 | 4746 | 0.01 | 2601 |
| 50 | 4746 | 0.03 | 2272 |
| 50 | 4746 | 0.05 | 2137 |
| 50 | 4746 | 0.1 | 1927 |
| 100 | 8946 | 0.1 | 5569 |

In the case when we used 100 bins we applied 0.1 as a variance threshold aiming to discard more features, but still over 5000 features remained. That is why we applied PCA (Principal Component Analysis) [12] and limited the selected features to 2000 explicitly. We have chosen the value of 2000 because it was close to the number of retained features obtained by the variance filter when using smaller number of bins.

When doing feature selection with PCA the results were similar in terms of the actual selected features, but for that the computation time was greater. We acknowledge that with more sophisticated feature selection methods like wrappers we might further lower the dimensionality and improve the classification performance. Nevertheless, the nature of the features is such that the features are different from each other because they represent different things. With this in mind, the expectation is that there are no redundant features in the dataset. Additionally, some machine learning algorithms like Support Vector Machines (SVMs) are able to cope with small number of redundant features without significant degrading of performance.

### *E. Data normalization*

Prior building any models we normalized the data using mean and standard deviation calculated from the training set. This process notably helps the next step while building prediction models. The process is recommended as part of the data preprocessing when using Support Vector Machines (SVM) [13] to make the classification model and is known to decrease the classification error [14] .

## IV. MODEL BUILDING

Prior building any models for the competition challenge one needs to define how the two different labels will be handled. One idea is to build a separate model for each label and then to merge the predictions, but also making sure that there are not any contradictions, i.e. combinations that are not possible. Another idea is to perform hierarchical multi-label classification, so first we would classify the training data based on the first label, and then to perform classification based on the second label. When building the second-level models one can perform one-vs-all classification based on the possible outcomes of the second label assuming the first label was correctly predicted. This approach helps by not needing to explore all possible classes of the second label. Nevertheless, given that the combinations of the second label (16) were close to the number of total combinations (24) and due to the limited time for the competition we did not explore these approaches significantly. Instead we used a one-level classification. The label of the instances is the combination of the two original labels, meaning that our classification model tries to predict both labels at the same time.

The set of features after the feature selection (i.e. preprocessed descriptor) is used to generate a classification model using SVM. SVM generates a classification model by finding the optimal support vectors that divide the feature space with the highest margin between the vector and the nearest points, so that all instances on one side of the support vectors belong to one class, and all other instances belong to other classes. For the purpose of our task we are using SVM with Radial Based Function (Gaussian function) that uses two parameters in the optimization process, C and gamma. Since most of the classification problems are not linearly separable, we are using the Gaussian SVM so that the separation is done in a higher dimension vector space generated with the nonlinear Gaussian kernel. To obtain the best parameters on the given data, we are using grid search as suggested in [15]. During the grid search we use exponentially increasing parameters. We have searched both C and gamma parameters in the interval $10^{-5}$ to $10^{5}$ evaluating $11 \times 11 = 121$ combinations. Then in the intervals that were giving best results we conducted finer grained grid search with smaller steps for gamma and C. Depending on the different training datasets (varied by the number of discretization bins and the variance threshold for feature selection) we have obtained different optimal values. For C the optimal values ranged from 1 to 1000 and for gamma they were usually from $10^{-5}$ to $10^{-4}$. Also important to realize is the unbalanced distribution on the classes. In order to address this problem, we used the class distribution to automatically adjust the weights inversely proportional to class frequencies. The estimated weights are then multiplied by the C parameter and those weighted C parameters are used when building the one-vs-all classification models for multi-class classification. This significantly improved the performance of the classifiers when using cross validation, but more importantly on the leaderboard set.

## V. EVALUATION OF THE PROPOSED METHODS ON THE COMPETITION DATASET

For the current challenge, we began our analysis with plotting and visual inspection of some of the sensor readings for random training samples. Before inspecting the data the impression was that the interval of 4.5 milliseconds between different readings could be too short for the sensors to output different values. On the contrary, the analysis showed that there are evident differences between consecutive readings, meaning that indeed all values in the series are potentially useful for building prediction models.

After we have modeled the characteristics of each movement and posture with the first derivatives and the deltas, as explained in subsections III-A and III-B the set of available features in the datasets is comprised of:

TABLE III. SCORE ON THE LEARDERBOARD DATASET DEPENDING ON VARIOUS DISCRETIZATION BINS AND SVM CONFIGURATIONS

| Id | Leaderbord Score | Bins | Variance | Retained features | SVM with RBF kernel |
|---|---|---|---|---|---|
| 1 | 0.8502 | N/A | N/A | N/A | Combination of configurations in rows 2 and 3 (below) |
| 2 | 0.8381 | 50 | 0.05 | 2137 | C=10 gamma=0.00002 weight=auto |
| 3 | 0.8380 | 30 | 0.05 | 1780 | C=10 gamma=0.000035 weight=auto |

| 23 | 0.8110 | 100 | 0.1 | 2000 (reduced from 5569 with PCA) | C=1.0 gamma=0.0001 weight=auto |
| 24 | 0.8077 | 50 | 0.05 | 2137 | C=1000 gamma=0.0001 weight=auto |
| 25 | 0.8062 | 50 | 0.05 | 2137 | C=10 gamma=0.0001 |

- 42 values representing the vital functions (specific to this case only).
- $2 \times N \times B$ for the first derivatives and the deltas. In this case $N = 42$, so $Hist = 2 \times 1260$ for $B = 30$, $Hist = 2 \times 2100$ for $B = 50$, and $Hist = 2 \times 4200$ for $B = 100$.
- $N \times 3 \times 4$ for the 4 aggregated values of the 3 series, which in this case is 504 additional features.

The first obvious problem is the number of features, which is way to high for most machine learning algorithms. More importantly, these features are dependent on the start of the time series. For instance, let us assume that we have an action (e.g. running) that is being performed with a total duration of 10000 milliseconds (10 seconds). If we extract two samples (training or test instances) from it, sample A spreading from $t_1 = 0ms$ to $t_2 = 1800ms$, and sample B spreading from $t_3 = 9ms$ to $t_4 = 1809ms$. The logic is that those two samples are nearly identical and should be treated accordingly in a good feature space. However, in the current representation they will be different because they are shifted by 2 periods of 4.5ms. Obviously this needs to be addressed, and this is performed by the histogram-based method described in subsection III-C. Then with the method described in subsection III-D we have reduced the number of features as shown with table II.

We have obtained many similar results based on the different alternatives we tried (different C and gamma parameters, number of discretization bins, etc.) on both the leaderboard dataset and with 5-fold cross validation with the training set. Table III shows some of the more significant configurations ordered by the score on the leaderboard dataset in descending order. Before explaining the best score, which is shown in the first line in this table, we first want to discuss the scores of the individual classifier configurations shown in all other rows.

The first obvious thing to notice is that when applying weights (denoted as “weight=auto” in table III to the C parameters improves the performance of the classifiers. Namely row 25 does not have weights applied to the C parameter, meaning the value of C=10 is used for all classes in the one-vs-all multi-class SVM. When applying weights proportional to the class frequencies in the training dataset the performance is improved as shown in row 22. We have noticed the same pattern in other configurations (i.e. different bin size, different C and gamma parameters) which are not shown in this table.

Next, we have noticed that when varying the values of the C and gamma parameters the classification score also varies when using the same feature set. This was expected and confirms the need for grid search, as described in section IV, to find the optimal values for those parameters.

Finally, the most important realization is that the greater number of discretization bins does not necessarily mean the score will be better. Most compelling evidence to this statement are the two best configurations shown in rows 2 and 3. Row 2 uses 50 bins, while row 3 uses 30 bins, but the difference between their score is 0.0001 in favour of the 50 bins feature set. On the other hand, the 30 bins feature set has 357 features less, which in turn leads to less training and test time. Another evidence that supports this claim is the case when we use 100 bins (rows 15, 16, 19, 20, 23). In those cases we obtain a much greater number of features than when using 50 or 30 bins, so we have to perform additional feature selection in order to reduce the training time. If we have retained more features and performed more detailed grid search for those feature sets, the results might have been better. Our initial tests showed that this in fact leads towards over-fitting and generating too many support vectors. For this reason this did not seem like worth doing, especially because we have managed to find better solutions with significantly less features.

The score difference between different configurations may seem negligible, but when looking at the actual predictions made by the 2 best models (rows 2 and 3) we came to an important realization. Namely, it was evident that both cross-validation and test predictions made by the 2 models are significantly different, yet the score of the 2 models was similar. This gave us an idea to train a second-level (ensemble) model. The features for this model were the predictions and probabilities of the 2 individual classifiers made with cross validation on the training dataset and the class was combination of the two labels. By applying this we further improved the score on the leaderboard dataset, and our final solution had a score of 0.8502. It was the third-placed score on the leaderboard and was only 0.001 behind the second-placed solution, 0.008 behind the first place, and 0.025 better then the fourth-placed solution. After the final results were published our score was still third - 0.8261, while the first was 0.8391, the runner-up was 0.82985 and the fourth placed score was 0.80408. We acknowledge that combining more individual models should be explored with a more generic approach.

## VI. Conclusion and future work

Based on the obtained results, we can conclude that the proposed descriptor gives a good model for the movements, while providing some invariance to deviation of the input values and also performing significant feature reduction. During the analysis of the predictions made by the different classification models we observed that most of the miss-classification errors were made when the classification model was trying to distinguish between very similar tasks for the given dataset, such as *moving* + *stairs-up* vs *moving* + *stairs-down* and *moving* + *manipulating* vs *crouching* + *manipulating*. These errors were inevitable since our approach for generating the descriptors is amplitude based and some specific movements have very similar amplitude characteristics. We believe that there is room for further improvement if we add additional descriptors to the feature space like: other statistics to describe the time series, amplitudes of the acceleration across all 3 axes, discovering and modeling the trend in the series, trying logarithmic transformations, adding second order derivatives, etc. Performing a better feature selection may also improve the performance. Finally, a better modeling that takes into account the hierarchical nature of the classification problems, as discussed previously, can further improve the results.

The main contribution of this paper is the proposed method for invariant modeling the time series by using first derivatives and deltas. Moreover, the novelty of our approach is in the proposed histogram-based method for feature reduction of the time series. Even though it was developed during the competition, it is applicable to time series regardless from their domain. In our future research we plan to affirm this method by analyzing time series from various domains and comparing it to other methods for modeling time series.

***Abstract*—We describe our submission to the AAIA'15 Data Mining Competition, where the objective is to tag the activity of firefighters based on vital functions and movement sensor readings. Our solution exploits a selective naive Bayes classifier, with optimal preprocessing, variable selection and model averaging, together with an automatic variable construction method that builds many variables from time series records. The most challenging part of the challenge is that the input variables are not independent and identically distributed (i.i.d.) between the train and test datasets. We suggest a methodology to alleviate this problem, that enabled to get a final score of 0.76 (team marcb).**

## I. Introduction

The AAIA'15 Data Mining Competition [1] is related to a problem of activity tagging. Firefighters are equipped with body sensors that register vital functions and movements. Vital function records are summarized by statistics (minimum, maximum, median...) using a fixed number of input variables, whereas movement records are available as 42 times series of length 1.8 s with measures every 4.5 ms. Train data consists of 20,000 samples for activities recorded from four firefighters, whereas the test data contains 20,000 samples coming from a different group of four firefighters. The objective is to tag the activity of firemen, among 24 activities, and the evaluation criterion is the balanced accuracy (BAC). In this paper, we present our submission to the challenge. It exploits a Selective Naive Bayes classifier together with an automatic variable construction method (Section II). We motivate the choice of this classification framework and describe its application to the challenge in Section III. A good classifier trained on the train data obtains a disastrous leaderboard score. This is not caused by over-fitting, but by a severe distribution drift between the train and test data. We suggest in Section IV a methodology to alleviate this problem. In Section V, we present related work and discuss our approach. Finally, Section VI summarizes the paper.

## II. Supervised Classification Framework

We summarize the Selective Naive Bayes (SNB) classifier introduced in [2]. It extends the Naive Bayes classifier [3] owing to an optimal estimation of the class conditional probabilities, a Bayesian variable selection and a Compression-based Model Averaging. We also describe the automatic variable construction framework presented in [4], used to get a tabular representation from times series.

### A. Optimal discretization

The Naive Bayes (NB) classifier has proved to be very effective in many real data applications [3], [5]. It is based on the assumption that the variables are independent within each class, and solely relies on the estimation of univariate conditional probabilities. The evaluation of these probabilities for numerical variables has already been discussed in the literature [6], [7]. Experiments demonstrate that even a simple equal width discretization brings superior performance compared to the assumption using a Gaussian distribution per class. Using a discretization method, each numerical variable is recoded as a categorical variable, with a distinct value per interval. Class conditional probabilities are assumed to be piecewise constant per interval, and obtained by counting the number of instances per class in each interval. These class conditional probabilities are used as inputs for the naive Bayes classifier. Figure 1 shows an example of discretization into three intervals, for the *Sepal width* input variable of the Iris dataset [8].

Fig. 1. Number of instances per class in the Iris dataset, for a discretization of the *Sepal width* input variable into three intervals

978-83-60810-66-8/$25.00©2015, IEEE

In the MODL approach [9], the discretization is turned into a model selection problem and solved in a Bayesian way. First, a space of discretization models is defined. The parameters of a specific discretization model $M$ are the number of intervals, the bounds of the intervals and the class frequencies in each interval. Then, a prior distribution is proposed on this model space. This prior exploits the hierarchy of the parameters: the number of intervals is first chosen, then the bounds of the intervals and finally the class frequencies. The choice is uniform at each stage of the hierarchy. Finally, the multinomial distributions of the class values in each interval are assumed to be independent from each other. A Bayesian approach is applied to select the best discretization model, which is found by maximizing the maximum a posteriori (MAP) model. Owing to the definition of the model space and its prior distribution, the Bayes formula is applicable to derive an exact analytical criterion to evaluate the posterior probability of a discretization model. The optimized criterion is $p(M)p(D|M)$, where $p(M)$ is the prior probability of a preprocessing model and $p(D|M)$ the conditional likelihood of the data given the model.

Efficient search heuristics allow to find the most probable discretization given the data sample. Extensive comparative experiments report high performance.

*Univariate informativeness evaluation:* A 0-1 normalized version of the optimized criterion provides a univariate informativeness evaluation of each input variable. Taking the negative log of the MAP criterion, $c(M) = -(\log p(M) + \log p(D|M))$, the approach receives a Minimim Description Length (MDL) [10] interpretation, where the objective is to minimize the coding length of the model plus that of the data given the model. The null model $M_\emptyset$ is the preprocessing model with one single interval, which represents the case with no correlation between the input and output variables. We then introduce the *I(V)* criterion in Equation 1 to evaluate the informativeness of a variable $V$.

$$I(V) = 1 - \frac{c(M)}{c(M_\emptyset)}. \tag{1}$$

The value of $I(V)$ grows with the informativeness of an input variable. It is a between 0 and 1, 0 for irrelevant variables uncorrelated with the target variable and 1 for variables that perfectly separate the target values.

### B. Bayesian Approach for Variable Selection

The naive independence assumption can harm the performance when violated. In order to better deal with highly correlated variables, the Selective Naive Bayes approach [11] exploits a wrapper approach [12] to select the subset of variables which optimizes the classification accuracy. Although the Selective Naive Bayes approach performs quite well on datasets with a reasonable number of variables, it does not scale on very large datasets with hundreds of thousands of instances and thousands of variables, such as in marketing applications or text mining. The problem comes both from the search algorithm, whose complexity is quadratic in the number of variables, and from the selection process which is prone to overfitting. In [2], the overfitting problem is tackled by relying on a Bayesian approach, where the best model is found by maximizing the probability of the model given the data. The parameters of a variable selection model are the number of selected variables and the subset of variables. A hierarchic prior is considered, by first choosing the number of selected variables and second choosing the subset of selected variables. The conditional likelihood of the models exploits the Naive Bayes assumption, which directly provides the conditional probability of each class. This allows an exact calculation of the posterior probability of the models. Efficient search heuristic with super-linear computation time are proposed, on the basis of greedy forward addition and backward elimination of variables.

### C. Compression-Based Model Averaging

Model averaging has been successfully exploited in bagging [13] using multiple classifiers trained from re-sampled datasets. In this approach, the averaged classifier uses a voting rule to classify new instances. Unlike this approach, where each classifier has the same weight, the Bayesian Model Averaging (BMA) approach [14] weights the classifiers according to their posterior probability. In the case of the Selective Naive Bayes classifier, an inspection of the optimized models reveals that their posterior distribution is so sharply peaked that averaging them according to the BMA approach almost reduces to the MAP model. In this situation, averaging is useless. In order to find a trade-off between equal weights as in bagging and extremely unbalanced weights as in the BMA approach, a logarithmic smoothing of the posterior distribution, called Compression-based Model Averaging (CMA), is introduced in [2]. The weighting scheme on the models reduces to a weighting scheme on the variables, and finally results in a single Naive Bayes classifier with weights per variable. Extensive experiments demonstrate that the resulting Compression-based Model Averaging scheme clearly outperforms the Bayesian Model Averaging scheme. In the rest of the paper, the classifier resulting from model averaging is called Selective Naive Bayes (SNB).

### D. Automatic Variable Construction for Multi-Table

In a data mining project, the data preparation phase aims at constructing a data table for the modeling phase [15], [16]. The data preparation is both time consuming and critical for the quality of the mining results. It mainly consists in the search of an effective data representation, based on variable construction and selection. Variable construction [17] has been less studied than variable selection [18] in the literature. However, learning from relational data has recently received an increasing attention. The term Multi-Relational Data Mining (MRDM) was initially introduced in [19] to address novel knowledge discovery techniques from multiple relational tables. The common point between these techniques is that they need to transform the relational representation. Methods named by propositionalisation [20], [21], [22] try to flatten the relational data by constructing new variables that aggregate the information contained in non target tables in order to obtain a classical tabular format.

In [4], an automatic variable construction method is proposed for supervised learning, in the multi-relational setting using a propositionalisation-based approach. Domain knowledge is specified by describing the multi-table structure of the data and choosing construction rules. The formal description of the data structure relies on a root table that contains the main statistical units and several secondary tables in 0 to 1 or 0 to n relationship with the root table. For example, Figure 2 describes the structure of the data for the challenge. The construction rules available for automatic construction of variables are detailed below:

- *Selection(Table, Num)→Table*: selection of records from a secondary table according to a conjunction of selection terms (membership in a numerical interval of a variable *Num* in the secondary table),
- *Count(Table)→Num*: count of records in a table,
- *Mean(Table, Num)→Num*: mean value of variable *Num*,
- *Median(Table, Num)→Num*: median value,
- *Min(Table, Num)→Num*: min value,
- *Max(Table, Num)→Num*: max value,
- *StdDev(Table, Num)→Num*: standard deviation,
- *Sum(Table, Num)→Num*: sum of values.

The space of variables that can be constructed is virtually infinite, which raises both combinatorial and over-fitting problems. When the number of original or constructed variables increases, the chance for a variable to be wrongly considered as informative becomes critical. A prior distribution over all the constructed variables is introduced. This provides a Bayesian regularization of the constructed variables, which allows to penalize the most *complex* variables. An effective algorithm is introduced as well to draw samples of constructed variables from this prior distribution. Experiments show that the approach is robust and efficient.

## III. Applying the Framework for the Challenge

We motivate our choice of the classification framework[1], then describe how we apply it on the challenge dataset.

### A. Choice of the classification framework

In all our challenge submissions, we exploit the framework described in Section II to train a selective naive Bayes classifier, with optimal discretization, variable selection and model averaging. The classifier is trained on a flat data representation, obtained using the automatic variable construction method (Section II-D) that builds many variables from the time series records data. Once the data schema is specified, the only parameter is the number of variables to construct. The method is fully automatic, scalable and highly robust, with test performance mainly equivalent to train performance.

The SNB classifier is resilient to noise and to redundancies between the input variables, but it is blind to non-trivial interactions between the variables. This can be leveraged by feature engineering, relying on domain expertise rather than on statistical expertise. More accurate classification methods are available, such as random forests, gradient boosting methods, support vector machines or neural networks. However, these methods require intensive feature engineering to get a flat input data table representation, are prone to over-fitting, are mainly black-box, not suitable for an easy interpretation of the models and finally require fine parameter tuning, both time consuming and expertise intensive. In an industrial context like the Orange telecommunication operator, the major issue is to quickly provide an accurate, robust and interpretable solution to many data mining problems, rather than a very accurate solution to few problems. In this context, the generic framework described in Section II and used in this challenge offers a good solution.

### B. Application to the challenge dataset

For the AAIA'15 Data Mining Competition, firefighters are described using a root table that contains the target activity as well as the summary variables for the vital function sensors and a secondary table for the movement sensors readings. An identifier variable *Id* is added in each record of both tables, to enable the join between the root and secondary tables.

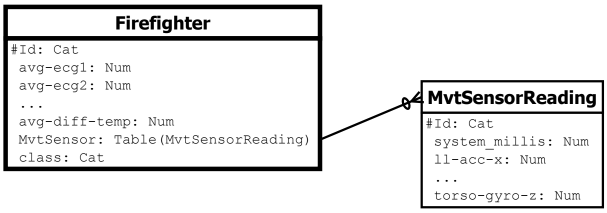

Fig. 2. Multi-table representation for the data of the AAIA'15 challenge

The multi-table representation of the challenge data is presented in Figure 2. The root table (*Firefighter*) contains 20,000 instances, with 44 variables: *Id*, the 42 vital function input variables (*avg-ecg1*, *avg-ecg2*, ... *avg-diff-temp*) and the class variable. The secondary table (*MvtSensorReading*) contains 20,000 × 400 records, with 44 variables: *Id* as a join key and the 43 time series variables for the movement sensor readings (*system_millis*, *ll-acc-x*, ... *torso-gyro-z*). Using the data structure presented in Figure 2 and the construction rules introduced in Section II-D, one can for example construct the following variables ("name" = *formula*: comment) to enrich the description of a *Firefighter*:

- "StdDev(MvtSensor.rl-acc-x)" =
  *StdDev(MvtSensor, rl-acc-x)*:
  standard deviation of rl-acc-x in the sensor readings,
- "Count(MvtSensor) where ll-gyro-y $>$ 60" =
  *Count(Selection(MvtSensor, ll-gyro-y $>$ 60))*:
  number of sensor readings where ll-gyro-y $>$ 0,
- "Max(MvtSensor.torso-acc-z) where torso-acc-x $>$ 5" =
  *Max(Selection(MvtSensor, torso-acc-x $>$ 5), torso-acc-z)*:
  max of torso-acc-z for sensor readings where torso-acc-x $>$ 5.

[1] Available as a shareware at http://www.khiops.com

The number of variables to construct is the only user parameter. An input flat data table representation is then obtained from the initial input variables coming from the root table and the set of all automatically constructed variables. All these variables are then preprocesses using the optimal discretization method (cf. SectionII-A) to assess their informativeness and evaluate their class conditional probabilities, before training the SNB classifier. For advanced use, it is possible to impose a constraint on the granularity of the discretizations (cf. Section II-A): instead of obtaining the optimal number of intervals, the preprocessing method output discretizations with at most $I_{Max}$ intervals, where $I_{Max}$ is a user parameter.

## IV. Challenge submission

In this section, we describe our submissions to the challenge and suggest a methodology to alleviate the problem of the drift between the train and test distributions of the challenge dataset.

### A. *First trials*

*a) Submission 1:* To get familiar with the challenge evaluation protocol, we made a first quick trial, using only the 43 vital function variables. We obtained a surprisingly high train accuracy, with few over-fitting: 0.9840 and 0.9680 on a 70%-30% split of the train dataset. However, our first submission obtained only a 0.1859 score on the challenge leaderboard. This dramatic drop of performance was not caused by overfitting, but by a drift between the train and test distributions (based on two different groups of four firefighters).

*b) Submission 2:* We then generated 100 additional variables to summarize the movement sensors times series, using the framework described in Section II-D. As we observed that the optimal discretizations (see Section II-A) were very fine grained, with up to hundred of intervals, we decided to constrain the discretization method to build at most 10 intervals. We obtained a 0.9499 train accuracy (on the test split of the train dataset), and a 0.4566 leaderboard score. Constraining the discretisations thus reduced the drift effect.

*c) Submission 3:* Using discretizations with at most two intervals, we obtained a 0.8603 train accuracy and a 0.6372 leaderboard score. This confirmed the benefit of the constrained discretisations to reduce the drift effect.

*d) Submission 4.:* Still using discretizations with at most two intervals, we generated 1,000 variables from the movement sensors times series. We obtained a 0.9254 train accuracy and a 0.6951 leaderboard score.

Table I summarizes the performance obtained for each preliminary submission as well as the related user parameters: number of constructed variables (cf. Section II-D) and constrain on the maximum number of intervals in the discretizations (cf. variable preprocessing in SectionII-A).

These preliminary trials took only one hour and gave interesting insights.

### B. *Analysis, trials and errors*

Let us consider two tasks: classification of the activity and detection of the drift. The drift detection task can be turned into a classification task as in [23], by merging the train and test datasets and using the dataset label ('train' or 'test') as the target variable. Intuitively, if we are able to select an input representation with good classification accuracy on the train dataset but poor drift detection, we expect that our classifier will be less sensitive to drift and that the performance drop on the test dataset will be reduced.

TABLE I
Method parameters and performance per submission

| Submission | Constructed variables | Interval max nb | Train accuracy | Leaderboard score |
|---|---|---|---|---|
| Submission 1 | 0 | | 0.9680 | 0.1859 |
| Submission 2 | 100 | 10 | 0.9499 | 0.4566 |
| Submission 3 | 100 | 2 | 0.8603 | 0.6372 |
| Submission 4 | 1000 | 2 | 0.9254 | 0.6951 |

The objective is then to explore varying input representations and select the one with the best classification accuracy together with the poorest drift detection. To do so, we mainly considered the following dimensions: max number of intervals for discretizations, representation of times series, selection of variables, both for the root and secondary tables, choice of construction rules, number of constructed variables. Exploiting the informativeness of variables both from the classification and drift detection tasks, we made many trials and errors and finally obtained a solution with a leaderboard score of 0.7892. This solution mainly consists of:

1) discretizations with at most two intervals,
2) no use of any vital function variables, selection of part of the movement variables (mainly, the *acc-x* and *acc-z* for the *torso*, the *acc-x, acc-z, gyro-x, gyro-y* for the *legs* and *acc-x, gyro-x, gyro-z* for the *hands*),
3) construction of 10,000 variables using only the *Count* and *Selection* construction rules.

### C. *A methodology to reduce the drift problem*

While the approach described in the preceding section was insightful and allowed to improve significantly the leaderboard score, it heavily relies on human expertise and is time consuming. We now suggest a methodology that aims at automatizing the approach. First, we use all the initial input representation and all the available construction rules to build 10,000 variables. Using discretizations with at most two intervals, we evaluate the informativeness of each input variable (cf. Formula 1), both for the drift detection and the classification tasks. The results, displayed in Figure 3, show that there are variables with large drift informativeness and small classification informativeness (top-left of the figure), or on the contrary variables with small drift informativeness and large classification informativeness (bottom-right). The interesting variables are those close to the X axis, with small drift informativeness.

We then sort the variables by increasing drift informativeness and select subsets of variables of increasing sizes, for a list of thresholds of drift informativeness (0, 0.0001, 0.00025...). Figure 4 displays the number of informative

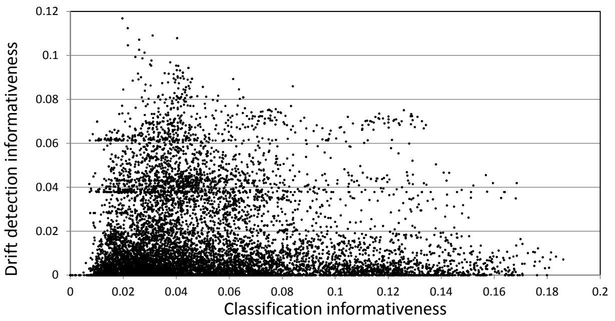

Fig. 3. Informativeness of 10,000 variables

variables for both the classification and detection tasks, for each drift threshold. For example, using a threshold of 0 that excludes any variable with drift informativeness, the smallest selected subset contains around 2,000 variables that are informative for the classification task.

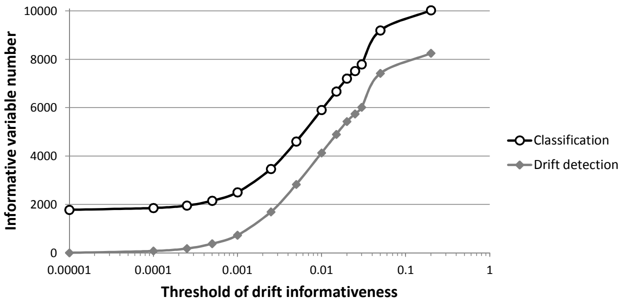

Fig. 4. Number of informative variables per drift threshold for the classification and drift detection tasks

For each of these subsets, we train the selective naive Bayes classifier both for the classification and drift detection tasks, collect the resulting accuracies as well as the leaderboard score obtained with the related submissions. For both tasks, we use a 70%-30% split of the data to evaluate the robustness of the classifier, and always observe a small difference ($\approx 1\%$) between the train and test performance.

Training times are more than ten times longer for the classification task (24 target values) than for the drift detection task (two labels). The largest classification task consists of 14,000 train instances (70%*20,000) and 10,000 constructed variables, each summarizing 400 movement sensor readings. On a PC Windows with Intel Xeon 2.3 Ghz processor, it took about half an hour for the data preparation and four hours to train the SNB classifier.

Figure 5 shows that the accuracy of drift detection rapidly decreases with smaller number of variables while the decrease is slower for the train classification accuracy. Meanwhile, the leaderboard score increases, from 0.7083 using all the variables to a plateau with a leaderboard score of about 0.78 between 2,500 and 6,000 variables . Using this methodology, our final chosen submission obtained a leaderboard score of 0.7856 (using around 4,500 variables) and a final score of 0.76.

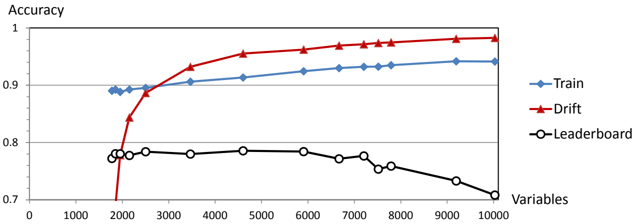

Fig. 5. Train classification, drift detection and leaderboard accuracies w.r.t. number of input variables

### D. *Insights on relevant variables*

Looking at Figure 4, we can see that the selected subset that contains around 4,500 variables is related to a drift threshold of 0.005, which is very small. Figure 3 shows that this corresponds to variables very close from the X axis, with potentially large class informativeness but very small drift detection informativeness.

For interpretability purposes, it is interesting to further investigate on which kind of variables are kept in the best classifier. In Figure 6, we reuse the same kind of plot as in Figure 3 and focus on the initial data representation, per family of variables. The 42 vital function variables are summarized in five families: EGC, heart rate, breath rate, respiration and temperature. The figure shows that these variables (especially the heart rate ones) have large drift informativeness and small classification informativeness. They are excluded from the best classifier. As for the 42 movement sensor time series, we divided the analysis using separate plots for the 7 body parts (torso, left and right hand, arm and legs) with 6 families per body part: x, y and z readings for the accelerometer and gyroscope. From the 10,000 automatically constructed variables, we collected the subset of variables related to each body part per family. The results are summarized in the 7 body part plots in Figure 6. This brings interesting insights w.r.t. to the relevance of each movement sensor for the classification task. For example, the arm sensors are the least interesting, since they are related to many variables with large drift informativeness. On the opposite, the other body part sensors are related to many constructed variable close to the X axis, with small drift informativeness and large classification informativeness. Overall, the torso and leg movement sensor bring the most useful information. The dissimilarity between the left and right body part sensors appears clearly. For example, for the left hand, the z accelerometer is too sensible to the drift, and for the left leg, this the case for the y accelerometer. All these insights may be useful to optimize data collection and pre-processing in order to improve the performance of the classifier.

### E. *Limits of the approach*

Using the leaderboard to chose the best solution is likely to overfit the test dataset, and the solution might not be reliable

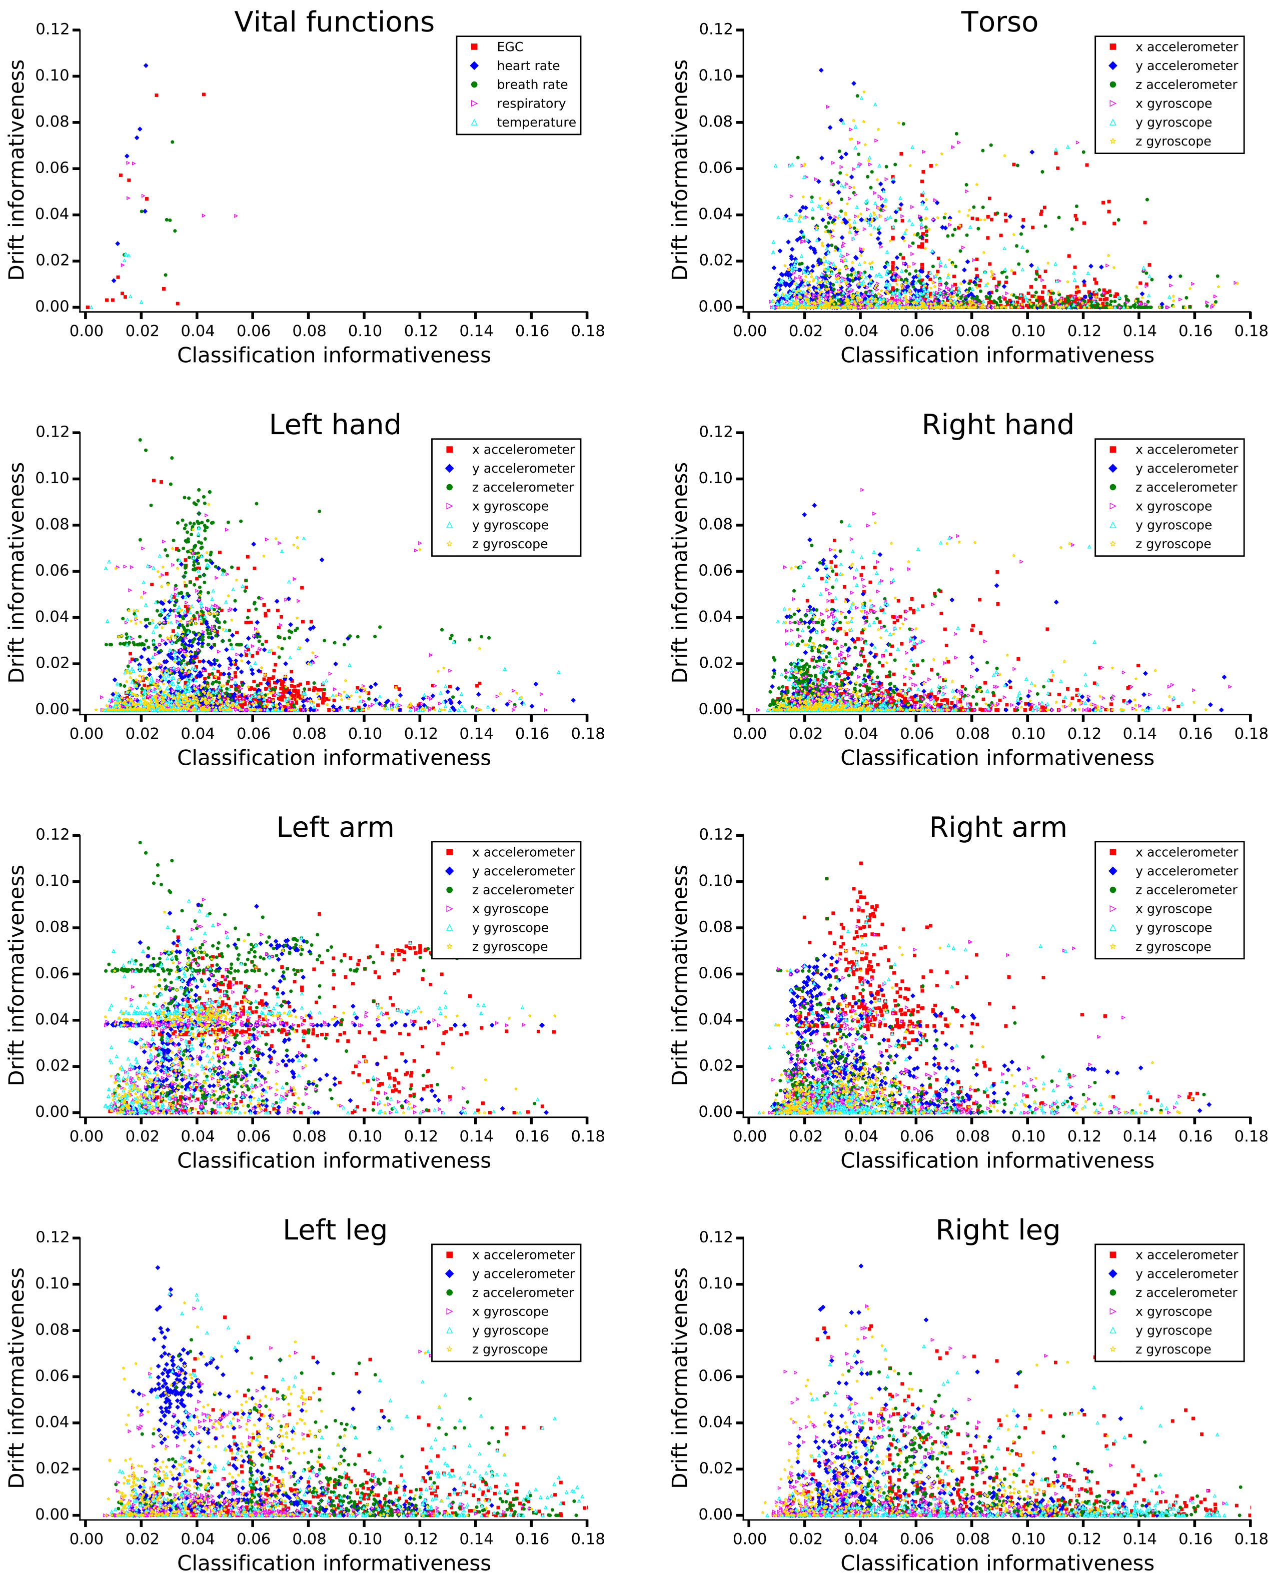

Fig. 6. Informativeness per family of variables

when applied to new firefighters not in the train nor test datasets. Ideally, data should be collected from more distinct firefighters to improve the reliability and performance of the solution. Also, the firefighter identifiers should be available in the datasets. This would enable a cross-validation process with splits based on distinct firefighters, to select the best solution using the train dataset only.

## V. Related work and discussion

The challenge settings rely on a train and test datasets with the same task. As in supervised learning, labels are available in the train dataset and not available in the test dataset. However, the train and test data do not come from the same distribution (different firefighters in train and test).

In semi-supervised learning, [24] the objective is to exploit both labeled and unlabeled data, as in our approach, but the distributions of the labeled and unlabeled data are assumed to be the same. The case of transfer learning (see [25] for a comprehensive survey) is close to the challenge settings. Transfer learning aims at exploiting two source and target domains and tasks, with or without available labels for each task. It has been studied under different names (learning to learn, knowledge transfer, inductive transfer, multitask learning...) and covers a variety of settings. The closest one is called *Transductive Transfer Learning* (also named Domain Adaptation, Sample Selection Bias, Co-variate shift...), where the source and target domains are different but related, the tasks are the same, and the labels are available only in the source domain. In this setting, our approach is related to *Feature-Representation Transfer* approaches, where the objective is to find a good feature representation that reduces the difference between the source and target domains and improves the accuracy for the target task. According to Pan and Yang [25], most feature-representation transfer approaches to the transductive transfer learning settings are under unsupervised learning frameworks. In structural correspondence learning (SCL) [26], a set of domain specific *pivot* features is defined and treated as a new label vector. The corresponding classification problems are assumed to be solved by linear classifiers. SCL then learns a matrix of parameters and applies a singular value decomposition on this matrix. This allows to create new features that encodes a correspondence between the source and target domains. The tricky part is how to well design the pivot features. This can be done heuristically or using mutual information [27]. Many approaches focus on the natural language processing (NLP) domain. In [28], a kernel-mapping function is proposed to map the data from both the source and target domains. However, the kernel is domain knowledge driven and is not easy to generalize to other applications. In [29], a co-clustering based approach is proposed to propagate the labels across the domains. In [30], an algorithm named *bridged refinement* is proposed to correct the labels predicted by a shift-unaware classifier toward a target distribution and take the mixture distribution of the training and test data as a bridge to better transfer from the training data to the test data. Other approaches summarized in [25] extend traditional approaches in the NLP domain, such as spectral analysis, probabilistic latent semantic analysis (PLSA) or dimensionality reduction.

Our approach is clearly related to the settings of Transductive Transfer Learning based on Feature-Representation Transfer. One main difference is that our method relies on a multi-table data representation of the data and exploits the automatic variable construction framework summarized in Section II-D to explore many representations. Still, in the flat table case, our approach could be applied in the NLP domain where many input variables are available using the bag of words representation of texts.

Compared to related transfer learning approaches, another difference is that our approach focuses on the methodology rather than on new specific modeling techniques. The unlabeled train and test data are first exploited jointly to sort the input variables by decreasing drift informativeness. Then, a list of embedded classifiers is build on subsets of variables of increasing size, with expected increasing classification performance but also increasing sensibility to drift. The final classifier can be found either using a tolerance threshold compared to the best classification performance in the source domain, or using labels in the target domain if they are partly available.

Let us now focus on some settings that could benefit from our approach or more generally from transfer learning:

- Like in the AAIA'15 Data Mining Competition, there are many problems where the train and test data are not governed by the same distributions, and where the task is to train a classifier from many train instances coming from few sources (like the many train samples coming from only four firefighters). This is the case in domains where data is hard to collect and relies on few volunteers, each contributing to several train instances. For example, the MNIST database of handwritten digits [31] contains 60,000 train instances and 10,000 test instances, with 250 train writers and 250 other test writers. The UCI repository [8] contains many other such datasets, including for example the *Australian Sign Language signs Data Set* with 95 signs were collected from five signers for a total of 6650 sign samples, or the *Spoken Arabic Digit Data Set* with 10 digits collected from 88 speakers for a total of 8800 samples (represented using timeseries of mel-frequency cepstrum coefficients).
- When the train and test data come from different time periods, the assumption of i.i.d. distribution is violated as soon as the data are not stationary. This applies to many times series prediction problems, where samples are collected from one single source in a train period and where the trained model is applied to a future test period. For example, the IJCRS'15 Data Mining Competition[2] is related to a problem of prediction of methane outbreaks in a coal mine equipped with 28 sensors of different types (barometer, anemometer, temperature meter, humidity

[2] https://knowledgepit.fedcsis.org/contest/view.php?id=109

meter, methane meter...), with 51,700 train samples and 5,076 test samples with time periods that do not overlap with those in the train data.

- A variant of the preceding settings usually occurs in the marketing field, where there is abundant data from millions of customers, which allows extracting train datasets with one sample per customer. However, the marketing tasks are not classification, but prediction on a future period in a non-stationary market environment (for tasks such as churn, fraud or up-selling for example). In the Orange telecommunication operator, we have many such problems and plan to evaluate our transfer learning approach.

## VI. Conclusion

Whereas most data mining methods rely on i.i.d. data, this is not the case in AAIA'15 Data Mining Competition, where the train and test data where collected from two different groups of four firefighters. In this case, a robust classifier was able to achieve 100% accuracy in a 70%-30% split of the train data, with a dramatic drop of the test performance down to 18% leaderboard score. This is not an overfitting problem, but a problem of distribution drift between the train and test datasets. In this paper, we have suggested a methodology to alleviate this problem by evaluating the informativeness of each variable for the classification and drift detection tasks. We follow the intuition that the classifiers that exploit input variables with high class informativeness and low drift informativeness are more likely to be resilient to drift. Applying this methodology, we were able to build a classifier with 0.76 final score, which is a tremendous improvement compared to our initial solution. In future work, we plan to refine the methodology and to evaluate it on new problems, in particular for Orange marketing prediction tasks, where the data are abundant, complex and governed by non stationary distributions.

*Abstract*—**The article introduces a novel mechanism for automatic extraction of features from streams of numerical data. It was originally designed for the purpose of processing multiple streams of readings generated by sensors in coal mines. The original research was conducted on methane concentration analysis in the DISESOR project. The article demonstrates an application of the elaborated mechanism for the case of tagging short series of readings from sensors that monitor activities and movements of firefighters during the action with labels corresponding to firefighter activities. The purpose of the experiment was to assess how the automatic feature extraction and construction of classifiers (without parameters tuning and without the use of classifier ensembles) can cope with the competition's task in comparison to other participants.**

## I. Introduction

Every day, the surrounding world is being monitored by a still increasing number of sensors. Starting with sensors from our neighborhood as: mobile phones, intelligent home appliances, GPS, automotive sensors, cardio-in watches etc. ending with specialized sensors that support the manufacturing processes deployed in factories, mines or platforms. The velocity of data acquisition makes that the methods of analysis are expected to adapt rapidly to the changes and the emergence of data. On the other hand, the similarity of the nature of the data generated by the sensors appears to allow the construction of generic, reusable mechanisms for data processing and analysis.

The recent emergence of data storage technologies like columnar databases with high level of compression as Infobright [24] and the solutions that can scale up to thousands of machines like MapReduce [8] allow us to store machine generated data that is extremely large. What has to be done at this point, is to develop a generic approach to process data and to introduce a mechanism for automatic (or semi-automatic) knowledge discovery from acquired data in order to support analysts. This aims to reduce the time needed to perform the laborious, manual data analysis.

This article introduces a novel mechanism for automatic extraction of features from streams of numerical data and verifies its effectiveness based on data mining competition results. The elaborated mechanism was originally prepared for the purpose of processing multiple streams of readings generated by sensors in coal mines. The article demonstrates an application of the developed mechanism for the case of the AAIA'15 Data Mining Competition[1]: Tagging Firefighter Activities at a Fire Scene[16] which was the continuation of the previous contest investigating key risk factors for Polish Fire Service [11]. The competition was concerned the process of automatic labels (activities) assignment to a short series of readings from sensors that monitor activities and movements of firefighters during the action. The aim of the competition was to maximize balanced accuracy measure which is defined as an average accuracy within all decision classes while the aim of our research was to assess how the automatic feature extraction and classifiers learning (without parameters tuning) can cope with the competition's task.

Another of our objectives was a requirement that the total effort spent on the data preparation and experiments should be limited, which enables easier management of human resources. The overall time was limited in advance by 2MD (two man days - that is 16 h) which has been recognized as sufficient for researchers to become familiar with the task and to adjust original data representation to a format accepted by the evaluated feature extraction mechanisms. A part of the available time was used for a classifier selection and learning process and was conducted by means of the algorithms available in packages for R programming language[2].

This paper is organised as follows. In Section II the original data set and features extraction mechanisms are presented. In Section III, the assumptions of experiments, an approach to the features selection, the final solution, as well as verified (but finally discarded) approaches to data analysis are shown. In Section IV, the original application of elaborated mechanisms for the extraction of features from multiple streams within the DISESOR project is described. Finally, in Section V a

summary of research, conclusions and plans for the nearest future are presented.

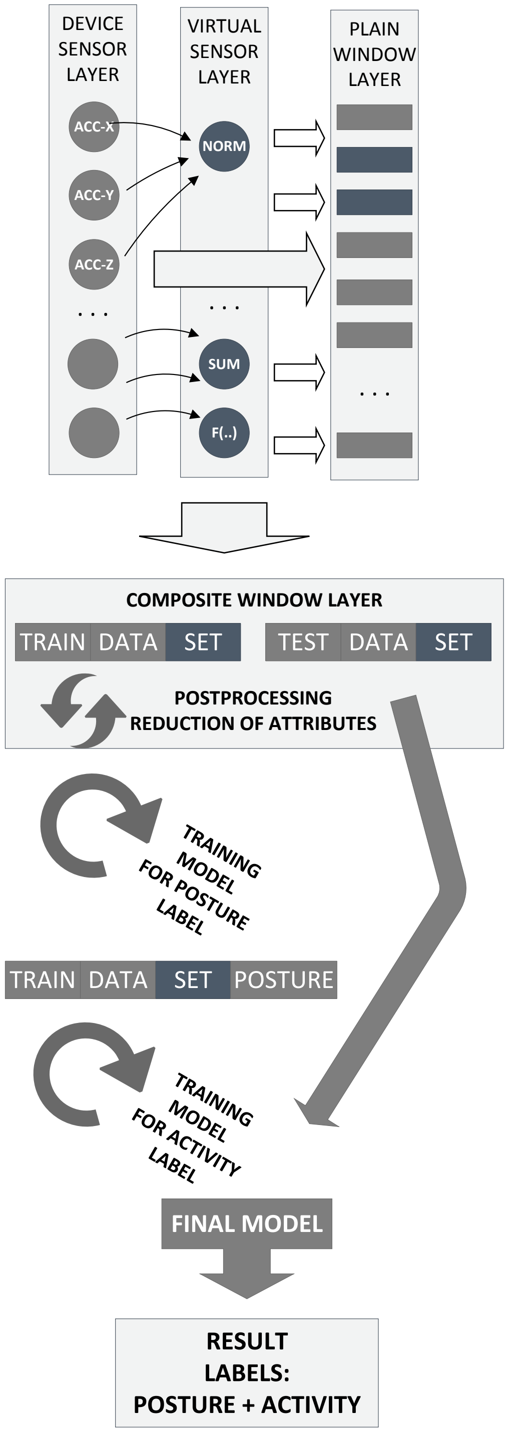

Figure 1. The diagram shows the whole process of feature extraction and model training which was carried out in order to solve the problem of labeling sensor time series with posture and main activity of a firefighter. Model responsible for recognizing a firefighter's posture uses windows constructed on the raw-sensory and virtual-sensory data. The model labeling main activity takes into account both sensory data and a posture label.

## II. Data preprocessing

### A. Original data set

The data provided in the competition were obtained during training exercises conducted by a group of eight firefighters from the Main School of Fire Service. The sensors placed on a chest were registering vital functions, while the sensors placed on torso, hands, arms and legs were registering movements of a firefighter. Along with recording the data from sensors, all training sessions were also filmed. The video recordings firstly synchronized with the sensor readings, were presented to experts who manually labeled them with actions performed during the exercises. The data were provided as CSV files.

The training and test data sets contain 20,000 rows and 17,242 columns each. A given row in a file corresponds to a short time series with length equal to approximately 1.8 s. The first 42 columns contain basic statistics (aggregations like mean, standard deviation, maximum, minimum, etc.) of data from sensors monitoring a firefighter's vital functions over the given fixed time period. The raw readings for the vital functions were recorded using Equivital Single Subject Kit (EQ-02-KIT-SU-4) fitted with two medical-quality ECG units, heart rate and breath rate units, and thermometers for measuring skin temperature. The remaining columns contain readings from a set of kinetic sensors attached to seven places on a body (torso, hands, both arms and both legs) identified as important during the realization of the main ICRA project's objectives. They are divided into 400 chunks that represent consecutive points in time. Each set is composed of readings from an accelerometer (dynamic bandwith: +/- 16G) and a gyroscope (scale up to 2,000 $deg/s$), therefore a total number of kinetic sensors are equal to 14. Each sensor of the both types (an accelerometer or a gyroscope) produces three readings $x, y, z$ corresponding to the tree dimensions, hence we have the total number of reading streams equals to 42. A single chunk of columns, therefore, consists of 43 numeric values, from which the first one is time from the beginning of the series and the following 42 values represent the readings from the accelerometers (measured in $m/s^2$) and gyroscopes (measured in $deg/s$). An average time difference between consecutive sensory readings in the data is 4.5 ms. The task is even more challenging since the training and test data sets consist of recordings from disjoint groups of firefighters.

The above description shows the details of the values arrangement in the provided data. We considered each row as a separate data set containing readings from many sensors. As described above, values from the vital sensors were aggregated externally, but the kinetic ones are provided in the raw form of time series. Let us present a fragment of an example in a visual form of data plots to better illustrate the amount of available data and their internal dependence. The references to the sensor readings are consistent with the naming from metadata provided by the organizers. There are seven places on a body that the sensors were placed on, i.e. left leg, right leg, left hand, right hand, left arm, right arm, and torso. The body areas corresponds to the following name prefixes:

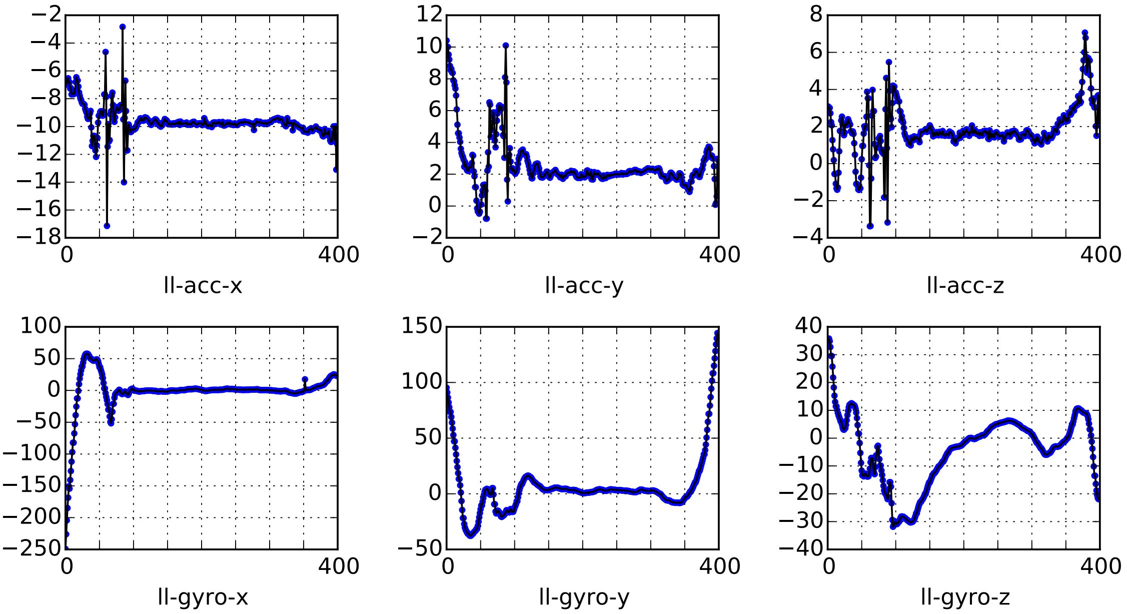

Figure 2. A fragment of an example row

$ll, rl, lh, rh, la, ra, torso$. An name infix *acc* or *gyro* refers to an accelerometer or gyroscope type of sensors. Finally, a suffix $x, y$, or $z$ names the axis from which the readings came from. In Figure 2 we present an example row that was tagged in the data with "standing" and "no_action" labels describing a posture of a firefighter and his current activity. The figure contain six time series (each consisted of 400 values that correspond to approximately 1.8 s) from the set of sensors placed on a left hand of a subject performing an exercise.

### B. Feature extraction

In the process of development of our feature extraction system we decided to follow the sliding window method. In general, for a given set of readings we put a window of a fixed *length* – the size of a window, i.e., a number of readings or a time interval, which travels through the values from the beginning to the end. We can control the amount of processed windows not only by setting the window length but also defining the *offset* for the consecutive windows – the extent to which the consecutive windows overlap to each other. Figure 3 presents four examples of sliding window set-ups. The first example, marked in red, shows the situation when the length of a sliding window is equal to the offset. The green and blue examples show the consecutive positions of a sliding window when the offset is equal to $\frac{1}{2}$ and $\frac{1}{3}$, respectively, of the length. The system is also capable to express the situation when the offset is greater than the length – the example marked in cyan.

For each basic window that is created during the process of moving a sliding window through the time series a defined aggregate function is applied. This step of the process may be adjusted for the actual task by supplying a specific implementation. The following list presents features which are calculated to represent the time series in a window:

- fill – a ratio of correct readings in the window $= \frac{nValid}{n}$,
- firstValue – a value of the first reading in the window,
- lastValue – a value of the last reading,
- max – a maximum value of the readings in the window,
- maxMinDiff – a difference between the max and min,
- mean – a mean value of readings in the window,
- min – a minimum value of the readings in the window,
- n – a total number of readings in the window,
- nValid – a number of valid readings in the window
- percentile25 – a percentile 25% for the readings,
- percentile5 – a percentile 5% for the readings,
- percentile50 – a percentile 50% for the readings (median),
- percentile75 – a percentile 75% for the readings,
- percentile95 – a percentile 95% for the readings,
- percentiles5Diff – a subtraction of the percentiles 95% and 5%,
- sourceFullId – a data source identifier included in the statistics of the window, e.g. ID or a name of the sensor,
- stdDev – a standard deviation of the readings,
- windowEndDate – a window end date
- windowEndMillis – an end timestamp of the window,
- windowMetaInfo – a meta information of the sliding window configuration, encoded in a form of a string, e.g. "o60l60" is equivalent to $offset = 60$ and $length = 60$,
- windowStartDate – a window start date,
- windowStartMillis – a start timestamp of the window,

A sliding window in a fixed position for which the aggregate function was applied and produced the statistics is referred later as a basic (or plain) window. An example of a basic window for an axis $x$ of the sensor placed on a left leg of a firefighter is presented in Table I.

For the purpose of the competition we have processed the data with three layouts of a sliding window. An illustration of our choice is presented in Figure 4. We have decided to

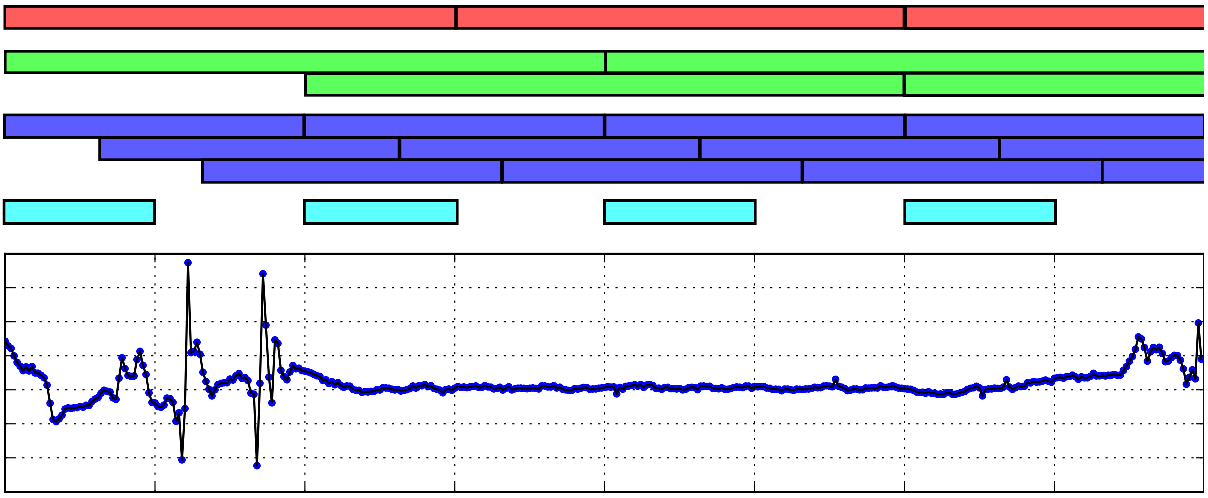

Figure 3. A set of examples showing the possible set-ups. Sliding windows are defined by a *length* and an *offset*. The length determines the size of a window, whether it is a fixed number of readings contained in a window or a fixed time interval. The offset is the extent to which the consecutive windows overlap to each other. The example marked in red shows the situation when the length of a sliding window is equal to the offset. The green and blue examples show the consecutive positions of a sliding window when the offset is equal to $\frac{1}{2}$ and $\frac{1}{3}$ of the length. The example marked in cyan illustrates the situation when the offset is twice as large as the length (or in general just greater) of a sliding window.

calculate statistics for each row by splitting each time series to 1, 2 or 5 consecutive non-overlapping windows.

We have described earlier in the section the capabilities of the feature extraction system to express different layouts of a sliding window in terms of its length and offset. If there is more than one window generated for the time series we can extract additional features in addition to those included in a basic window statistics. We have implemented also inter-window stats extraction, i.e., a set of values that express the changes between a pair of consecutive windows. We have introduced the following inter-window stats:

- firstFill – a ratio of correct readings in the first window,
- firstN – a total number of readings in the first window,
- firstNValid – a number of valid readings in the first window,
- firstWindowDate – a start date in the first window,
- firstWindowMillis – a start timestamp in the first window,
- maxDiff – a difference between *max* statistics in the windows,
- meanDiff – a difference between *mean* statistics in the windows,
- minDiff – a difference between *min* statistics in the windows,
- percentile25Diff – a difference between *percentile25* statistics in the windows,
- percentile5Diff – a difference between *percentile5* statistics in the windows,
- percentile50Diff – a difference between *percentile50* statistics in the windows,
- percentile75Diff – a difference between *percentile75* statistics in the windows,
- percentile95Diff – a difference between *percentile95* statistics in the windows,
- secondFill – a ratio of correct readings in the first window,
- secondN – a total number of readings in the second window,
- secondNValid – a no. of valid readings in the second window,
- secondWindowDate – a start date in the second window,
- secondWindowMillis – a start timestamp in the second window,
- sourceFullId – a data source identifier,
- windowMetaInfo – a meta information of the sliding window,

An example of the inter-window stats for an axis $x$ of the sensor placed on a left leg of a firefighter is presented in Table II. A sliding window configuration used in the example, i.e., the length of the window is equal to its offset, has produced two basic non-overlapping windows that split the time series from a given row into two halves.

| | stat | value |
|---|---|---|
| 1 | fill | 1 |
| 2 | firstValue | -7 |
| 3 | lastValue | -11.2 |
| 4 | max | -2.8 |
| 5 | maxMinDiff | 14.3 |
| 6 | mean | -9.6 |
| 7 | min | -17.1 |
| 8 | n | 400 |
| 9 | nValid | 400 |
| 10 | percentile25 | -9.9 |
| 11 | percentile5 | -10.8 |
| 12 | percentile50 | -9.8 |
| 13 | percentile75 | -9.5 |

Table I
AN EXAMPLE OF AGGREGATION FUNCTION COMPUTATION – A BASIC WINDOW STATS FOR THE FIRST ROW OF THE TRAINING DATA.

### C. Virtual sensors

According to the task description, the kinetic sensors (accelerometers and gyroscopes) used during the exercises have symmetric scales with 0 as their neutral reading. The specificity of the firefighter activities like walking, running, moving up the stairs or ladder, may cause the readings to be more

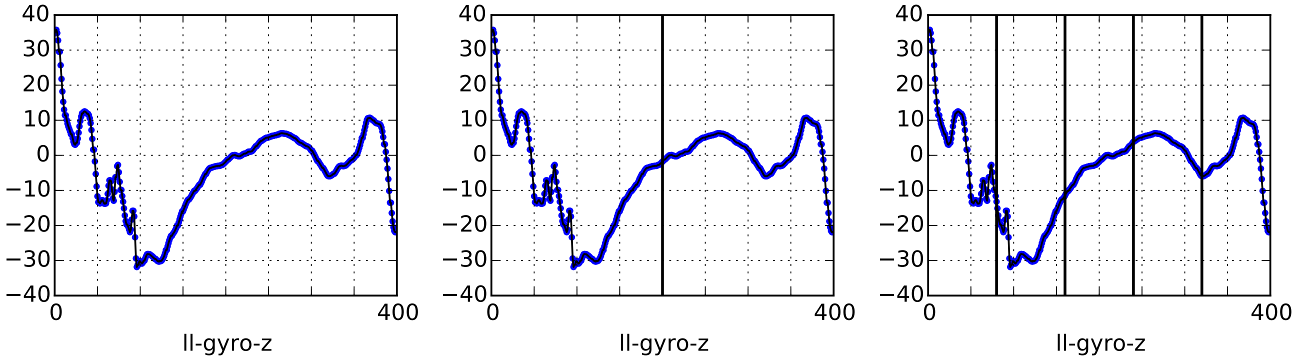

Figure 4. An illustration of the sliding window configurations applied in our solution. We have decided to process the time series with a varied granularity, ranging from the statistics computed for the whole time series, to calculate them for 2 or 5 shorter, non-overlapping windows which divided the time series to the parts of equal length.

| | stat | value |
|---|---|---|
| 1 | firstFill | 1 |
| 2 | firstN | 200 |
| 3 | firstNValid | 200 |
| 4 | firstWindowDate | 2015-05-03 00:00:00 |
| 5 | firstWindowMillis | 1430604000000 |
| 6 | maxDiff | 6.6 |
| 7 | meanDiff | 0.6 |
| 8 | minDiff | -4 |
| 9 | percentile25Diff | 0.3 |
| 10 | percentile50Diff | 0.2 |

Table II
AN EXAMPLE OF INTER-WINDOW STATISTICS

significant when considered as a group, e.g. a whole tuple $(x,y,z)$ from a given sensor rather than separate readings $x$, $y$, and $z$, to express the intensity of the movement. We have decided to introduce a concept of *virtual sensors*. Besides applying the aggregate functions to the original time series available in the delivered files, we have implemented an idea of creating artificial time series derived from the original ones. The virtual sensors are created on the basis of one or more time series from other sensors (whether original or virtual) after applying a particular function. In our solution, we decided to create virtual sensors for readings from all accelerometers and gyroscopes' axes separately, applying an *abs* (absolute value) function. We created also virtual sensors for readings grouped in tuples $(x,y,z)$ for each kinetic sensor – computing the Manhattan and Euclidean norms for the $(x,y,z)$ vectors. An example that illustrates the concept of virtual sensors that we have used in our solution can be seen in Figure 5.

After all basic windows for original and virtual sensors that comes from a given data row are calculated, they are joined (in the sense of appending all their values) together, forming a row of data that will serve as an input for further steps of data analysis and experiments.

## III. EXPERIMENTS

### A. Evaluation

The submitted solutions were evaluated using the balanced accuracy measure which is defined as an average accuracy within all decision classes. It was computed separately for the labels describing the posture and main activities of firefighters. The final score is a weighted average of balanced accuracies computed for those two sets of labels and is defined as follows:

$$score(s) = \frac{BAC_p(s) + 2 \cdot BAC_a(s)}{3}.$$

Where $BAC_p$ is the balanced accuracy for labels describing the posture and $BAC_a$ for the main activity. Precise definition of balanced accuracy is as follows:

$$BAC(preds, labels) = \frac{\sum_{1<i<l} ACC_i(preds, labels)}{l}$$

$$ACC_i(preds, labels) = \frac{|\; j : preds_j = labels_j = i \;|}{|\; j : labels_j = i \;|}.$$

### B. Constraints

We considered the competition as a good opportunity to verify the developed mechanisms of automation of knowledge discovery process and their usefulness in the production environment. Therefore, working on the solution we have imposed a few additional constraints and requirements. All have been set arbitrarily for the issue of labeling firefighters activity. We consider them to be satisfactory for the task:

1) Overall working time, to be spent on solving of the problem by all members of the research team must not exceed a total of 2MD.

2) The overall time required to train the classifiers must not exceed the total of 10 minutes. In case of classifiers which are mutually independent this is 10 minutes for training each of them, since the process can be run in parallel.
3) The time required to pre-process a single row of data to a format accepted by classifier and assignment of both labels must not exceed one second.

The first of the imposed restrictions is intended to help to verify whether it is possibile to immediately familiarize analysts with both data and the problems. In the simulated case, two analysts were working on adaptation of the data provided in the new format to the already existing mechanisms. Possibility to adapt quickly to new data and to new expectations while maintaining a satisfactory accuracy of the model is very important especially in the threats monitoring.

The second point poses a constraint on the time that is necessary to re-train the model on the new data, in case after a certain time the quality of the assessment has fallen below the a predetermined score level due to, e.g. concept shift/drift [6]. We assumed that the time required to re-training the model should not exceed 10 minutes. Nevertheless, we consider this point to be the least important and in our opinion exceeding proposed limit should not disqualify the approach. However, in the final embodiment, the total time of training classifiers did not exceed 7 minutes, wherein the classifiers are independent and can be trained simultaneously.

The last point we consider to be the most important because it imposes limits on the permissible delay in operation of preprocessor and classifiers when acting in a production environment. According to the assumptions maximum delay between data collection and complete processing and labeling of single row of data should not exceed one second. This is one of the main reasons for excluding from consideration all object based methods as well as heavy classifier ensembles. Generation of all the features, including those for both: raw and virtual-sensors readings, took approximately 450 milliseconds per a single csv file row. The postprocessing and assignment of the labels has been performed in the R - software environment for statistical computing and consisted of: importing data (overall 30 seconds per 20000 rows of test data set), feature selection (overall 10 seconds per 20000 rows of test set) and labeling (classification with SVM took overall of 70 seconds for both labels for 20000 rows).

### C. Post processing

Generated data sets have the following quantity of attributes for each of 20000 objects, depending on configuration:

- 2199 – one sliding window per short time series
- 6315 – two sliding windows per short time series
- 18663 – five sliding windows per short time series

Making a total of 27177 attributes [27] from the conditional- and inter-sliding windows constructed for both raw and virtual sensors. Elements of the automatic feature selection and reducing the number of attributes are in the study phase and still have not been introduced to the data processing mechanisms. Hence, the feature selection was carried out manually.

In a first step, all features exhibiting signs of identifiers and all constants values, that is: fill, n, nValid, sourceFullId, windowEndDate, windowEndMillis, windowMetaInfo, windowStartDate, windowStartMillis have been removed from the prepared data set. We have also removed maximum and minimum of values in windows to limit the influence of outliers on the final result. After applying the model on acquired attributes of training data set we have noticed that the model has been extremely overfitted. As the main reason for this, we find the fact that the training data set was prepared based on the observation of a small number of firefighters, hence data could not contain all possible patterns of motor behavior and vital signs. This observation led us to change our approach and forced to look for features that maintain a quality of prediction for test set.

In the process of feature selection we used a wrapper approach[13]. We have been progressively enlarging the number of utilized features and making periodic evaluations, after each step we have either remained the selected features or we resigned from them, depending on the result of the evaluation. Ultimately, the SVM was run on the 163 attributes for the classifier that labels the objects with posture and with one additional attribute (the computed posture label) for the second SVM model which classifies the data with a main activity. Beyond selected features in sliding windows, described in Section II final set of objects includes additional attributes to exclude the symmetry of right- and left-handed people e.g. the sum of the selected features for the left and right hand as well as sum for the left and right leg. This is very important since the training samples were created basing on the behavior of different people than the test samples. Moreover, training and test set data were acquired during observation of small group of firefighters, hence the training sample could not contain all possible patterns. The situation when training set differs significantly from the test set forced us to make additional step during verification of selected attributes.

### D. Classifier training and labeling

Because of the pre-processing of data that has been provided in the competition, the real problem of monitoring the firefighters activities, which is originally associated with processing of streams of sensor readings [10] that constituting time series [2], has been reduced for the problem of classification [25], more precisely to multi-labeling [26]. Original sensor readings has been pre-processed and subdivided into frames [21], [28] of given length and made available in a csv file. To apply the developed feature extraction mechanism each row of the csv file has been split into short time series of readings from sensors respectively to csv header names: "ll-acc-x", "ll-acc-y", "ll-acc-z", etc. and passed as an input stream to the feature extraction mechanism. Eventually, we obtained a set of elaborated features ready for multi-labeling [14].

During data analysis, not only the conditional variables have been inspected but also posture and activity labels. The preliminary conclusions of labels aggregation allowed to state that there is a huge imbalance [29] in classes defined by

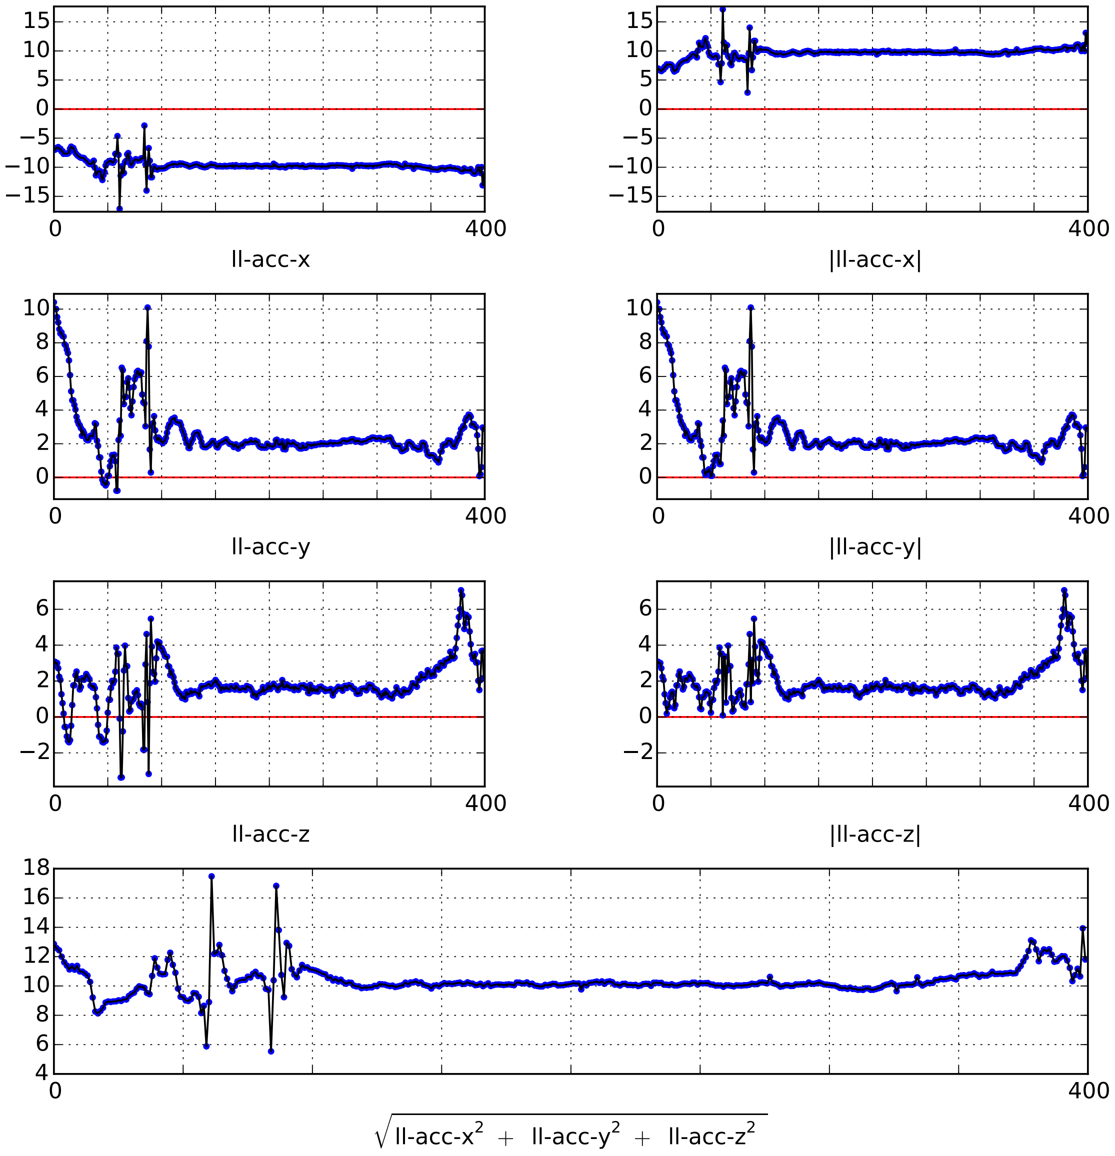

Figure 5. An example of deriving virtual sensors by applying an absolute value function and the Euclidean norm to the original time series.

particular labels and that the labels for firefighters posture and activity are not independent [20] and there is a connection between them [19]. The application of label power-set methods [23], [30] did not provide satisfactory results but classifier chains[22] improved the achieved score significantly. The way in which assessment of solutions was defined, that is uneven importance of labels for posture and activity encouraged to consider various concepts like a multilabel classification with label ranking [9] or a graded multilabel classification [5].

Experiments have been implemented and carried out in the R software environment. We have experimented with the following classification algorithms: rPart (decision trees [4]), rFerns (random forests [3]) and e1071 (support vector machines [1]). The final solution is based on SVM. While learning classifiers we have used the relationship between labels by training two SVM models on slightly different data.

Model 1, which recognizes posture, is SVM with 4356 support vectors. Model has been trained on the basis of the features described above with the default parameters, that is:

- SVM-Type: C-classification
- SVM-Kernel: radial
- Cost: 1
- Gamma: 0.006134969

$$model1 \leftarrow svm(posture \sim .,$$
$$data = trainSet[,c(selectedFeatures, posture)]);$$

Model 2, which recognizes the main activity, is SVM with 5011 support vectors. Model has been trained on data enriched by the posture label with the default parameters, that is:

- SVM-Type: C-classification
- SVM-Kernel: radial
- Cost: 1
- Gamma: 0.005952381

$$model2 \leftarrow svm(activity \sim .,$$
$$data = trainSet[,c(selectedFeatures, posture, activity)])$$

During labeling, data were firstly described with the posture label, and after that with the main activity label:

$$testLabelsForPosture \leftarrow predict(model1,$$
$$newdata = testSet[,selectedFeatures],$$
$$type = "class");$$
$$testSet\$posture \leftarrow testLabelsForPosture;$$
$$testLabelsForActivity \leftarrow predict(model2,$$
$$newdata = testSet[,c(selectedFeatures, posture)],$$
$$type = "class");$$

## IV. DISESOR

The most significant application of the presented solution for automated feature extraction is the ongoing DISESOR project. DISESOR aims to build a decision support system for threats monitoring and early warnings in coal mines.

Nowadays, the coal mining is playing a crucial role on Polish energy market and is employing hundreds of thousands of people. Coal mines are well equipped with monitoring, supervising and dispatch systems connected with machinery, devices and transport facilities. There are a lot of systems that support essentially different aspects of the mine operation, e.g.: ARES, ARAMIS, HESTIA for seismo-acoustic monitoring; RODOS, ALFA for quality control, MAKS, Ergon, Hades for machinery monitoring; SMP, STAR, CTT, UTS, Venturon, Univers for risk control, ZEFIR, THOR, sD2000 - central systems and many, many others. Each of these gathers readings from specific sensors placed in mines, depending on their domain: methane sensor, $CO$ and $CO_2$ sensor, seismic sensor, shearer state sensors etc. Assembly of a variety of data from multiple systems enables performing a wide-ranging analysis.

Monitoring systems are developed by many providers what causes problems with integration and proper interpretation of the data, therefore there is need to deploy a decision support system integrating different aspects of coal mine operations, what is the main task of the DISESOR system. The high level design of DISESOR takes into account the data cleaning process, the process of building data mining models and online predictive reasoning for the latest data readings. The most important use cases of the DISESOR system are:

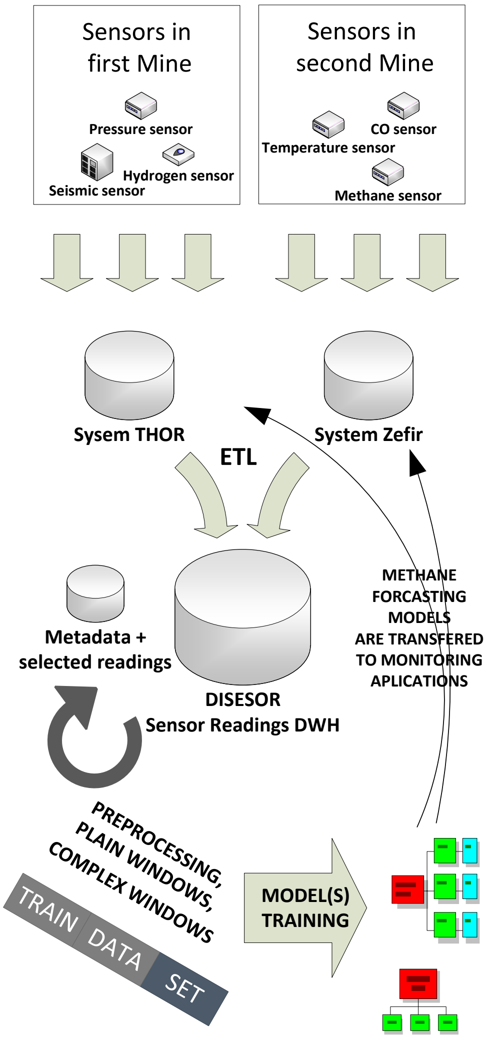

Figure 6. DISESOR ETL process collects sensor readings from mine monitoring systems like THOR or ZEFIR. Raw data is cleand and after preprocesing predictive models are generated.

- The assessment of seismic hazard probabilities in the vicinity of the mine.
- Forecasting dangerous increase of the methane concentration in the mine shafts.
- Detection of endogenous fires and conveyor belts fires.
- Detecting anomalies in the consumption of media.
- Diagnostics of machines: roadheaders and shearers.

## V. Conclusions and Further Research

The developed feature extraction system can be configured to accept a data set consisted of readings from multiple sensors. The algorithm that builds sliding windows divides reading streams into consecutive fragments and then processes each of them separately. This approach allows for effective parallelization of the whole feature extraction process. However, there are some important issues that have not been addressed in a prepared solution or have been taken into account in a very simplified manner, e.g. a quantization of real value attributes [17], [18] or an attribute selection [7], [12] which we recognize as very important elements of a knowledge discovery [15] process. We are going to extend the discussed mechanisms with modules covering those issues in the nearest future.

The conducted experiments showed that the features prepared by the elaborated mechanism are suitable for machine learning algorithms, which in the next step can give very promising results without neither long lasting manual data cleaning nor classifier tuning. The results of experiments turned out to be significantly better than the baseline solution. Therefore, it seems that the elaborated system is prepared to work in production. However, there is still a lot of space for further improvements since results achieved by other participants in case of manual transformation of data and tuning of classifiers turned out to be even better.

***Abstract*—During the recent decade we have experienced a rise of popularity of sensors capable of collecting large amounts of data. One of most popular types of data collected by sensors is time series composed of sequences of measurements taken over time. With low cost of individual sensors, multivariate time series data sets are becoming common. Examples can include vehicle or machinery monitoring, sensors from smartphones or sensor suites installed on a human body. This paper describes a generic method that can be applied to arbitrary set of multivariate time series data in order to perform classification or regression tasks. This method was applied to the 2015 AAIA Data Mining Competition concerned with classifying firefighter activities and consecutively led to achieving the second-high score of nearly 80 participant teams.**

## I. Introduction

IN THIS paper I present a generic approach to classification of multivariate time series data. This approach was developed and evaluated in the context of the 2015 AAIA Data Mining Competition, where it led to the second highest score of nearly 80 solutions.

During the recent decade we have experienced a rise of popularity of sensors capable of collecting large amounts of data. One of most popular types of data collected by sensors is time series composed of sequences of measurements taken over time. With low cost of individual sensors, multivariate time series data sets are becoming common. Examples can include vehicle or machinery monitoring, sensors from smartphones or sensor suites installed on human body. The collected measurement data is typically not directly useful to the users, as it consists of typically a large number of data points and is very noisy. It should be processed and transformed into knowledge that can be useful to the user. Because of the sheer volume of the data and typically non-trivial patterns present in data this task is suitable for data-mining approaches. In fact in recent years we observe a significant increase of applications that rely on data mining to interpret sensor data and provide useful and actionable knowledge to the users. One of such areas is human body monitoring that can be valuable for healthcare applications, such as post-surgery patient monitoring, monitoring patients with chronic diseases and general well-being promotion, among others.

In this paper the time series data was generated by a sensor suite worn by firefighters during training sessions. The main focus will be on time series generated by a set of accelerometers and gyroscopes installed on different parts of human body. The data generated by sensors will be used to fully automatically identify activities performed by a subject such as running, climbing a ladder, etc.

The rest of the paper is composed as follows: in the next section the competition task will be introduced with details of the sensors, available data and the evaluation. In the following section I will discuss the proposed approach to classification of multivariate time series data. Consequently each step in of the proposed approach will be discussed in more detail: feature engineering, feature selection, and actual classification. I will finish the paper with a short discussion.

## II. The Competition Task

This paper describes a solution to the AAIA‘15 data mining competition [1] was organized using the Knowledge Pit competition platform [2]. The objective of the competition was to develop efficient methods for automatic labeling of short series of the sensory data in the context of firefighter training activities.

The basic task of the competition was to create a data mining model to predict training activities performed by a firefighter based on data collected from sensor readings installed on the firefighter body. For this purpose a commercial off-the-shelf body sensor suite was used to generate the data.

### A. Data

The data for the competition was generated using *smart jacket* – a wearable set of body sensors for monitoring kinematics and psycho-physical condition of firefighters. For each record the data was divided into two subsets.

The first subset consisted of 42 columns that represented aggregations of data from sensors monitoring firefighter‘s vital functions. Examples of measurements taken are ECG, heart rate, respiration rate, skin temperature, etc. The data for those measurements was pre-processed by the organizers and made available in the form of statistics (mean, standard deviation, skewness, etc.) rather than time series.

The second subset of data consisted of a set of 42 time series, each consisting of 400 data points. The time series was generated by a set of accelerometers and gyroscopes.

978-83-60810-66-8/$25.00©2015, IEEE

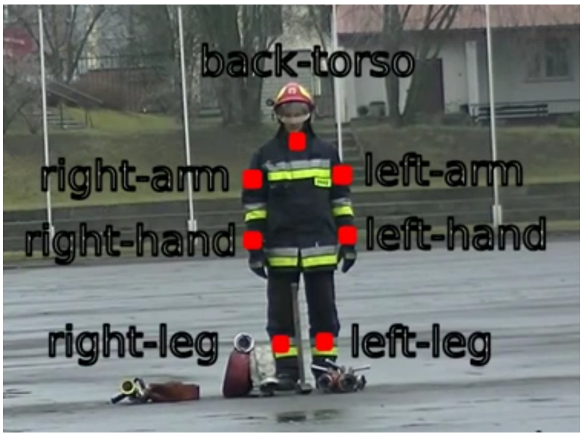

Fig. 1. Distribution of sensors on a firefighter body.

There were 7 pairs of accelerometer-gyroscope installed on firefighter‘s body. The locations of the sensors are shown in Figure 1. Each pair of sensors generated 6 data streams ($x$, $y$, and $z$ axes for an accelerometer and $x$, $y$, and $z$ axes for a gyroscope). The 400 points corresponded to approximately 1.8 second period of continuous measurement. Since the measurements in the time series were not taken in equal intervals (but all of them were taken at the same time for a given set of 42 time series), the the organizers provided a set of 400 time stamps that corresponded to time of measurements.

In total a data record consisted of 17,242 columns, all of them were real numbers.

There were two class attributes associated with data record. They related to activities during the firefighter's training. The first attribute was the body posture that had 5 states: *standing*, *stooping*, *moving*, *crawling* and *crouching*. The second attribute related to the main activity with 16 different activities, such as *no action*, *walking*, *running*, *searching*, *stairs up*, *manipulating*, *throwing hose*, etc.

The data sets consisted of 20,000 training records and 20,000 test cases that were collected during firefighter training. Multiple firefighters participated in data collection.

### B. Evaluation

The evaluation of the model performance was determined using the score $s$ which was defined in the following manner:

$$s(p, y) = \frac{1}{3}\big(BAC_p(p, y) + 2 * BAC_a(p, y)\big),$$

where $BAC_p(p, y)$ and $BAC_a(p, y)$ are *balanced accuracies* for posture and main activity respectively, determined for a set of predictions $p$ given true labels $y$. The balanced accuracy $BAC$ is defined as as the average of accuracies for individual labels. Let $l$ be the number of all possible labels, then the balanced accuracy is defined as follows:

$$BAC(p, y) = \frac{1}{l}\sum_{i=1}^{l} ACC_i(p, y),$$

where $ACC$ is accuracy for a given label $i$ and it is defined as:

$$ACC_i(p, y) = \frac{|j : p_j = y_j = i|}{|j : y_j = i|}.$$

The goal was to propose a model that would generate a set of predictions $p$ for the cases for which are known true labels $y$ in order to maximize the score $s$. The true labels were known only to the organizers, but not to the competitors. The competition platform was used to present provisional evaluation results based on the subset of the actual evaluation set. The final evaluation was made on the remaining test data set.

## III. Solution Overview

In this section I present overview of the solution to the competition task that I developed. The basic steps are presented in Figure 2.

The first, and probably the most critical step was the feature engineering step. At this step the original data set was converted to a secondary data set that consisted of the features generated from the time series data. This step is discussed in detail in the Section IV. It is important to note, that I decided to reject the features related to firefighter's vital measurements and I completely relied on data generated by kinetic sensors. That meant that the data used consisted entirely of a set of 42 time series, each of the same length and all of coupled. The next decision was to ignore time stamp data and to assume that measurements were taken in equal intervals. This decision was dictated entirely by desire to simplify the data processing.

There was another important decision related to data preprocessing I made: I decided to collapse two class attributes into one. Initially, I approached the two class classification problem as two independent classification problems – building two two models one for body posture and the other for activity, with no information shared between the two models. However, I noticed that even though theoretically there were $5 \cdot 16 = 80$ possible states of combined class attributes, in practice only 24 were present in the training data set, which was only slightly higher than the number of states for the second class attribute. Using one class attribute led to dramatic increase of classification performance.

As the competition progressed and the number of features increased, it has become clear that feature selection step would provide benefit. Toward the end of competition a typical features data set would consist of 4,000 to 8,000 attributes. By experimentation it has become clear that reducing the number of attributes to the number between 200 and 600 would clearly improve classification performance. I used a feature selection algorithm to reduce the number of features. It turned out that selecting different number of features from the same feature data set can have quite profound effect on the classification performance. Feature selection led to generation of the reduced feature data set that was used for actual classification task.

As the basic classifier I used combination of the Random Forest classifier with the Multi-Class classifier that converted multiple class problem into set of forests each corresponding

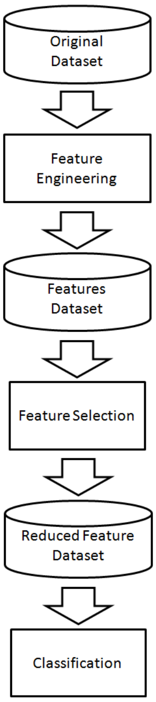

Fig. 2. The outline of the basic tasks used during the competition.

to a set of binary problem Random Forests. I experimented with other classification algorithms available in Weka such as Neural Networks, Logistic Regression, Naive Bayes, Decision Trees, Support Vector Machines, but all other algorithms seemed to perform significantly worse or were taking too long to finish. I did not attempt to compensate for imbalanced distribution of attribute classes.

For feature selection and classification I used Weka software [3]. The feature engineering step was performed using my own code written especially for the purpose of the competition.

For the sake of competition I decided to ignore checking my results for over-fitting. This decision was made strictly for pragmatic reasons – initial attempts to cross-validation did not seem to be representative to the results obtained on the leaderboard. The models that were achieving 100% accuracy on the test set seemed to perform better on the leaderboard than those with lower accuracies on the test set. Obviously, getting the right prediction of the accuracy error would likely lead to improved results, but because of the limited time I wanted to spend on the competition and the fact that it was possible to test results using the submission system I did not focus on getting proper handling of over-fitting.

## IV. Feature Engineering

The first step in data pre-processing was transformation time series data into a set of numerical values that would summarize different aspects of the time series data. This step is commonly referred as *feature engineering*. The features can be derived from individual time series (e.g. mean, standard deviation) or from some form of a function that can take more than one data series (such example can be a correlation coefficient between two time series).

### A. Original signals

For the feature engineering I used the original 42 time series (generated by accelerometers and gyroscopes). I ignored the time stamps provided and assumed that the measurements are taken in equal intervals.

### B. Derived Signals

For the feature generation I decided to use additional time series data that were derived from the original time series. In particular, I combined $x$, $y$, and $z$ coordinates using Eucleadian norm for each of the accelerometers and gyroscopes, which led to additional 14 derived time series.

### C. Extracted Features

For each of the time series (either original or derived) the following features were extracted:

- the mean value
- the maximal value
- the minimal value
- the range (difference between the maximal and minimal values)
- the sum of squared values (mean power)
- the logarithm of the sum of squared values (log mean power)
