- the standard deviation
- skewness
- kurtosis
- the 5th central moment
- the maximal difference between two consecutive measurements
- autocorrelation taken at $t$=1,2,5,20, and 50
- power for the bin with the maximal value (power) Fast Fourier Transform (excluding the zeroth frequency)
- maximal value of frequency (in the form of an index) for the bin with maximal value for Fast Transform (excluding the zeroth frequency)
- slope and intercept for the linear regression
- mean square error for the linear regression
- parameters for polynomial fitting with $n = 2$ $(a_0, a_1, a_2)$

Each of the above features generated a single number that was used as an individual feature for further analysis. This produced 1400 features.

### D. Correlations

Finally, I decided to add correlation coefficients between time series. I did it for the original and derived signals separately, that led to 861 features and 91 features, respectively.

## V. Feature Selection

The feature selection has quickly become a necessity as the number of features in the feature set increased. I tested various feature selection algorithms available in Weka. The best results were achieved with the `CfsSubsetEval` algorithm.

The algorithm determines the worth of attribute' subsets by considering the individual predictive ability of each attribute along with the degree of redundancy between attributes in the subset. Subsets of features that are highly correlated with the class while having low inter-correlation are preferred. The Weka's default best first search method was used with default parameters. I used 10-cross validation.

One of the challenges was to decide on the actual number of features to be used. For the winning solution, the feature data set had 2352 features. The 10 runs of cross-validation for feature selection resulted with 541 features that were selected by the feature selection in at least 1 fold. However by trying only those features that were selected at least in 8 out of 10 folds, turned out to result with better prediction score. This resulted in the reduced set having 394 attributes for the best score I could achieve. I did not have chance to explore the effect of the number of features further, but clearly it may have been an important factor.

## VI. Classification

I used Random Forest [5] as the basic classifier. An interesting twist was applying a multi-class meta classifier which resulted with a classifier that had multiple Random Forests, one for each class. This approach was effectively comparing the class records vs. remaining records for each class. This step, although not strictly required, resulted in improved classification score.

One of the challenges with applying Random Forest effectively is selection of optimal number of features used for each tree. In the case of competitions it is typically done by trial and error approach. That was the case in this case – I experimented with different numbers of features per tree and for the particular feature set the numbers between 40 and 80 features seemed to work well. For the best score I could achieve, each Random Forest had 1000 trees. The number of features for each tree was limited to 40.

## VII. Conclusions

In this paper I presented an approach to classification of multivariate time series. The approach was developed for the data mining competition and this approach led to scoring the second high result from nearly 80 solution.

I believe that the approach presented in this paper can be easily generalized to similar problems for which multiple measurements in form of time series are available. It should be expected that different features may turn out to be more predictive or even different classifier may prove to be more suitable. Actually, the author used this approach to another competition where the method allowed to achieve the highest score of nearly 50 submitted solutions.

## Acknowledgment

The author would like to thank to Krasin Georgiev for inspiring discussions.

***Abstract*—This paper describes authors' solution to the task set in *AAIA'15 Data Mining Competition: Tagging Firefighter Activities at a Fire Scene* (https://knowledgepit.fedcsis.org/contest/view.php?id=106). Method involves LDA classification on a preprocessed time series data with a unique label transformation technique using K-Means clustering. Data were collected from accelerometer and gyroscope readings.**

## I. Introduction

ACTIVITY recognition of a person using motion data aims to label actions and activities. The task has applications in medicine, sports and surveillance, depending on the technology used. One of the most interesting approaches is sensor-based human activity recognition using data collected from accelerometer and gyroscope readings. By applying machine learning methods to the time series data and labels prepared by the experts, it becomes possible to classify a single person's motion or more general set of motions that can be assigned to a specific group, for instance: firefighters. With the use of a tracking system we can monitor their position and infer potential threats during the action. Such classification task was introduced to the contestants of *AAIA'15 Data Mining Competition: Tagging Firefighter Activities at a Fire Scene* [1].

The organizers provided contestants with data generated by ”smart jacket”—a wearable set of body sensors for monitoring kinematics and psychophysical condition of firefighters. The sensors were registering firefighter's vital functions (i.e. ECG, heart rate, respiration rate, skin temperature) and movement (i.e. seven sets of accelerometers and gyroscopes placed on torso, hands, arms and legs).

Each row represented a window data. The consecutive devices' data were placed one after another, creating 17242 elements long row. First 42 elements described vital functions and last 17200 elements (43 chunks of 400 readings) - the movement. One chunk stood for the time between a reading and the start of time window. The window data consisted of triaxial readings (from every accelerometer/gyroscope) that were collected during the 1.8s period (every 4.5ms, on average). Figure 1 presents some window data from three accelerometers. The importance of Z axis (for the classification of posture) can be easily noticed (torso). We can observe long right leg motion that started the whole body move, and during it, a short and firm motion of the left leg appeared. It is already hard to link it to any of the postures, but it can be interpreted as three-step move (right leg → left leg → right leg). Torso Z axis (blue) reading points out a motion toward bottom that was disrupted when left leg slowed down. It is probably crouching. Similar analysis can be performed for the activity label, but it seems to be a much more complicated task.

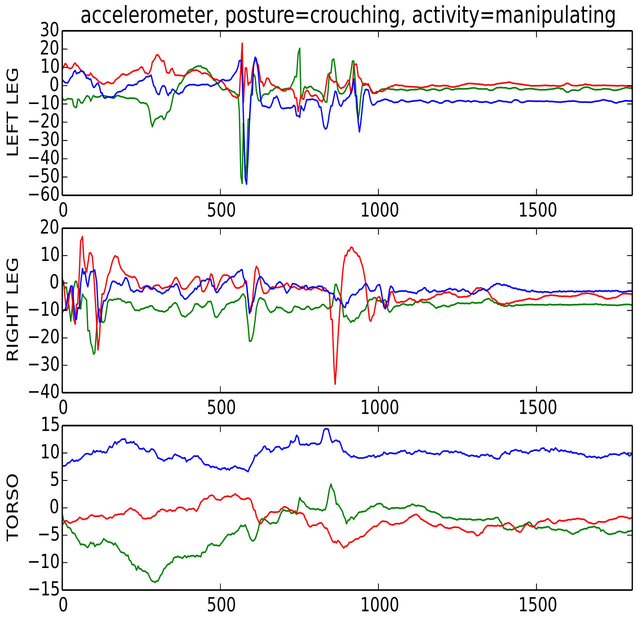

Fig. 1. Triaxial accelerometer readings from different body parts.

There were three sets of data: one training (20000 rows) and two testing datasets (respectively 2000 and 18000 rows). The first testing dataset was a random selection of observations from a bigger set (20000 rows) and obviously the second one was only the remaining part. All the data were labeled by experts. There were two labels (posture and main activities). The task was to find a classification method that maximizes the *score* value. The contestants had to compute (a solution $s$ that consisted of) two vectors of label predictions (a matrix with two $preds$ columns). Each one was compared to the proper

978-83-60810-66-8/$25.00©2015, IEEE

vector of label values (from a matrix with two $labels$ columns) to calculate the final score in the following manner: for $l$ - total amount of label values, $i \in \{1, \ldots, l\}$ (if we replace names with numbers) and $j \in \{1, \ldots, 18000\}$ we have

$$ACC_i(preds, labels) = \frac{|\{j : preds_j = labels_j = i\}|}{|\{j : labels_j = i\}|}$$

$$BAC(preds, labels) = \left( \sum_{i=1}^{l} ACC_i(preds, labels) \right) / l$$

and we denote by:

$BAC_p$ – balanced accuracy for labels describing the posture,
$BAC_a$ – bal. acc. for labels describing the main activity,

then the final score in the competition for a solution s will be computed as:

$$score(s) = (BAC_p(s) + 2 * BAC_a(s)) / 3.$$

To gain satisfactory performance and reduce the amount of data needed to perform the task, authors proposed the following steps:

1) preprocessing - data columns were processed to produce new and less numerous set of columns;
2) label transformation - new data, original labels and K-Means clustering method were used to generate new and more numerous set of label values;
3) classification - new data and new label(s) provided input for learning. The resulting classifier allowed authors to predict new label values for testing set (testing data had to be transformed in the same way as the training data in the preprocessing stage). In the end these new label values were translated to original label values.

It's important to notice that authors' method requires every new dataset to pass the preprocessing stage, because the classification is performed on the preprocessing's output. Clustering is perfomed (only once) for the training dataset.

## II. Related work

There are various approaches to the problem of activity recognition, for instance: feature extraction ($FE$) using moving window over time series and subsequent matching. The raw data are converted differently and treated as input for the main processing. Many works describe sensor-based systems, e.g. [2], Their authors create usually specific set of devices (including accelerometers) to collect data for a model training. The data can be collected from one or more subjects. Using more than one subject can significantly affect the overall accuracy. In paper [4] authors contribute a linear-time method for extracting features from acceleration sensor signals in order to identify human activities, that is based on Support Vector Machines ($SVM$) classifier with a linear kernel. For three types of activities they gained high accuracy ($> 92\%$ for each one), when one person's activity was the data source. When the number of subjects was increased by 4, they gained about $10\%$ loss. The amount of 20 was critical for the efficiency in the case of one of these activities (the accuracy decreased to $16.67\%$). The loss is serious, but it must be considered that if we produce realtime systems, it is expected to prefer simpler but robust systems.

Feature extraction is used to produce new attributes and is usually combined with machine learning algorithms. It is supplied with the data in a form of windows that were collected arbitrarily from the raw dataset. Every window includes readings from devices and is converted to one row usually by setting readings one after another.

Authors of [6] present the whole procedure from receiving the acceleration signal to the final classification. The simplest method is to transform every window to a vector of statistics. More sophisticated methods include Principal Component Analysis ($PCA$), Linear Discriminant Analysis ($LDA$), Fourier Transform or Autoregressive Model. There are various techniques to enrich context awareness by adding enviromental variables and analyzing vital signs, but there are no effective techniques to automatically select windows or choose proper windows length. The size of a window is strongly related to the activity and type of extracted features. Authors mentioned windows from 0.08 up to 30 seconds long which they found during their research. It is also needed to reject attributes that contain redundant or irrelevant information and perform Feature Selection ($FS$). The common method is Minimum Redundancy Maximum Relevance [7], which minimizes average mutual information between selected features and maximizes mutual information between classes and features. There are many different algorithms applied to the learning stage, including decision trees, Naive Bayes, Bayesian Networks, $SVM$, Hidden Markov Models, regression methods and $k$ Nearest Neighbours ($kNN$). The most standard evaluation metric is the $accuracy$ measure, which is the total fraction of correctly predicted label values.

In subsequent matching we introduce time series set of patterns and use some technique to measure similarity like distance measure (Euclidean, cosine etc.). There are effective ways to handle shifts by using Dynamic Time Warping (as in [2]). Since it is not a statistical approach, the pattern data should be carefully chosen. The choice is much more difficult, when the data are noisy and variations within classes are large.

Some authors include (to the moving window approach) special representation like bag-of-features (BoF) representation [5], which produces local features vectors out of windows smaller than the activity vectors itself, that allow them to create a "motion" vocabulary. The authors even compare their framework to another obtained using subsequent matching approach. Across all vocabulary sizes, the average misclassification error for subsequent matching approach ranges from $37\%$ to $54\%$. Although the BoF framework performs better for almost every size value, it is more important that it becomes stable in the sense of the misclassification error (for the vocabulary sizes of 50 and more, the variation decreases significantly).

## III. Clustering approach to the competition task

The basic strategy of finding the best solution was to follow the *score* value changes and apply such method modifications that brought even small improvement. In general, it was indeed a trial and error approach. It should be emphasized that the training dataset and test dataset were obtained from recordings of different groups of firefighters and that fact could lead to overfitting issues making crossvalidation useless (such situation is mentioned at the end of (III-A)).

After simple preprocessing stage (that is described in next paragraphs) the calculations were performed for different classifiers and three most efficient were left for further research. Those three classifiers used $LDA$, $SVM$ and $kNN$ algorithm. When authors decided to include label transformation, they left only $LDA$ and $SVM$ classifiers (and examined the performance of $SVM$ classifier with One vs Rest strategy). When there was no $score$ improvement some simple modifications of the preprocessing stage were included (by adding more statistical values to the set).

The three-step method is based on the feature extraction approach. Authors had no previous experience and wanted to introduce themselves to this kind of methodology. Preprocessing stage consists of generating statistical values and scaling. Each row is taken and reshaped to a matrix that represents a window data. We count $10$ statistics and scale columns separately (by substracting mean and dividing by standard deviation). We obtain new data and cluster observations to create new labels. The algorithm for creating new labels requires two kinds of data: label values and labels from the clustering. K-Means clustering method was chosen. The algorithm produces vector of new label values. The new training data and the new label values are an input for machine learning algorithms. Before the testing stage it is necessary to preprocess the testing data the same way as described above. When we have trained the classifier and produced new testing data we can perform prediction. The label values that we obtain are the ones that need to be translated to the original values.

### A. Preprocessing

Authors decided to choose only movement data for the learning process. Due to time constraints and other obligations there was no opportunity to focus on vital data, which seemed to be much more complicated to analyze.

Each row in dataset represeted one observation. There were a total of $42$ devices (accelerometers and gyroscopes), which generated simultaneous data for a short period (every row was reshaped to a window that had $42$ time series columns). Each time series column consisted of $400$ readings.

$$(D_1, \ldots, D_{16800}) \to$$
$$\to \left| D_{(i \bmod 400+1)(i \operatorname{div} 400+1)} \right|_{i=1,\ldots,16800}$$

The starting point was to keep all the $42$ sources of data, but it had to be preprocessed to lower its dimension. For each device and axis data there were created $10$ new attributes (minimum, maximum, mean, standard deviation, first quartile, median, third quartile, interquartile range, skewness and kurtosis). If we introduce some simplification and write that $D^{jk}$ stands for a column of $j$th device's $k$th statistic value (for every observation), then we can easily write new dataset as

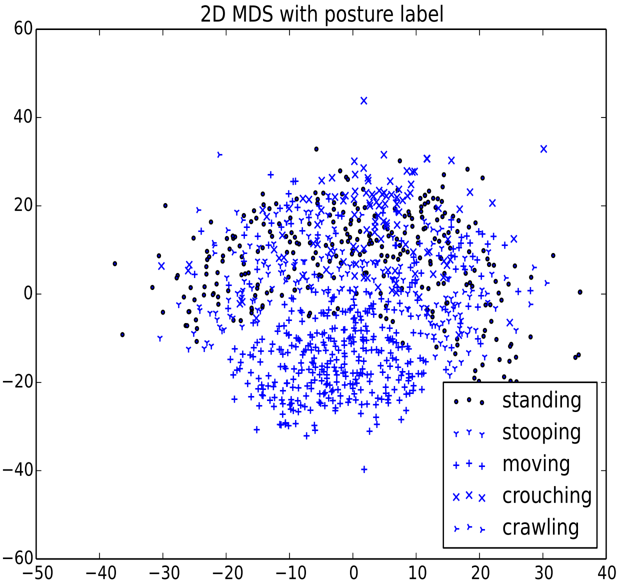

Fig. 2. The result of 2D MDS with posture label.

$$D = (D^{jk}),$$

for $j = 1, \ldots, 42$
and $k \in \{max, min, std, q25, med, q75, IQR, skew, kurt\}$.

$D$ consisted of $420$ columns, where every $D^{jk}$ was standarized.

When a crossvalidation was performed (using randomly selected halves of the unstandarized data), the crossvalidation $score$ values were always greater than $0.9$. Using the same classifiers to generate solutions ended up with receiving competition $score$s around $0.2$.

When the final classifier set was chosen, a new (ineffective and finally abandoned) strategy was introduced to improve the $score$ by adding new quantiles ($0.1$ and $0.9$ quantiles and/or $0.4$ and $0.6$ quantiles).

### B. A premise to label modification

It was an original authors' idea to improve $score$ by transforming the given set of label values. Furthermore, a new set of label values had to be generated according to the new data $D$. The foundation of this procedure lies in assumption that some of label values form too vast data aggregates due to physical differences between firefighters (there was no information about the number). The task would be much more complicated if these aggregates were intermingled. Multi-Dimensional Scaling (MDS) gives some insight into data structure. Figure 2 shows two-dimensional MDS performed on $D$ ($1000$ observations) plotted with distinction on the first label values.

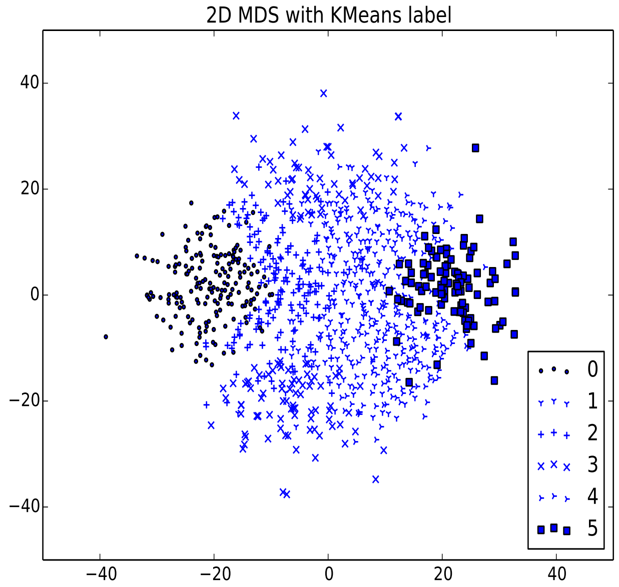

Fig. 3. The result of 2D MDS with K-Means label.

Most of the elements labeled as 'moving' form a structure that is easily separable. On the other hand, if we consider 'standing' posture there is no compact subset that could be separated from other points. It is important to note, that correspondingly larger weights are assigned to smaller sets (for the purposes of *score* evaluation), then any dispersion should be treated as equally serious. Therefore there is strong reason to think that this kind of posture could be difficult to classify. If we label previous data with K-Means (for $k = 6$, Figure 3) we get another graph that strongly indicates existence of apparent groups. It should be understood that the example is only an outline to the idea and does not imply any general statement. Similar proceedings can be made for the main movement label. There would be some clarity issues with plotting (16 values to be marked), so authors decided to leave it. Obviously, the actual calculations for the second label were performed and the resulting graph points to the same conclusions.

### C. Label transformation

K-Means clustering was performed on $D$ and it tagged observations with $CLV$ labels. To generate the label for further training we needed original label values $LV$. Both $CLV$ and $LV$ were vectors of equal length of 20000. We got two mappings

$$D \xrightarrow{K-Means} CLV,$$

$$(LV, CLV) \xrightarrow{algorithm} NLV.$$

### D. Algorithm

K-Means algorithm (python's $sklearn.cluster.KMeans$ implementation which uses $kmeans{+}{+}$ algorithm for choosing initial seeds) allowed us to label observations. The second mapping was carried out as shown in Algorithm 1.

**Algorithm 1** The algorithm for creating a new label

```
Require: $LV$ (names replaced with numbers), $CLV$
Ensure: $NLV$
  Find the length $lenLV$ of $LV$ vector
  Create $NLV$ vector with the length equal to $lenLV$
  for each unique $i \in LV$ do
      Create $l\_num$ vector of every observation number
      that has its $LV$ equal to $i$
      Create $l\_list$ vector by finding all unique $CLV$s
      within the observations with numbers from $l\_num$
      Create a dictionary $dict$ with keys from $l\_list$, such that
      for an element $l\_list[j]$ assign a value of $(lenLV \cdot j + i)$
      for each consecutive $k$ from $l\_num$ do
          $NLV[k] \leftarrow dict(CLV[k])$
      end for
  end for
```

To find the best $k$ value authors proposed to seek for a local maximum within a tiny range of small $k$ values (from 2 to 8). There were only 13 test computations at all, because prediction of values can be done separately for every label. We set one $k$ value (for one label and other $k$ was fixed for the remaining label), performed clustering, learning (and classification) and then checked the *score* of our prediction. The maximum *score* (one of seven) indicated $k$ value, which we treated as optimal value and from this moment this $k$ value was fixed. If we found more than one maximum *score*, then we would chose the one with the smallest $k$ value. The *score* maximum for the second label indicated a pair of $k$ values (the one fixed and the new found) that was the optimal choice. Finally, $k = 6$ was selected for the first label and $k = 5$ was selected for the second label.

When the $k$ value was chosen, it was necessary to create and preserve a dictionary to be able to translate every new label value to the original label value. The other way was to propose a method that did employ the clustering to the testing stage, but authors wanted to avoid such requirement. If our machines provided better computing performance we would examine larger range of $k$ values. Then, if the optimum was very high, the computing time would be significantly extended (and the clustering would have to be performed twice, if we included it into testing stage). Due to possible practical applications such effect is not expected.

The probability distribution of the new label seems to be quite obvious to count. If we assume that $lv_i$ stands for $i$th possible label value and $clv_j$ stands for $j$th possible cluster level value (derived from K-Means clustering), and we assume that the probability distributions of appropiate labels are known, then the probability of the occurence of the new label value ($nlv_{i,j}$) produced using those two values can be counted as below

$$P(nlv_{i,j}) = P(clv_j|lv_i) = \frac{P(clv_j, lv_i)}{P(lv_i)}.$$

Furthermore, a big score difference (about $0.2$) was observed between the approach that implied use of label transformations as described above and the one that did not (in the favor of the first one).

Another approach is to use only one label with all possible (96) combinations of values. When it was applied to the training labels, there could be found only 24 values. However, the $scores$ were so low that in authors' opinion there was no premise to examine it more precisely (for instance by applying K-Means).

### E. Classification

The classifier training phase was conducted using newly generated data and vectors of new label values. Then, the trained classifier was used to predict label values for the preprocessed testing dataset. Its output consisted of values that had to be translated to original label values. It had to be an unambiguous transformation, so a new set of label values had to be more numerous than the original one (an equinumerous case is trivial). This assumption was provided if we examine the specifics of the label transformation algorithm. Let $T$ be the test data preprocessed in the same way as $D$, $LV_{pred}$ be the vector of predicted labels (which is part of the submitted solution) and respectively $NLV_{pred}$ be the vector of predicted new label values. Generally, we can enclose this stage in three steps

$$(D, NLV) \xrightarrow{learning} classifier,$$

$$T \xrightarrow{classifier} NLV_{pred},$$

$$NLV_{pred} \xrightarrow{dictionary} LV_{pred}.$$

### F. Results

Authors constructed several classifiers (pairs of classifiers, one for every label):

- $LDA$ with clustering approach, $k \in \{2, \dots, 8\}$, 13 classifiers, dataset $D$;
- $LDA$ with clustering approach, $k \in \{2, \dots, 6\}$, 9 classifiers for a dataset obtained in the same manner as $D$, but with different set of statistics
$$(min1, max1, std1, q25, med1, q75, kurt1, skew);$$
- $LDA$ with clustering approach, $k \in \{2, \dots, 6\}$, 9 classifiers for a dataset obtained in the same manner as $D$, but with different set of statistics
$$(min1, max1, std1, med1, kurt1, skew1);$$
- $LDA$ with clustering approach, fixed $k$s, a dataset obtained in the same manner as $D$, but with different set of statistics
$$(max, min, std, q10, q25, med, q75, q90, IQR, skew, kurt);$$
- $LDA$ with clustering approach, fixed $k$s, a dataset obtained in the same manner as $D$, but with different set of statistics
$$(max, min, std, q25, q40, med, q60, q75, IQR, skew, kurt);$$
- $LDA$ with clustering approach, fixed $k$s, a dataset obtained in the same manner as $D$, but with different set of statistics
$$(max, min, std, q10, q25, q40, med, q60, q75, q90, IQR, skew, kurt);$$
- $LDA$ without clustering approach, dataset $D$;
- $SVM$ (kernels: $rbf$, $linear$) for the first label, $LDA$ for the second label, both with clustering approach, $k \in \{3, 4, 5\}$, $k$ for the second label was fixed, 6 classifiers, dataset $D$;
- $SVM$ (kernels: $rbf$, $linear$) with One vs Rest strategy for the first label, $LDA$ for the second label, both with clustering approach, $k \in \{3, 4, 5\}$, $k$ for the second label was fixed, 6 classifiers, dataset $D$;
- $kNN$ without clustering approach, (number of neighbours) $k \in \{5, 7, 10\}$, 5 classifiers, dataset $D$;

To sum up the overall classification performance, $LDA$ classifier that uses approach described in part (III-D) with $k = 6$ for the first label and $k = 5$ for the second label performed best among other classifiers.

The *score* for the less numerous testing set was $0.8067$ and for the remaining set of observations was $0.77288289$.

## IV. Conclusion

When the $SVM$ classifier with One vs Rest strategy (for the first label) and $LDA$ classifier (for the second label) were combined, they produced only slightly worse *score*s (about $0.79$) than the best one ($0.8067$), assuming that predictions for the second label remained unchanged. An interesting observation was made when the vector of predictions for the first label was compared to the corresponding output of the final solution. Only about half of label value predictions were the same, which probably indicates a problem with a proper classification of the first label.

Taking into account simplicity and significant improvements in evaluation of the model due to application of K-Means approach and small difference between first and second stage scores, the authors' method can be treated as suitable for the activity recognition task. Furthermore, the model behaved stable (for different $k$s) and performed very efficiently in terms of learning time.

The authors are also aware that the results and performance can be dependant on implementation issues, so it should be noticed that everything was prepared in Python with the use of $sklearn$ library (standarization, clustering, classifiers) [3].

# 8th Workshop on Computational Optimization

MANY real world problems arising in engineering, economics, medicine and other domains can be formulated as optimization tasks. These problems are frequently characterized by non-convex, non-differentiable, discontinuous, noisy or dynamic objective functions and constraints which ask for adequate computational methods.

The aim of this workshop is to stimulate the communication between researchers working on different fields of optimization and practitioners who need reliable and efficient computational optimization methods.

We invite original contributions related to both theoretical and practical aspects of optimization methods.

## Topics

The list of topics includes, but is not limited to:

- unconstrained and constrained optimization
- combinatorial optimization
- continues optimization
- global optimization
- multiobjective optimization
- optimization in dynamic and/or noisy environments
- large scale optimization
- parallel and distributed approaches in optimization
- random search algorithms, simulated annealing, tabu search and other derivative free optimization methods
- nature inspired optimization methods (evolutionary algorithms, ant colony optimization, particle swarm optimization, immune artificial systems etc)
- hybrid optimization algorithms involving natural computing techniques and other global and local optimization methods
- computational biology and optimization
- distance geometry and applications
- optimization methods for learning processes and data mining
- application of optimization methods on real life and industrial problems
- computational optimization methods in statistics, econometrics, finance, physics, chemistry, biology, medicine, engineering etc

***Abstract*—In this investigation recently developed InterCriteria Analysis (ICA) is applied to examine the influences of two main genetic algorithms parameters – crossover and mutation rates during the model parameter identification of *S. cerevisiae* and *E. coli* fermentation processes. The apparatuses of index matrices and intuitionistic fuzzy sets, which are the core of ICA, are used to establish the relations between investigated genetic algorithms parameters, from one hand, and fermentation process model parameters, from the other hand. The obtained results after ICA application are analysed towards convergence time and model accuracy and some conclusions about derived interactions are reported.**

## I. Introduction

INTERCRITERIA Analysis (ICA), given in details in [3], is a contemporary approach for multi-criteria decision making. ICA implements the apparatuses of index matrices (IM) and intuitionistic fuzzy sets (IFS) in order to compare some criteria reflecting the behaviour of considered objects. Recently ICA has been successfully applied for EU Member States competitiveness analysis [8], thus provoking the search for further ICA applications. The idea to implement ICA in the field of tuning of the optimization techniques parameters has intuitively appeared.

Fermentation processes (FP) are objects of increased research interest because of their widespread use in different branches of industry. The FP modeling and optimization are a real challenge for the investigators due to the fact that FP models have complex structures based on systems of non-linear differential equations with several specific growth rates [9]. The choice of appropriate model parameter identification procedure is the most important problem for FP adequate modeling. Among others biologically inspired optimization techniques, genetic algorithms (GA) [12] has been proved as a global search method [10] for solving different engineering and optimization problems [18], among that for parameter identification of FP [1], [16], [17], [19]. GA efficiency strongly depends on the tuning of different operators, functions, and parameters. These settings are specifically implemented to different problems. Current investigation is focused on the examining the impact of two of the main GA parameters, namely crossover ($xovr$) and mutation ($mutr$) rates. Simple GA (SGA) is applied for the purposes of model parameter identification of two fed-batch FP – *S. cerevisiae* and *E. coli*. Both yeast and bacteria have numerous applications in food and pharmaceutical industries. Also both microorganisms are widely used as model organisms in genetic engineering and cell biology due to their well known metabolic pathways [11], [14].

In this investigation the obtained results from SGA parameter identification of considered here FP models are used to determine some dependencies between some criteria preliminary defined as of significant importance. The establishment of the influences and relations between criteria – model parameters, from one hand, and GA parameters crossover and mutation rates, from the other hand, is performed by the ICA implementation. This is expected to lead to additional exploring of the models or the relation between models and optimization algorithm outcomes, which will be valuable especially in the case of modelling of living systems, such as FP.

## II. Problem Formulation

### *A. Mathematical models of fermentation processes*

Two Case studies are going to be presented here – for the fermentation processes of *S. cerevisiae* (Case study 1) and of *E. coli* (Case study 2).

**Case study 1. *S. cerevisiae* fed-batch fermentation model**

The mathematical model of *S. cerevisiae* fed-batch process is presented by the following non-linear differential equations system [16]:

$$\frac{dX}{dt} = (\mu_{2S}\frac{S}{S+k_S} + \mu_{2E}\frac{E}{E+k_E})X - \frac{F_{in}}{V}X \qquad (1)$$

$$\frac{dS}{dt} = -\frac{\mu_{2S}}{Y_{S/X}}\frac{S}{S+k_S}X + \frac{F_{in}}{V}(S_{in} - S) \qquad (2)$$

$$\frac{dV}{dt} = F_{in} \qquad (3)$$

where $X$ is the biomass concentration, [g/l]; $S$ – substrate concentration, [g/l]; $E$ – ethanol concentration, [g/l]; $F_{in}$ – feeding rate, [l/h]; $V$ – bioreactor volume, [l]; $S_{in}$ – substrate concentration in the feeding solution, [g/l]; $\mu_{2S}$, $\mu_{2E}$ – the maximum values of the specific growth rates, [1/h]; $k_S$, $k_E$ – saturation constants, [g/l]; $Y_{S/X}$ – yield coefficient, [-].

For the considered here model (Eqs. (1-3)), the vector of parameters to be identified is as follows:

$$p_1 = [\mu_{2S}\ \mu_{2E}\ k_S\ k_E\ Y_{S/X}].$$

978-83-60810-66-8/$25.00©2015, IEEE

**Case study 2. *E. coli* fed-batch fermentation model**

The mathematical model of *E. coli* fed-batch process is presented by the following non-linear differential equations system [9], [16]:

$$\frac{dX}{dt} = \mu_{max} \frac{S}{k_S + S} X - \frac{F_{in}}{V} X \tag{4}$$

$$\frac{dS}{dt} = -\frac{\mu_{max}}{Y_{S/X}} \frac{S}{S + k_S} X + \frac{F_{in}}{V} (S_{in} - S) \tag{5}$$

$$\frac{dV}{dt} = F_{in} \tag{6}$$

where all notations keep their meaning as described above, and, additionally, $\mu_{max}$ is the maximum value of the specific growth rate, [1/h].

For the considered here model (Eqs. (4-6)), the vector of parameters to be identified is as follows:

$$p_2 = [\mu_{max}\ k_S\ Y_{S/X}].$$

Model parameters identification of both fed-batch FP is performed based on experimental data for biomass, glucose and ethanol concentrations. The detailed description of the process conditions and experimental data can be found in [16].

### B. Optimization criterion

The objective function is designed aiming at identification of parameter vectors $p_1$ and $p_2$ in order to obtain the best fit to a data set and is defined as:

$$J = \sum_{i=1}^{m} (X_{\text{exp}}(i) - X_{\text{mod}}(i))^2 + \sum_{i=1}^{n} (S_{\text{exp}}(i) - S_{\text{mod}}(i))^2 \rightarrow \min \tag{7}$$

where $m$ and $n$ are the experimental data dimensions; $X_{\text{exp}}$ and $S_{\text{exp}}$ – available experimental data for biomass and substrate; $X_{\text{mod}}$ and $S_{\text{mod}}$ – model predictions for biomass and substrate with a given model parameter vector.

### C. Simple genetic algorithms for parameter identification

Simple genetic algorithm, initially presented in Goldberg [12], searches a global optimal solution using three main genetic operators in a sequence selection, crossover and mutation. SGA starts with a creation of a randomly generated initial population. Each solution is then evaluated and assigned a fitness value. According to the fitness function, the most suitable solutions are selected. After that, crossover proceeds to form a new offspring. Mutation is then applied with determinate probability aiming to prevent falling of all solutions into a local optimum. The execution of GA has been repeated until the termination criterion (i.e. reached number of populations, or found solution with a specified tolerance, etc.) is satisfied.

Crossover and mutation are among of the most important operators that can increase the efficiency of GA. The crossover operator is used to generate offspring by exchanging bits in a pair of parents chromosomes chosen from the population. Crossover occurs with a crossover probability (crossover rate, $xovr$), that indicates a ratio of how many couples will be picked for mating. The mutation operator changes some elements in selected chromosomes with a mutation probability (mutation rate, $mutr$). As such, the operator introduces genetic diversity and helps GA to escape the local optimum. It is well known that optimal crossover and mutation rates vary for different problems and the success of GA depends on their choice [13]. Usually, determining what rates of crossover and mutation should be used is doing on the trial-and-error basis. In the literature there exist a number of guidelines how crossover and mutation rates to be tuned [12], [13], [15]. Recommended values of crossover rate are high, usually in the range 0.5-1.0 [13], [15]. On the other hand, low mutation rate values for preventing search process to be turn into a simple random search are commonly adopted in GA. Typical values of mutation rate are in the range 0.001-0.1 [13], [15].

In this investigation the impact of crossover and mutation rates is going to be examined choosing different values of the both GA parameters. In Case study 1 SGA is applied with the following values of crossover rate: $xovr$ = {0.65; 0.75; 0.85; 0.95}, while in Case study 2 – with $xovr$ = {0.5; 0.6; 0.7; 0.8; 0.9; 1}. Due to the specific peculiarities of two fed-batch FP, again different strategies were applied for mutation rates in both Case studies. In Case study 1 SGA is applied with the following values of mutation rate: $mutr$ = {0.02; 0.04; 0.06; 0.08; 0.1}, while in Case study 2 – with $mutr$ = {0.001; 0.01; 0.1; 0.5; 1}. The selected values of $xovr$ and $mutr$ are chosen based on the following prerequisites: i) concerning the recommended by the literature values and trying to comprise different values in the ranges for both Case studies [12], [13], [15]; ii) concerning the previous authors' experience of modelling of FP using GA [1], [16], [17], [18], [19]. All other GA operators and parameters are tuned as presented in [1], [19].

## III. InterCriteria Analysis

InterCriteria analysis, based on the apparatuses of index matrices and intuitionistic fuzzy sets, is given in details in [3]. Here, for a completeness, the proposed idea is briefly presented.

An intuitionistic fuzzy pair (IFP) [4] is an ordered pair of real non-negative numbers $\langle a, b\rangle$, where $a, b \in [0, 1]$ and $a + b \leq 1$, that is used as an evaluation of some object or process. According to [4], the components ($a$ and $b$) of IFP might be interpreted as degrees of "membership" and "non-membership" to a given set, degrees of "agreement" and "disagreement", degrees of "validity" and "non-validity", degrees of "correctness" and "non-correctness", etc.

The apparatus of index matrices (IM) is presented initially in [5] and discussed in more details in [6], [7]. For the purposes of ICA application, the initial index set consists of the criteria (for rows) and objects (for columns) with the IM elements assumed to be real numbers. Further, an IM with index sets consisting of the criteria (for rows and for columns) with IFP elements determining the degrees of correspondence between the respective criteria is constructed, as it is doing to be briefly presented below.

Let the initial IM is presented in the form of Eq. (8), where, for every $p, q,\ (1 \leq p \leq m, 1 \leq q \leq n)$, $C_p$ is a criterion, taking part in the evaluation; $O_q$ – an object to be evaluated; $a_{C_p,O_q}$ – a real number or another object, that is comparable about relation $R$ with the other $a$-objects, so that for each $i, j, k$: $R(a_{C_k,O_i}, a_{C_k,O_j})$ is defined. Let $\overline{R}$ be the dual relation of $R$ in the sense that if $R$ is satisfied, then $\overline{R}$ is not satisfied, and vice versa. For example, if "$R$" is the relation "$<$", then $\overline{R}$ is the relation "$>$", and vice versa. If $S^{\mu}_{k,l}$ is the number of cases in which $R(a_{C_k,O_i}, a_{C_k,O_j})$ and $R(a_{C_l,O_i}, a_{C_l,O_j})$ are simultaneously satisfied, while $S^{\nu}_{k,l}$ is the number of cases is which $R(a_{C_k,O_i}, a_{C_k,O_j})$ and $\overline{R}(a_{C_l,O_i}, a_{C_l,O_j})$ are simultaneously satisfied, it is obvious, that

$$S^{\mu}_{k,l} + S^{\nu}_{k,l} \leq \frac{n(n-1)}{2}.$$

Further, for every $k, l$, satisfying $1 \leq k < l \leq m$, and for $n \geq 2$,

$$\mu_{C_k,C_l} = 2\frac{S^{\mu}_{k,l}}{n(n-1)}, \quad \nu_{C_k,C_l} = 2\frac{S^{\nu}_{k,l}}{n(n-1)} \tag{9}$$

are defined. Therefore, $\langle \mu_{C_k,C_l}, \nu_{C_k,C_l} \rangle$ is an IFP. Next, the following IM is constructed:

$$\begin{array}{c|ccc} & C_1 & \dots & C_m \\ \hline C_1 & \langle \mu_{C_1,C_1}, \nu_{C_1,C_1} \rangle & \dots & \langle \mu_{C_1,C_m}, \nu_{C_1,C_m} \rangle \\ \vdots & \vdots & \ddots & \vdots \\ C_m & \langle \mu_{C_m,C_1}, \nu_{C_m,C_1} \rangle & \dots & \langle \mu_{C_m,C_m}, \nu_{C_m,C_m} \rangle \end{array},$$

that determines the degrees of correspondence between criteria $C_1, ..., C_m$.

In the most of the obtained pairs $\langle \mu_{C_k,C_l}, \nu_{C_k,C_l} \rangle$, the sum $\mu_{C_k,C_l} + \nu_{C_k,C_l}$ is equal to 1. However, there may be some pairs, for which this sum is less than 1. The difference

$$\pi_{C_k,C_l} = 1 - \mu_{C_k,C_l} - \nu_{C_k,C_l} \tag{10}$$

is considered as a degree of "uncertainty".

## IV. Numerical Results and Discussion

In order to obtain reliable results for convergence time, optimization criterion and model parameters estimations, thirty independent runs of SGA have been performed for each value of crossover and mutation rates for both examined here Case studies. Obtained results have been averaged and two IMs are constructed for each Case study, involving values for crossover or mutation rates, respectively. In other words, altogether four IMs are constructed: IMs $A_{1(xovr)}$ (Eq. (11)) and $A_{1(mutr)}$ (Eq. (12)) for the Case study 1 and IMs $A_{2(xovr)}$ (Eq. (13)) and $A_{2(mutr)}$ (Eq. (14)) for the Case study 2.

IM $A_{1(xovr)}$ presents average estimates of the model parameters $\mu_{2S}, \mu_{2E}, k_S, k_E$, and $Y_{S/X}$, as well as the resulting convergence time $T$ and objective function value $J$, respectively for $xovr = \{0.65; 0.75; 0.85; 0.95\}$, denoted as $\text{GA}^{xovr}_{1,1} \div \text{GA}^{xovr}_{1,4}$. In the same way, IM $A_{1(mutr)}$ presents the results for $\mu_{2S}, \mu_{2E}, k_S, k_E$, and $Y_{S/X}, T, J$ and $mutr$, respectively for $mutr = \{0.02; 0.04; 0.06; 0.08; 0.1\}$, denoted as $\text{GA}^{mutr}_{1,1} \div \text{GA}^{mutr}_{1,5}$.

IMs $A_{2(xovr)}$ and $A_{2(mutr)}$ for the Case study 2 have been created by analogy with the Case study 1.

Based on Eq. (9), ICA algorithm calculates the IFP $\langle \mu, \nu \rangle$ for every two pairs of considered criteria based on the obtained IMs $A_{1(xovr)}$, $A_{1(mutr)}$, $A_{2(xovr)}$ and $A_{2(mutr)}$. Values of $\pi$ (Eq. (10)) are calculated too. Obtained results are grouped in Table 1 for both Case studies, considering dependences between crossover and mutation rates, optimization criterion, convergence time and model parameters themselves.

Applied here non-linear models for two Case studies (respectively Eqs. (1)-(3) and Eqs. (4)-(6)) are a prerequisite some closer relations between observed criteria to be expected after ICA application. On the other hand, some differences in the parameters relations might appear caused by the different specific growth rates in *S. cerevisiae* and *E. coli* FP.

As it could be seen from Table 1, there is a strong relation between $T \leftrightarrow xovr/mutr$ for the Case study 1, while in the Case study 2 a weak relation is observed. The similar discrepancy is identified in the correlation between $Y_{S/X} \leftrightarrow xovr/mutr$: in the Case study 2 there is a strong relation for GA parameter $xovr$, while in the Case study 1 – a weak. These discrepancies might be explained by the stochastic nature of GA. Crossover rate strongly influences evaluation of model parameter $\mu_{2E}$ in Case study 1. In the Case study 2, there is a significant indication for high correlation between $J \leftrightarrow mutr$. For the rest of model parameters the observed correlations are weak – there are no significant dependencies between $T$ and these parameters.

Going further in investigation of relations between algorithm accuracy $J$ and model parameters, higher $\mu$-values is observed between $Y_{S/X} \leftrightarrow J$ in Case study 1 and for GA parameter $mutr$. Less stronger correlations are identified in the Case study 1 for GA parameter $mutr$ between $\mu_{2S} \leftrightarrow J$, as well as in Case study 2 for GA parameter $mutr$ between $Y_{S/X} \leftrightarrow J$. These similarities are caused by the physical meaning of considered model parameters. For the rest of parameters the observed correlations are weak – there are no significant dependencies between these parameters and $J$.

When considering the influence of convergence time $T$ over the model parameters, higher $\mu$ is observed in pairs $\mu_{2E} \leftrightarrow T$ in Case study 1 for GA parameter $xovr$. In the Case study 2, higher $\mu$-values are observed between $\mu_{max} \leftrightarrow T$ and $k_S \leftrightarrow T$ for $mutr$ GA parameter. Observed $\mu$-values for the rest of pairs of model parameters and $T$ show that there are no significant correlations between them.

The last group of examined correlations is between model parameters themselves in both considered Case studies. Different model structures in both FP complicate the extraction of some common correlations. Although that fact, there are some coincidences for both Case studies. In the Case study 1 for GA parameter $xovr$, the strongest correlations are found respectively for $\mu_{2S} \leftrightarrow k_S$ and $\mu_{2S} \leftrightarrow Y_{S/X}$, while less stronger correlations are identified for the pairs $k_S \leftrightarrow k_E$,

$$A = \begin{array}{c|ccccccc} & O_1 & \ldots & O_k & \ldots & O_l & \ldots & O_n \\ \hline C_1 & a_{C_1,O_1} & \cdots & a_{C_1,O_k} & \cdots & a_{C_1,O_l} & \cdots & a_{C_1,O_n} \\ \vdots & \vdots & \ddots & \vdots & \ddots & \vdots & \ddots & \vdots \\ C_i & a_{C_i,O_1} & \cdots & a_{C_i,O_k} & \cdots & a_{C_i,O_l} & \cdots & a_{C_i,O_n} \\ \vdots & \vdots & \ddots & \vdots & \ddots & \vdots & \ddots & \vdots \\ C_j & a_{C_j,O_1} & \cdots & a_{C_j,O_k} & \cdots & a_{C_j,O_l} & \cdots & a_{C_j,O_n} \\ \vdots & \vdots & \ddots & \vdots & \ddots & \vdots & \ddots & \vdots \\ C_m & a_{C_m,O_1} & \cdots & a_{C_m,O_k} & \cdots & a_{C_m,O_l} & \cdots & a_{C_m,O_n} \end{array}, \tag{8}$$

**Case study 1**, IM $A_{1(xovr)}$:

$$A_{1(xovr)} = \begin{array}{r|cccc} & \text{GA}_{1,1}^{xovr} & \text{GA}_{1,2}^{xovr} & \text{GA}_{1,3}^{xovr} & \text{GA}_{1,4}^{xovr} \\ \hline J & 0.0222 & 0.0222 & 0.0222 & 0.0221 \\ T & 69.140600 & 70.212400 & 69.475000 & 71.359200 \\ xovr & 0.65 & 0.75 & 0.85 & 0.95 \\ \mu_{2S} & 0.962120 & 0.949840 & 0.974790 & 0.923920 \\ \mu_{2E} & 0.103840 & 0.107940 & 0.115320 & 0.129580 \\ k_S & 0.124640 & 0.119580 & 0.128700 & 0.119780 \\ k_E & 0.799020 & 0.798700 & 0.798860 & 0.798960 \\ Y_{S/X} & 0.417885 & 0.413705 & 0.413850 & 0.409500 \end{array} \tag{11}$$

**Case study 1**, IM $A_{1(mutr)}$:

$$A_{1(mutr)} = \begin{array}{r|ccccc} & \text{GA}_{1,1}^{mutr} & \text{GA}_{1,2}^{mutr} & \text{GA}_{1,3}^{mutr} & \text{GA}_{1,4}^{mutr} & \text{GA}_{1,5}^{mutr} \\ \hline J & 0.022200 & 0.022167 & 0.022133 & 0.022300 & 0.022100 \\ T & 71.677000 & 76.104333 & 90.479000 & 101.400667 & 98.161667 \\ mutr & 0.02 & 0.04 & 0.06 & 0.08 & 0.1 \\ \mu_{2S} & 0.963433 & 0.987333 & 0.943333 & 0.960033 & 0.914933 \\ \mu_{2E} & 0.113100 & 0.111900 & 0.129733 & 0.094967 & 0.146100 \\ k_S & 0.124000 & 0.123333 & 0.128167 & 0.117033 & 0.121300 \\ k_E & 0.799867 & 0.799500 & 0.799600 & 0.792433 & 0.797833 \\ Y_{S/X} & 0.410841 & 0.411348 & 0.407914 & 0.421965 & 0.398290 \end{array} \tag{12}$$

**Case study 2**, IM $A_{2(xovr)}$:

$$A_{2(xovr)} = \begin{array}{r|cccccc} & \text{GA}_{2,1}^{xovr} & \text{GA}_{2,2}^{xovr} & \text{GA}_{2,3}^{xovr} & \text{GA}_{2,4}^{xovr} & \text{GA}_{2,5}^{xovr} & \text{GA}_{2,6}^{xovr} \\ \hline J & 0.010700 & 0.000310 & 0.000320 & 0.000170 & 0.000450 & 0.000310 \\ T & 143.156 & 77.782 & 218.234 & 104.719 & 158.078 & 86.953 \\ xovr & 0.5 & 0.6 & 0.7 & 0.8 & 0.9 & 1 \\ \mu_{max} & 0.553000 & 0.549000 & 0.550000 & 0.551000 & 0.549000 & 0.548000 \\ k_S & 0.011700 & 0.009800 & 0.010100 & 0.010000 & 0.009800 & 0.009900 \\ Y_{S/X} & 0.500275 & 0.499975 & 0.499950 & 0.500000 & 0.500250 & 0.500500 \end{array} \tag{13}$$

$Y_{S/X} \leftrightarrow k_S$ and $Y_{S/X} \leftrightarrow k_E$. Considering GA parameter $mutr$, the strongest correlations are between $k_S \leftrightarrow k_E$ and $\mu_{2S} \leftrightarrow Y_{S/X}$. Comparing to Case study 2 and taking into account the simpler specific growth rate model structure, the similar result for the pair $\mu_{max} \leftrightarrow k_S$ is observed. The highest correlation is observed for both GA parameters $xovr$ and $mutr$. These strong parameter dependencies are again caused by the physical meaning of FP models parameters. For the rest correlations between model parameters themselves, the $\mu$-values are low – there are no significant dependencies.

It is also interesting to be noted that during the investigation of $xovr$ influence, there are some pairs of considered criteria with reported degree of uncertainty $\pi$. For the Case study 1, all observed appearances of degrees of uncertainty are in pairs with optimization criterion value, while in Case study 2 – in pairs of optimization criterion value or specific growth rate. All

**Case study 2**, IM $A_{2(mutr)}$:

$$A_{2(mutr)} = \begin{array}{c|ccccc} & \text{GA}_{2,1}^{mutr} & \text{GA}_{2,2}^{mutr} & \text{GA}_{2,3}^{mutr} & \text{GA}_{2,4}^{mutr} & \text{GA}_{2,5}^{mutr} \\ \hline J & 0.019000 & 0.000360 & 0.007300 & 4.130700 & 25.622800 \\ T & 53.250000 & 116.594000 & 193.641000 & 70.937000 & 39.234000 \\ mutr & 0.001 & 0.01 & 0.1 & 0.5 & 1 \\ \mu_{max} & 0.546000 & 0.550000 & 0.554000 & 0.599000 & 0.432000 \\ k_S & 0.007800 & 0.010200 & 0.011000 & 0.044400 & 0.002300 \\ Y_{S/X} & 0.499500 & 0.500250 & 0.500501 & 0.500325 & 0.518403 \end{array} \tag{14}$$

these facts have an obvious explanation – as it can be seen from IM $A_{1(xovr)}$ for Case study 1, there are equal values for optimization criterion value. In analogy, as seen from IM $A_{2(xovr)}$, there are equal evaluations of optimization criterion value and specific growth rate in Case study 2. Observed equal values logically cause an uncertainty and makes difficult the process of decision making.

As a summary of ICA implementation, the following main results might be outlined:

- Considered GA parameters $xovr$ and $mutr$ show a high correlation with $T$ in both Case studies. In Case study 2, parameter $mutr$ is in a high correlation with $J$ and model parameter $Y_{S/X}$. The values of $xovr$ and $mutr$ reflect on $T$ because of the more complex model used in Case study 1 [1], [12], [15]. In opposite, the more simple model structure in Case study 2 allows the relations between $mutr$ and $J$ and one of the most sensitive model parameter $Y_{S/X}$ [17] to be outlined.
- When looking at $T$ and $J$ relations, strong connections are observed for $J \leftrightarrow Y_{S/X}$, especially in Case study 1; between specific growth rates (respectively $\mu_{2E}$ and $\mu_{max}$) and $T$ in both Case studies, as well as for $k_S \leftrightarrow T$ in Case study 2. The stochastic nature of GA is a preposition of a relatively small number of observed strong relations [10], [12], [15].
- In the last group of examined correlations between model parameters themselves, higher dependencies are obtained between specific growth rates $\mu_{2S}$ and $\mu_{max}$ and model parameter $k_S$ in both Case studies, especially in Case study 2 at GA parameter $mutr$. Considering Case study 1, strong correlations are observed for $k_S \leftrightarrow k_E$ and for $Y_{S/X} \leftrightarrow \mu_{2S}$. The ascertained results are caused by the physical meaning of FP models parameters, as well as by the strong non-linearity of FP model structures [9], [11], [14], [16].

## V. Conclusion

In this paper the recently proposed InterCriteria Analysis is applied to establish the relations and dependencies between two GAs parameters – crossover and mutation rates, on one hand, and convergence time, model accuracy and FP model parameters, on the other hand. Simple GA with different values of crossover and mutation rates is used for parameter identification of two FP models – of yeast *S. cerevisiae* and bacteria *E. coli*.

The obtained results from ICA show some existing relations and dependencies that result from the physical meaning of the model parameters, on one hand, and from stochastic nature of the considered meta-heuristic, on the other hand. Moreover, derived additional knowledge for ascertained correlations will be useful in further identification procedures of FP models and, in general, for more accurate SGA application.

***Abstract*—We suggest an effective method for solving the problem of correlation clustering. This method is based on an extension of a partial tolerance relation to clusters. We present several implementation of this method using different data structures, and we show a method to speed up the execution by a quasi-parallelism.**

## I. Introduction

THE principle of minimum total potential energy (MTPE) is a fundamental concept used in physics, chemistry, biology and engineering. It asserts that a structure or body shall deform or displace to a position that minimizes the total potential energy. This concept could be used at other fields, too. In this paper, we show its application in clustering. The clustering is an important tool of unsupervised learning. Its task is to group the objects in such a way, that the objects in one group (cluster) are similar, and the objects from different groups are dissimilar, so it generates an equivalence relation: the objects being in the same cluster. If we want to apply the principle MTPE, then we can say that the objects aim to achive a situation in which they are in a cluster containing minimal number of dissimilar, and maximal number of similar objects. In the last fifty years, many different clustering methods were invented based on different demands.

Correlation clustering is a new method, Bansal at al. published a paper in 2004, proving several of its properties, and gave a fast, but not quite optimal algorithm to solve the problem [1]. Naturally, correlation clustering has a predecessor. Zahn proposed this problem in 1965, but using a very different approach [2]. The main question is the following: which equivalence relation is the closest to a given tolerance (reflexive and symmetric) relation? Bansal et al. have shown, that this is an NP-hard problem [1]. The number of equivalence relations of $n$ objects, i.e. the number of partitions of a set containing $n$ elements is given by Bell numbers $B_n$, where $B_1 = 1$, $B_n = \sum_{i=1}^{n-1} \binom{n-1}{k} B_k$. It can be easily checked that the Bell numbers grow exponentially. Therefore if $n > 15$, in a general case we cannot achieve the optimal partition by exhaustive search, thus we need to use some optimization methods, which do not give optimal solutions, but help us achieve a near-optimal one.

This kind of clustering has many applications: image segmentation [3], identification of biologically relevant groups of genes [4], examination of social coalitions [5], improvement of recommendation systems [6] reduction of energy consumption [7], modelling physical processes [8], (soft) classification [9], [10], etc.

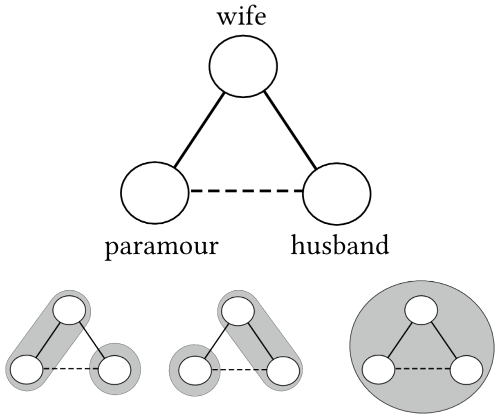

Fig. 1. Minimal frustrated graph and its optimal partitions

At correlation clustering, those cases where two dissimilar objects are in the same cluster, or two similar objects are in different clusters are treated as a conflict. Thus the main question could be rewritten as: which partition generates the minimal number of conflicts? It can be shown, that in the general case—where the transitivity does not hold for the tolerance relation—the number of conflicts is a positive number for all partitions of a given set of objects. Let us take a graph on Figure 1, where the similarity is denoted by solid, and dissimilarity by dashed lines. In case of persons, the similarity and dissimilarity are treated as liking or disliking each other, respectively. Mathematically, the similarity is described as a weighted graph, where 1 denotes similarity, and -1 denotes dissimilarity. As the absolute value of these weights are the same, thus it is enough to only use the signs of the weights. Hence the graph is called a *signed graph* in the literature. The lower part of this figure shows the three optimal partitions from the five, each of them containing only one conflict. As all partitions of the graph on Figure 1 have at least one conflict, it is called a *frustrated graph*, and this one is the smallest such graph.

If the correlation clustering is expressed as an optimization problem, the traditional optimization methods (hill-climbing, genetic algorithm, simulated annealing, etc.) could be used in order to solve it. We have implemented and compared the results in [11]. With these methods the authors were able to determine a near optimal partition of signed graphs with 500 nodes.

978-83-60810-66-8/$25.00©2015, IEEE

In this paper we introduce a new method which was invented directly to solve the problem of correlation clustering, and can use the specialities of the problem. The main idea is extremely simple, but it needs several witty concepts, to get a fast and effective algorithm.

Before going into details, let us see the hierarchical clustering—where the solution is usually received as a result of a series of contractions. The user needs to choose a dissimilarity metric of clusters. These metrics are based on the distance of the members (objects) of the clusters. Next, the hierarchical clustering constructs a hierarchy, which starts with singleton clusters, and each higher level is earned by joining two clusters of the previous level. The last level consists of one cluster which contains all the objects. This clustering is an automatic process, where the user selects one level of this hierarchy (and the equivalence relation generated by it), and uses accordingly.

In case of correlation clustering the user has limited options. If the hierarchy, according to the tolerance relation is generated, the cost function (i.e. the number of conflicts) can be calculated for each level (for each partition) of the hierarchy, and we take the minimal. This does not mean, that we reach the optimal partition for each tolerance relation. This hierarchy has $n$ levels ($n$ partition) from the $B_n$ possible ones, e.g. if $n$ is 500, then we have 500 levels, and $1.6 \cdot 10^{844}$ different partitions. Therefore we need to choose carefully which partitions to add to the hierarchy.

There are two ways to construct the hierarchy: bottom-up and top-down. In the latter, we split one cluster into two. If the original cluster contains $k$ objects, there are $2^k - 2$ ways to split it, thus the full search is not feasible. There are other methods to find a good split, but the hierarchy construction by splitting is not so common. The bottom-up way is based on joining clusters. There are $k(k-1)/2$ ways of joining clusters, and after the contraction of two clusters we update the pre-calculated distances of clusters accordingly, as if we had $k$ clusters before contraction.

In this paper we will use Python programs to present the algorithms. The Python programming language is perfect tool for prototyping:

- Python code listings are shorter than pseudo codes, because we can use program-libraries without long explanations or repetition of well-known algorithms.
- Python has high level data structures (list of set, set of lists, etc.) which simplify the programs.
- Although Python programs are slow, we are not interested in exact running times, but in the time rates: the effect of replacing an algorithm with a better one?

We tested programs on one core of a 2.3 GHz double core processor under Linux and Python 3.4.0. The times are given in seconds.

The first implementation uses the most trivial data structure to store a graph: the adjacency matrix. The adjacency matrix of a tolerance relation contains elements $-1$ and $1$ only, so its graph is total. The asymptotic behaviour of the correlation clustering of tolerance relation is known from [8]. If we allow zero values in the adjacency matrix, i.e. we have a partial tolerance relation, the behaviour of the clustering changes. The more zeros are in the adjacency matrix, the bigger the difference in behaviour. These behaviours are not yet described or explained mathematically, computer experiments for many objects are needed to discover the exact tendencies. Hence for us the most interesting graphs are the sparse graphs. In general, it is easy to implement the generation of Erdős–Rényi type random graphs [12], but it is hard to ensure that it generates a connected graph for small probability parameter $p$. Therefore in our experiments we used Barabási-Albert type random graphs [12] (we refer to them as BA graphs in the following) where the connectivity follows from the algorithm of the generation.

The structure of the paper is the following: Section 2 explains the correlation clustering and shows the result of joining two clusters. In Section 3 we present a naive contraction method. Next we specialize the method for sparse graphs. In Section 5 we give the quasi-parallel version of the specialized algorithms. Finally we discuss our plans and conclude the results.

## II. Correlation clustering

In the paper we use the following notations: $V$ denotes the set of the objects, and $T \subset V \times V$ the tolerance relation defined on $V$. We handle a partition as a function $p : V \to \{1, \ldots, n\}$. The objects $x$ and $y$ are in a common cluster, if $p(x) = p(y)$. We say that objects $x$ and $y$ are in conflict at given tolerance relation $T$ and partition $p$ iff value of $c_T^p(x,y) = 1$ in (1), i.e. if they are similar and are in different clusters, or if they are dissimilar and in the same cluster.

$$c_T^p(x,y) \leftarrow \begin{cases} 1 & \text{if } (x,y) \in T \text{ and } p(x) \neq p(y) \\ 1 & \text{if } (x,y) \notin T \text{ and } p(x) = p(y) \\ 0 & \text{otherwise} \end{cases} \tag{1}$$

We are ready to define the cost function of relation $T$ according to partition $p$:

$$c_T(p) \leftarrow \frac{1}{2} \sum c_T^p(x,y) = \sum_{x<y} c_T^p(x,y) \tag{2}$$

As relation $T$ is symmetric, we sum $c_T^p$ twice for each pair, or restrict the summing in order to use each pair only once. The objects are usually represented with numbers, hence we can calculate the cost function as the last part of (2) shows.

Our task is to determine the value of $\min_p c_T(p)$, and one partition $p$ for which $c_T(p)$ is minimal. Unfortunately this exact value cannot be determined in practical cases, except for some very special tolerance relations. Hence we can get only approximative, near optimal solutions.

The statistical software R has 6 different distance functions for determining distance of objects. In our case the tolerance relation replaces these metrics. The same software has 8 different cluster distance functions. None of them is suitable for our needs.

Let us see, what is the result of joining two clusters according to the cost function. Let $A$ and $B$ be these clusters, moreover let us denote the partition before and after joining by $p$ and $q$, respectively.

1) If $\{x, y\} \cap (A \cup B) = \emptyset$, then $c_T^p(x, y) = c_T^q(x, y)$ holds.
2) If $x \in (A \cup B)$ and $y \notin (A \cup B)$ (or in reverse), then $c_T^p(x, y) = c_T^q(x, y)$ holds.
3) If $x \in A$ and $y \in B$, then $c_T^p(x, y) = 1 - c_T^q(x, y)$ holds. As objects $x$ and $y$ are from different clusters, $p(x) \neq p(y)$. So if $c_T^p(x, y) = 1$, then $(x, y) \in T$, but after the joining $q(x) = q(y)$, hence $c_T^q(x, y) = 0$. Similarly if $c_T^p(x, y) = 0$, then $(x, y) \notin T$, so $c_T^q(x, y) = 1$.
4) Finally, if $x, y \in A$ (or $x, y \in B$), then $c_T^p(x, y) = c_T^q(x, y)$.

To determine $c_T(q)$ if we know $c_T(p)$, it is enough to calculate the difference $c_T(q) - c_T(p)$. From the previous list it is obvious that we only need to take into account the third item. Before the contraction between clusters $A$ and $B$ there were $\#\{(x, y) | x \in A, y \in B, (x, y) \in T\}$ conflict, and after the contraction these conflicts disappear. But $\#\{(x, y) | x \in A, y \in B, (x, y) \notin T\}$ new conflicts are created by the contraction. The change is the difference of these numbers.

If we treat the conflict of two objects as a distance, then the aggregating function is the difference of two sums. At hierarchical clustering the closest clusters are joined. For us, the contraction method is a greedy algorithm, and we promote the joining of those possible ones which produce maximal profit, which mostly decreases the cost function. These two ideas are confluent, because the difference mentioned before becomes negative, and we join those clusters where the absolute value of this difference is maximal, so where the difference is minimal. Unfortunately, according to its negativity we cannot call the difference as *distance*.

We note that our programs use notations of Bansal, and if the tolerance relation holds for two objects, the number denoting it is positive. From this, it naturally follows that the program uses the differences $c_T(p) - c_T(q)$, i.e. the profits of joining. We only execute the contraction if this difference is positive.

The upper part of the Figure 2 shows a relation. For the sake of simplicity of the picture, this relation is a partial tolerance relation. The middle part of the figure displays the "distances" of the singleton clusters earned from the relation. We formally define it in the next chapter. Finally the lower part of the figure shows the updated distances when some clusters are contracted. These distances are the superposition of the predecessor clusters.

## III. Contraction method

We can now define the Contraction method for correlation clustering. Algorithm 1 is implemented in Python. In the following formulae the brackets refer to the lines of the code. The implementations use the routines of https://www.ics.uci.edu/~eppstein/PADS/UnionFind.py for handling disjoint sets: it contracts two clusters in line 8. We do not present the preprocessing of neither the tolerance relation, nor of the result, but the clustering phase is emphasized.

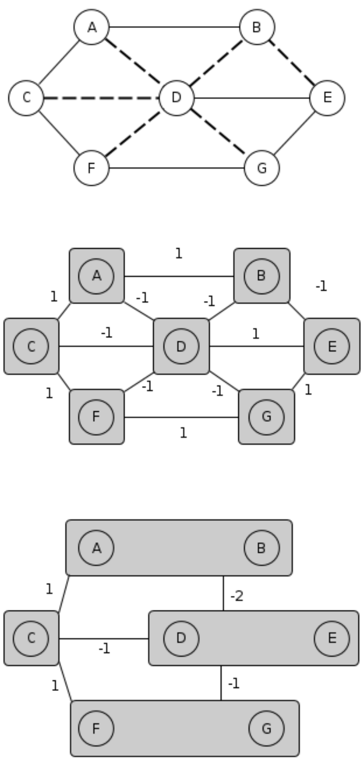

Fig. 2. The partial tolerance relation, the generated "distances" at the beginning and after several contraction steps.

1) Construct a "distance" matrix $D$ based on a tolerance relation $T$:

$$d(i, j) \leftarrow \begin{cases} 1 & \text{if } (i, j) \in T, \\ -1 & \text{if } (i, j) \notin T, \end{cases} \tag{3}$$

Although $d(i, i)$ would be 1 by definition, we set up 0, in order to avoid contracting any clusters by themselves. We denote the preprocessing $T$ and setup of $D$ with dots. [line $3 - 4$]
2) Now, each object—as a singleton cluster—in one-one bijection with rows and columns of $D$. Select one maximal element of matrix $D$, and then its row and column coordinates will refer to the clusters to join. Let these be $x$ and $y$ [line 6].
3) If the maximal element is not positive, the algorithm ends [line 7].
4) Otherwise add to column $x$ the column $y$ (contraction), next delete column $y$, i.e. fill it with zero [lines $9 - 12$]. Then repeat this for the rows.
5) Continue from Step 2. [line 13]

The statistics describing the running time of Algorithm 1 is given in Table I. Here the columns denote graphs with different sizes, and the rows tagged by the value of $q$. This parameter gives the ratio of fulfilment of tolerance relation $T$ among objects. If this number is small, only a few clusters can be joined, so the Contraction method finishes soon and

**Algorithm 1** Naive contraction with matrix

```
import numpy; import UnionFind
N=2000; q=0.4
d = numpy.zeros( (N,N), dtype = numpy.int)
...
uf = UnionFind.UnionFind()
x,y = numpy.unravel_index(d.argmax(),d.shape)
while d[x,y] > 0:
    uf.union(x,y)
    for z in range(N):
        d[x,z] += d[y,z] ; d[z,x] += d[z,y]
    d[...,y] = 0; d[y,...] = 0
    d[x,x] = 0
    x,y = numpy.unravel_index(d.argmax(),
                 d.shape)
```

TABLE I
RUNNING TIMES FOR COMPLETE SIGNED GRAPHS.

| | 100 | 500 | 1000 | 2000 | 5000 |
|---|---|---|---|---|---|
| $q = 0.1$ | 0.017 | 0.598 | 3.015 | 16.080 | 174.511 |
| $q = 0.5$ | 0.027 | 0.773 | 3.736 | 19.152 | 198.269 |
| $q = 0.9$ | 0.029 | 0.785 | 3.789 | 19.226 | 197.325 |

the solution contains many but quite small clusters. But if this ratio is large, there are lot of possibilities to join clusters, and the Contraction method runs for a long time and gives only a few, but big clusters. It can even occur, that we get only one cluster, containing all the elements.

In our previous article we examined the behaviour of contraction of tolerance relation on $n$ objects [13]. For this, we took 101 different values for $q$ from 0 to 1, and for each $q$ we tested the clustering for 10 different relations (graphs), and used their average. By using this implementation to calculate everything for 2000 objects, took more than 5 hours. These are independent calculations, so they can be run in parallel. We note that this program uses the low-level routines of Numpy extensions, which speeds up the execution according to the conventional Python implementation.

This 8-line-long naive implementation does not take into account such details, which are obvious for the reader. As we contract rows and columns, and delete one row and one column (fill up with zeros), in the future the program will not put any non-zero number into these rows and columns, thus it is unnecessary to include these elements of the matrix in the calculations. We could tag them, and later skip them in the cycles. It could be a better solution, however, to change the deletion of a row and a column by swapping them with the last row and column, respectively. Next, we can logically reduce the size of the matrix $D$, and set the upper limit in cycles to the size of the matrix.

Up to here, for any pair of objects the tolerance relation either holds or does not, i.e. the objects are either similar or dissimilar. However, in some cases we have no knowledge about either, thus the relation is partial. (A well-known partial relation is the ordering of $n$-tuples, where the relation holds only if one tuple Pareto dominates the other.) We can use (1) for any partial tolerance relation. By definition, if two objects are neither similar nor dissimilar, there is no conflict between them. The partial tolerance relations are visualized by signed graphs: if two objects are comparable then there is an edge between them, otherwise there is not, like in Figure 2. If the relation holds, the weight of the edge is 1, if not, its weight is -1. If the relation is not defined between the objects, the weight of the non-existent edge could be defined as 0. From these weights we can construct the “distance matrix” $D$ for any partial relation.

TABLE II
RUNNING TIME OF ALGORITHM 1 ON RANDOM ER GRAPHS WITH PARAMETERS $(2000, p_i)$, WHERE THE RATE OF THE POSITIVE EDGES IS $q$

| | $q = 0.1$ | $q = 0.5$ | $q = 0.9$ |
|---|---|---|---|
| $p_1 = 0.9$ | 16.870 | 19.294 | 19.418 |
| $p_2 = 0.5$ | 18.040 | 19.240 | 19.372 |
| $p_3 = 0.1$ | 18.148 | 19.112 | 19.371 |

It is not suprising that Algorithm 1 could be used for partial tolerance relations without any modification. We generated several partial relations with 2000 objects, to test our algorithm. The graphs of the partial tolerance relations were Erdős–Rényi type random graphs, where any two nodes are connected with probability $p_i$. Next, the weight of this edge (if exists) would be 1 with probability $q$ and $-1$ with probability $1 - q$.

The algorithm is the same, it takes the same steps, therefore we can assume, that we get very similar results for clustering. But the data in Table II refutes this assumption. If many edges are missing from the complete graph ($p_i$ is small) and most of the edges are negative ($q$ is small), then the algorithm does not stops after a few steps, as did it for a bigger $p_i$. Similarities force the contractions. The more 1s in $D$, the more contractions are executed by the algorithm, which takes time. The more -1s in $D$—the contractions are obstructed—the less contractions are executed by the algorithm, and the process stops early. The zeros (i.e. missing edges) here decrease the effects of 1 and -1: the number of contractions fall between the two extreme cases (when all zeros are replaced with 1 and -1, respectively).

As we wrote before, Néda at al. described the asymptotic behaviour of correlation clustering for complete graphs [8], thus the computer simulations in this case are not challenging. In case of any signed graph (including the partial tolerance relations) we have conjectures only about the asymptotic behaviour. Néda at al. simulated correlation clustering of BA graphs with 140 nodes in 2009, which we extended to 500 nodes in 2014 [13], and even though the results are impressive, they are not quite sufficient to see the tendencies.

The BA graphs are sparse graphs, they have $O(|V|)$ edges. It is superfluous to reserve $O(|V|^2)$ memory cells in a matrix to store these edges. In the next section we show a memory efficient algorithm to solve the correlation clustering problem for sparse graphs.

## IV. Refining the method

The previous Python implementation shows the crucial questions of the method:

Q1 For constructing a greedy algorithm we need the most profitable contraction, i.e. from the stored and updated (recalculated) values we need to select the biggest one, or one of the biggest ones.

Q2 We need to be able to reach the element $d_{x,y}$ of the matrix $D$, to read it, to update it, or to delete it.

As the previous implementation stores matrix $D$ as a two-dimensional array (matrix), the solution of Q2 is trivial, however to solve Q1, we need a full search in $D$.

In BA graph with ten thousands of nodes, a node is only part of a few edges. This means that in its row of "distance" matrix $D$ there are only a few non-zero elements (which are interesting at calculations). Therefore it is worth to represent the matrix $D$ as a sparse matrix. There are several ways to store a sparse matrix in the memory. The simplest way is to store the list of $(row,\ column,\ value)$ triplets. This storage type is called a *coordinate list*.

In case of using a coordinate list, the solution to Q1 does not change substantially, because a full search is needed in triplets. (Now we have no element without valuable information.) Yet, the solution of Q2 becomes more complicated. Until now, $d_{x,y}$ was reachable in constant time (with pointer-arithmetic). Now the triplets of $D$ are in a list, so in a worst case scenario, a full-search is needed. If this list is ordered, a binary search is enough, but it is very hard to preserve this ordering during contractions:

- If $d_{x,z} = -d_{y,z}$, then after contraction $d_{x,z}$ becomes 0, but we do not want to store this element, so we need to delete it.
- If $d_{x,z} = 0$ and $d_{y,z} \neq 0$, then after the contraction, one new item is created and needs to inserted into the list, while an old one is to deleted.

The hash table could help us solve Q2 effectively, because its speed is near to $O(1)$ at insertion. The hash table is a possible (and fast) implementation of the data structure *associative arrays* (dictionary in Python). Algorithm 2 is the reimplementation of the Contraction method with an associative array.

**Algorithm 2** Contraction by associative array

```
 1  import UnionFind
 2  def contraction(d, s):
 3      d2 = {}
 4      for pair, value in d.items():
 5          x,y = pair
 6          if x in s:
 7              x = s[x]
 8          if y in s:
 9              y = s[y]
10          if x == y:
11              continue
12          if x > y:
13              x,y = y,x
14          if (x,y) in d2:
15              d2[(x,y)] += value
16              if d2[(x,y)] == 0:
17                  del d2[(x,y)]
18          else:
19              d2[(x,y)] = value
20      return d2
21
22  N=1000; q=0.2
23  d = ...
24  uf = UnionFind.UnionFind()
25  if len(d) < 2:
26      return
27  max_d = max(d.values())
28  while max_d > 0:
29      pairs = [pair for pair,value in
30          d.items() if value ==max_d]
31      i,j = pairs[0]; s = {j:i}; uf.union(i,j)
32      d2 = contraction(d,s)
33      if len(d2) < 2:
34          break
35      d = d2.copy()
36      max_d = max(d.values())
```

As before, we only indicate the phase of preprocessing [line 23]. This code is much longer than the previous one, we need to care about more details. While in the previous program, we retrieved the indices of the biggest element of $D$ with one complicated instruction, we needed to take it into pieces here: from the values of the associative array the algorithm selects the biggest one [line 27], and collects the keys belonging to this maximal value [lines 29–30]. From these keys it chooses a pair. We refer the members of this pair as $i$ and $j$. We wish to reuse the part of this code, which describes the contraction, therefore we implemented the contraction step as a function [lines 2–20]. For similar reasons, the pair $(i, j)$ is stored in an associative array, called $s$. Our construction guaranties, that $i < j$, and at contraction we keep the smaller one. This means, that upon meeting a key (which is a coordinate-pair), we need to check whether one of it is equal to $j$ (to the key in the associative array $s$) or not. If it is, then we need to replace it with $i$ (with the value according the key) [lines 6–9]. In the diagonal of $D$, only zero values are allowed, but we do not store them, so if something gets into this diagonal it is ignored [lines 10–11]. We store the indices by ordering [lines 12–13]. If a known pair occurs, then we update its value, whereas unknown pairs are stored [lines 14–19]. Sometimes one cluster is connected with two different clusters, and their effects are opposite. Remember on Figure 1 the husband who loves her wife (+1) but hates her paramour (-1). If the wife left him with her paramour, these numbers add up, and we get 0. So the best if he forget about this new couple. We can speed up our method by not storing zero values, so we omit this one, too [lines 16–17].

Unfortunately the associative arrays do not allow us to pick items by specific needs, hence, to get all the keys in form $(j, \cdot)$ and $(\cdot, j)$, we need traverse the whole associative array, and check whether the actual item is concerned in the contraction or not. In the BA random graphs, the nodes $i$ and $j$ have only a few nearby node (connected to it by an edge), hence this traverse needs extra effort (in comparison to direct access of the edges of a node).

The statistic demonstrating Algorithm 2 is in the first data column—denoted with $D$—in Table IV. The numbers in this table are not seconds or number of conflicts, but rates of benchmarks. Figure 3 and Table III shows the real running times of the bases of the benchmarks. The real running times of Algorithm 2 are much smaller than the running times of Algorithm 1. But if we think about it, we can realize, that these numbers are incomparable. The naive algorithm used total graphs, and a total graph with two thousands nodes has about two millions edges, but a BA random graph has only four thousands. To find the one with the maximal value (Q1) is not the same job, and even the solution of Q2 is easier in the case of associative arrays. We have about five-hundredths many edge, and the running time only one third. To tell the truth Algorithm 2 only uses the conventional Python here—does not use any extension compiled to fast machine code—i.e. overall the execution of the code is much slower.

This programming language enables us to combine different data structures. Hence we can construct one associative array about profits related to a given cluster, and organize these associative arrays into an associative array. This *two level dictionary* is very common in the Python literature. To speed up the solution of Q2, we store one "distance" at two places: in each node's associative array of the according edge. This helps us collect all the edges belonging to the clusters needing to join. This double storage complicates our programs. Moreover, the empty associative arrays generate errors, so we need to check whether the associative arrays become empty, or all the objects are in one cluster.

**Algorithm 3** Contraction by associative array of associative arrays.

```
import UnionFind                                                1
N=1000; q=0.2                                                   2
d = ...                                                         3
uf = UnionFind.UnionFind()                                      4
max_d = max([max(di.values()) for di in d])                     5
while max_d > 0:                                                6
    pairs = [(i,j) for i,di in d.items()                        7
        for j,value in di.items()                               8
        if value == max_d]                                      9
    i,j = pairs[0]                                             10
    del d[i][j]; del d[j][i]                                   11
    di_k = list(d[i].keys())                                   12
    uf.union(i,j)                                              13
    dj = list(d[j].items())                                    14
    for z,value in dj:                                         15
        if z in di_k:                                          16
            d[i][z] += value; d[z][i] += value                 17
            if d[i][z] == 0:                                   18
                del d[i][z]; del d[z][i]                       19
        else:                                                  20
            d[i][z] = value; d[z][i] = value                   21
        del d[z][j]                                            22
        if d[z] == {}:                                         23
            del d[z]                                           24
    del d[j]                                                   25
    if d[i] == {}:                                             26
        del d[i]                                               27
    if len(d) == 1:                                            28
        break                                                  29
    max_d = max([max(di.values())                              30
             for i,di in d.items()])                           31
```

TABLE III
RUNNING TIMES FOR $D^2_r$ IN SECONDS

| N | 0.1 | 0.5 | 0.9 |
|---|---|---|---|
| 100 | 0.004–0.009 | 0.004–0.012 | 0.008–0.015 |
| 500 | 0.076–0.227 | 0.075–0.227 | 0.165–0.327 |
| 1000 | 0.483–1.126 | 0.488–1.267 | 0.863–1.581 |
| 2000 | 2.370–5.867 | 2.397–5.927 | 3.985–8.506 |
| 5000 | 0.230–3.310 | 3.576–25.155 | 15.386–36.270 |
| 10000 | 6.205–23.424 | 15.298–104.581 | 122.131–265.172 |

Here the values of the profits of contractions are distributed among the associative arrays. Hence to find the maximal value we need to search for the maximal value in each associative array, and to select the maximal one among these maximal values (line 5). Lines 7–9 is a list comprehension, in which we traverse all associative arrays, and check, whether there is a key, for which this maximal value is assigned. If yes, we record the pair of the key $i$ of the associative array, and the key $j$ of the maximal value. If all the maximal values have been found, we select one (more precisely the first) key from the keys of the maximal values. This key is a pair, and we refer to its elements by $i$ and $j$ in the following (line 10). We delete the edge belonging to the selected pair (line 11), and we store the keys in the associative array belonging to $i$ (line 12). It is an important step, Python does not allow to modify a data structure while traversing it. (Do not cut off the tree you are standing on!) Similarly, we docket the associative array belonging to $j$ (line 14), and by traversing this associative array we update the weights of the edges in contact to the contracted cluster (lines 16–19). If it is not possible (there is no corresponding $(i, z)$ edge to the edge $(j, z)$) then we construct the missing edge. When all edges $(j, \cdot)$ are processed, we can delete the associative array belonging to $j$ (line 25), and the all references to this cluster (i.e. $(\cdot, j)$ type edges), too (line 22). If the contracted cluster becomes empty (any strange, sometimes it can happen), we need to delete it (lines 26–27). If only one cluster remains, we can stop the method (lines 28–29).

The statistics about Algorithm 3 can be found in the third column—denoted with $D^2$— of Table IV. From this table it is obvious, that the two level dictionary is more effective than the ordinal dictionary.

In Python the associative arrays are implemented as hash tables. It is well known, that here the deletion is a costly operation, and thus we delete the whole structure in small steps. By examining the handling of the hash table in Pythonic way, we rewrote the code in Algorithm 3 in a such way, that at contraction we do not delete directly from the joined cluster, but we create a new associative array for the joined cluster, and fill it with its predecessors. As deletion from dictionary is solved by replacing data with dummy items, the recreation of

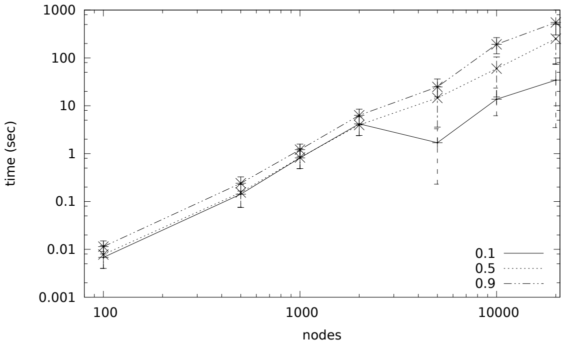

Fig. 3. Running time of implementation $\overline{D_r^2}$ for graphs with different $N$ and $q$

the joined cluster can free up memory and speed up problem Q2. The deletion from the nearby clusters remains the same. It would be very time consuming to recreate them, too. By the fifth column—denoted with $D_r^2$— of Table IV this extra effort has no evident profit: the accuracy is almost the same, but the running time is slightly longer.

## V. Quasi-parallel variant

The hierarchical clustering sometimes has very natural interpretations. For a given distance function $d : V \times V \to \mathbb{R}$, where $d(x, x) = 0$ for any $x \in V$ Sibson defined a *dendogram* function $c : [0, \infty) \to E(V)$ [14], where $E(V)$ is the set of equivalence relations on $V$. This function $c$ fulfils the following criteria:

- If $h \leq h'$ then $c(h) \subseteq c(h')$,
- The final value of $c(h)$ [i.e. $c(\infty)$] is $V \times V$ and
- $c(h + \delta) = c(h)$ for any small $\delta > 0$.

In case of a minimal distance (the distance of clusters defined by the minimum of distances of their elements), let $E = \{(x, y)|x, y \in V, d(x, y) < h\}$, i.e. add to the set of nodes $V$ all the edges shorter than $h$. This is a symmetric relation. Next, take the transitive closure of this relation, which becomes an equivalence relation. Taking these equivalence relations for all $h \geq 0$, we get the dendogram $c$.

Can we use this idea? Unfortunately not. If we have a chain of objects connected by edges, then their optimal clustering produces pairs and maybe one singleton cluster [15]. In the case of a star topology we got a pair and singletons. Therefore the transitive closure of a (partial) tolerance relation is not suitable for us. But we can try to contract independent pairs. As they are independent, the contraction can be done in parallel! This means that we lose the purely greediness of the contraction method. Moreover the dynamics of the method is changing. If we started by contracting two singleton clusters $i$ and $j$, for which there was a third cluster $k$ such that $d_{i,k} > 0$ and $d_{j,k} > 0$, then the next contraction used clusters $i \cup j$ and $k$ at algorithms before. Moreover if there was a fourth cluster $l$, for which $d_{i,l} > 0$, $d_{j,l} > 0$ and $d_{k,l} > 0$, then the following contraction used clusters $i \cup j \cup k$ and $l$, and so on. In other words the initial combined cluster grows in each steps until it is surrounded with clusters only, for which the profit of the contraction with this giant cluster is negative. If we execute the contractions in parallel, then we have more centres (not so giant clusters).

**Algorithm 4** Determining the independent edges

```
def independent(pairs):
    s = {}
    random.shuffle(pairs)
    for i,j in pairs:
        if len({i, j} &
            (s.keys() | s.values())) == 0:
             s[j] = i
    return s
```

We do not need to rewrite the whole Algorithm 2 as most of the code is reusable. For example, to get the independent pairs we have the list of best pairs. Previously we used the first pair from the list, now we will use more. Algorithm 4 selects the independent ones. This algorithm gets all best pairs, and constructs an associative array from the independent edges. The algorithm traverses the best edges, and an edge is independent from the stored ones, if its nodes do not occur in the associative array, neither as a key, nor as a value. The original ordering limits the set of independent edges, so we shuffle the starting list, in order for the subsequent runs to give a different results, therefore the clustering becomes indeterministic, and by repeating the whole process it should be possible to choose the best of them.

The Algorithm 5 is a slight modification of Algorithm 2 so we only provide the difference: you need to replace lines 25–36 in Algorithm 2 with the listing of Algorithm 5. The main difference is that Algorithm 2 which allowed only one pair in the associative array, now allows any number of pairs, which need to be independent.

In this case, the question arises: it is worth to complicate things? Based on the first idea, it could speed up the process, because we can omit the superfluous steps, as we do not need to traverse the associative array several times, it is enough only once, to get the same number of contractions. The second

**Algorithm 5** Quasi-parallel contraction, associative array

```
if len(d) < 2:
    return
max_d = max(d.values())
while max_d > 0:
    pairs = [pair for pair,value
        in d.items() if value ==max_d]
    s = independent(pairs)
    for i,j in s.items():
        uf.union(i,j)
    d2 = contraction(d, s)
    if len(d2) < 2:
        break
    d = d2.copy()
    max_d = max(d.values())
```

TABLE IV
COMPARISON OF RUNNING TIMES AND ACCURACY ON 3/2 BA GRAPHS

| | $D$ | $\overline{D}$ | $D^2$ | $\overline{D^2}$ | $D^2_r$ | $\overline{D^2_r}$ |
|---|---|---|---|---|---|---|

column—denoted by $\overline{D}$—of Table IV shows the numbers of the quasi-parallel variant. It is obvious that this parallel variant is better than the original according to the running time. But if we learned that there is no free lunch, maybe the accuracy of method were worse. Let us see the numbers. By Table IV Algorithm 2 produces less conflict, thus gets closer to the optimum. We measured the whole process at three different values of $q$. We wish to repeat this investigation in more details. We executed the original (Algorithm 2) and the parallel (Algorithm 5) version of the Contraction method on the same signed graphs. The original graph was 3/2 BA graph with thousands of nodes. The weight of the edges were given randomly according the value of $q$ for 101 different $q$. After the contraction method we calculated the cost-functions. Figure 4 shows the result. Moreover we summed the values of the cost functions (calculated the "integral" of the curves), and at the parallel version the sum was 94.8–96.0 percent of the original version (these numbers denote conflicts, so the smaller is better here). Five experiments show similar results, so we believe that this is the tendency. This is not a big difference, but disproves our hypothesis. This fact undermines our beliefs in greedy algorithm, so a careful examination is needed. We think, that the giant cluster is the result of an early decision at non-parallel algorithms. This decision could be perfect or bad. Maybe the latter occurs more often. The parallel version postpones the decision, it executes several contractions in parallel, gets smaller clusters, and maybe causes less vital mistakes.

By examining the Table IV, we can see, that the parallel version really is faster than the original. Surprisingly, at different values of $q$ the speed rate is different. For small $q$ we see big differences, while at big $q$ the parallel version will not be twice as fast as the original.

Let us compare this parallel version ($\overline{D}$) with the variant using an associative array of associative arrays ($D^2$), because until now this was the fastest implementation. If $q$ is small, the parallel version is remarkably faster for big $N$. If $q$ is big, the variant with double dictionary is the clear winner.

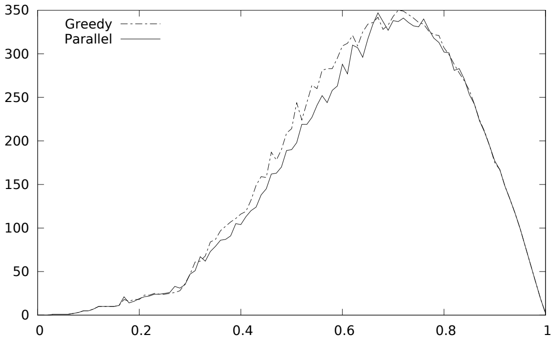

Fig. 4. Cost functions earned by the original and parallel algorithms. $x$-coordinate denotes the rate $q$ of positive edges and $y$-coordinate denotes the value of the cost function.

Of course, the following question arises: It is worth to construct the parallel version of Algorithm 3, or not? The modification is minimal:

- We need to replace line 10 with a cycle for the independent pairs from `pairs`.
- We need to indent lines 11–29, to treat this lines as the core of the cycle in line 10.

We leave these modifications to the reader, and do not present this as a next code listing. Table IV shows the statistics of this parallel variant—denoted by $\overline{D^2}$. If $q$ is small—we only need a small number of contractions to get the near optimal solution—then the second parallel variant ($\overline{D^2}$) is much faster then its origin ($D^2$), but for big $N$s it is slower than the first parallel implementation ($\overline{D}$). Surprisingly if we need a lot of contraction (e.g. $q$ is big), then the parallel version ($\overline{D^2}$) is much slower than its origin ($D$). By observing the accuracy of the last implementation, the tendency is more evident: 84.3–87.7 percent of conflicts of the non-parallel version.

We could continue the comparison of greedy and parallel variants, but we compared the accuracy of the different parallel implementations. The rates of the integrals were 99.9–101.0 percent.

The running times of the three parallel versions are comparable by Table IV. Hence we run the different "parallel" implementations on BA graphs with 20,000 nodes to find the differences. Each implementation solved 15 problems in one hour and a half. The implementation $\overline{D}$ was the slowest, about 8 percent slower than the others. But its accuracy was the best: the difference was less than half percent.

We tried the skip-list data structure for Contraction, where the complexity of the insertion, deletion and search is $O(\log n)$, and not constant. By our statistics this implementation was five times slower than the implementation with double dictionary. The results based on these prototypes suggest for us that the industrial implementation will based on a (double) dictionary, too.

## VI. Future plans

There are tools to find the weakness of codes presented in this paper, and their execution could be optimized. Moreover by choosing a different programming language it gives (maybe several magnitudes) faster implementation. We refer to a quote of D. E. Knuth: *We should forget about small efficiencies, say about 97% of the time: premature optimization is the root of all evil. Yet we should not pass up our opportunities in that critical 3%.* We would like to invent new algorithms and not to patch this ones.

Our main aim was to introduce a simple idea, and its little improvements. We have fulfilled our plans and broke through our former limits of 500 nodes (with significantly higher results), although previously we used faster languages. To solve the correlation clustering problem for bigger and bigger set of objects is challenging for us, so we will continue this path. We believe to go futher we need to use other kind of parallelism: divide and empire.

The zero "distances" of clusters were left along the whole article. We did not examine whether they have any effect to contract clusters where the corresponding distance is zero. This contraction does not decrease and does not increase the number of conflicts *immediately*. It is worth to examine whether this kind of contractions has any future effects, or not. We do not know any examples that could assist this question from neither the natural nor the social sciences.

We can imagine three clusters $i$, $j$ and $k$, where $d_{i,j} = 0$ $d_{i,k} = c$ and $d_{j,k} = -c$. It is obvious, that contracting $i$ and $j$ the value of $d_{i\cup j,k}$ becomes zero, so the number of conflicts does not lessen. While by contracting $i$ and $k$ the number of conflicts decreases by $c$, if $c > 0$. But it is not clear when we have thousands of clusters, the situation is the same, or not. If we have BA random graphs, the zero "distance" clusters, i.e. independent clusters are very common.

## VII. Conclusion

We introduced a correlation clustering problem, and extended the (partial) tolerance relation to clusters. Using this concept we have shown the Contraction method, and its several implementation in Python. Despite of the weakness of this programming language these implementations gave fast results for big sets, although the problem is NP-hard. By our knowledge these are the state of the art algorithms in correlation clustering. We found a near-optimal solution for a problem where the upper bound of the number of possible partitions is $10^{64,079}$ [16].

Our previous measurements show, that the accuracy of this method is among the best optimization methods [11]. These two properties enable the usage of this method in real-life applications.

*Abstract*—**In this paper, the performance research on CPython's latest interpreter is presented, concluding that bytecode dispatching takes about 25 percent of total execution time on average. Based on this observation, a novel bytecode dispatching mechanism is proposed to reduce the time spent on this phase to a minimum. With this mechanism, the blocks associated with each kind of bytecodes are rewritten in hand-tuned assembly, their opcodes are renumbered, and their memory spaces are rescheduled. With these preparations, this new bytecode dispatching mechanism replaces the time-consuming memory reading operations with rapid operations on registers.**

**This mechanism is implemented in CPython-3.3.0. Experiments on lots of benchmarks demonstrate its correctness and efficiency. The comparison between original CPython and optimized CPython shows that this new mechanism achieves about 8.5 percent performance improvement on average. For some particular benchmarks, the maximum improvement is up to 18 percentages.**

## I. Introduction

The past decade has witnessed the widespread use of Python, which is a typical dynamic language designed to execute on virtual machines. Several software engineering advantages over statically compiled binaries, including portable program representations, thread manage -ment, some safety guarantees, built-in automatic memory, and dynamic program composition through dynamic class loading, are provided by Python. These advanced features enhance the user programming model and drive the success of Python language. However, these features also require the dynamic compilers to do quite a lot of extra operations, such as type checking, wrapping/unwrapping of boxed values, virtual method dispatching, bytecode dispatching, etc. These extra operations usually make Python programs several or dozens of times slower than static programs achieving the same functionality. Moreover, traditional static program optimiza -tion technologies are frustrated, introducing new challenges for achieving high performance.

In response, more and more researchers have paid their attention to optimize dynamic language compilers. The technologies proposed aim to improve performance by monitoring programs' behavior and using this information to drive optimization decisions [1]. The dominant concepts that have influenced effective optimization technologies in today's virtual machines include JIT compilers, interpreters, and their integrations.

JIT (just-in-time) techniques exploit the well-known fact that large scale programs usually spend the majority of time on a small fraction of the code [2]. During the execution of interpreters, they record the bytecode blocks which have been executed more than a specified number of times, and cache the binary code associated to these blocks. The next time these bytecode blocks are executed, it has no need to interpreter these bytecodes once again, just jumps to the cached binary code, and continues the execution. By this way, much interpreting work is omitted, and performance improvement can be achieved. However, since the threshold is quite large in general, the interpreting stage still accounts for a large proportion of total execution time. JIT strategies work well for *for/while* blocks which likely exist in science compute field. For the programs, whose purposes are remote configuration, warning, tracing, statistics, communication, etc, it is very hard to find hot blocks. Though not large, these programs are usually executed quite frequently.

Interpreters have a series of advantages which make them attractive [3]. Firstly, optimizing interpreters reduces the uptime of all Python programs with or without hot blocks. Secondly, they are quite simpler to construct than JIT compilers, making them quicker, more reliable to construct and easier to maintain. Thirdly, interpreters require less memory than JIT compilers, for both the interpreted virtual machine code and the interpreter itself. Interpreters for dynamic language have two main structures [1]: switch-based structure and threaded-based structure, whose details are given in section 2 part B. The latter is the latest and most efficient mechanism. Recently, many researchers have applied dynamic techniques to improve the performance of threaded-based structure. Piumarta and Riccardi [4] describe their techniques to dynamically generate threaded codes for purpose of eliminating a central dispatch site and inlining common bytecode sequences. Ertl and Gregg [5] extend Piumarta and Riccardi's work by duplicating bytecode sequences, researching various interpreter generation heuristics,

[1] Corresponding author. Email: gunj@ustc.edu.cn

978-83-60810-66-8/$25.00©2015, IEEE

and concentrating on improving branch prediction accuracy. Gagnon and Hendren [6] adapt Piumarta and Riccardi's research to work in the context of multithreading and dynamic class loading. Sullivan et al. [7] describe a combination between an interpreter implementation and a dynamic binary optimizer, which enhances the efficacy of the underlying dynamic binary optimizer during the execution of interpreter.

Despite the enhancements above, interpreters are still worse than static compilers from the runtime perspective. The purpose of our research is to explore new ways to achieve further performance improvement. In this paper, the performance research on CPython's latest interpreter is presented, finding that bytecode dispatching takes about 25 percent of total execution time on average. Then, a novel bytecode dispatching mechanism, which aims at reducing memory reading operations during bytecode dispatching and reducing the time spent on this phase to a minimum, is proposed. This mechanism is implemented inside CPython's interpreter. Experiments on lots of benchmarks demonstrate the correctness and efficiency of our new mechanism. The comparisons between original CPython and optimized CPython show that our new mechanism can achieve about 8.5 percent performance improvement on average. For some particular benchmarks, the maximum improvement is up to 18 percentages.

The remainder of this paper is structured as follows: In the next section, we make comparisons among different compilers of Python and present both switch-based and threaded-based mechanisms. Section 3 reports our performance research on CPython's interpreter. Section 4 discusses the main techniques we adopted to construct a new bytecode dispatching mechanism. Benchmarks and Experiments are given in section 5. Section 6 discusses the related work. We conclude this paper in the last section.

## II. Background

### *A. CPython VS Other Python compilers*

A series of dynamic compilers are designed to run Python programs, such as CPython, Jython [8], IronPython [9], Pyston [10], PyPy [11], etc. The comparisons among them are shown on Table I, and these benchmarks are provided officially by Pyston/minibenchmarks and Pyston/microbenchmarks. Among these compilers, CPython is the official and standard compiler for Python language, it can support all the grammars and extensions. Others are developed for special applications. They focus on particular scenarios and take in-depth optimization passes. In this context, these compilers show their excellent performances for some benchmarks, but for other benchmarks, they may be several times slower than CPython. As shown on Table I, taking fid.py for example, it takes CPython 3.696 seconds to execute this script, while IronPython, Pyston and PyPy spend less than 2 seconds on the same script. However, it takes CPython 1.082 seconds to execute emwomding.py, while JPython, IronPython, Pyston and PyPy spend more than 3.700 seconds on the execution of emwomding.py.

What's more, some benchmarks, like pydigits.py, empth_lo -op.py, vecf_add.py, nq.py, raytrace.py, cannot be executed successfully by some of these compilers. Based on these comparisons, our research focuses on CPython, and has not only practical application value, but also instruction meaning for the improvement of other interpreters.

### *B. Switch-based Mechanism VS Thread-based Mechanism*

The performance of interpreters depends heavily on their bytecode dispatching mechanisms. CPython's interpreter provides two main bytecode dispatching mechanisms: switch-based mechanism and thread-based mechanism.

The inner loop of switch-based interpreters is quite simple: jump to the dispatch point, fetch the next bytecode and dispatch to its implementation through a switch statement. Its typical framework is shown in Fig. 1.

As shown in Fig. 1, the interpreter is an infinite loop with a big switch block to dispatch bytecodes successively. Each bytecode are implemented by a particular case in the body of this switch block. At the end of each case, control are passed back to the beginning of the infinite loop by breaking out of this switch block. Traditional C compilers like GCC translate this switch block into a series of comparison statements. Considering a particular bytecode whose opcode is BINARY_SUBTRACT, five indispensable comparisons should be executed before reaching its associated block. Assuming that all bytecodes have the same probability of occurrence, it takes N/2 (N is the total kinds of bytecodes) comparisons on average to find the corresponding block. As to

TABLE I.
COMPARISONS AMONG CPYTHON, JYTHON, IRONPYTHON, PYSTON AND PYPY

CPython, N is 101. So, performing bytecode dispatching wastes the majority of execution time and it is very inefficient.

Threaded-based mechanism is the latest and most efficient mechanism for interpreters, popularized by the Forth programming language [12]. There are many kinds of threaded-based interpreters, and direct threading is regarded as the most efficient one. Direct threading mechanism improves performance by eliminating redundant comparisons. In addition, rather than returning to a central dispatch point, the implementation of each direct threading opcode ends with the particular code required to dispatch the next opcode. This optimization eliminates the centralized dispatch, removing lots of jump instructions. The framework of direct threading mechanism is shown in Fig. 2.

As shown in Fig. 2, execution starts with fetching the address of the very first bytecode's implementation and then jumping to that address. For each bytecode, it performs its own work at first, then increases the instruction pointer, thirdly fetches the address of next bytecode's implementation from memory, and jumps to the target address to handle successive bytecode. The native instructions associated with bytecode dispatching is shown in Fig. 3, with one stack reading, one memory reading and one jump. It can be seen from Fig. 3 that the bytecode dispatching overheads associated with direct threading mechanism are quite lower than those associated with switch-based mechanism.

## III. Motivation: Performance Research

So far, it can be seen that bytecode dispatching plays a very important role in the performance of CPython. To make this concept intuitional, a series of meticulous experiments are conducted and the experimental results are shown in table II.

To make the results credible and accurate, this work utilizes hardware performance counters provided by Intel, and calculates the number of ticks which are consumed by the procedure to find next bytecode. The results are shown in Table II column 2. The ticks, which are consumed by the total program execution are also recorded and listed in Table II column 3. In Table II column 4, the ratios between them are calculated and listed. According to this table, it can be sure that the time consumed by bytecode dispatching is 25 percent of the total execution time on average. So if this stage could be further optimized, the total performance of CPython will be improved obviously.

As shown in Fig. 3, the bytecode dispatching in direct threading mechanism is composed of one stack reading, one jump and one memory reading. Inside the memory reading, there are an addition and a multiplication. Since operations on stack are quite frequent, the first stack reading instruction will also hit the L1 cache. Table III [13] lists the time needed to read data from register, L1 cache, L2 cache, memory and disc. According to this table, the first instruction takes about 2ns. The second instruction contains an addition operation, a multiplication operation and a load operation. The first two operations can be finished within several ticks. However, since L1 cache can only contain eight pages (32k L1 cache, page size 4k), reading the address of successive bytecode's implementation leads to lots of L1 cache misses. In this context, it has to get the right value from L2 cache, or even memory, which may take dozens of nanoseconds. Assuming that reading from these three memory structures has the same probability of occurrence, it takes about 30ns to finish this memory reading. So, it can be seen that the second instruction takes the majority of the time spent on bytecode dispatching, and optimizing this instruction will contribute a lot to bytecode dispatching.

## IV. THE NEW DISPATCHING MECHANISM

According to the above section, bytecode dispatching spends most of the time on memory reading. To optimize bytecode dispatching procedure, a new bytecode dispatching mechanism is proposed and the framework of CPython's interpreter is reconstructed, drawing the inspiration from [14]. Our new techniques proceed in three phases and their functionalities are described below.

Phase 1: Rewriting and statistics. This phase rewrites the statements associated with each kind of bytecodes in hand-tuned assembly, and calculates the length of the final binary code of each case. The results are shown at Table IV. According to this table, there are 19 kinds of bytecodes which own less than 64 byte binary code, 51 kinds of bytecodes which own less than 128 byte but more than 64 byte binary code, 22 kinds of bytecodes which own more than 128 byte but less than 256 byte binary code, and 9 kinds of bytecodes which own more than 256 byte binary code.

TABLE IV
STATISTICS ON LENGTH OF BYTECODES' FINAL BINARY CODE

| length | [0,64] | (65,128] | (128,256] | (256,512] |
|---|---|---|---|---|
| number | 19 | 51 | 22 | 9 |

Phase 2: calculation. This phase calculates the proper size of each memory unit, named BSIZE. Inside the optimized interpreters, the memory allocated to each kind of bytecodes is an integral multiple of BSIZE bytes. Mark *binary[i]* as the length of binary code associated with *i*th kind of bytecodes, the BSIZE should be the minimum positive number which conforms to condition (1) and condition (2).

$$\exists i : 2^i = BSIZE \tag{1}$$

$$\sum_{i=0}^{100} \left\lceil \frac{binary[i]}{BSIZE} \right\rceil \leq 256 \tag{2}$$

The first constraint assures the calculation of next bytecode's address is simplified to a quick left shift. The second constraint assures that the maximum opcode of bytecodes isn't bigger than the threshold value (256) defined by CPython. If the BSIZE is too big, there will be a lot of NOP instructions and the executable file will be quite big, causing damage to the performance. That's why BSIZE should be set as small as possible. According to Table IV, the proper value of BSIZE is 128.

Phase 3: opcode redefinition. This phase redefines the opcodes of bytecodes, with their order stay the same. Let *opcode[i]* be the new opcode of *i*th kind of bytecode, and the algorithm used here is shown as follows:

$$\begin{aligned} &opcode[0] = 0 \\ &opcode[i] = opcode[i-1] + \left\lceil \frac{binary[i-1]}{BSIZE} \right\rceil, 1 \leq i \leq 100 \end{aligned} \tag{3}$$

Taking the first three bytecode (POP_TOP, ROT_TWO and ROT_THREE) as an example, their original opcodes are 1, 2 and 3, respectively. Assuming the first bytecode has 200 byte binary code, the second bytecode has 350 byte binary code, and the third bytecode has 100 byte binary code, their final opcodes will be 1, 3 and 6. The memory allocation of the interpreter with new dispatching mechanism is shown in Fig. 4.

As shown in Fig. 4, POP_TOP's binary code is stored in the first grid region (from top to bottom), ROT_TWO's binary code is stored in the second grid region, while the ROT_THREE's binary code is stored in the third grid region. There are gaps between neighboring kinds of bytecodes. In addition, the framework of the new interpreter of CPython is shown in Fig. 5. Inside this new interpreter, the binary code of all kinds of bytecodes is arranged in numerical order and each of them occupies several BSIZE memory spaces. So, every time CPython jumps to the implementation associated to next bytecode, it just need to execute this simple statement: "goto (base + BSIZE*opcode)". Fig. 6 shows the native instructions associated with this statement, including one stack reading, one left shift, one addition and one jump. The middle two instructions are operations on registers and can be finish within

2 ticks (0.8ns). Hence, it just takes 2.8ns to get the address of next bytecode's implementation, instead of 30ns. Since NEXTOP operation is executed so many times, this new structure will bring a lot of performance promotion.

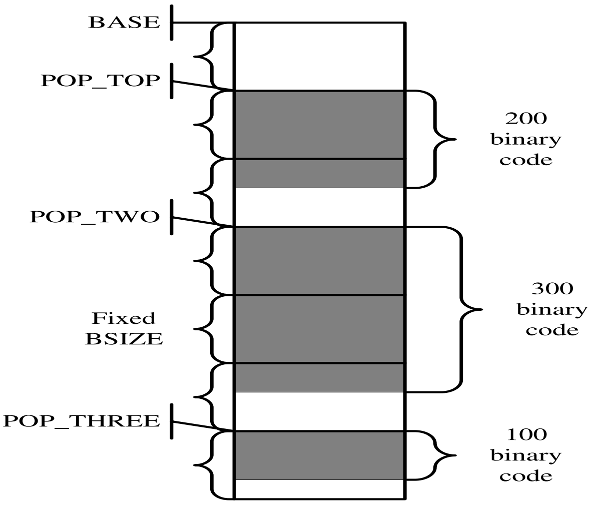

Fig. 4 The memory allocation of post-construction interpreter.

```
bytecode implementations:
BASE:
….;
asm(“.balign BSIZE \n\t”);
LOAD_FAST:
    …;
    opcode = get_opcode(insn_next);
    goto (BASE+opcode* BSIZE);
asm(“.balign BSIZE \n\t”);
LOAD_CONST:
    …;
    opcode = get_opcode(insn_next);
    goto (BASE+opcode* BSIZE);
asm(“.balign BSIZE \n\t”);
BINARY_ADD:
    …;
    opcode = get_opcode(insn_next);
    goto (BASE+opcode* BSIZE);
asm(“.balign BSIZE \n\t”);
BINARY_SUBTRACT:
    …;
    opcode = get_opcode(insn_next);
    goto (BASE+opcode* BSIZE);
….

## V. Experimental Evaluation

This new bytecode dispatching mechanism has been implemented under Ubuntu-12.04 on Intel(R) Core(TM) 2 CPU E6550 2.33GHz with 2 processors, 2G memory, 32k L1 cache and 4M L2 cache. When assess the optimized CPython, about 35 benchmarks are gathered from CPython-3.3.0 and Pyston-0.2. Two criterions are considered here: (1) correctness (optimized CPython can provide the same functionality as original one.), and (2) efficiency (optimized CPython can execute benchmarks faster than original one).

### A. Correctness

Taking benchmark *diff.py* as an example, file sysmodule.c and file _testcapimodule.c are chosen from CPython's source files randomly and are used as two parameters of *diff.py*. Then, *diff.py* is executed by optimized CPython and original CPython separately, and two result files are produced. Later, Linux command *diff* are used to compare these two result files, concluding that there is no difference between them.

In addition, the benchmarks, which are listed in Table I and cannot be executed successfully by Jython, IronPython, Pyston or PyPy, can be executed successfully by optimized CPython. Actually, optimized CPython can execute all these 35 benchmarks and the time spent on these benchmarks is shown in Fig. 7.

### B. Efficiency

Optimized CPython and original CPython are compiled with the same parameters, and both of them are used to execute these benchmarks separately. Each benchmark is executed one thousand times to reduce volatility, and the final results are shown in Fig. 7. As to some benchmarks taking too little time to run, we recode the time spent on their several times running. Taking *image.py* for example, it just takes original CPython 0.046 seconds to run this benchmark. So, running *image.py*100* takes 4.6 seconds. Similarly, running *queen.py/10* takes 10.23 seconds, for the reason that it takes CPython 102.3 seconds to finish the queen.py. It can be seen from Fig. 7 that all of these benchmarks achieve performance improvement with our new bytecode dispatching mechanism. The average performance improvement is about 8.5%. In particularly, benchmark *image.py* achieves up to 18% performance improvement.

The performance improvement happens for two main reasons. Firstly, this new interpreter replaces slow memory reading operations with quick operations on registers, and reduces the time spent on bytecode dispatching. Secondly, less memory reading operations cut down on the cache misses, especially for low specification machines. Perf [15] is used to measure L1 data cache misses for part of these benchmarks and the results are shown at Table V. Table V column 2 lists the cache misses reported by original CPython when it is used to execute these benchmarks, while Table V column 3 lists the cache misses reported by optimized CPython when it is used to do the same jobs. The last column in Table V shows that about 14.64 percent of cache misses are left out on average. The more memory reading operations it reduces, the greater chance that

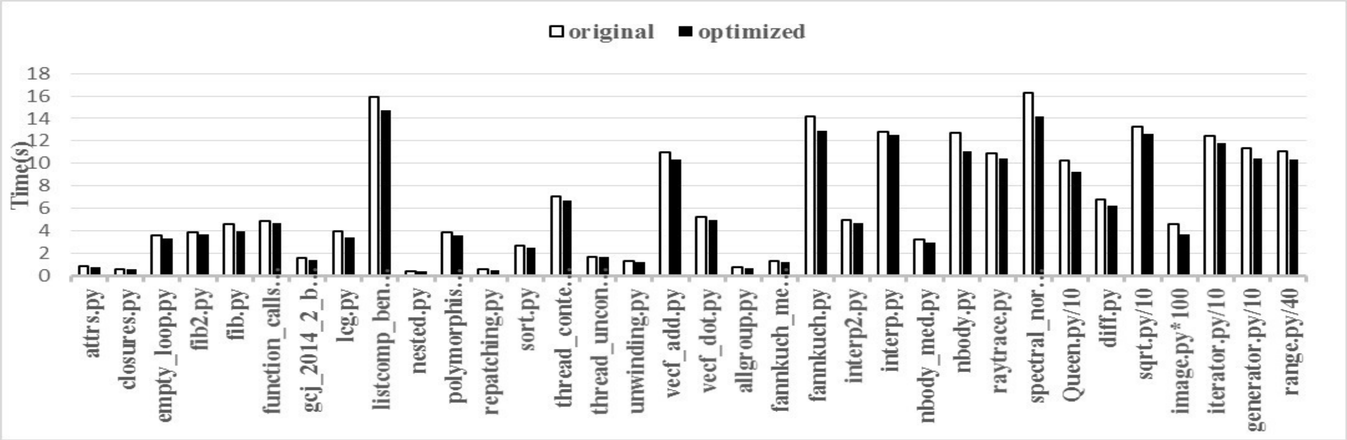

Fig. 7 Ratio of  benchmarks before and after optimization.

TABLE V
STATISTICS ON L1 DATA CACHE MISSES

| Benchmarks | ori-CPython | opti-CPython | 1-(opti/ori) |
|---|---|---|---|
| queen.py | 64M | 43M | 32.8% |
| pow.py | 3.93M | 3.54M | 9.9% |
| diff.py | 36.9M | 33.1M | 10.3% |
| sqrt.py | 3.46M | 2.56M | 26.0% |
| image.py | 1.37M | 1.14M | 16.8% |
| iterator.py | 83.5M | 80.7M | 3.35% |
| generator.py | 170M | 148M | 12.9% |
| range.py | 292M | 270M | 7.53% |
| while.py | 295M | 259M | 12.2% |
| average | - | - | 14.64% |

Note: “ori-CPython” stands for “original CPython”, “opti-CPython” stands for “optimized CPython”, and “1-(opti/ori)” stands for “1 - (optimized CPython / original CPython)”.

remaining memory reading operations hit the cache. In another word, the remaining memory reading operations can be finished in less time.

## VI. RELATED WORK

There are a large quantity of recent papers researching interpreter performance. Romer et al. [16] have reported the performance characteristics of some interpreters. Later, Ertl and Gregg [3] investigated the performance of recent efficient interpreters. Both of these two studies have found that almost every interpreters perform an exceptionally high number of indirect branches. Since most of indirect branches are caused by bytecode dispatching, their conclusion is consistent with this performance research reporting in section 3. Our research aims at reducing the time spent on the second instruction in Fig. 3 to a minimum, while their work aims at optimizing the third instruction in Fig. 3 and reducing indirect branches mispredictions. This is the main difference between us.

Several techniques are used to reduce indirect branches mispredictions. J Hoogerbrugge and L Augusteijn [17], [18] have proposed that software pipelining interpreters is a way to reduce dispatch branch cost on architectures with split indirect branches. In addition, Subroutine threading [19] has also been proposed to avoid the overheads of indirect branches in intrepreter implementations. Each bytecode is implemented with a particular C function. Instead of dispatching or interpreting bytecode, a simple JIT compiler generates executable code for a sequence of calls to these functions. This method can eliminate indirect branches at the cost of sacrificing both simplicity and portability.

Cache misses have a significant impact on the program performance [20]. Brunthaler [21] have proposed a formalization of interpreter opcode ordering (bytecode scheduling) for an interpreter with an extended opcode set, and concluded that high cache miss ratio is another bottleneck of interpreters. A lot of techniques, like feedback-guided technique [22], profile-guided technique [23], etc, are conducted to achieve better orderings, improving code locality and reducing cache misses. Jason McCandless and his co-worker [24] implement a metaheuristic (Monte Carlo) to generate better orderings, achieving considerable performance improvement. As shown in section 5, cache misses can also be reduced by our new mechanism, making the new interpreter perform better.

Another method which is widely used is combining sequences of VM instructions into super-instructions [25]. This technique focuses on reducing the number of bytecode dispatches, and has two variants: static super-instructions and dynamic super-instructions. The comparison between these two variants are shown in [5].

As far as we know, the nearest research to our work is [14]. The main difference is that their research plans for each bytecode a fixed-size block of instructions. In such a case, bytecodes with short instruction implementation will incur a lot of NOP instructions, which increases the code size of the interpreter dispatch loop and reduce cache hit ratio. In addition, bytecodes with long instruction implementation will lead to lots of extra jump instructions. Relatively speaking, our mechanism is more flexible and efficient than that, with much less NOP instructions and no extra jump.

## VII. CONCLUSIONS

In this paper, the performance research on CPython’s interpreter is carried out, figuring out that bytecode dispatching has a big influence on interpreters. Then, a novel bytecode dispatching mechanism is designed, aiming at removing memory reading operations during bytecode dispatching and reducing the time spent on this phase to a minimum. The final binary code of each kind of bytecodes is arranged in numerical order and each of them occupies several BSIZE memory spaces.

This novel mechanism is implemented, and its correctness and efficiency are demonstrated by a large number of benchmarks. Comparisons are made between original CPython and optimized CPython to show that the new mechanism achieves about 8.5 percent performance improvement on average. For some particular benchmarks, the maximum improvement is up to 18 percentages. This performance improvement happens for two main reasons: lesser memory reading operations and lesser cache misses. The novel mechanism proposed here can also be adopted by other interpreters, and will contribute to their performance improvement.

***Abstract*—This paper presents the issue of fuzzy arithmetic calculations in two different notations. The well-known L-R notation proposed by Dubois-Prade, which enjoys a well-earned recognition of the researchers dealing with fuzzy logic was presented on one hand. On the other hand, a OFN notation introduced by Kosiński was discussed. Comparative calculations were performed using the data of the benchmark "Dam and Crisis control center paradox". That benchmark is available in two versions, where the opposite trend is visible at the dam and at the CCC (Crisis control center). In one of the versions, the water level at the observed area decreases and increases at the dam, while in the other version the situation is opposite. The trend difference detection can aid the short-term forecast of the situation change at the monitored area. Results of the applied calculations in OFN notation show that this arithmetic is sensitive to trend differences related to the order characteristic for those numbers. Relationship between the fuzzy logic and the trend of the observed phenomena is an added value to the generalization of OFN and it is also a good signal for the future development of applications of such fuzzy calculations, being their unique feature at the same time.**

## I. Introduction

THE HISTORY of artificial intelligence shows that new ideas were often inspired by natural phenomena. Many tourists come back with passion to beaches at the Oceanside and many sailors sail on tide water. The phenomenon of high and low tides, although well known, has been stimulating imagination and provoking reflexion on the perfection of the Creation for many ages. The casual observer in unable to precisely specify water level decline, but he or she can easily describe it using fuzzy concepts such as "less and less", "little" and "a bit". The same applies to increase of water in the observed basin. The observer can describe it such linguistic terms like "more", "lots of" or "very much". Such linguistic description of reality is characteristic to powerful and dynamically developing discipline of artificial intelligence like fuzzy logic. The author of Fuzzy logic is an American professor of the Columbia University in New York City and of Berkeley University in California - Lotfi A. Zadeh, who published the paper entitled "Fuzzy sets" in the journal "Information and Control" in 1965 [1]. He defined the term of a fuzzy set there, thanks to which imprecise data could be described using values from the interval (0,1). The number assigned to them represents their degree of membership in this set. It is worth mentioning that in his theory L.Zadeh used the article on 3-valued logic published 45 years before by a Pole - Jan Šukasiewicz [2]. That is why many scientists in the world regard this Pole as the "father" of fuzzy logic. Next decades saw rapid development of fuzzy logic. Another milestones of the history of that discipline should necessarily mention L-R representation of fuzzy numbers proposed by D.Dubois and H.Prade [3], [4], [5], which enjoys great successes today. Coming back to the original analogy, one can see some trend, i.e. general increase during rising tide or decrease during low tide, regardless of momentary fluctuations of the water surface level. This resembles a number of macro and micro-economic mechanisms where trends and time series can be observed. The most obvious example of that seem to be bull and bear market on stock exchanges, which indicate to the general trend, while shares of individual companies may temporarily fall or rise. The aim is to capture the environmental context of changes in economy or another limited part of reality. Changes in an object described using fuzzy logic seem to be thoroughly studied in many papers. But it is not necessarily the case as regards linking those changes with trend. Perhaps this might be the opportunity to apply generalization of fuzzy logic which are, in the opinion of authors of that concept, W.Kosiński [6] and his team, Ordered Fuzzy Numbers.

As the basis for experiments, let us assume the example of the dam and the impounding basin presented in the figure below (Fig. 1). Letter A indicates the water level measured during last evening measurement. Then there was a rapid surge of water in the night. Whereas morning measurement was marked using letter C. Measurements were imprecise to some extent due to rapid changes of weather conditions. It is also known that during the last measurement the safety valve $z2$, was open and then the valve $z1$ activated. The management of the dam faces the problem of reporting rapid surges of water to the disaster recovery centre.

## II. Theoretical background description of OFN

### A. Some definitions of OFN

Each operation on fuzzy numbers, regardless if it is addition, subtraction, division or multiplication, can increases the carrier value. Several operations performed on given L-R numbers can result in numbers that are too broad and as a result they can become less useful. Solving equations using conventional operations on fuzzy numbers [7] is usually impossible either. An $A+X=C$ equation can always be solved using conventional operations on fuzzy numbers only when A is a real number. First attempts to redefine new operations on fuzzy numbers were undertaken at the beginning of the 1990-ties by Witold Kosiński and his PhD student - P. SŞysz [8]. Further studies of W. Kosiński published in cooperation with P. Prokopowicz and D. Ślęzak [9], [7], [10] led to introduction of the **ordered fuzzy numbers model - OFN**.

*Definition 1: An* ***ordered fuzzy number*** *A was identified with an ordered pair of continuous real functions defined on the interval* $[0,1]$*, i.e.,* $A=(f,g)$ *with* $f,g:[0,1]\longrightarrow R$ *as continuous functions.*

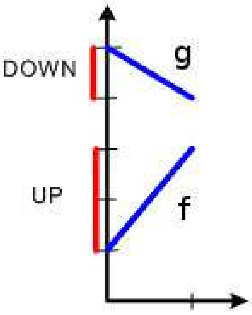

Fig. 2. Ordered fuzzy number

We call f and g the up and down-parts of the fuzzy number $A$, respectively. To be in agreement with the classical denotation of fuzzy sets (numbers), the independent variable of both functions $f$ and $g$ is denoted by $y$, and their values by $x$. [6]

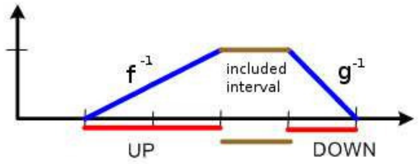

Fig. 3. OFN presented in a way referring to fuzzy numbers

Continuity of those two parts shows that their images are limited by specific intervals. They are named respectively: $UP$ and $DOWN$. The limits (real numbers) of those intervals were marked using the following symbols: $UP=(l_A,l_A^-)$ and $DOWN=(l_A^+,p_A)$. If both functions that are parts of the fuzzy number are strictly monotonic, then there are their inverse functions $x_{up}^{-1}$ and $x_{down}^{-1}$ defined in respective intervals $UP$ and $DOWN$. Then the following assignment is valid:

$$\begin{array}{c} l_A := x_{up}(0),\;\; l_A^- := x_{up}(1), \\ l_A^+ := x_{down}(1),\;\; p_A := x_{down}(0) \end{array} \tag{1}$$

If a constant function equal to 1 is added within the interval $[1_A^-,1_A^+]$ we get UP and DOWN with one interval (Fig. 2), which can be treated as a carrier. Then the membership function $\mu_A(x)$ of the fuzzy set defined on the R set is defined by the following formulas:

$$\begin{array}{lll} \mu_A(x)=0 & for & x\notin[l_A,p_A] \\ \mu_A(x)=x_{up}^{-1}(x) & for & x\in UP \\ \mu_A(x)=x_{down}^{-1}(x) & for & x\in DOWN. \end{array} \tag{2}$$

The fuzzy set defined in that way gets an additional property which is called order. Whereas the following interval is the carrier:

$$UP\,\cup\,[1_A^+,1_A^-]\,\cup\,DOWN \tag{3}$$

The limit values for up and down parts are:

$$\begin{array}{l} \mu_A(l_A)=0 \\ \mu_A(1_A^-)=1 \\ \mu_A(1_A^+)=1 \\ \mu_A(p_A)=0 \end{array} \tag{4}$$

Generally, it can be assumed that ordered fuzzy numbers are of trapezoid form. Each of them can be defined using four real numbers:

$$A\;=\;(l_A,1_A^-,1_A^+,p_A). \tag{5}$$

The figures below (Fig. 4) show sample ordered fuzzy numbers including their characteristic points.

Functions $f_A$, $g_A$ correspond to parts $up_A$ , $down_A\subseteq R^2$ respectively, so that:

$$up_A=(f_A(y),y):y\in[0,1] \tag{6}$$

$$down_A=(g_A(y),y):y\in[0,1] \tag{7}$$

The orientation corresponds to the order of graphs $f_A$ and $g_A$. The figure below (Fig. 5) shows the graphic interpretation

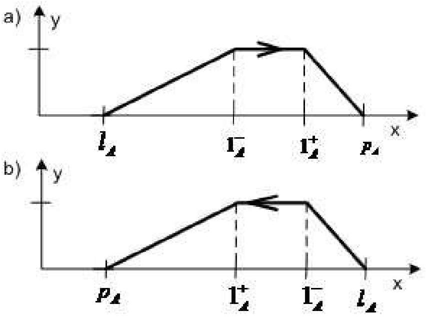

Fig. 4. Fuzzy number that is ordered a) positively b) negatively

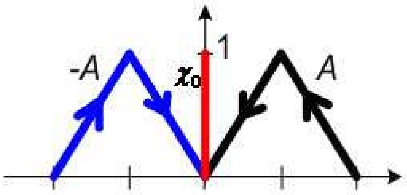

Fig. 5. Opposite numbers and the real number

of two opposite fuzzy numbers and the real number $\chi_0$. Opposite numbers are reversely ordered [11].

*Definition 2: A **membership function of an ordered fuzzy number** $A$ is the function $\mu_A : R \to [0,1]$ defined for $x \in R$ as follows [9], [6]:*

$$\mu(x) = \begin{cases} f^{-1}(x) & \text{if} \quad x \in [f(0), f(1)] = [l_A, 1_A^-] \\ g^{-1}(x) & \text{if} \quad x \in [g(1), g(0)] = [l_A^+, p1_A] \\ 1 & \text{if} \quad x \in [l_A^-, 1_A^+] \end{cases} \tag{8}$$

The above membership function can be used in the control rules similarly to the way membership of classic fuzzy numbers is used. All quantities that can be found in the fuzzy control describe selected part of the reality. Process of determining this value is called **fuzzy observation**.

### B. Arithmetic operations in OFN

The operation of adding two pairs of such functions is defined as the pair-wise addition of their elements, i.e., if $(f1, g1)$ and $(f2, g2)$ are two ordered fuzzy numbers, then $(f1 + f2, g1 + g2)$ will be just their sum. It is interesting to notice that as long as we are dealing with an ordered fuzzy number represented by pairs of affine functions of the variable $y \in [0,1]$, its so-called classical counterpart, i.e., a membership function of the variable $x$ is just of trapezoidal type. For any pair of affine functions $(f, g)$ of $y \in [0,1]$ we form a quaternion of real numbers according to the rule $[f(0), f(1), g(1), g(0)]$ which correspond to the four numbers $[l_A, 1_A^-, 1_A^+, p_A]$ as was mentioned in previous paragraph. If $(f, g) = A$ is a base pair of affine functions and $(e, h) = B$ is another pair of affine functions, then the set of typical operation will be uniquely represented by the following formulas respectively:

- addition $A + B = (f + e, g + h) = C$,
$$C \to [f(0)+e(0), f(1)+e(1), g(1)+h(1), g(0)+h(0)] \tag{9}$$
- scalar multiplication $C = \lambda A = (\lambda f, \lambda g)$,
$$C \to [\lambda f(0), \lambda f(1), \lambda g(1), \lambda g(0)] \tag{10}$$
- subtraction $A - B = (f - e, g - h) = C$
$$C \to [f(0)-e(0), f(1)-e(1), g(1)-h(1), g(0)-h(0)] \tag{11}$$
- multiplication $A * B = (f * e, g * h) = C$
$$C \to [f(0)*e(0), f(1)*e(1), g(1)*h(1), g(0)*h(0)] \tag{12}$$

### C. Association of OFN order with the environmental trend

In order to explain calculations presented in this sections, authors made the following assumptions concerning the context of changes taking place in the studied object (the impounding basin).

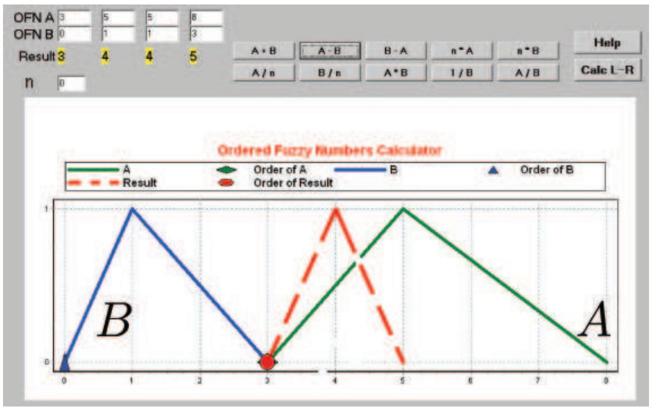
- **close context** - understood us the trend visible locally in the basin. It defines the trend of the object, i.e. if it is gradually filled or if the water level gradually falls. It is defined locally by the management of the dam,
- **further (environmental) context** - understood as the global trend for the observed area. It specifies trend of specific section of the river, intensity of precipitation as well as the set of other regional data which give better image of the environment. It is defined in the disaster recovery centre.

Two context types described above will be associated with the order of OFN numbers as follows. As the current water level state is reported to the disaster recovery centre, numbers that represent that state will always be oriented according to the environmental trend (reported to the centre). Whereas order of fuzzy numbers that represent changes of the water level in the impounding basin will be consistent with the local trend defined by the management of the dam. As a result, the order will be positive when the basin will be gradually filled, regardless the rate of that process. Whereas negative order can be observed when the outflow of water from the basin starts. Trend order changes themselves, as well as boundary conditions of the moment when they should occur, will make a separate process defined be the disaster recovery centre and the dam management respectively. Nothing stands in the way to ultimately use known segmentation methods for those processes and to determine the trend. Such issues are currently present in numerous publications and their detailed description is beyond the scope of this paper. Authors of that study assumed that the order equivalent to the trend changes is provided by a trusted third party and represents the expert's opinion concerning short-term weather forecast in the region important for the water level in the impounding basin as well as for the basin itself.

## III. An experimental comparison of fuzzy numbers arithmetic

### A. Elementary arithmetic operations

To automate computational experiments, authors of this study developed dedicated programme Ordered FN, which also efficiently supports graphic interpretation of operations being performed on ordered fuzzy numbers. Additionally, it is equipped with the Calc L-R module.



OFN A 3 5 5 8
OFN B 0 1 1 3
Result 3 4 4 5
n 0

Fig. 6. Main screen of the programme

Ordered FN is equipped with an additional module which is started using the Calc L-R button. It includes procedures to calculate the sum, the difference and the product of L-R numbers. This allows to compare some results obtained from operation on L-R and OFN numbers. The introduced fuzzy number has a form of $(m, \alpha, \beta)$ where $\alpha$ and $\beta$ are left and right-side dispersions. Shown here is an example of the software application. It includes the summary of simple arithmetic operation results in OFN and L-R notation. As shown in the attached figures (Fig. 6), subtraction of 3-3 is different for L-R than for OFN numbers.

### B. Comparison of calculations on ***L-R*** and ***OFN*** numbers

Majority of operation performed on L-R numbers, regardless if it is addition or subtraction, increases the carrier value, i.e. the areas of non-accuracy. Hence performance of several operations on those numbers can cause such big fuzziness that the resulting quantity will be useless. It is impossible to solve an $A + X = C$ equation using L-R representation through operations because for that interpretation $X + A + (-A) \neq X$ and $X*A*A^{-1} \neq X$. Whereas every inverse operation on L-R numbers will increase the carrier. It is often impossible to solve the equations using analytical (computations) method either. However, it is possible to break the stalemate using certain empirical methods. The situation is totally different in case of operation on ordered fuzzy numbers. It is possible to solve the above mentioned equation using an analytical method.

*Example 3.1:* Problem: There was a rapid surge of water in the impounding basin at night. The management of the dam has to send reports to the disaster recovery centre including the value of the water level change comparing to the previous state. Unfavourable weather conditions do not allow for precise measurement.

Data:

| | |
|---|---|
| $A(1, 1, 2)$ | - previous measurement [mln $m^3$] |
| $C(5, 2, 3)$ | - current measurement in [mln $m^3$] |

Mathematic interpretation:Hence the problem comes down to determining $X$ number that satisfies the equation $A+X = C$ as $A(1, 1, 2) + X = C(5, 2, 3)$

| **Solution versions:** |
|---|

| | |
|---|---|
| **Version I:** | *Solution using computational*<br>*method of OFN arithmetic.* |

$$A(0, 1, 1, 3) + X = C(3, 5, 5, 8)$$
$$X = C - A$$
$$X = (3, 4, 4, 5)$$

***Verification:*** $A + X = C$

$$A(0, 1, 1, 3) + X(3, 4, 4, 5) = C(3, 5, 5, 8)$$

| | |
|---|---|
| **Version II:** | *Solution using computational*<br>*method of L-R arithmetic.* |

$$A(1, 1, 2) + X = C(5, 2, 3)$$
$$X = C - A$$
$$X = (4, 4, 4)$$

***Verification:*** $A + X = C$

$$A(1, 1, 2) + X(4, 4, 4) \neq C(5, 2, 3)$$

As a result of operations on L-R numbers we obtain the outcome $(4, 4, 4)$. However, the verification through addition $(A + X)$ gives the result different from $C$. Correct result $(4, 1, 1)$ can only be achieved using empirical method. It is problematic and not always feasible.

## IV. Conclusion

Operations performed on ordered fuzzy numbers are often more accurate than operations performed on classic fuzzy numbers. Results of operations performed on them are the same as those obtained from operations on real numbers. Performing multiple not necessarily causes large increase of the carrier. The situation is different for L-R fuzzy numbers, where several operations often lead to numbers of high fuzziness. An infinitesimal carrier is interpreted as a real number and thus for OFN numbers one can apply commutative and associative property of multiplication over addition. The possibility to perform back inference on them allows to reproduce input data by solving an appropriate equation. This very property is an added value that makes this fuzzy logic extension worth to promulgate. Calculations performed on ordered fuzzy numbers are easy and accurate. It is worth mention the multiplication here, where the same procedure is used for all ordered fuzzy numbers regardless their sign. Whereas multiplication of L-R numbers is different for two positive numbers than for two negative ones. Another completely different procedure is used for multiplication of numbers of indefinite signs and for fuzzy zeros. It also seems to be very interesting to associate OFN numbers with trend of changes taking place for studied part of the reality. We are convinced that new applications of this property of OFN, shown here in the example of the fuzzy observation of the impounding basin in unfavourable weather conditions, will be introduced with the passing of time. Hence it seems that introduction of OFN gives new possibilities for designers of highly dynamic systems. With this approach it is possible to define trend of changes, which gives new possibilities for the development of fuzzy control and it charts new ways of research in the fuzzy logic discipline. Broadening it by the theory of ordered fuzzy numbers seems to allow for more efficient use of imprecise operations. Simple algorithmization of ordered fuzzy numbers allows to use them in a new control model. It also inspires researchers to search for new solutions. Authors did not use defuzzyfication operators [12] in this paper, which in themselves are interesting subject of many researches. They will also contribute to development of the comparative calculator created here. Although authors of this study are not so enthusiastic like the creators of OFN as regards excellent prospects of this new fuzzy logic idea, but they are impressed by possibilities for arithmetic operations performed using this notation. Even sceptics who treat OFN with reserve as it is generalization of fuzzy logic, can benefit from this arithmetic. After all OFN can be treated as internal representation of fuzzy numbers (heedless of it's authors' intention). With this new kind of notation for fuzzy numbers and fuzzy control, it is possible to achieve clear and easily interpreted calculation, which can be arithmetically verified regardless of the input data type. Perhaps the OFN idea will become another paradigm of fuzzy logic, just like the object oriented programming paradigm has become dominant in software engineering after the structured programming paradigm. Whichever scenario wins, at least some aspects of OFN arithmetic seem to be hard to ignore a priori.

***Abstract*—In this paper we present a method of synthesis of adaptive schedulers for real-time embedded systems. We assume that the system is implemented using multi-core embedded processor with low-power processing capabilities. First, the developmental genetic programming is used to generate the scheduler and the initial schedule. Then, during the system execution the scheduler modifies the schedule whenever execution time of the recently finished task occurred shorter or longer than expected. The goal of rescheduling is to minimize the power consumption while all time constraints will be satisfied. We present real-life example as well as some experimental results showing advantages of our method.**

## I. Introduction

BESIDES the cost and performance, power consumption is one of the most important issue considered in the optimization of embedded systems. Design of energy-efficient embedded systems is important especially for battery-operated devices. Although the minimization of power consumption is always important, since it reduces the cost of running and cooling the system.

Embedded systems are usually real-time systems, i.e. for some tasks time constraints are defined. Therefore, power optimization should take into consideration that all time requirements should be met. Performance and power consumption are orthogonal features, i.e. in general, higher performance requires more power. Hence, the optimization of embedded system should consider the trade-off between power, performance, cost and perhaps other attributes.

Performance of the system may be increased by applying a distributed architecture. The function of the system is specified as a set of tasks, then during the co-design process, the optimal architecture is searched. Distributed architecture may consist of different processors, dedicated hardware modules, memories, buses and other components. Recently, the advent of embedded multicore processors has created an interesting alternative to dedicated architectures. First, the co-design process may be reduced to task scheduling. Second, advanced technologies for power management, like DVFS (Digital Voltage and Frequency Scaling) or big.LITTLE [1], create new possibilities for designing low-power embedded systems.

Optimization of embedded systems is based on assumptions that certain system properties are known. For example, to estimate the performance of the system, execution times for all tasks should be known. Sometimes it is difficult to precisely predict all required information. Therefore, to guarantee the proper design, the worst case estimation is used. During the operation of the system it may occur that certain system properties may significantly differ from estimations or may dynamically change. It may be caused by too pessimistic estimation, by data-dependence or by some unpredictable events. In such cases the idea of self-adaptivity may be used to optimize some system properties.

In this paper we present the novel method for synthesis of the power-aware scheduler for real-time embedded systems. We assume that the function of the system is specified using the task graph that should be executed by the multicore processor supporting the big.LITTLE technology. The scheduler is generated automatically using the developmental genetic programming (DGP). The scheduler is self-adaptive, i.e. it dynamically reschedules tasks whenever any task finished its execution earlier or later than expected. In the first case the goal of the rescheduling is the reduction of power consumption by moving some tasks to low-power cores. In the second case, the system is rescheduled to satisfy all time constraints by moving some tasks to high-performance cores. Example shows the benefits of using our methodology.

The rest of the paper is organized as follows. Next section presents the related work. Section III presents the concept of the developmental genetic programming with respect to other genetic approaches. In Section IV we present our method. Section V describes an example and experimental results. The paper ends with conclusions.

## II. Related Work

Although there are a lot of synthesis methods for low-power embedded systems [2], the problem of optimal mapping of a task graph onto the multicore processor is rather a variant of the resource constrained project scheduling (RCPSP)[3] one, than the co-synthesis. Since the RCPSP is NP-complete, only

978-83-60810-66-8/$25.00©2015, IEEE

heuristic approach may be applied to real-life systems. Among the proposed heuristics for solving RCPSP, ones of the most efficient are methods based on genetic algorithms [4][5][6].

For systems that may dynamically change during operation, some methods of rescheduling was proposed. In [7] the number of tasks that receives a new start time, after rescheduling, is minimized. Another approach [8] proposes to reschedule the remaining tasks, such that the sum of deviations of the new finishing times from the original ones is minimized. In [9] the sum of deviations of starting and finishing times of all tasks is minimized. Proactive scheduling [10] does not perform rescheduling, but it minimizes the perturbations, caused by delays, by maximization of the minimum or total free slacks of task executions.

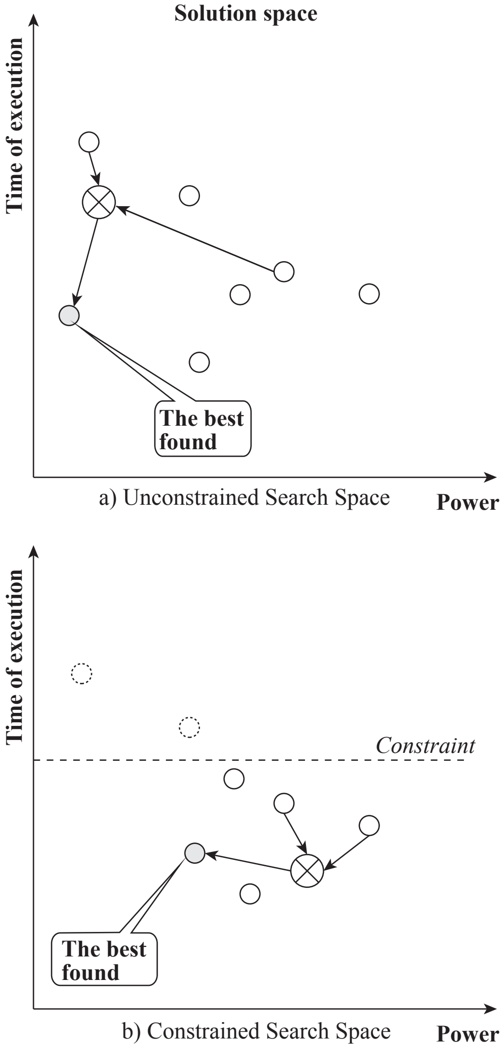
Three different methods of applying big.LITTLE technology for minimizing the power consumption were proposed[11]. In the cluster switching, low-power cores are grouped into “little cluster", while high performance cores are arranged into “big cluster". The system uses only one cluster at a time. If at least one high performance core is required then the system switches to the “big cluster", otherwise the “little cluster" is used. Unused cluster is powered off. In CPU migration approach, low-power and high-performance cores are paired. At a time only one core is used while the other is switched off. At any time it is possible to switch paired cores. The most powerful model is a global task scheduling. In this model all cores are available at the same time.

The big.LITTLE technology is quite new and is mainly used in mobile devices. According to our best knowledge there are no applications of this technology to design low power real-time embedded systems, as well as an adaptive scheduling method for such systems.

## III. Developmental Genetic Programming

Genetic algorithms (GA) [12] are very commonly used in wide spectrum of optimisation problems. Main advantage of GA approach is the possibility of getting out from the local minima of optimization criterion. Thus, GA is efficient for global optimization of complex problems, like RCPSP or multi-objective optimization of distributed real-time systems [13].

Although GA approach usually give satisfactory results it may be inefficient for hard constrained problems. In these cases a lot of individuals obtained using genetic operators correspond to not feasible solutions (e.g. schedule that exceeds required deadline or incorrect schedule, in the RCPSP). Such individuals should not be considered during the evolution. It is provided by defining the constrained genetic operators, that produce only correct solutions. But such constrained operators may create infeasible regions in the search space. Such regions may contain optimal or close to optimal solutions. This problem is illustrated on Fig. 1. Assume that we optimize the power consumption of the real-time system. Due to constraint violation, the solutions above the dotted line are not valid, hence they are never produced during the evolution. But it is possible that such “forbidden" individuals may be used during the crossover or mutation to produce highly optimized solutions (Fig. 1a). Unfortunately, the search space should be limited to consider only valid solutions (Fig.  1b) and the optimal solution may never be obtained.



a) Unconstrained Search Space

b) Constrained Search Space

Fig. 1. Search space in GA

Above problem may be eliminated by using the Developmental Genetic Programming (DGP). DGP is an extension of the GA by adding the developmental stage. This method first time was applied to optimize analog circuits [14]. The main difference between DGP and GA is that in the DGP genotypes represent the method building the solution, while in the GA genotypes describe the solution. Thus, during the evolution, a method of building a target solution is optimized, instead of a solution itself.

In the DGP the search space (genotypes) is separated from the solution space (phenotypes). The search space is not constrained, all individuals are evolved. Thus, all of them may take part in the reproduction, crossover or mutation. There is no “forbidden" genotypes.

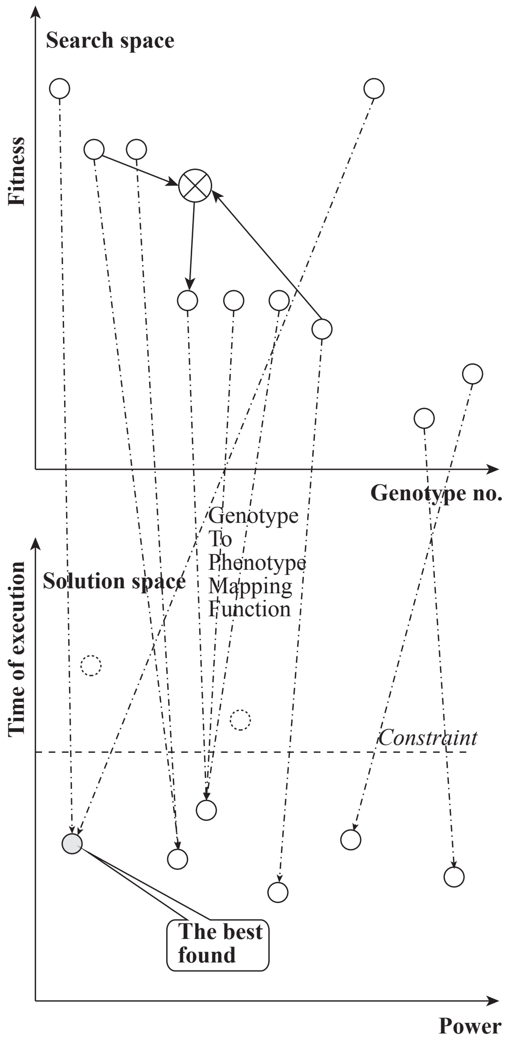


Fig. 2. Genotype to Phenotype mapping

Phenotypes are created by using genotype-to-phenotype mapping function, which always produces a valid solution. During the evolution, the fitness of the genotype is evaluated according to the quality of the corresponding phenotype. Fig. 2 presents the idea of the DGP. The search space consists of the genotypes that evolve without any restrictions. Any genotype may be mapped onto phenotype representing valid solution. This can be assured by using constrained mapping function. This function never produces solutions above the constraint line.

This idea of DGP is taken from biology, where the genotype corresponds to the chromosome containing information used for synthesis of proteins. The application of DGP occurred successful in many domains [15], where human-competitive results were obtained. High efficiency of the DGP-based optimization was also proved for hardware-software codesign[16] and cost minimization in real-time cloud computing[17].

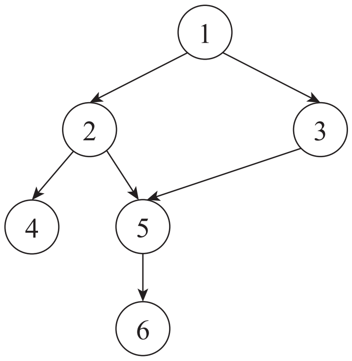

Fig. 3. A sample task graph

## IV. Synthesis of Adaptive Scheduler

Idea of our approach is based on the observation that when the DGP will be applied for the RCPSP problem, then except the final schedule we also obtain the scheduler dedicated to the optimized system. Thus, instead of the implementation of static schedule we may implement this scheduler, which may adapt to any perturbation during the system operation. We assume that the system is specified as a task graph. This is very widely used method of specification of real-time embedded systems. We also assume that for each task, the time of execution and the average power consumption is known for each available processor core. Usually these parameters are estimated using the worst case estimation methods. During the system operation, the scheduler will dynamically modify the schedule to minimize the power consumption whenever it will be possible to move some tasks to low-power cores, i.e. when execution time of finished tasks will occur shorter than estimated. In our method it is also possible to use average execution time, instead of the worst case estimation. When same task will be delayed then the scheduler will try to find the new schedule that satisfies the time requirements. We use ARM multicore processors with big.LITTLE technology for implementation of the target systems. Such system consists of two processors, usually quad-core. The first of them has higher performance (about 40%), but consumes more power. The second one is slower, but it is optimized to use much less energy (about 75%), to execute the same task. The goal of optimization is to find the makespan for which the power consumption is as small as possible, while all time constraints are met.

### *A. Task Graph*

The function of an embedded system is specified as a set of tasks. Between certain tasks may be the relationship that specifies the order of their execution. This may be specified as a task graph, which is the acyclic directed graph where nodes correspond to tasks and edges describe required order of execution. A sample task graph is given on Fig.3.

### B. Resources

Estimated execution parameters are given in a library of available resources. A resource is a core of a processor, which is able to execute a task. For each core the execution time and the power consumption are given. Part of a sample ARM Cortex-A15/Cortex-A7 database, for task graph from Fig.3, is presented in Table I.

### C. Strategies of scheduling

The scheduler creates a makespan in two steps:

1) task assignment: tasks are assigned to cores according to preferences specified for each group of tasks (Table II),
2) task scheduling: this step is executed only when more than one task is assigned to the same core. During this step a selected group of tasks is scheduled using the scheduling strategy specified for this group (Table II).

Initial population consists of randomly generated genotypes. During initialization, preferences defining the decision table for the scheduler are assigned to each gene. Table II contains the set of possible preferences that the scheduler may choose. The last column in Table II shows a probability of the selection.

The first option prefers the core with the highest performance. Second one prefers a core with the lowest power consumption. Third option prefers a core with the best ratio of the power consumption to the time of execution. Fourth option allows using a core, that cannot be obtained as a result of the remaining options. The next option prefers a core, which could start an execution of the task as soon as possible (other cores might be busy). The last option prefers a core which could be the first to finish a task (be freed). For the second step only one option is available, the list scheduling method.

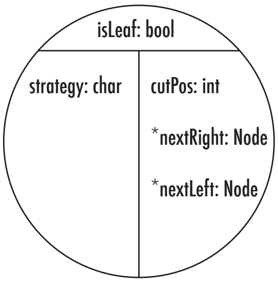

Fig. 4. A node of the genotype

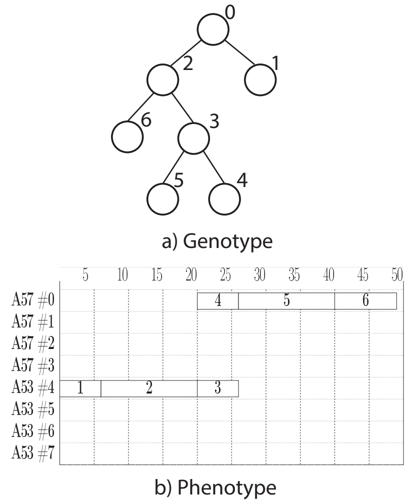

a) Genotype

b) Phenotype

Fig. 5. A sample genotype (a) and the corresponding phenotype (b)

### D. Genotype

The genotype has a form of binary tree corresponding to the certain procedure of task scheduling[18]. Every node in the genotype has the structure presented on Fig. 4.

The first field *isLeaf* determines a type of the node in a tree. When the node is a leaf this field equals true. Then, the field named *"strategy"* defines the strategy of scheduling for group of tasks assigned to this node. All possible strategies are given in Table II. In this case, information from the other fields is omitted. When the node is not a leaf, a content of the field *"strategy"* is neglected. In this case, *cutPos* contains a number describing which group of tasks should be assigned and scheduled by the left node and which one by the right one. Thus, *nextLeft* and *nextRight* must not be null pointers.

The simplest genotype consists of only one node, which is also a leaf and a root. A sample genotype and the corresponding phenotype are presented on Fig. 5.

During the evolution a genotype may grow up but the size of the tree is limited. If a tree will be too large, the performance of genotype to phenotype mapping, required for the fitness evaluation, would be slightly decreased. Size limit of the genotype also avoids constructing too many unused branches.

An initial genotype tree may grow up as an effect of genetic operators: mutation and crossover. An action associated with

TABLE III
THE RULES OF MUTATIONS

| Is a leaf? | | | |
|---|---|---|---|
| Yes | | No | |
| Draw: switch leaf/node or not? | | | |
| Yes | No | Yes | No |
| Set *isLeaf* as FALSE. If *nextLeft* or *nextRight* is NULL - create a new leaf for it. | Draw new strategy | Set isLeaf as TRUE | Change value for a randomly chosen field: *cutPos*, *nextLeft* or *nextRight* |

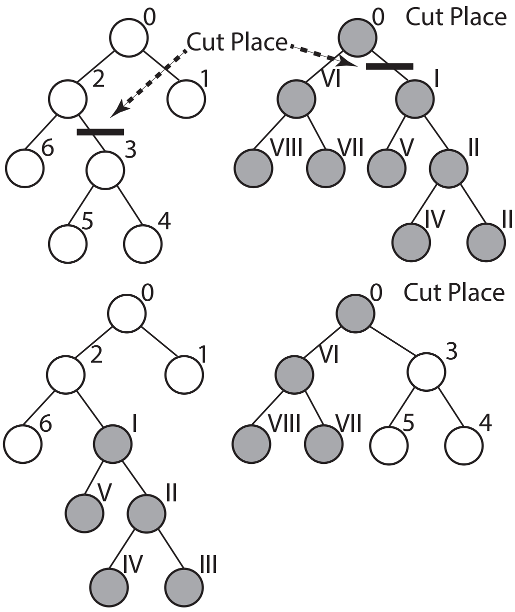

Fig. 6. An example of the crossover

the mutation depends on the type of the node and is presented in the Table III [18].

The crossover is used to create new individuals that are a combination of genes of parent genotypes. First, points of cut for both trees are drawn, then the cut branches are exchanged. In this way two new genotypes are created. A sample crossover is presented on Fig. 6.

With every genotype an array is associated. Its size is equal to the number of tasks and contains indexes of cores. If for given task, strategy 'd' is chosen, the core with an index taken from the array is used. During the mutation, a position in the array is randomly chosen. Then, a new index is randomly generated. During the crossover, parts of the arrays from both genotypes are swapped. The array defines the alternative scheduling strategy that is not driven by the performance or power consumption.

### E. Genotype to phenotype mapping

The first step, during the genotype-to-phenotype mapping, is to assign strategies to tasks (i.e. preferences for assigning tasks to resources). For the example from Fig. 11, this step is illustrated on Fig. 7. Node 0 groups tasks into two sets: {1,2,3} and {4,5,6}. The first set is partitioned by node 2 into next two groups. In the first one, there is only task 1. Tasks 2 and 3 belong to the second one, which is partitioned again by node 3. The *cutPos* parameter of node 3 equals 4, this means that tasks should be partitioned into group from 2 to 5 and the rest. But tasks 5 and 6 are outside of the set assigned to node 3, these tasks are assigned to node 1. Thus, there is only one group of tasks {2, 3} assigned to node 5.

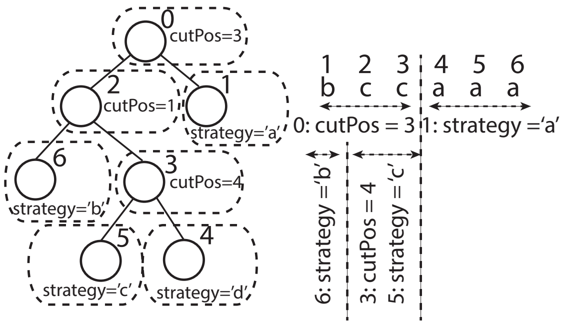

Fig. 7. The first step in genotype-to-phenotype mapping

In the second step, all tasks without any predecessor in the task graph, or with predecessors having already assigned core, are being searched for. These tasks are assigned to cores according to preferences determined in the first step. This step is repeated as long as there are tasks without assigned cores. In the third step, the total power consumption of the solution is calculated. For this purpose, the resource library (Table I) is used.

### F. Parameters of DGP

During the evolution, new populations of schedulers are created using genetic operations: reproduction, crossover (recombination) and mutation. After the genetic operations are performed on the current population, a new population replaces the current one. The evolution is controlled by the following parameters:

- *population size*: the number of individuals in each population is always the same. The value of this parameter is determined according to the value of "number of tasks" * "number of cores",
- *reproduction size*: number of individuals created using the reproduction,
- *crossover size*: the number of individuals created using the crossover,
- *mutation size*: the number of individuals created using the mutation.

Finally, the selection of the best individuals by a tournament is chosen [12]. In this method, chromosomes (genotypes) are drawn with the same probability in quantity defined as a size of the tournament. The best one is taken to the next generation. Hence, the tournament is repeated as many times as the number of chromosomes for a reproduction, crossover and mutation is required. A size of the tournament should be defined carefully. It should not be too high, because the selection pressure is too strong and the evolution will be too greedy. It also should not be too low, because the time of finding any better result would be too long.

### G. Self-adaptability of the scheduler

Finding the best makespan for low-power real-time embedded system is not the only goal of our approach. DGP methods are very effective in solving optimization problems and very often give the optimal solution. From the other side, they give results in relatively long time, thus genetic approach can not be used for rescheduling in real-time systems.

In the DGP the scheduling is performed during the genotype to phenotype mapping. This process is very fast, therefore it can be executed during the system operation. So, instead of implementing the final schedule we implement the method which creates this schedule. We observed that such approach has great self-adaptability capabilities.

Since the DGP has to consider only valid makespans. The genotype to phenotype mapping is a constrained process. If for a set of preferences defined by the genotype, it is not possible to obtain the valid phenotype then the mapping selects the next matching resource. Thus, the preferences specified by the genotype need not be strictly adhered. For example, if for given task preference suggest assigning this task to the low-power core, then if this decision will lead to an infeasible makespan, the scheduler will choose another, faster core that best matches to this preference.

Therefore, scheduler is able not only to build a correct solution, but also modify it if any unpredictable events will occur. E.g. if a task execution will be longer than expected, then the scheduler could move some tasks from a slower to a faster core, to fulfill time requirements. Similarly, if a task will be finished before its predicted end time, scheduler can move other tasks from a faster core to slower one, to save some energy.

### H. Fitness function

A fitness function determines the optimization goal of the DGP. In the presented approach, two options are possible. In the first one, the cheapest solution which has to be finished before a deadline is searched for. Such fitness function is applied when hard real time constraints have to be satisfied. In the second one, the DGP should find the fastest solution, which does not exceed a given power consumption. This case concerns systems with soft real-time requirements.

## V. Example and Experimental Results

We have verified advantages of the presented method using example of the complex multimedia system, which was described in [19]. The result has been compared with the method based on Least-Laxity-First Scheduling Algorithm [20].

### A. Task Graph and Run-time Parameters

The sample system is a multimedia player implemented as a real-time embedded system. The specification of the system consists of 40 tasks. Fig. 8 presents the task graph describing the system, details are given in [19]. We consider shared memory architecture, thus the communication between tasks may be neglected. The execution time is critical - it is typical soft real-time system. If the deadline is only slightly exceeded, the quality of the system is decreased, but the solution may be accepted. If the system exceeds hard deadline, then result is unacceptable and system should be redesigned.

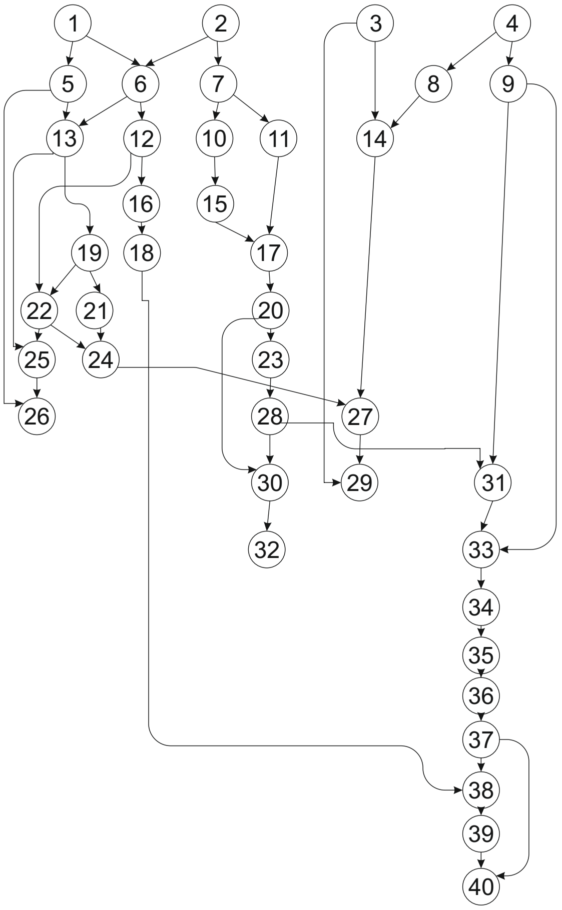

Fig. 8. Task graph of the multimedia system

We assumed, that the application will be implemented in software running on system consisting of two 4-core processors. One of them is ARM Cortex A57 and the second is ARM Cortex A53. The first processor is faster for about 25%, but consumes about 50% more power. Both processors support ARM big.LITTLE technology. Run-time parameters for both processors are given in Table IV.

The goal of our methodology is to create a self-adapting scheduler, which run the program tasks, balancing them between the cores, to minimize the power usage. The scheduler should be able to reschedule remaining tasks, whenever any task will finish its execution before or after expected time frame.

TABLE IV
EXECUTION TIME AND POWER CONSUMPTION

| **Task** | **Processor cores** | | | |

| 40 | 2 | 176 | 1 | 220 |

### B. Genetic parameters

We assumed that the deadline for the system from Fig.4 is equal to 100000 ns. The Power Aware Scheduler and the optimized makespan were generated using DGP. During the experiments, the following values of genetic parameters were used:

- the evolution was stopped after 100 generations,
- each experiment was repeated 7 times,
- the population size was equal to 128,
- tournament size was equal to 10,
- the number of mutants in each generation, was equal to 20%,
- the crossover was applied for creation of 40% genotypes,
- 20% of individuals were created using reproduction.

The values of parameters described above were tuned according to method described in our previous work [18], thus we will describe it here very shortly. In the first step, we estimated an influence of the tournament size. When this parameter was too small, the evolution got stuck. When the tournament size was too big, the DGP found semi optimal solution very fast, but a further optimization was not possible. Next, the influence of crossover and mutation for obtaining the best solution has been tested. It has been done by searching for the best solution using different combination of these parameters. Thus the best values of these parameters have been chosen. Finally, the best combination of other evolution parameters has been evaluated.

### C. Least-Laxity-First Algorithm

One of the most known algorithms for scheduling tasks in real-time embedded systems is the Least-Laxity-First Algorithm (LLF). Basic LLF method schedules task according to the least laxity (slack time). The laxity is defined as a difference between an execution time and a task deadline. The goal of LLF is to find the schedule that satisfies all deadlines. It does not take into account power or cost optimization. Therefore, we modify this method by favouring energy-efficient cores. In other words, during scheduling, the method first tries assign a task to low-power core, only when it will violate the time constraint, the task will be assigned to more efficient core. Our Low Power LLF (LPLLF) method is used only for reference, to verify that the DGP is efficient also for power optimization in real-time embedded systems.

### D. Power-aware Scheduling

The makespans obtained using DGP and LPLLF methods are presented on Fig. 9. On Y-axis different cores are represented, while the time of execution is represented by the X-axis. Numbers correspond to the following tasks. The experimental results proved that the presented method is more efficient than LPLLF. Energy consumption for the system scheduled using DGP equals 990mJ, while the same example scheduled using LPLLF requires 1018mJ. To meet the deadline, the LPLLF method assigned the long task 36 to the most efficient core. But in the DGP, more energy-efficient solution was found by assigning some shorter tasks, that in total consume less power than task 36, to the faster core.

Above experiment showed that the scheduler constructed using DGP is able to find highly optimized solutions. More experiments proving this remark are given in our previous work [16][17][18].

### E. Self-adaptivity capabilities

Static scheduling is based on estimation of execution times for all tasks. During the system operation, time of execution may significantly be shorter (e.g. if the worst case estimation was applied) or longer (e.g. in case of the most likely estimation). Therefore, the system may be additionally optimized during run-time, by using self-adaptive scheduling. In this way certain system parameters (power consumption, performance) may be improved. Scheduler generated using our method consists of series of system construction functions, corresponding to each gene. These functions are flexible, i.e. design decisions

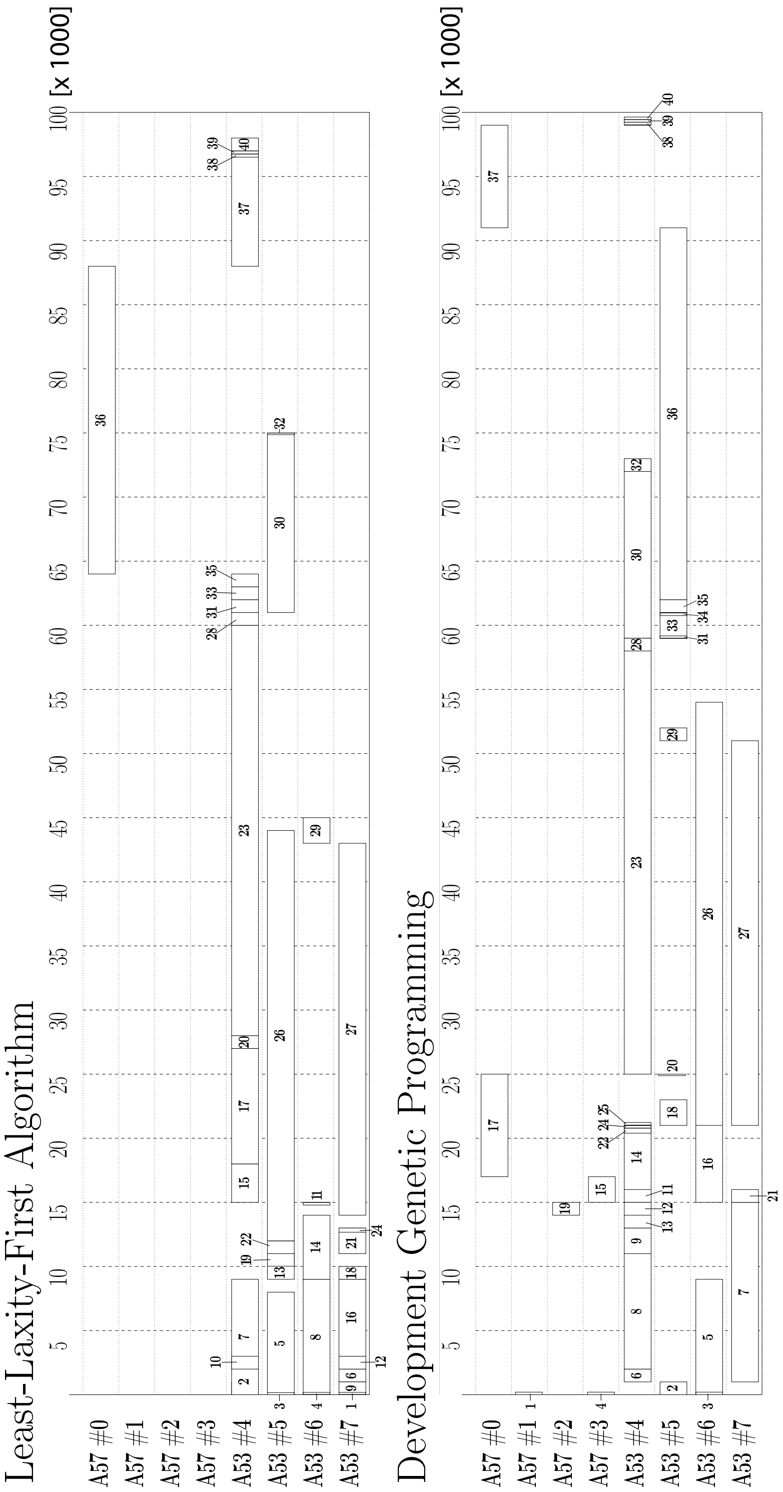

Fig. 9. Makespans obtained using LLF and DGP

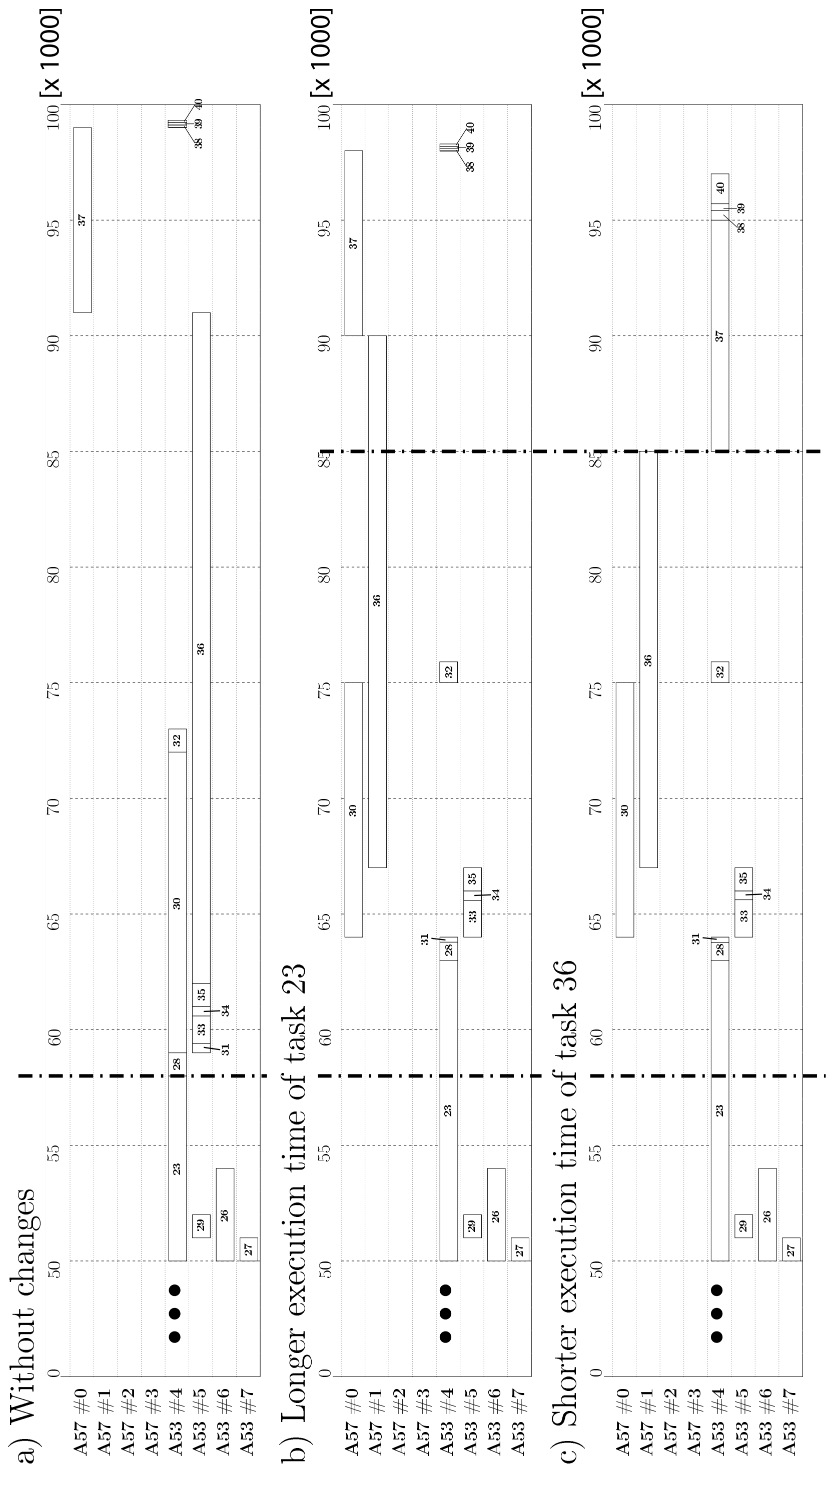

Fig. 10. Self-adaptation capabilities of power-aware scheduler

are driven by preferences, they are not strictly defined. This is necessary to assure that only feasible makespan will be created. Flexibility of the system construction functions provides to self-adaptivity capabilities of the scheduler.

An example of the self-adaptivity is presented on Fig. 10. If the execution time of task 23 will be too long, then all succeeding tasks should be postponed and the system would exceed the deadline. But our scheduler adapts to the delayed end time of task 23, and despite the fact that it uses the same construction functions, some tasks (tasks 30 and 36 in our example) will be assigned to more efficient cores (Fig. 10b). In other case, if an execution time of a task 36 will be shorter than it was expected, the scheduler will assign some tasks (task 37 in our example) to low power core (Fig. 10c). In this way power consumption will be reduced.

To verify the capabilities of self-adaptivity of the scheduler we performed some simulations of different changes in execution times for some task. Table V presents results obtained for cases when execution times occurred longer than estimated. In all cases our scheduler was able to adapt to this situation and new makespans that satisfied the deadline were created.

Table VI presents results obtained for another cases, where execution times for some tasks occurred shorter than expected, i.e. estimation was too pessimistic. In such case the scheduler has an opportunity to reduce the power consumption. It should be noticed that in some cases the scheduler found more energy-efficient makespans, but a lot of makespans were not changed. The main reason is that in the most cases there was not possible to improve the power consumption because all remaining tasks were already assigned to low-power cores. It is visible when we compare results obtained for different deadlines. When the deadline is shorter than 95 000 there is still a possibility for improvement. For longer deadlines, even when all tasks were faster it was not possible to decrease the power consumption.

## VI. Conclusions

In this paper the method of automatic synthesis of power-aware schedulers for real-time distributed embedded systems was presented. Starting from the system specification in the form of the task graph, we use developmental genetic programming to optimize the scheduling strategy that minimizes the power consumption. Finally, the best makespan as well as the optimized scheduler are generated. The scheduler has powerful capabilities of self-adaptation. This feature may be used to dynamically minimize the power consumption as well as to increase the system performance.

The presented method is dedicated to ARM big.LITTLE technology, developed for a low power systems. But, since we use general optimization method, it would be easily adapted to other energy-efficient architectures.

The computational experiments confirmed, that the schedulers, generated using DGP, are efficient and flexible. For the sample system our method gave better results than results obtained using LLF-based method. Moreover, simulations showed that the scheduler is able to quickly and effectively react to any changes of task execution times, by rescheduling remaining tasks.

Despite the above advantages of our method, there is still possible to improve the methodology. In the future work, we will consider special types of adaptive genes, that could support more possibilities for self-adaptation, we will also consider using other scheduling methods, alternative to list scheduling, e.g. based on mathematical/constrained programming [21].

***Abstract*—In the article the control and optimization of multistage technological processes were discussed. In the presented research, it was assumed, that in the complex technological processes, the multistage differential-algebraic constraints with unknown consistent initial conditions were considered. To rewrite the infinite-dimensional optimal control problem into the finite-dimensional optimization task, the direct shooting method was applied. Simulated annealing algorithm was proposed as the method for solving nonlinear optimization problem with constraints. Stretching function was used to allow us to locate the globally optimal solution. The complex process constraints were treated using constraints aggregation methods. The presented methodology was tested with optimal control problem of the two-reactors system. The numerical simulations were executed in MATLAB environment using Wroclaw Center for Networking and Supercomputing.**

***Index Terms*—optimal control, DAE systems, simulated annealing, constraints aggregation, stretching function.**

## I. Introduction

NOWADAYS, technological processes have been modeled using more general and complex systems of equations. To model technological processes in such branch of industry, like chemical engineering, biotechnology and aerospace engineering, both dynamics and physical conservation laws have been under consideration [2], [3], [8], [16]. Then, a validated model of the process can be applied to control and optimize the technological systems. In the other words, to ensure an efficient and trouble free technological processes, an optimization problem subject to nonlinear differential-algebraic constraints need to be solved [4], [13].

In the last years, deterministic, as well as stochastic optimization algorithms, are adjusted to solve new advanced technological problems. New methods in modeling, algorithmic procedures and globalization of the obtained solutions can be observed in all areas of optimization [9], [10], [26]. In the presented work we would like to indicate the simulated annealing algorithm, which has been seen as one of the main global optimization procedures . In this work the new aspects of the simulated annealing algorithm were given and discussed.

Direct shooting method enables us to transform the optimal control problem into medium- or large-scale nonlinear optimization problem. Then, using aggregation and disaggregation procedures, the considered model can be represented by other system, which reflects the most important features of the original process, but is better adjusted for computational optimization methods [14]. Then, the obtained results can be applied to control the original system.

The presentation of new methodology was performed in the following way. In the next section optimal control with differential-algebraic constraints was introduced. Then, in section III, optimization with aggregated constraints was discussed. ”Stretching” function technique in optimization procedures was presented in section IV. Then, a new simulated annealing algorithm with constraints was given and tested in sections IV and V. The considerations were concluded in section VI.

## II. Optimal control with differential-algebraic constraints

The optimal control algorithms are highly connected with the available modeling methods. The main objective of the control is always the same - we need to find the control function, which optimizes one of the known forms of the process performance index. But the assumptions, conditions and complexity of the considered processes are increasingly challenging and difficult to solve.

In the last years, new particular types of systems have become popular due to many practical applications. There are the multistage dynamical systems and processes with differential-algebraic equations, which are more general, than the pure dynamical processes.

The most important common features of the systems mentioned above, is the presence of the dynamics in the model. The difference, which has a far-reaching consequences in the calculation methods comes from the non-dynamical part of the model.

In the multistage processes, the state variables have to be continuous across the stages. It means, that in the known points, at the interface between the processes, algebraic continuity constraints are introduced. Therefore, the additional algebraic constraints have a pointwise character.

In processes with differential-algebraic constraints, the algebraic relations are justified by physical laws, which take place in the process and are reflected in the model. In this way, both the differential and algebraic equations have a continuous

978-83-60810-66-8/$25.00©2015, IEEE

character and can be treated as a one differential-algebraic system [6].

The presented work concerns the case, when the process is multistage and each stage was described using its own system of differential-algebraic equations. In this way, new theoretical assumptions have to be made and new computational concepts should be designed and implemented.

The features presented above lead us to the optimal control problems in the known form. At first, the process performance index, which can be treated as the measure of the control quality, has to be defined as follows

$$\min_{u(t)} Q = \int_0^{t_F} \mathcal{L}(y(t), z(t), u(t), p, t)dt + \mathcal{E}(y(t_F), z(t_F), t_F) \tag{1}$$

with single system of differential-algebraic constraints in semi-explicit form

$$\begin{array}{rcl} B(t)\dot{y}(t) & = & f(y(t), z(t), u(t), p, t) \\ 0 & = & g(y(t), z(t), u(t), p, t), \end{array} \tag{2}$$

where $y(t) \in \mathcal{R}^{n_y}$ is a differential state, $z(t) \in \mathcal{R}^{n_z}$ is an algebraic state and $u(t) \in \mathcal{R}^{n_u}$ denotes the unknown control function. The independent variable (e.g. time or length of the chemical reactor) is denoted as $t \in \mathcal{R}$. As $p \in \mathcal{R}^{n_p}$ was denoted the vector of global parameters constant in time. The variables in the process are defined by vector-valued functions:

$$f : \mathcal{R}^{n_y} \times \mathcal{R}^{n_z} \times \mathcal{R}^{n_u} \times \mathcal{R}^{n_p} \times \mathcal{R} \to \mathcal{R}^{n_y} \tag{3}$$

and

$$g : \mathcal{R}^{n_y} \times \mathcal{R}^{n_z} \times \mathcal{R}^{n_u} \times \mathcal{R}^{n_p} \times \mathcal{R} \to \mathcal{R}^{n_z}. \tag{4}$$

To ensure, that the system (2) consists of differential-algebraic equations in semi-explicit form, it is assumed, that the matrix $B(t)$ is invertible for all values of $t$.

As it was mentioned, the quality of the process is measured by the value of $Q \in \mathcal{R}$. It is an important assumption, that quality of the whole complex process can be specified by only one real number.

When the multistage processes are considered, then each stage can be described using its own system of differential-algebraic equations

$$\begin{array}{rcl} B^i(t)\dot{y}^i(t) & = & f^i(y^i(t), z^i(t), u^i(t), p, t) \\ 0 & = & g^i(y^i(t), z^i(t), u^i(t), p, t), \\ & & i = 1, \cdots, NS, \end{array} \tag{5}$$

where $NS$ denotes number of the stages in the considered process.

One of the most important progresses in the optimal control methods has been connected with parametrization of the control problem. Because in this way the optimal control problem can be treated as a nonlinear optimization problem, efficient numerical optimization algorithms can be applied.

The parametrization of the control function has been proposed in the article [24] in 1994. Today, the piecewise continuous control parametrization using constant, linear or quadratic functions has been a commonly used approach.

In this way, instead to search for optimal solution using advanced analytical methods, the efficient algorithm of numerical optimization can be applied to obtain the best solution in the assumed class of piecewise continuous functions [7].

The parametrization of the control function in optimal control problems has been often used together with the multiple shooting technique. The multiple shooting method is appropriate to decompose the complex technological processes as well as to stabilize the solutions of both the unstable and highly nonlinear systems.

The multiple shooting method together with the control function parametrization lead us to the direct shooting approach. In this methodology, at the first step, the independent variable domain is divided into the assumed number of intervals

$$t = \bigcup_{i=1}^{NS-1} [t_{i-1} \quad t_i) \cup [t_{NS-1} \quad t_{NS}], \tag{6}$$

where $t_0$ is the time instant, when the process starts and $t_{NS}$ is the final time.

Therefore, the control function as well as the differential-algebraic system can be parametrized in each interval. In practical applications, when the control function is parametrized as piecewise constant, then

$$u^i(t) = u_i, \qquad i = 1, \cdots, NS. \tag{7}$$

The differential-algebraic model of the technological process is parametrized in the sense of the unknown initial conditions. This approach enables us to solve the DAE system using the efficient numerical procedures [17]. The initial conditions of differential-algebraic system can be parametrized in the following way

$$\begin{array}{rcl} y^i(t_{i-1}) & = & s_y^i \\ z^i(t_{i-1}) & = & s_z^i \end{array} \tag{8}$$

for $i = 1, \cdots, NS$.

Therefore, the differential-algebraic constraints have been obtain the new form

$$\begin{array}{rcl} B^i(t)\dot{y}^i(t) & = & f^i(y^i(t), z^i(t), u^i, p, t^i) \\ 0 & = & g^i(y^i(t), z^i(t), u^i, p, t^i), \end{array} \tag{9}$$

with $t^i \in [t_{i-1} \quad t_i]$ and $i = 1, \cdots, NS$. Because the consistent initial conditions are needed to solve the DAE systems, the algebraic part can be extended by damping factor $\alpha$

$$0 = g^i(y^i(t), z^i(t), u^i, p, t^i) + \alpha^i(t) g^i(s_y^i, s_z^i, u^i, p, t^i) \tag{10}$$

for $t^i \in [t_{i-1} \quad t_i]$ and $i = 1, \cdots, NS$.

The process performance index has been rewritten as follows

$$\min_{s_y^i, s_z^i, u^i} \hat{Q} = \sum_{i=1}^{NS} \int_{t_{i-1}}^{t_i} \mathcal{L}(s_y^i, s_z^i, u^i, p, t)dt + \mathcal{E}(s_y^{NS}, s_z^{NS}, t_F). \tag{11}$$

It is worth to note, that the trajectories of the differential states are continuous. It means, that the additional relations have to be incorporated to the model

$$y^i(t_i) = y^{i+1}(t_i) = s_y^{i+1}, \qquad i = 1, \cdots, NS-1, \tag{12}$$

which results as additional pointwise algebraic constraints of the following form

$$y^i(t_i) - s_y^{i+1} = 0, \qquad i = 1, \cdots, NS-1. \tag{13}$$

In the most practical situations, the unknown parameters have their physical interpretation. Among them can be distinguished an unknown volume of the chemical reactor, concentration of the substrates or value of the temperature. The interpretation of the decision variables and technological restrictions defines the feasible region and can be rewritten as the inequality constraints in the form of lower and upper bounds.

Direct shooting approach enables us to transform the optimal control problem into the nonlinear programming problem with the vector of decision variables designed as

$$x = [s_y^i \quad s_z^i \quad u_i \quad p]^T, \tag{14}$$

the process performance index in the form of the objective function

$$\min_x \hat{Q}(x) \tag{15}$$

differential-algebraic constraints

$$\begin{array}{rcl} B^i(t)\dot{y}^i(t) & = & f^i(y^i(t), z^i(t), u^i, p, t^i) \\ 0 & = & g^i(y^i(t), z^i(t), u^i, p, t^i), \end{array} \tag{16}$$

consistency constraints

$$0 = g^i(y^i(t), z^i(t), u^i, p, t^i) + \alpha^i(t) g^i(s_y^i, s_z^i, u^i, p, t^i) \tag{17}$$

continuity constraints

$$y^i(t_i) - s_y^{i+1} = 0, \tag{18}$$

and the constraints of upper and lower bounds type

$$x_L \leq x \leq x_U \tag{19}$$

for $t^i \in [t_{i-1} \quad t_i]$ and $i = 1, \cdots, NS$.

This causes, that the various numerical optimization algorithms can be treated as an important part of the control algorithms [18]. This transformation is a main effect of the direct shooting method applied in the optimal control problems.

## III. Optimization with aggregated constraints

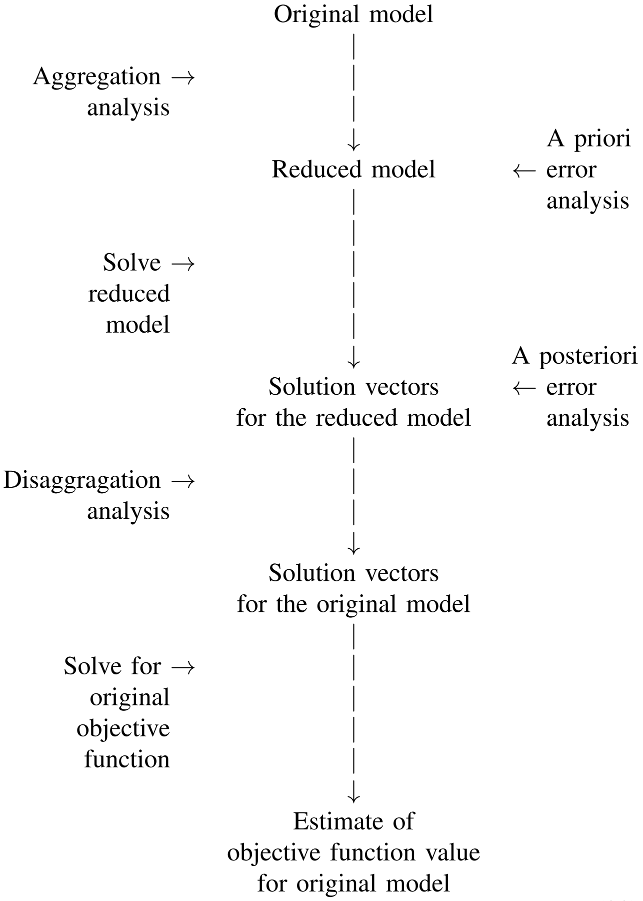
The complexity of the considered models and large number of decision variables makes, that the analytical solutions and some intuitive numerical approaches can be inappropriate in the control of the real-life technological processes.

One of the most important question in modern optimization and control theory is, how to solve the problems with thousands or millions variables and comparable number of equality and inequality constraints. The second important question is, how to compare two unfeasible solutions and to make a decision, which one proposed solution is better than the others.

To analyze the complex process, both the aggregation and disaggregation techniques were used. There is a general methodology, how to obtain useful information about the process by a possibly little model modifications and computations amount [5].

In the previous section, the optimal control problem was reformulated as a middle- or large-scale nonlinear optimization problem. To do this, the direct shooting method was applied. At this point, the consecutive question cannot more wait for the answer - how to treat optimization problems with so many variables and subject to huge number of constraints? The question, which has been just imposed, is considered in this section.

The general way to obtain the useful information about the complex process can be constructed as follows [23]



Original model
Aggregation → analysis
A priori ← error analysis
Reduced model
Solve → reduced model
A posteriori ← error analysis
Solution vectors for the reduced model
Disaggragation → analysis
Solution vectors for the original model
Solve for → original objective function
Estimate of objective function value for original model

(20)

In a general sense, in model aggregation, large-scale optimization models are reformulated as less complex systems. The obtained in this way models reflect the most important features of the original systems, but should be much more suitable to perform numerical simulations.

In the other words, the aggregation technique is a method to specified parts of the model, which can be described using only one single element. At this step, the new single element should be explicitly defined. Therefore, aggregation analysis consists of two levels:

- process of determining, which data are in some sense similar and can be considered as elements in the same group; this step is known as cluster analysis,
- the method of combining the clustered data to define the reduced model.

In contrast to the aggregation analysis, the disaggregation is a method, which can derive the information about the complex model using results obtained by reduced system analysis. The disaggregation analysis, often known as the reversal aggregation analysis, enables us to estimate the solution of the original system using only results obtained from solving the reduced model.

The last stage, which is connected with aggregation and disaggregation methodology, is an error analysis. The error analysis determines the resulting error, which can be introduced by algorithms with aggregate models and disaggregate solutions. From practical point of view, the error analysis can be useful for selection of appropriate aggregation and disaggregation procedures. In the literature two main types of error are defined

a) a priori error bounds, which are the bounds placed upon the optimal value of an original optimization model after aggregation stage, but before the aggregate model is solved,

b) a posteriori error bounds are the bounds placed upon the optimal value of an original optimization model after the aggregated model has been formed and solved.

In practical applications, the iterative optimization algorithms with successive aggregation-disaggregation schemes are used. Such procedures are known as an Iterative Aggregation-Disaggregation (IAD) technique.

As it was mentioned, the direct shooting method allows us to transform the optimal control problem into a nonlinear optimization problem. Therefore, solution of the original infinite-dimensionally task can be obtained by solving finite-dimensional optimization problem. But the question posed in this section does not refer to the optimal control problems. It concerns the much more fundamental task - how to solve medium- and large-scale optimization problems?

It is expected, that the efficient numerical optimization methods enable us to solve optimal control problems.

Therefore, we would like to propose aggregation methods, which can be useful to define new reduced process performance index, as well as reduced constraints.

At this place, we would like to focus on the constraints function aggregation. It was mentioned, that two main types of the constraints need to be considered in the process - there are continuous and pointwise constraints. In particular, it means, that some group of functions are connected with process description by continuous differential-algebraic constraints. There is the second group of constraints, which denotes the additional constraints at the prescribed time instances in the process.

Let us consider the system of the continuous differential-algebraic equations. This particular system can be solved by implementation of efficient numerical algorithms. After that, the process performance index, as well as fulfillment of the constraint can be determined. There is an important question, which refers to consistent initial conditions, which enables us to solve the differential-algebraic system. Although the initial conditions are defined at the specific point, they strictly refer to the continuous process constraints and should be perceived with continuous differential-algebraic constraints. In this work, we refer to this type of constraints as *the consistency constraints* and denote as

$$c_{cons}(\{s_y^i, s_z^i, u^i, p, t_{i-1}\}_{i=1}^{NS}) =$$

$$= \begin{bmatrix} g^1(s_y^1, s_z^1, u^1, p, t_0) \\ g^2(s_y^2, s_z^2, u^2, p, t_1) \\ \vdots \\ g^{NS}(s_y^{NS}, s_z^{NS}, u^{NS}, p, t_{NS-1}) \end{bmatrix} = 0. \qquad (21)$$

The other group of constraints represents the pointwise constraints, which are connected with the fact, that the multistage system is considered. In the other words it means, that the differential state trajectories are continuous across the process stages. The vector of pointwise algebraic constraints denoted as $c_{cont}$ is defined as follows

$$c_{cont}(\{s_y^{i+1}, s_z^{i+1}, u^i, p, t_i\}_{i=1}^{NS-1}) =$$

$$= \begin{bmatrix} y^1(t_1) - s_y^2 \\ y^2(t_2) - s_y^3 \\ \vdots \\ y^{NS-1}(t_{NS-1}) - s_y^{NS} \end{bmatrix} = 0. \qquad (22)$$

In some numerical optimization algorithms, e.g. Sequential Quadratic Programming, it is suggested to treat each constraint function in the same way. Therefore, in each iteration, a large-scale and possibly structured matrix of constraint functions derivatives can be obtained. In general case, when the structure of the process constraints is unknown, the matrix of partial derivatives of the constraints might be time and memory consuming.

If, in general, $c(x)$ denotes

$$c(x) = \begin{bmatrix} c_1(x) \\ c_2(x) \\ \vdots \\ c_{NS}(x) \end{bmatrix} = 0, \qquad (23)$$

then the vector of the constraint functions can be replaced using one of the following real-valued aggregated functions

$$\tilde{c}(x) = \|c(x)\|_1, \qquad (24)$$

$$\tilde{c}(x) = \|c(x)\|_2 \qquad (25)$$

or

$$\tilde{c}(x) = \|c(x)\|_\infty. \qquad (26)$$

One cannot determine, which one measure of the constraints infeasibility has the best features. The constraints aggregation function can be chosen depending on the considered process, optimization methods and, first of all, available computing resources.

The other question is, how to treat the process performance index. Parametrization of the control function, as well as differential and algebraic states, enables us to rewrite the process performance index as the objective function in nonlinear optimization problem. In some applications the penalty function approach and many variations of it can be observed. Advanced optimization methods focus on methods without penalty function [12], [22]. For these reasons, in presented methodology, the objective function $\hat{Q}(x)$, which represents control quality index, was remained unchanged.

## IV. Stretching function

In the previous section it has been indicated, how to apply the direct shooting method to transform the optimal control problem into the nonlinear optimization task. In general, the presented methodology enables us to consider the optimization problem over the feasible region

$$\min_x f(x), \qquad \forall x \in \mathcal{A}, \tag{27}$$

where $f(x)$ is a real-valued objective function

$$f : \mathcal{A} \to \mathcal{R} \tag{28}$$

where $\mathcal{A} \subseteq \mathcal{R}^D$ is the D-dimensional compact set.

The important question is, how to treat the nonlinear optimization problem with the large number of equality, as well as inequality constraints.

To solve the optimization problem on the compact set, the ”stretching” technique for the objective function can be applied [19].

Let us consider the objective function $f(x)$ defined on the compact set. Let the objective function $f$ get the local minimum in a point $x^\star$. Therefore, the point $x^\star$ is a local minimizer of the function $f$. As a consequence, it means, that in the neighborhood $\mathcal{NB}$ of the point $x^\star$, the inequality

$$f(x^\star) \leq f(x) \tag{29}$$

is satisfied for all $x \in \mathcal{NB}$.

In real-life optimization and control problems, it is highly undesirable, that one of the low quality local minima can be treated as the global solution. The ”stretching” function method was designed as a remedy for described situation. This method enables us to alleviate the local minimum using the following two-step transformation.

Let $x^{\hat{\star}}$ be the local minimum of the function $f$, then in the step 1, the function $f(x)$ elevates and all the local minima, which are above the point $f(x^{\hat{\star}})$, disappear

$$\mathcal{G}(x) = f(x) + \frac{\gamma_1}{2}\|x - x^{\hat{\star}}\|\Big(sign(f(x) - f(x^{\hat{\star}})) + 1\Big) \tag{30}$$

In the step 2, the neighborhood of the point $x^{\hat{\star}}$ is stretched upwards, in this way, that it assigns higher values of those points

$$\mathcal{S}\Big(f(x)\Big) = f^{\mathcal{S}}(x) = \mathcal{H}(x) =$$

$$= \mathcal{G}(x) + \frac{\gamma_2\Big(sign(f(x) - f(x^{\hat{\star}})) + 1\Big)}{2\tanh\Big(\mu(\mathcal{G}(x) - \mathcal{G}(x^{\hat{\star}}))\Big)}. \tag{31}$$

The parameters $\gamma_1$, $\gamma_2$ and $\mu$ are the positive constants with arbitrary chosen value. The authors, who proposed the ”stretching” function technique as the global optimization method, suggested the values of the mentioned parameters as $\gamma_1 = 10000$, $\gamma_2 = 1$, $\mu = 10^{-10}$. It was suggested, that the choice of the considered parameters seems not to be critical for the success of the optimization, but they can influence the convergence rate. For these reasons, the parameter tuning was suggested [20].

It is an important question, how the ”stretching” function technique can be applied for optimization problems, when a feasible region is no more a compact set? The mentioned situation can be meet in all cases, when optimization problems with equality constraint are considered [21].

To find the answer for the question posed above, the constraints aggregation methodology is very helpful.

## V. Simulated annealing with constraints

The main ideas connected with simulated annealing algorithm have their origin in thermodynamics. The physical laws, which governs cooling of molten metal in annealing process, have been used to design new optimization methods. After slow cooling in annealing process, the metal tends to reach a state with a low energy. In general, the state with the minimum energy is desired. In analogy to annealing process, the energy represents the possible solution of the optimization problem. Therefore, the state with the minimal energy represents the solution in the optimization algorithm [15], [25].

The simulated annealing algorithm is constructed as follows.

**The simulated annealing algorithm**

```
Initialization $(x_0, T_0)$
Calculation of $f(x_0)$
Until convergence
  Generation of new state $x_1$
  if $f(x_1) < f(x_0)$
    $x_0 = x_1$
  else
    if $\exp\left(\frac{f(x_0)-f(x_1)}{T}\right) > Rand(0,1)$
      Accept new solution $x_0 = x_1$
    else
      Reject new solution
      Decrease the temperature
end (Until)
```

At this moment we would like to introduce new simulated annealing method for optimal control of the multistage differential-algebraic systems. We start the presentation with some remarks.

**Remark 1.** *The optimal control problem with index-1 differential-algebraic constraints using the direct shooting approach has been transformed into nonlinear optimization* *problem with equality constraints of the following form*

$$\begin{array}{c} \min_x \hat{Q}(x) \\ c_{cons}(x) = 0 \\ c_{cont}(x) = 0. \end{array} \tag{32}$$

**Remark 2.** *The quality $\mathcal{Q}$ of any proposed solution $x$ can be specified using a triple*

$$\mathcal{Q}(x) = \begin{bmatrix} q_1(x) \\ q_2(x) \\ q_3(x) \end{bmatrix} = \begin{bmatrix} \hat{Q}(x) \\ c_{cons}(x) \\ c_{cont}(x) \end{bmatrix}. \tag{33}$$

**Remark 3.** *The "stretching" function technique applied for some proposed solution transforms the vector, which parametrized the quality of the proposed solution*

$$\mathcal{S}\Big(\mathcal{Q}(x)\Big) = \mathcal{Q}^S(x) = \begin{bmatrix} q_1^S(x) \\ q_2^S(x) \\ q_3^S(x) \end{bmatrix} = \begin{bmatrix} \hat{Q}^S(x) \\ c_{cons}^S(x) \\ c_{cont}^S(x) \end{bmatrix}. \tag{34}$$

The decisions of the new solution acceptance can be made by quality comparison of the considered solutions

**Definition 4.** *Any two values $\mathcal{Q}_a$ and $\mathcal{Q}_b$ are in the relation $\oplus$ if*

$$\begin{array}{c} q_1(a) \oplus q_1(b) \\ q_2(a) \oplus q_2(b) \\ q_3(a) \oplus q_3(b) \end{array} \tag{35}$$

**Theorem 5.** *Let $x_0$ and $x_1$ be any two solutions. The solution $x_0$ is unconditionally better than solution $x_1$ if and only if*

$$\mathcal{Q}(x_0) < \mathcal{Q}(x_1). \tag{36}$$

Let us transform the triple, which defines the quality of the solution, using the "stretching" function technique.

**Theorem 6.** *Let $x_0$ and $x_1$ be any two solutions. If*

$$\begin{array}{c} q_1^S(x_0) < q_1^S(x_1) \\ q_2^S(x_0) < q_2^S(x_1) \\ q_3^S(x_0) < q_3^S(x_1) \end{array} \tag{37}$$

*then*

$$\mathcal{Q}(x_0) < \mathcal{Q}(x_1). \tag{38}$$

The question is, how to compare two solutions, which are not in the relation presented in Theorem 6.

One of the most important features of simulated annealing algorithm is a possibility of accepting a step, which does not improve the current solution. Therefore, to compare any two solution, which are not in clear relation, a conditional acceptance mode can be applied. In simulated annealing methodology, it is known as *an acceptance with probability.* In the presented work, because of three-dimensional quality solution index $\mathcal{Q}(x)$ under considerations, a new extended method of acceptance with probability was proposed.

**Proposition 7.** *Let $x_0$ be the current solution and $x_1$ be any other solution generated by simulated annealing algorithm from the neighborhood of the point $x_0$, and $T$ denote the value of the temperature in the current iteration. If the point $x_1$ cannot be unconditionally accepted as a new solution, then it can be accepted with the probability $p \in \mathcal{N}(0,1)$. The acceptance probability is dependent on the index quality in the following way*

$$\exp\Big( - \frac{\hat{Q}^S(x_1) - \hat{Q}(x_0)}{T} \Big) > p$$

*or*

$$\exp\Big( - \frac{c^S_{cons}(x_1) - c_{cons}(x_0)}{T} \Big) > p$$

*or*

$$\exp\Big( - \frac{c^S_{cont}(x_1) - c_{cont}(x_0)}{T} \Big) > p.$$

There are two important remarks connected with the presented acceptance condition

**Remark 8.** *The multiple conditions increase the general acceptance probability of the worse solution.*

**Remark 9.** *Application of the "stretching" function technique transforms the bad solution in the worse one. Moreover, "stretching" function technique supports searching for better solutions and alleviate the local minima.*

The presented simulated annealing "stretching" function algorithm with new conditional solution acceptance approach was applied to solve the optimal control problem of the multistage rectors system.

## VI. Numerical examples

The presented methodology was tested on the optimization problem of the three-stage technological process. The presented system consists of two chemical reactors with mixing [24]. The sketch of the process was presented in the Fig. 1.

At the beginning, the first reactor was loaded with the substrate $A$ with the volume 0.1 m$^3$ and concentration 2000 mol/m$^3$. Due to reactions taking place in the system, the products $B$ and $C$ are obtained according to the following scheme

$$2A \to B \to C. \tag{39}$$

Additionally, the first reactor was equipped with a heating exchanger, which can be used to control the process temperature and in this way - to influence the trajectories of the process variables. The concentrations of the substrate and products were changing in the following way

$$\dot{C}_A = -2k_1(T)C_A^2 \tag{40}$$

$$\dot{C}_B = 2k_1(T)C_A^2 - k_2(T)C_B \tag{41}$$

$$\dot{C}_C = k_2(T)C_B \tag{42}$$

with the kinetics constraints

$$k_1(T) = 0.0444\exp(-2500/T) \tag{43}$$

and

$$k_2(T) = 6889.0\exp(-5000/T). \tag{44}$$

Then, in the mixing stage at the time $t_1$, the component $B$ of concentration $C_B^0 = 600$mol/m$^3$ and some volume $S$ was added. Therefore, the volume and consecrations of the substrates were changing, so the following relations were satisfied

$$V_2C_A(t_2^0) = V_1C_A(t_1) \tag{45}$$

$$V_2C_B(t_2^0) = V_1C_B(t_1) + SC_B^0 \tag{46}$$

$$V_2 C_C(t_2^0) = V_1 C_C(t_1) \tag{47}$$

where $V_1$ is the volume of substrates loaded at the beginning of the first reactor. Therefore, the volume $V_2$ in the second reactor was given by

$$V_2 = V_1 + S \tag{48}$$

The volume $S$ is a decision parameter with

$$0 \le S \le 0.1(m^3) \tag{49}$$

After the mixing stage, the substrates were loaded into the last reactor, where three reactions were taking a place

$$B \to D \tag{50}$$

$$B \to E \tag{51}$$

$$2B \to F \tag{52}$$

In the $2nd$ reactor, the reactions take place under isothermal conditions. The state variables are changing in the following way

$$\dot{C}_A = 0 \tag{53}$$

$$\dot{C}_B = -0.02 C_B - 0.05 C_B - 2 \times 4.0 \times 10^{-5} C_B^2 \tag{54}$$

$$\dot{C}_C = 0 \tag{55}$$

$$\dot{C}_D = 0.02 C_B \tag{56}$$

$$\dot{C}_E = 0.05 C_B \tag{57}$$

$$\dot{C}_F = 4.0 \times 10^{-5} C_B^2 \tag{58}$$

The combined processing time for both reactors is equal to 180 min

$$t_1 + t_2 = 180, \tag{59}$$

$$t_1 > 0, \qquad t_2 > 0. \tag{60}$$

The decision variables are the profile of the temperature $T(t)$, the duration time of the reactions in each stage, and the amount $S$ of component $B$, which is added at the mixing step.

The process is aimed to maximize the amount of the product $D$ at the output of the $2nd$ reactor

$$\max_{t_1, t_2, S, T(t)} V_2 C_D(t_2) \tag{61}$$

subject to the constraints on the temperature profile

$$298 \le T(t) \le 398(K), \qquad t \in [0 \quad t_1]. \tag{62}$$

The direct shooting method enables us to transform the multistage optimal control problem as an nonlinear optimization problem with both continuous and pointwise constraints. In classical approaches, the nonlinear optimization problem with constraints can be solved using penalty function approach or NLP algorithms, like Sequential Quadratic Programming or Barrier methods. In this way, the process in first reactor was divided into 10 equidistance intervals. Additionally, the initial conditions for the second reactor should be consistent with the results of the mixing stage. Therefore, the considered NLP problem consisted of 27 continuity constraints, 3 consistency constraints and 42 decision variables.

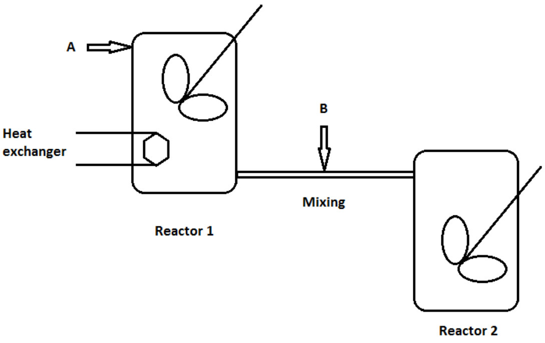


Fig. 1. System of the two-reactors with mixing.

The aggregated model was defined using 3 scalar functions

$$\hat{Q}(x) = Q(x) \tag{63}$$

$$c_{cont}(x) = \sum_{i=1}^{27} \|c_{cont,1}(x)\|_1 \tag{64}$$

$$c_{cons}(x) = \sum_{i=1}^{3} \|c_{cons,1}(x)\|_1 \tag{65}$$

In the next step, all three function were transformed using "stretching" function technique

$$\mathcal{S}\Big(\hat{Q}(x)\Big) = \hat{Q}^{\mathcal{S}}(x) \tag{66}$$

$$\mathcal{S}\Big(c_{cont}(x)\Big) = c_{cont}^{\mathcal{S}}(x) \tag{67}$$

$$\mathcal{S}\Big(c_{cons}(x)\Big) = c_{cons}^{\mathcal{S}}(x) \tag{68}$$

and optimized using presented simulated annealing algorithm with new acceptance method.

The parameters of the methods were adjusted automatically. Therefore, the simulations were performed with the following parameters

- number iterations in the outer loop $MaxIter = 500$,
- inner iterations in cooling loop $MaxIterCool = 10$,
- diameter of the considered neighborhood $\alpha = 0.4$
- initial temperature $T_0 = 100$,
- temperature update factor $T_{i+1} = \beta T_i$ is $\beta = 0.6$.

The obtained results, which were obtained for the aggregated model, were applied to the original model of the considered process. After 702 model evaluations, the final value of the original process performance index was equal to 22.7233 mol. The obtained state trajectories were presented in the Fig. 2.

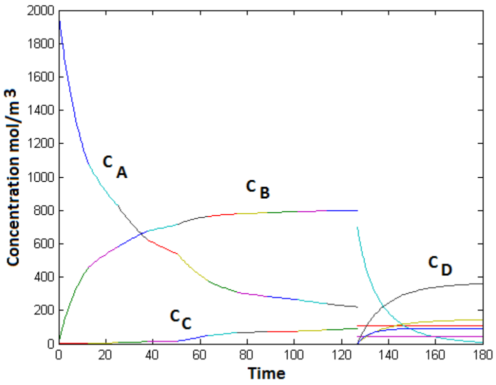

Fig. 2. Trajectories of the state variables.

## VII. Conclusion

In the article a problem of solving complex multistage technological processes was considered. The new methodology, which was presented, applies aggregation-disaggregation approach. The optimal control problem was transformed into the nonlinear optimization problem using the direct shooting approach. Then, the NLP problem has been defined using only three functions, which reflects the characteristics features of the process. The first one denotes the value of the process performance index. Then, the second one is connected with the continuity of the differential state trajectories, and the last one denotes the consistent initial conditions of the process. The quality of the proposed solution was defined using only values of these three functions. To compare any two proposed solutions, the new decision approach was proposed. The presented methodology was applied to the two-stage reactor system.

The future research will be devoted to error analysis of the aggregation-disaggregation procedures for control and optimization of the multistage technological processes with nonlinear differential-algebraic constraints.

*Abstract*—**Development of sophisticated photonic transmission systems enabled evolution of photonic data transport networks towards cost-efficient and energy-efficient platforms capable to carry enormous traffic. Given access to technologically advanced equipment, network operator faces a series of decision problems related to how to efficiently use this technology. In this paper, we propose a functional model of modern photonic network with wavelength division multiplexing (WDM). Proposed functional model is a basis for formulating corresponding flow design problem in terms of mathematical programming.**

## I. Introduction

RECENT advances in the photonic networking enabled rapid growth of the transmission rates in the modern photonic data transport networks. Thus, photonic data transport networks became considerable alternative for traditional electric-based transmission systems, and are more and more widely deployed in the Autonomous Systems composing the Internet.

An important area of research in the domain of photonic data transport networks is associated with development of functional models of photonic networks and mathematical models of the decision problems associated with designing such networks.

Modeling telecommunication network is not a trivial task. On one hand, development of functional models requires detailed knowledge of transmission technology and networking protocols. Thus, such functional models must be sufficiently detailed to accurately represent costs of equipment. On the other hand, it is necessary to consider a number of specific aspects that may further turn into design constraints. Most important of these include:

- architecture of switching equipment and transmission,
- mechanisms for traffic grooming and consolidation,
- network reconfiguration in case of failure,
- physical effects associated with signal propagation.

In the balance of this paper we propose mathematical (optimization) model of the flow design problem related to photonic data transport network. Developed model is expressed in terms of integer programming. It refers to generic input data, including: network topology, infrastructure, and considered products. In particular, on one hand, input data must determine full cost characteristics of the considered equipment, usually in form of cost of particular expansion cards. On the other hand, input data are supposed to include locations of client devices and their demand for data transport services. It is therefore assumed that knowledge possessed by a network operator about demand structure is certain. In practice, knowing exact demand for transport services can be difficult, and sometimes even impossible. Still, we assume that through appropriate statistical methodology, it is possible to determine demand value with reasonable degree of confidence.

Paper is organized as follows. In Section II we present general principles of photonic data transport networks, including: standardized interfaces (Section II-A), architecture (Section II-B) and configuration (Section II-B) of photonic devices, signal impairments (Section III-F), performance aspects (Section II-E), and cost model (Section II-F). All elements presented throughout Section II define functional model of photonic network. Further, in Section III we define corresponding mathematical model associated with designing flows in photonic data transport network. Assumptions and construction of network graph are discussed in Sections III-A and III-B, respectively. Considered flow design problem is formulated as mixed-integer programme in Section III-C. Further, we investigate modeling specific aspects of the photonic data transport networks, related to: consistency of client flow at technology level (Section III-D), redundancy (Section III-E), impairments (Section III-F), and network cost (Section III-G). Paper is summarized with estimation of formulation complexity in Section IV, and conclusions in Section V.

## II. Photonic data transport networks

Photonic data transmission exploits optical tracks (fibers) to send photonic signals between transceivers (lasers) and receivers (photo-diodes). Photonic signal is modulated to represent values of consecutive bits, composing transmitted piece of data. Low interference with other electromagnetic signals makes photonic signals stable and robust to distortions. Thus, photonic signals can be successfully sent over long distances, reaching thousands of kilometers, and transmitted messages can be still reproduced with small error rate.

This work presents results of realization of first phase of ongoing project "Optymalizacja przepływów w wielowarstwowych sieciach dostępu do Internetu w technologii DWDM/IP/MPLS" (ODIN). Project is co-founded by The National Centre for Research and Development, Poland.

978-83-60810-66-8/$25.00©2015, IEEE

Photonic signals can be easily multiplexed in the frequency domain. Frequency in the case of photonic networking is called wavelength, and the corresponding multiplexing is called Wavelength Division Multiplexing or WDM. WDM is also a term describing the related channel-oriented transport technology, exploiting regular channel widths and spacing (so-called optical grid [1]). Each wavelength constitutes thus an isolated communication channel, in the following referred to as $\lambda$.

### A. Optical Transport Network

G.709 [2] is an ITU-T recommendation defining interfaces of Optical Transport Network (OTN), defined in another ITU-T recommendation G.872 [3]. It characterizes so-called Optical Transport Hierarchy (OTH), i.e., structured hierarchy of interfaces that can be treated as an extension of the SDH hierarchy, defined in ITU-T recommendation G.707 [4]. Interfaces defined in G.709 are considered at two levels: user-to-network (UNI) and network-to-network (NNI). UNI interface is exposed towards an OTN client, and NNI interface is exposed towards an OTN network.

According to recommendation G.709, the basic OTH information structure is called Optical Channel (OCh). OCh spans between line ports of each pair of adjacent transponders, responsible for converting electrical data signal into photonic signal, modulated as single wavelength (and vice versa). Each OCh is associated with out-of-band signaling channel used for management and supervision of optical channel. OCh payload is filled with lower layer information structure called Optical Transport Unit (OTU). Similarly as OCh, OTU spans between two adjacent transponders, but it is associated with data connection in the electric domain. OTU signaling creates a control channel to exchange information related to supervision and conditioning signal for transport (including Forward Error Correction). Payload of OTU is further filled with information structure called Optical channel Data Unit (ODU). ODU is a function of termination point of digital end-to-end data path between two optical devices, crossing amplification and regeneration sections. ODU signaling is used to exchange control information related to end-to-end path supervision and monitoring so-called tandem connections.

Finally, client signal is mapped into information structure called Optical Payload Unit (OPU). OPU structure is responsible for the adaptation of the client signals and lower layer ODU signals. OPU overhead comprises information required to perform rate adaptation between the client signal rate and the OPU payload rate, and other OPU overheads supporting the client signal transport. OPU structure is filled into the ODU payload.

A number of the OCh structures is multiplexed into structure called Optical Multiplex Section (OMS). OMS is a function of termination point of the (de-)multiplexing section. OMS is further filled into the payload of structure called Optical Transport Section (OTS), responsible for transporting multiplexed optical channels between two adjacent amplification points through single fiber span. OTS is a function of termination point of optical line which transports multiplexed optical channels from one node to another. OTN layers are presented in Figure 1. In the following, the introduced notation is used to map particular OTN functions into generic types of photonic cards needed to build OTN compatible networks.

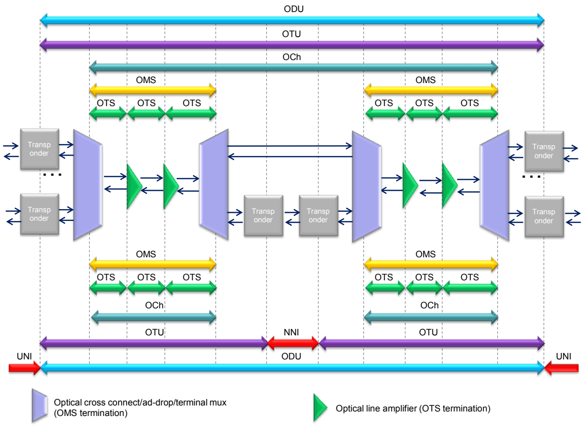

Fig. 1. OTN layers

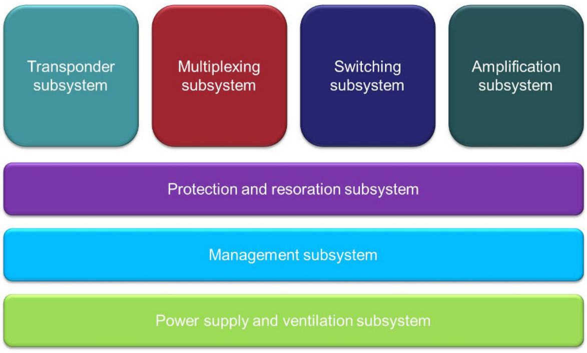

Fig. 2. ONE architecture

### B. Architecture of optical network element

Architecture of Optical Network Element (ONE) is composed of seven functional blocks presented in Figure 2. Each of these functional blocks is briefly described in the following.

*1) Transponder subsystem:* Transponder subsystem is a functional block responsible for adapting client black&white signals, typically in $1310nm$ band, to colorful $\lambda$ signals within $1550nm$ band, according to used optical grid definition. Adaptation concerns both signal frequency and signal rate. Transponder is typically available in the form of expansion card, required for each add-drop channel. It provides UNI interface, and optionally NNI interface. Transponders are sometimes combined with Forward Error Correction blocks, that allow to correct some transmission errors, and decrease bit error rate.

Some vendors combine transponders with concatenation function, which allows to concentrate a number of low order speed signals into high order speed signal. For instance, four STM-16 ($2.5Gbps$) signals can be concentrated into one

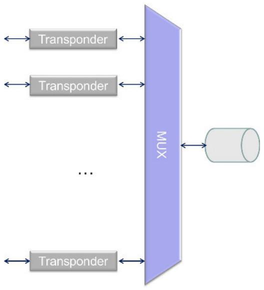

Fig. 3. Multiplexing subsystem: 1-stage multiplexer

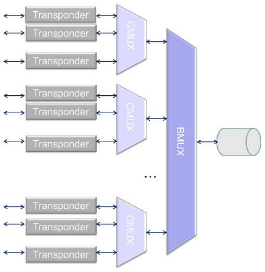

Fig. 4. Multiplexing subsystem: 2-stage multiplexer

ODU2 signal ($10.709 Gbps$). Sometimes, concentrators are provided as stand-alone cards, further connected to transponder tributary interfaces. For instance, two GigabitEthernet signals ($1 Gbps$ each) using Generic Framing Procedure (GFP) can be concentrated into one STM-16 signal ($2.5 Gbps$), further combined with mentioned $4 \times 2.5 Gbps$ transponder card. Such concentrating stand-alone card is called concentrator. Using concentrating function allows network operator to maintain fine grain granularity of transmitted signals, and optimized usage of the WDM network resources.

*2) Multiplexing subsystem:* Multiplexing subsystem is responsible for multiplexing multiple colorful add $\lambda$ signals produced by transponders into single multi-channel signal, according to definition of used optical grid. Similarly, demultiplexer separates particular drop channels from single multi-channel WDM signal. Thus, tributary side of multiplexing subsystem expose a number of physical interfaces towards transponder subsystem and single line interface towards switching subsystem.

For the sake of flexibility, vendors of optical devices often use multi-stage multiplexers. as those presented in figures 3 and 4. In 2-stage multiplexer, presented in Figure 4, multiplexing is decomposed in two stages: band multiplexing (BMUX) and channel multiplexing (CMUX). For instance, $N = 80 \times \lambda$ loading plan, constructed according to 50GHz optical grid, can be decomposed into ten bands, each containing eight channels. Cost of 2-stage multiplexing with expandable CMUX cards can be more granular than 1-stage multiplexing. In particular, network operator may add new CMUX cards as its demand for capacity grows.

*3) Switching subsystem:* Switching subsystem is responsible for directing selected channels to the add-drop multiplexing block and creating pass-through connections (between different ONE directions) for the other channels. In the pass-through mode, channel in one adjacent fiber is switched to channel in another adjacent fiber. Example 4-direction switching module is presented in Figure 5. Presented module is based on using Wavelength Selective Switches (WSS) and Optical SPlitters (SPL).

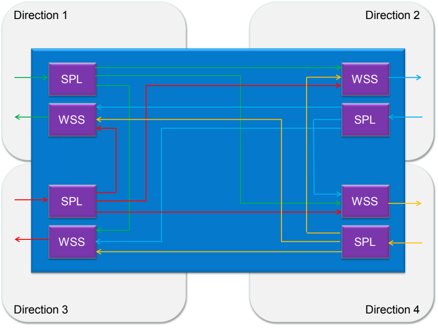

Fig. 5. Switching subsystem

*4) Amplification subsystem:* Although optical signals do not interfere with other electromagnetic signals, power of optical signals is dispersed due to impurity of transmission medium. Thus, power of transmitted signal in the source node is much higher than power of received signal in the destination node. To assure right power level received by photo-detectors, optical signal may need to be amplified. Today, there are three types of optical amplifiers in common use:

- Semiconductor optical amplifier,
- Raman fiber amplifier,
- Erbium doped fiber amplifier.

Semiconductor Optical Amplifier (SOA), in a similar manner as Fabry-Perot laser diodes, uses a semiconductor to provide the gain medium. Signal amplification is realized in SOA by inducing energetic level of medium material. SOA amplifiers need anti-reflection components at the end faces, so amplifier not turns into a laser diode. SOA amplifiers in practice operate at signal wavelengths between $0.4 \mu m$ and $2.0 \mu m$, and generate gain up to $30 dB$. Compared with other amplifier types (mainly EDFA) SOA may generate higher noise, lower gain, moderate polarization dependence, and high non-linearity with fast transient time. Still, SOA amplifiers may have compact design, easily plug-able into fiber-pigtailed components. Despite relatively high noise level, high amplification and wide amplification spectrum make SOA amplifiers attractive option in certain optical applications. In particular, SOA amplifiers are widely used as wavelength convertors.

Raman Fiber Amplifier (RFA) exploits Raman distortion effect, i.e., nonlinear interaction between signal and pump laser within an optical fiber. In RFA amplifier, pump laser generates optical signal in lower range of optical spectrum ($1535 nm$) that is further coupled with operational signal in higher optical spectrum ($1540 nm$ – $1580 nm$). In other words, RFA amplifier induces energy transfer from optical signal generated by pump laser to operational signal. RFA amplifier in practice generates low noise level, has high amplification level, and can produce high power signal. Construction of RFA amplfier may be relatively complex to provide smooth and wide gain characteristics, i.e., multiple pumping signals with different frequencies may be required.

Erbium Doped Fiber Amplifier (EDFA) is likely most widely used type of amplifiers. EDFA amplifier is composed of a short Erbium doped fiber span (typically several kilometers) and pump laser. Optical signal generated by the pump laser is absorbed by Erbium atoms, that in turn release absorbed energy to the operational signal transmitted through doped fiber. EDFA amplifiers in practical applications use $980nm$ – $1480nm$ pumping signal to amplify operational signals transmitted at wavelength $1550nm$. EDFA amplifiers in a process of Amplified Spontaneous Emission (ASE) generate noise that further decrease signal-to-noise ratio.

*5) Protection subsystem:* Typically, data stream, transmitted through WDM network, may be protected by parallel optical channel spreading between the same type of transponders in the same end devices as the nominal channel. For this purpose, vendors provide special protection cards responsible for activating protection channel in case of unavailability of the nominal channel. Such cards can work in one of two commonly used modes:

- source switched,
- destination switched.

Source switch mode is realized by turning off laser in the nominal channel, and immediate activation of laser in the protection channel, as only failure is detected. Source switch is thus completely transparent to carried data, and directly switches optical signals. Besides, source switch mode allows to use simple optical couplers at receiver side, because only one signal: nominal or protection is transmitted at time.

Destination switch is realized as data switch at receiver side. Switch continuously compares quality of nominal and protection signals, and according to result of this comparison passes one of them to client interface. It means that lasers of both signals must be active all the time, and data stream must be replicated to both channels at source.

*6) Management subsystem:* According to OTH hierarchy, overhead information can be sent in-band only to certain layer defined by OTU. Below OTU layer, signaling is sent out-of-band through so-called Optical Supervisory Channel (OSC). OSC organization is proprietary.

### *C. ONE configuration*

Basic element of the WDM network is device called Optical Add-Drop Multiplexer (OADM). In general, OADM is responsible for multiplexing and concatenating tributary signals into line signals transmitted towards other devices. Depending on its configuration and design, optical devices can be used in different fashions. Typical optical device configurations include:

1) Line terminal (LT),
2) Back-to-back (BtB),
3) Band optical add-drop multiplexer (BOADM) – 2-stage multiplexer only,
4) Reconfigurable optical add-drop multiplexer (ROADM),
5) Tunable and reconfigurable optical add-drop multiplexer (T&ROADM).

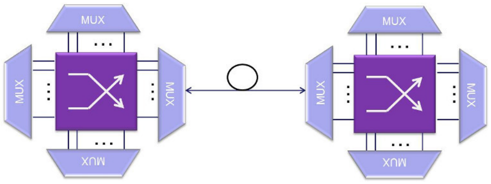

Fig. 6. Opaque mode

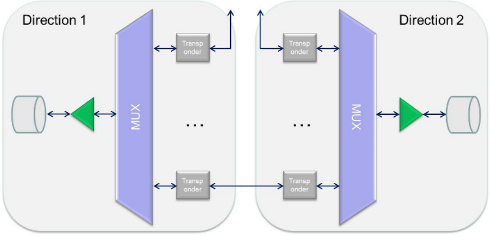

Fig. 7. Back-to-back configuration

Below, we briefly characterize each of these configurations.

1. Line terminal is the most basic configuration of an optical device. Device configured as a line terminal is responsible for adopting and modulating tributary signals as colorful signals and multiplexing resulting signals into $\lambda$ channels according to selected optical grid definition. Line terminals are commonly used in so-called opaque mode (see Figure 6), to build simple point-to-point optical spans. In opaque mode, device receiving optical signal transforms it to the electric domain and switches obtained electrical signals. Opaque mode is common configuration of the SDH/Sonet devices. Line terminal can be equipped with transponders, concentrators, multiplexers, and amplifiers.

2. Back-to-back configuration allows to create simple multi-point optical networks, by static coupling tributary ports in transponders. Back-to-back configuration is presented in Figure 7.

3. Band optical add-drop multiplexer is an extension of back-to-back configuration which additionally allows subset of band signals to be transmitted in pass-through mode directly between band multiplexers (BOADM configuration, presented in Figure 8, refers to 2-stage add-drop multiplexers.)

4. Reconfigurable optical add-drop multiplexer is a configuration of optical device capable to add, drop, and pass-through wavelengths (switch between adjacent fibers). It can be (remotely) configured (through management system) to put each channel within line fiber into one of two states: pass-through or add-drop (see Figure 9).

5. Tunable and reconfigurable optical add-drop multiplexer is the most advanced configuration that extends remote configuration of ROADM with wavelength conversion function.

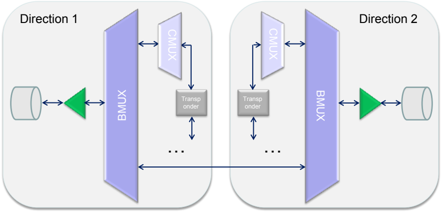

Fig. 8. Band optical add-drop multiplexer configuration

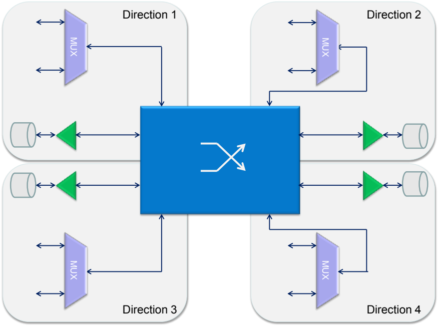

Fig. 9. Remote optical add-drop multiplexer configuration

### D. Optical impairments

Fiber attenuation is the most fundamental impairment that affects optical signal propagation. Attenuation is a fiber property resulting from using various material, structural, and modular impairments. Still, fiber attenuation is an effect with intensity linearly proportional to fiber length and number of optical elements: connectors, splitters, etc. Thus, optical signal power lost due to fiber attenuation can be recovered by using so-called Linearized Optical Fiber Amplifier (LOFA) cards, containing amplification modules described in Section II-B4. Beyond amplifiers itself, LOFA cards may also contain a module called Variable Optical Attenuator (VOA), responsible for enforced attenuation of optical signal, so volume of power received by photo-diode is contained in strictly defined working window. Attenuation of VOA modules is typically dynamically set in a closed-loop feedback between adjacent ONE's. Unfortunately, amplifiers, as all active optical elements, introduce into transmitted signal some portion of noise. Fiber attenuation is well standardized for particular fiber types (cf. [5]).

Further, shape of optical signal can be distorted due to dispersion. Dispersion cause that optical impulse is widened in time. In extreme case, two consecutive impulses can overlap, leading to potential reception errors. Two types of dispersion ca be categorized: chromatic dispersion and polarization mode dispersion.

Chromatic dispersion is related to velocity difference between different wavelengths in particular medium. Due to linear character of chromatic dispersion, impairments introduced by this effect can be eliminated by using fiber spans with reverse dispersion characteristics. Compensating modules, called Dispersion Compensating Fiber (DCF), are typically attached after each fixed-length section of long-haul connection.

Polarization mode dispersion is caused by asymmetry of the fiber-optic strand. Polarization mode dispersion has thus completely random character. According to ITU-T recommendation G.652 [5], unit dispersion coefficient of optical fiber G.652B should not cross $17ps/(nm \times km)$ for chromatic dispersion and $0.20ps/(\sqrt{km})$ for polarization mode dispersion.

Another serious source of impairments is light scattering. Light scattering results from localized non-uniformity in the fiber medium. It can be seen as a deflection of a ray from a straight path. Deviations from the law of reflection due to irregularities on a surface of optical connectors are also usually considered to be a form of scattering. Among light scattering effects, several effects can imply serious impairments in photonic networks: stimulated Brillouin scattering and stimulated Raman scattering. Scattering effects are non-linear, and they tend to manifest themselves when optical signal power is high.

Other serious non-linear impairments in photonic networks are related to: Four-Wave Mixing, Self-Phase Modulation, and Cross-Phase Modulation. These effects result from transmitting multiple wavelengths over single fiber. Non-linear effects increase level of noise in the optical signal.

### E. Network performance

During transmission in medium, optical signals are distorted by certain optical effects. Resulting transmission errors affects OTN service quality. Some of effects, having linear characteristics, like fiber attenuation or chromatic dispersion, can be compensated by using dedicated modules. Other effects introduce distortions that cannot be recovered without translation to electric domain.

Major performance indicator of OTN service quality, called Bit Error Rate or simply BER, is thus related to the number of erroneously transmitted bits in digital client signal. In relation to noise introduced by non-linear optical effects and active optical elements, BER can be treated as a function of Optical Signal to Noise Ratio (OSNR), representing gap between power of optical signal and power of noise. In relation to effects not changing power level, but its distribution in time, BER can be treated as a function of dispersion coefficients.

OSNR related to sequence of active elements can be calculated according to formula (1).

$$1/OSNR = \textstyle\sum_i 1/OSNR_i, \qquad (1)$$

where $OSNR_i$ determines partial OSNR of $i$-th element in the sequence.

### F. Network cost model

Adjacent optical devices are connected by optical fibers, attached to their line interfaces. Multiple fibers are further combined into optical cables, connecting network sites and wells. Cables are attached to optical distribution frames, where incoming fibers are interconnected in order to establish end-to-end optical spans between devices. Signaling between WDM devices is realized via proprietary out-of-band channel, outside optical grid.

Optical device is a complex device, equipped with variety of specialized functions required for photonic signal processing. Typically, those specialized functions are realized by expansion cards, fitted into device slots. Cards can be further interconnected by back-plane device wiring or through external patch-cords, fitted manually into their front panel interfaces. In practice, to transport client signals, optical device must be equipped with a minimal set of supervisory cards, responsible for device control and management. Those cards implement proprietary vendor-specific algorithms to enable proper transmission and reception of photonic signals between adjacent devices. In the following, cost related to those cards is treated as a part of device fixed cost, being in turn a part of CAPital EXpenditure (CAPEX) related to network deployment.

In practice, optical devices are sold in the form of racks (for example, one rack per direction), equipped with certain number of slots for shelves. Each shelf in turn may be equipped with a number of slots to host expansion cards. Tributary and linear cards may be combined with embedded or external Network Interface Controllers (NICs). In the latter case, external NICs are fitted into appropriate slots on cards. ONE slots must thus be filled with a set of required expansion cards providing specialized functionality. Expansion cards can be classified into two categories:

- fixed cards: switching matrices, band multiplexers, supervision cards, fans, power suppliers, etc.,
- elastic cards: channel multiplexers, transponders, and muxponders.

Number and type of fixed cards is predefined by system vendor. Cost of fixed cards, together with cost of racks and shelves, is accounted into system installation cost. In other words, cost of the fixed cards is independent of traffic amount handled by ONE. Contrary to fixed cards, number and type of elastic cards can vary according to specific usage of the WDM system. In particular, network operator may choose between different types of transponders providing different modulation types, capacity, and forward error correction methods. In some ONE designs, channel multiplexers can be not expandable, and full range of multiplexers must be installed in the form of fixed cards. However, in the following, we consider elastic channel multiplexer cards as more general case. Band multiplexers are typically fixed cards. Still, due to particular composition of the switching matrices, some ONE designs may require installation of one rack per each direction (representing long-haul connection with neighboring ONE). In that case, predefined set of fixed cards, including band multiplexers, must be installed in each rack.

According to ITU-T recommendation G.709 [2], signals transmitted through OTN network compose the OTH hierarchy. OTH also defines structure and bandwidth of tributary signals crossing the UNI interface of OTN network. As bandwidth of single WDM channel may be greater than bandwidth of typically used Layer 2 signals, multiple client signals may be concatenated into larger signals, better fitted to bandwidth of WDM channels. Signals are typically concatenated in the time domain through dedicated concentrator cards.

Tributary signals need to be further framed according to ODU definition, coupled with error correction overhead, and transformed into colored optical signals to be transmitted through WDM network. Card responsible for these functions is called transponder. Optical signal transmitted by source transponder is again converted to the digital domain in the destination transponder. Between transponders, signal remains in the optical domain. Still, certain control information related to the transmitted signal is carried along signal path through dedicated administration channel.

## III. Flow design

In this section we consider flow design problem related to OTN/WDM photonic networks. Considered flow design problem is formulated in terms of mathematical programming. Having given basic WDM network topology and set of traffic demands to be realized, OTN/WDM flow design problem is aimed at identifying a flow distribution and composition of expandable WDM components (e.g., muxponders, transponders, multiplexers, etc.) leading to optimized value of certain objective function. In particular, feasible solution of the considered problem identifies design of the ONE nodes in terms of number, type, and configuration of expansion cards necessary to realize traffic demands, and associated cost.

Considered problem is described in the literature as Routing Wavelength Assignment (RWA) problem. It is commonly considered in combination with objective function maximizing the number of concurrent connections. Example integer linear programming formulation of this problem can be found in [6]. Independently in [7] and [8] it was proved that RWA problem is $\mathcal{NP}$-complete. Formulations proposed in the literature ([9], [10], [11], [12], [13], [14], [15], [16], [17], [18], [19], [20]) differ from formulation proposed in the following in terms of graph construction. Namely, in this paper it is assumed that each $\lambda$ channel constitutes separate edge in the network graph. Such assumption is not common in other works, but it allows to simplify formulation, and increase problem flexibility through graph construction. Moreover, classical RWA problem is concerned with routing and $\lambda$ selection only. Here, problem is extended with consideration of the access side. This extension is motivated by usage of objective function related to cost of elastic expansion cards.

### A. Assumptions

Traffic demands are assumed to be known in advance, e.g., they can be sourced from some external business forecast and measurement tool. As demand variation is out of the scope at considered network design problem, demand volumes may be additionally adjusted with some security margin. Each traffic demand is defined by triple: source, destination, and bandwidth volume. Demand source and destination are external clients connected to local ONE nodes through intra-office or short-haul black&white fibers.

Client devices and ONE devices are installed within Points of Presence (PoPs) of a network operator, and each client device is connected to uniquely defined ONE, usually in the same PoP. Even if in some PoP, ONE device is not installed, client localized in such PoP must be unambiguously assigned and connected to one ONE in one of the other PoPs.

After installing full suite of channel multiplexers, ONE device is capable to handle $N$ channels, equal to its maximum capacity. Each channel has precisely defined central frequency and width. Central frequencies of consecutive channels are supposed to be compatible with one of optical grids defined by ITU-T.

### B. Network graph

Network topology at the simplest level defines locations, configuration, and type of network elements, and arrangement of long-haul fibers connecting network elements. Depending on required level of granularity, network topology can be more or less detailed. At level of details required by flow optimization, this simple topology needs to be extended with deeper insight into composition of network elements. For this purpose, we define a directed graph $\mathcal{G}(\mathcal{V},\mathcal{E})$ composed of set of nodes $\mathcal{V}$ and set of edges $\mathcal{E}$. Graph composition is used in the following as a basic modeling methodology. It allows to formulate considered flow design problem in terms of multi-commodity flow optimization.

*1) Graph nodes:* In general, node set $\mathcal{V}$ can refer to four types of physical elements (cards or whole devices):

- optical network element - device responsible for multiplexing, switching, and (optionally) converting colorful $\lambda$ signals ($\mathcal{O}$),
- transponder - expansion card responsible for adopting colorless tributary signals and modulating them as colorful $\lambda$ signals ($\mathcal{T}$),
- muxponders - expansion card responsible for concatenating multiple colorless signals into higher-order colorful signals ($\mathcal{M}$),
- client - non-WDM device, consuming OTN services ($\mathcal{C}$).

In order to model switching and converting colorful $\lambda$ signals, each ONE is represented in the network graph $\mathcal{G}$ by a set of graph nodes (referred to as *colorful nodes*), each associated with exactly one $\lambda$ and one direction towards adjacent ONE. Accordingly, number of colorful graph nodes associated with single ONE is equal to $N \times D$, where $D$ is the number of ONE neighbors. Similarly, basic graph of long-haul fiber connections is replicated, so there exists $N$ (equal to number of $\lambda$'s) parallel subgraphs, each topologically isomorphic with original network graph. If ONEs are capable to convert $\lambda$ frequencies, all colorful nodes associated with single ONE needs to be interconnected. For example, if in the feasible solution, such artificial link is crossed on path between colorful nodes associated with $\lambda_1$ and $\lambda_2$, it means that signal incoming to the related ONE at $\lambda_1$ is transmitted out through $\lambda_2$. Example subgraph of colorful nodes associated with two neighboring 3-direction ONEs in ROADM configuration is presented in Figure 10. T&ROADM counterpart extends the ROADM subgraph with full mesh connections between colorful nodes inside ONE, as presented in Figure 11.

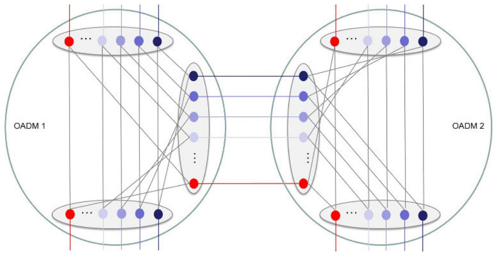

Fig. 10. ROADM subgraph

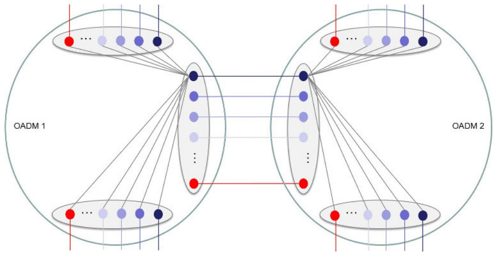

Fig. 11. T&ROADM subgraph

Transponder and concentrator are sometimes combined as one expansion card – muxponder. If not combined, clients can be connected to transponders two-fold: through direct connections or indirectly through hierarchy of compatible concentrators. In the network graph, stand-alone transponders are associated with a subset of graph nodes $\mathcal{T}$, where each graph node is associated with one transponder type and one ONE location. Associated subgraph is presented in Figure 12. In the figure, there are three transponder types (say 10Gbps, 40Gbps, and 100Gbps) and two clients. Transponder graph nodes representing each transponder type in one location are connected to all colorful nodes.

Muxponders form subset of graph nodes $\mathcal{M}$, where each muxponder type is replicated $N$ times, so each colorful node

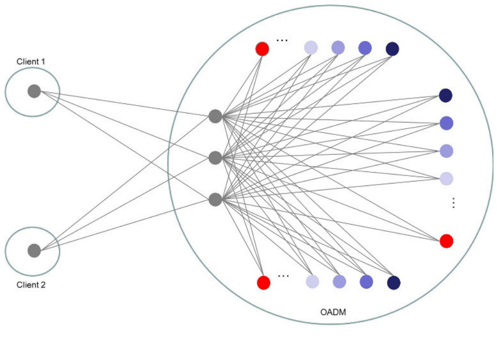

Fig. 12. Transponder subgraph

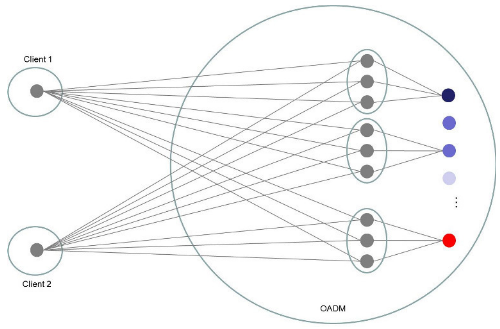

Fig. 13. Muxponder subgraph

can be connected to its own unique suite of muxponders. Despite graph contains all potential muxponder cards, only some subset of cards may be required in the optimal solution. All muxponder graph nodes are connected with graph nodes representing compatible interfaces in the client devices, as it is presented in Figure 13. Whole muxponder hierarchy is represented by single graph node, which means that multiple different connection types (different transport technology modules) are represented as parallel graph links, each associated with one transport technology type.

Client devices are not replicated in the network graph, and there exists exactly one graph node associated with each physical client device.

*2) Graph edges:* Nodes $\mathcal{V}$ are connected by set of edges $\mathcal{F}$, referring to physical connections:

- long-haul fibers connecting ONEs ($\mathcal{H}$),
- intra-office fibers connecting line ports in client devices and tributary ports in muxponders/transponders,
- patch-cords and back-plane wiring connecting line ports in transponders and tributary ports in ONE multiplexers.

All enumerated types of connections: fibers, patch-cords, and wiring are further described by common term link. Set $\mathcal{F}$ is assumed to be a superset of the link set defined by the basic network topology. In particular, it contains replicated edges between adjacent colorful nodes. Finally, not all edges contained in $\mathcal{F}$ will be deployed, because some graph nodes represent non-existent components and link deployment will depend on card installation. A subset of these potential links will be selected for deployment or activation.

## C. Mathematical formulation

Based on introduced network graph definition, the WDM flow design problem can be formulated as below mixed integer programme.

**object sets**

| | |
|---|---|
| $\mathcal{E}$ | (directed) demands (e.g., IP links) |
| $\mathcal{V}$ | nodes |
| $\mathcal{O} \subset \mathcal{V}$ | colorful ONE nodes |
| $\mathcal{T} \subset \mathcal{V}$ | transponders |
| $\mathcal{M} \subset \mathcal{V}$ | muxponders |
| $\mathcal{C} \subset \mathcal{V}$ | clients (e.g., IP routers) |
| $\mathcal{F} = \mathcal{H} \cup \mathcal{L}$ | (directed) edges (WDM links) |
| $\mathcal{G} \subset \mathcal{F}$ | edges associated with transponder links |
| $\mathcal{H} \subset \mathcal{F}$ | edges associated with long-haul links |
| $\mathcal{L} \subset \mathcal{F}$ | edges associated with intra-office links |
| $\mathcal{A}_v \subset \mathcal{F}$ | edges outgoing from node $v \in \mathcal{V}$ |
| $\mathcal{B}_v \subset \mathcal{F}$ | edges incoming to node $v \in \mathcal{V}$ |
| $\mathcal{P}_v \subset \mathcal{F}$ | edges associated with add-drop (tributary)<br>ports in colorful ONE nodes $v \in \mathcal{O}$ |
| $\mathcal{Q}$ | data transmission technologies |

**predefined objects**

| | |
|---|---|
| $a(e) \in \mathcal{C}$ | originating client node (source) of demand $e \in \mathcal{E}$ |
| $b(e) \in \mathcal{C}$ | terminating client node (sink) of demand $e \in \mathcal{E}$ |
| $a(f) \in \mathcal{V}$ | originating client node (source) of edge $f \in \mathcal{F}$ |
| $b(f) \in \mathcal{V}$ | terminating client node (sink) of edge $f \in \mathcal{F}$ |
| $\alpha(fe) \in \mathcal{L}$ | terminating line related to originating link $f \in \mathcal{L}$ with regard to demand $e \in \mathcal{E}$ |

**constants**

| | |
|---|---|
| $c_e$ | volume of demand $e \in \mathcal{E}$ |
| $l_f$ | capacity module of link $f \in \mathcal{F}$ |
| $t_v$ | equal to the maximum number of active tributary links of muxponder, if $v \in \mathcal{M}$;<br>equal to 1, if $v \in \mathcal{O}$ |
| $n_f$ | equal to $N$, if $f \in \mathcal{G}$;<br>equal to 1, if $f \in \mathcal{F} \setminus \mathcal{G}$ |

**variables**

| | |
|---|---|
| $s_{fe} \in \{0,1\}$ | variable equal to 1 if demand $e \in \mathcal{E}$ is realized on link $f \in \mathcal{F}$, and 0 otherwise |
| $z_f \in \mathbb{Z}$ | variable equal to the number of transport modules on link $f \in \mathcal{F}$ |

**constraints**

$$\sum_{f \in \mathcal{A}_v} l_f s_{fe} = c_e \qquad e \in \mathcal{E}, v = a(e) \in \mathcal{C} \tag{2a}$$
$$\sum_{f \in \mathcal{B}_v} l_f s_{fe} = c_e \qquad e \in \mathcal{E}, v = b(e) \in \mathcal{C} \tag{2b}$$
$$\sum_{f \in \mathcal{A}_v} s_{fe} = \sum_{f \in \mathcal{B}_v} s_{fe} \qquad e \in \mathcal{E}, v \in \mathcal{V} \setminus \{a(e), b(e)\} \tag{2c}$$
$$\sum_{e \in \mathcal{E}} s_{fe} \leq z_f \qquad f \in \mathcal{L} \tag{2d}$$
$$\sum_{e \in \mathcal{E}} s_{fe} \leq M z_f \qquad f \in \mathcal{H} \tag{2e}$$
$$\sum_{f \in \mathcal{A}_v} z_f = \sum_{f \in \mathcal{B}_v} z_f \qquad v \in \mathcal{O} \tag{2f}$$
$$\sum_{f \in \mathcal{B}_v} z_f \leq t_v \qquad v \in \mathcal{M} \cup \mathcal{O} \tag{2g}$$

$$\textstyle\sum_{f\in\mathcal{A}_v} z_f \le 1 \qquad v\in\mathcal{M}\cup\mathcal{O} \qquad (2h)$$
$$z_f \le n_f \qquad f\in\mathcal{F}. \qquad (2i)$$

Presented formulation is a modified form of classical formulation of multi-commodity flow optimization problem (see [21] and [22]). In this formulation, flow distribution is described by values of binary variables $\boldsymbol{s}$ representing flows on particular network links. Having given feasible values of $\boldsymbol{s}$ one can easily reconstruct particular paths selected to carry traffic.

Integer variables $\boldsymbol{z}$ determine in general number of transmission modules on particular links. However, in case of links associated with nodes $v\in\mathcal{M}\cup\mathcal{O}$ this number is strictly binary (due to constraints (2h) and (2i)). For the rest, variable $\boldsymbol{z}$ is integer (due to constraints (2g) and (2i)).

Due to classical flow conservation constraints (see [21]), in relation to specific demand, in all nodes, except end nodes of this demand, the total volume of incoming flows must be balanced by total volume of outgoing flows. Formulation (2) involves two groups of flow conservation constrains: constraints (2a)-(2c) related to variables $\boldsymbol{s}$ and constraints (2f) related to variables $\boldsymbol{z}$.

Usage of particular network links, including all types of inter-card patch-cords and back-plane wiring, by flows determines consumption of transport modules (their number is expressed by variables $\boldsymbol{z}$), according to constraints (2d) and (2e).

Constraints (2g) assure that only one transponder or muxponder can be coupled with each channel tributary port in ONE multiplexer. Similarly, number of active tributary and line links connected to muxponder ports are limited by constraints (2g) and (2h), respectively.

Formulation (2) gathers constraints related to using WDM transport to carry client traffic. Based on this formulation, in the following we consider a number of its extensions and composition of objective function related to the overall cost associated with WDM transport.

### D. L2 technology

To express that each demand can be realized using homogenous L2 technology, like GigabitEthernet, FC800, STM64, binary variable vector $\boldsymbol{k}$ was introduced. Non-zero value of variable $k_{ge}$ enforces through constraints (3a) that demand $e\in\mathcal{E}$ can be realized using only links compliant with technology $g\in\mathcal{Q}$. If one technology (say $g\in\mathcal{Q}$) is selected (value $k_{ge}$ is 1), links associated with other technologies cannot be used, what is assured by constrains (3b).

$$\textstyle\sum_{f\in\mathcal{R}_g} s_{fe} \le |\mathcal{R}_g| k_{ge} \qquad g\in\mathcal{Q}, e\in\mathcal{E} \qquad (3a)$$
$$\textstyle\sum_{g\in\mathcal{Q}} k_{ge} \le 1 \qquad e\in\mathcal{E}. \qquad (3b)$$

Above, $\mathcal{R}_g \subset \mathcal{F}$ denotes set of edges associated with technology $g\in\mathcal{Q}$.

### E. Redundancy

To provide uninterrupted services, able to survive failures of optical network elements and fiber connections, client devices need additional bandwidth, allocated along paths not affected by considered failures. Additional bandwidth, required by protection, is associated with certain level of resource redundancy. Redundant resources are either not used in the nominal network state or can be used for transmitting low priority traffic, preempted in case of failure occurrence.

In case of the WDM networks, redundant resources can be provided either at client digital signal level (called client protection) or photonic signal level (called photonic protection). In the former case, client device is responsible for activating redundant resources. Redundant resources cover optical channels allocated along protection path, and transponder/muxponder cards and ports. In the latter case, specialized protection cards are required. Such protection cards split power of the protected optical signal between multiple (usually two) ports connected to different add-drop ports within multiplexer subsystem. In both cases, the nominal and protection paths should be topologically disjoint with regard to failure occurrence, so under any failure at least one of the paths survives.

Let set $\mathcal{F}_i, i\in\mathcal{I}$ represents an arbitrary set of links that share risk of failure. Such group is described in the literature as Shared Risk Link Group (SRLG) or in general Shared Risk Resource Group (SRRG) [23]. Each SRLG associated with single link $f\in\mathcal{F}$ failure contains exactly one element. Each SRLG associated with node $v\in\mathcal{O}$ failure contains all adjacent links, i.e., $\mathcal{A}_v\cup\mathcal{B}_v$. SRLG should be constructed case by case in relation to specific needs and requirements of a network operator. Specific composition of SRLG thus remains out of scope of this paper.

In order to determine capacity $c_{ei}$ allocated to demand $e$ and available during failure state $i$, constraints (4a)–(4b) should be added to the problem formulation (2):

$$0 \le c_e - c_{ei} \le M r_{ei} \qquad e\in\mathcal{E}, i\in\mathcal{I} \qquad (4a)$$
$$0 \le c_{ei} \le M(1-r_{ei}) \qquad e\in\mathcal{E}, i\in\mathcal{I} \qquad (4b)$$
$$0 \le r_{ei} \le \textstyle\sum_{f\in\mathcal{F}_i} s_{fe} \le M r_{ei} \qquad e\in\mathcal{E}, i\in\mathcal{I}. \qquad (4c)$$

Above, each variable $c_{ei}$ expresses volume of link flow associated with demand $e$ in failure state $i$. Value of variable $r_{ei}$ indicates if link $e$ is available throughout failure state $i$. Consequently, if for some pair $(e,i)$ $r_{ei}=1$ then associated $c_{ei}$ is equal to $c_e$, and $c_{ei}$ is zero otherwise. In according to constraints (4c), value of $r_{ei}$ is positive if and only if at least one link $f$ realizing demand $e$ is affected by failure $i$, i.e., when $\sum_{f\in\mathcal{F}_i} s_{fe} \ge 0$.

Redundancy required by protection mechanisms can be also modeled through multiplication of demand volume to be realized by the transport WDM/OTN network, and additional constraints assuring that only fraction of demand volume is transmitted through specific resources (network element or link). Protection method associated with described resource redundancy requirement is commonly described in the literature as path diversity [24]. To assure introduced requirement constraints (2a)–(2b) must be rewritten as:

$$\textstyle\sum_{f\in\mathcal{A}_v} l_f s_{fe} = 2c_e \qquad e\in\mathcal{E}, v=a(e) \quad (5a)$$
$$\textstyle\sum_{f\in\mathcal{B}_v} l_f s_{fe} = 2c_e \qquad e\in\mathcal{E}, v=b(e) \quad (5b)$$
$$\textstyle\sum_{f\in\mathcal{F}_i} l_f s_{fe} \le c_e \qquad e\in\mathcal{E}, i\in\mathcal{I}. \quad (5c)$$

Constraints (5c) assure that any link flow do not exceed demand volume. In result, each demand must be realized on at least two disjoint paths.

### F. Optical impairments

Optical impairments (described in Section III-F) affecting optical signals, transmitted through photonic network, can be modeled in the form of three limitations:

- fiber length limit,
- hop-count limit,
- noise accumulation limit.

Chromatic dispersion is responsible for spreading duration of optical signal peaks. As a linear effect, proportional to the total length of fiber, chromatic dispersion can be eliminated by using DCM modules. DCM modules are supposed to introduced chromatic dispersion in reverse direction than dispersion introduced by regular fiber. DCM modules compensate thus chromatic dispersion related to central frequency of the optical signal. Consequently, dispersion affecting frequencies far from the central frequency are not compensated completely. Amount of uncompensated chromatic dispersion is called residual dispersion. Residual dispersion is an important factor that limits the total length of fiber traversed by optical signal. Maximum admissible fiber length depends on transponder type and characteristics.

Optical signal propagating through fiber medium is attenuated. Fiber attenuation is proportional to the total length of fiber spans crossed by the signal. To restore signal power to the level required by photo-detector, optical signal is amplified by LOFA cards localized in selected points along the path. However, LOFA cards, beside signal amplification, introduce some portion of noise. To keep signal quality at high level, network operator should control the total amount of introduced noise. On one hand, low noise level can be assured by hop-count constraints. On the other hand, noise characteristic of active optical elements, as mentioned LOFA cards, can be expressed in terms of ONSR value. As described in Section II-E, total value of OSNR is proportional to partial OSNR of particular elements in the path.

All introduced in this section limitations can be associated with additive metrics: length, hop-count, and inverse OSNR. Accordingly, all can be modeled similarly by set of so-called shortest path constraints. Formulation of shortest path constraints is based on path length variables $\boldsymbol{p} = (p_v : v\in\mathcal{O})$. Each $p_v$ represents the length of the shortest path from $v$ with respect to weight system $\boldsymbol{q}$. Then, for each link $f$ outgoing from node $v$ ($a(f)=v$) contained in the shortest path crossed by edge the following shortest path condition must hold.

$$p_{a(f)} + q_f = p_{b(f)}. \qquad (6)$$

Condition (6) is commonly used by the shortest path algorithms to validate if the path traversing edge $f$ is shorter than the shortest path found so far. For our purposes we adopt condition (6) to formulate shortest path constraints:

$$p_{a(f)} + q_f - p_{b(f)} = 0 \text{ if value of } z_f \text{ is } 1 \quad f\in\mathcal{E} \quad (7a)$$
$$p_{a(f)} + q_f - p_{b(f)} \ge m \text{ if value of } z_f \text{ is } 0 \quad f\in\mathcal{E}. \quad (7b)$$

Conditions (7a)-(7b) state that if and only if edge $f$ is contained in the shortest path to $b(f)$, length of this path must be equal to sum of the length of a shortest path to $a(f)$ and weight $q_f$. Otherwise; the value of the expression $p_{a(f)} + q_f - p_{b(f)}$ must be greater or equal to $m$, which is the smallest difference between lengths of two paths. Accordingly, length limitation constraints can be formulated as follows:

$$m(1-z_f) \le p_{a(f)} + q_f - p_{b(f)} \le Mz_f \qquad f\in\mathcal{E} \quad (8a)$$
$$p_v \le p^* \qquad v\in\mathcal{V}. \quad (8b)$$

Considered limitations require additional constraints (8b) to enforce that values of required parameters remain under maximum admissible level $p^*$. Weight system $\boldsymbol{q}$ is constant, and is supposed to express value of required parameter:

- link length,
- number of active elements associated with link (usually one),
- inverse OSNR associated with link.

### G. Network cost

Cost of WDM transport is mostly related to the number and type of used elastic expansion cards: channel multiplexers, transponders, and muxponders. Cost related to installation of transponder and muxponder cards can be expressed as follows:

$$\textstyle\sum_{v\in\mathcal{O}}\sum_{f\in\mathcal{P}_v} \frac{1}{2} g_v z_f. \qquad (9)$$

Above, unitary cost related to card associated with node $v\in\mathcal{M}\cup\mathcal{T}$ is given by constant $g_v$.

To calculate cost related to installation of multi-stage multiplexer expansion cards we need to introduce additional variables and constrains. Binary variable $m_j$ associated with multiplexer $j\in\mathcal{J}$ states if card is installed or not. Variable is positive if at least one channel associated with this particular multiplexer is used. This relation is expressed by constrains (10). Set of colorful channel links and cost associated with multiplexer $j\in\mathcal{J}$ are given by $\mathcal{S}_j$ and $h_j$, respectively.

$$\textstyle\sum_{f\in\mathcal{S}_j} z_f \le |\mathcal{S}_j| m_j \qquad j\in\mathcal{J}. \quad (10)$$

Finally, with respect to (10) and other constraints defined above, the objective function can be formulated as:

$$\boldsymbol{min}\ F(\boldsymbol{z},\boldsymbol{m}) = \textstyle\sum_{v\in\mathcal{O}}\sum_{f\in\mathcal{P}_v} \frac{1}{2} g_v z_f + \sum_{j\in\mathcal{J}} h_j m_j. \qquad (11)$$

Objective function (11) is related to minimization of number of expansion cards.

## IV. Complexity

Throughout this section we estimate complexity of the considered formulation of the WDM flow design problem. Complexity estimation is based on calculation of the numbers of variables and constrains necessary to formulate the considered WDM flow design problem in relation to the selected instances of network instances defined in the SNDLib library [25]. Referenced network instances are characterized in Table I, where particular columns contain the numbers of network nodes, network links, and traffic demands, respectively.

Further, assuming 80-channel WDM technology and three types of transponders (10Gbps, 40Gbps, 100Gbps) we calculate the numbers of particular types of graph elements related to the considered network instances. Calculation results are presented in Table II.

Finally, Table III contains the numbers of constrains and variables necessary to formulate the considered WDM flow design problem in relation to the selected SNDLib network instances. Number of constraints is contained in a range from 19 thousands to 26 millions. Number of variables is even larger and is contained in a range from 164 thousands to 387 millions. Such enormous numbers of constraints and variables make in practice the considered formulations numerically intractable for resolving with exact optimization methods.

## V. Conclusion

Paper investigates mathematical modeling of photonic networks applying wavelength division multiplexing. Based on standardization efforts, research work, and commercial offerings, a functional model of WDM network is proposed. Proposed network model involves a series of specific aspects of photonic transmission, like fiber attenuation, dispersion, and noise accumulation. Developed functional model is a basis for development of mathematical models of multicommodity flows in WDM network.

Number of integer variables used in a mathematical model in high degree determines computational complexity of optimization formulations based on this model. In case of the proposed model, this number is proportional to the squared number of WDM devices and number of WDM channels. For even small network instances (composed of several devices), this number can be at level of thousands. Thus, in the future work, in order to reduce complexity of the proposed model to numerically tractable level, authors will try to decompose it. In particular, future work will focus on adopting general decompositions methods proposed in context of large-scale linear programming, like Dantzig-Wolfe decomposition, Lagrangean relaxation, and Benders decomposition, for the case of proposed model.

***Abstract*—The generalized Wiener polarity index $W_k(G)$ of a graph $G = (V, E)$ is defined as a number of unordered pairs $\{u, v\}$ of $G$ such that the shortest distance between $u$ and $v$ is equal to $k$:**

$$W_k(G) = |\{\{u, v\}, d(u, v) = k, u, v \in V(G)\}|$$

**In this paper we give some results for 2-trees in case of mentioned index. We present an infinite family of 2-trees with maximum value of generalized Wiener polarity index.**

## I. Introduction

Let $G = (V(G), E(G))$ be a connected, simple graph with $V(G)$ the vertex set and $E(G)$ the edge set. Let $n$ be the number of vertices and $m$ the number of edges. By $d(u, v)$ we denote the distance between two vertices $u$ and $v$ in the graph $G$. What we call a diameter $diam(G)$ is the longest distance between two vertices of $G$. The degree of the vertex $u$ in the graph $G$ is denoted by $deg(u)$. Other definitions, not mentioned here can be found in [1].

The Wiener polarity index of a graph $G = (V(G), E(G))$ is defined as

$$WP(G) = |\{\{u, v\} : d(u, v) = 3; u, v \in V(G)\}|$$

which is a number of unordered pairs of vertices $\{u, v\}$ of $G$ such that $d(u, v) = 3$. Authors of [4, 5, 7, 13] studied this index for trees with different parameters such that number of pendant vertices, diameter or maximum degree. Additionally, in [12] there are described algorithms for counting $W_k(T)$ for trees.

The generalized Wiener polarity index of a graph $G = (V(G), E(G))$ is defined as

$$W_k(G) = |\{\{u, v\}, d(u, v) = k, u, v \in V(G)\}|$$

which is a number of unordered pairs of vertices $\{u, v\}$ of $G$ such that the distance between $u$ and $v$ is equal to $k$.

Let us now remind the definition of the Wiener index $W(G)$

$$W(G) = \sum_{\{u,v\} \subseteq V(G)} d(u, v) = \frac{1}{2} \sum_{v \in V(G)} D(v),$$

where $D(v) = \sum_{u \in V(G)} d(u, v)$ is the sum of all distances from the vertex $v$. As we can see $W(G)$ is defined as the sum of the distances between all pairs of vertices in the graph $G$. Note that: $W(G) = \sum_{k=1}^{diam(G)} kW_k(G)$. The Hosoya polynomial (Wiener polynomial) of $G$ in $x$ is defined as follows

$$W(G, x) = \sum_{u,v \in V(G)} x^{d(u,v)} = \sum_{k=1}^{diam(G)} W_k(G) \cdot x^k$$

More information about Hosoya polynomial the reader can find in [9].

The applications of mentioned indices are described in the papers [2, 3] and also in [9, 10]. Probably the best known topological index is the Wiener index and this is the one described by many authors, for example [2, 8].

## II. Generalized Wiener polarity index

In case of generalized Wiener polarity index for trees there are some known results presented in [12]. Let $T$ be a tree. If $k = 1$ then $W_1(T) = m$, where $m$ is the number of edges. If $k = 2$ then

$$\begin{aligned} W_2(T) &= \sum_{v \in V(T)} \binom{deg(v)}{2} = \frac{\sum_{v \in V(T)} deg^2(v)}{2} - m \\ &= \frac{M_1(G)}{2} - m \end{aligned}$$

where $M_1(G)$ is the first Zagreb index of a graph. For detailed information on Zagreb indices the reader is referred to [11].

If $k = 3$ we have

$$\begin{aligned} W_3(T) &= \sum_{uv \in E(T)} (deg(v) - 1)(deg(u) - 1) \\ &= \sum_{uv \in E(T)} deg(u)deg(v) - \sum_{v \in V(T)} deg^2(v) + m \\ &= M_2(T) - M_1(T) + m \end{aligned}$$

where $M_2(T)$ is the second Zagreb index of a graph.

Let us now assume that $k \geq 3$. In a situation when diameter of $T$ is less than $k$ we have $W_k(T) = 0$ and that is why the minimum value of $W_k(T)$ is equal to zero. This is

978-83-60810-66-8/$25.00©2015, IEEE

achieved for all trees for which $diam(T) < k$. Actually, this is simple fact for each graph.

Now we will study the generalized Wiener polarity index for 2-trees. Let us define a 2-tree first. The smallest 2-tree is a complete graph $K_3$ of order $n = 3$. A 2-tree of order $n$ is obtained from a 2-tree $G$ of order $n-1$ by attaching a new vertex $v$ and two edges $\{vx, vy\}$ such that $\{x, y\} \in E(G)$. Concerning 2-trees with $diam(G) \geq k$ is more difficult than for trees.

Let $G$ be a 2-tree of order $n$ and size $m$. A pendant vertex in a 2-tree is a vertex with degree equal to 2. Now, for $k = 1$ the value of $W_1(G)$ stays the same as for trees. For $k = 2$ we have

$$W_2(G) = \sum_{v \in V(G)} \left( \binom{deg(v)}{2} - m \right)$$

But let us move on to what will be considered now and this are the maximum values of $W_k(G)$ where $G$ is a 2-tree.

What we are going to do is to decompose all vertices $v$ in $G$ with $deg(v) = 2$ into some number of groups. Each group has the following property

$$A_i = \{v \in V(G) : deg(v) = 2 \wedge \exists_{e_i = \{u_i, w_i\}}; vu_i, vw_i \in E(G)\}$$

for $i = 1, 2, ...$

We have at least two such groups. Let us say that the distance between two arbitrary pendant vertices from different groups is not equal to $k$. Distances between vertices in each group are equal to 2.

Let $p_1$ and $p_2$ be the numbers of vertices on distance $k$ from an arbitrary pendant vertex from $A_1$ and $A_2$, respectively. We can ssume that $p_1 \geq p_2$ with no loss of generality. After removal of all pendant vertices from $A_2$ and addition to the group $A_1$ we get the transformed 2-tree $G'$

$$\begin{aligned} & W_k(G') - W_k(G) \geq \\ & = (|A_1|p_1 + |A_2|p_1) - (|A_1|p_1 + |A_2|p_2) = \\ & = |A_2|(p_1 - p_2) \geq 0 \end{aligned} \tag{1}$$

Note this is true for two groups. If there are more of them inequality in (1) may not hold.

By repetition of this transformation we will get a new 2-tree with possibly greater generalized Wiener polarity index. The diameter of $G'$ after each transformation is less or stays the same as the one for $G$. Each transformation gives us also one new pendant vertex. If we will choose the most distant groups of pendant vertices we will get a 2-tree with diameter equal to $k$. After that we can apply the transformation finitely many times until all pendant vertices are on distance $k$ and no other vertex of the final 2-tree has eccentricity equal to $k$. During this process the $W_k(G)$ may be changing by decreasing or increasing. Some example is presented in $Fig.1$.

Let us assume we have $p$ groups of pendant vertices with sizes: $a_1, a_2, ..., a_p$ and $a_1 + a_2 + ... + a_p = q$. We consider a 2-tree with $diam(G) = k$. We have then $n - 2(k-1) \geq q \geq 2$. Assume that the distance between any two pendant vertices not from the same group is equal to $k$ and that is why

$$W_k(G) = \frac{1}{2} \sum_{i=1}^{p} a_i(q - a_i) = \frac{1}{2}\left( q^2 - \sum_{i=1}^{p} a_i^2 \right) \tag{2}$$

In the case when the distance between the group $A_i$ and $A_j$ for $i \neq j$ is less than $k$ the generalized Wiener polarity index is less than the one presented above. If $p = 2$ we have $W_k(G) = a_1 a_2$. This value is maximum for $a_1 + a_2 = n - 2(k-1)$, $a_1 = \left\lfloor \frac{n-2(k-1)}{2} \right\rfloor$ and $a_2 = \left\lceil \frac{n-2(k-1)}{2} \right\rceil$.

$$\begin{aligned} W_k(G) &= \left\lfloor \frac{n-2(k-1)}{2} \right\rfloor \left\lceil \frac{n-2(k-1)}{2} \right\rceil = \\ &= \left( \left\lfloor \frac{n}{2} \right\rfloor - (k-1) \right) \left( \left\lceil \frac{n}{2} \right\rceil - (k-1) \right) = \\ &= \left\lfloor \frac{n}{2} \right\rfloor \left\lceil \frac{n}{2} \right\rceil - (k-1) \left( \left\lfloor \frac{n}{2} \right\rfloor + \left\lceil \frac{n}{2} \right\rceil \right) + (k-1)^2 \end{aligned}$$

so

$$W_k(G) = \left\lfloor \frac{n}{2} \right\rfloor \left\lceil \frac{n}{2} \right\rceil - (k-1)(n-(k-1)) \tag{3}$$

Let $p > 2$ and $k > 2$. First we consider the even $k$. By $n \geq 2 + p(k-2) + q$ and $2 < p \leq q$ we have $p \leq \frac{n-2-q}{k-2}$, so

$$p < \frac{n-2}{k-2}. \tag{4}$$

We have the following

$$q = \sum_{i=1}^{p} a_i,$$

$$n = 2 + 2p\left( \frac{k}{2} - 1 \right) + \sum_{i=1}^{p} a_i = 2 + p(k-2) + \sum_{i=1}^{p} a_i.$$

Hence

$$n \geq 2 + p(k-2) + q. \tag{5}$$

We apply Cauchy - Schwarz ineqality to the formula (2) with $q \leq n - 2 - p(k-2)$

$$W_k(G) = \frac{1}{2}\left( q^2 - \sum_{i=1}^{p} a_i^2 \right) \leq \frac{1}{2}\left( q^2 - \frac{q^2}{p} \right) \leq \frac{1}{2} f(p) \tag{6}$$

where

$$f(p) = (n - 2 - p(k-2))^2 \left( 1 - \frac{1}{p} \right).$$

The extremal generalized Wiener polarity index $W_k(G)$ is obtained for the case when we have equality in (6). We are going to study this case. We will give some examples of extremal 2-trees and then we will state the final result in Theorem 1.

So for real variable $p$ we study

$$\begin{aligned} f(p) = & \left( (n-2)^2 + p^2(k-2)^2 \right) \left( 1 - \frac{1}{p} \right) \\ & - 2(k-2)(n-2)(p-1). \end{aligned} \tag{7}$$

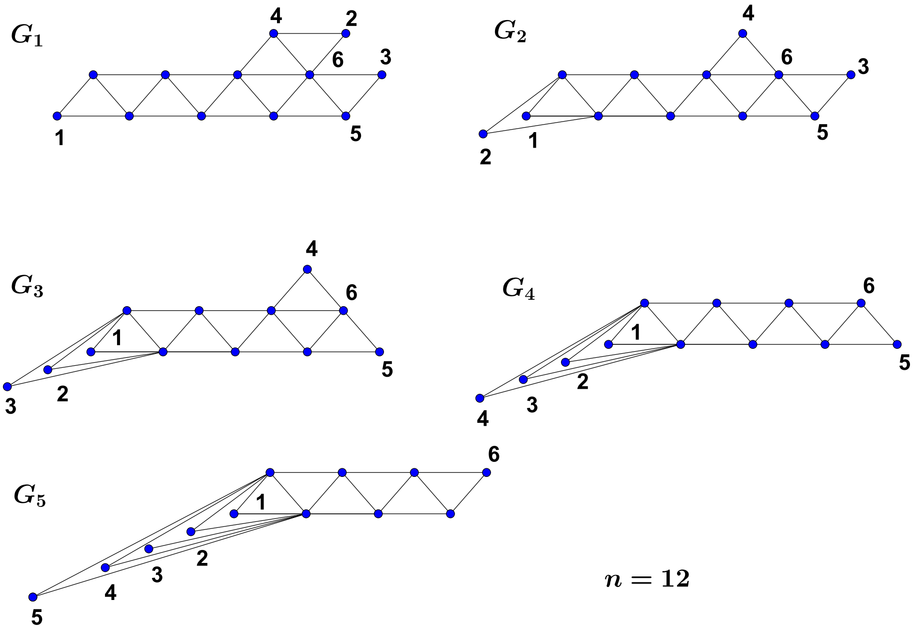

Fig. 1. A process of moving pendant vertices $G_1 \to G_2 \to G_3 \to G_4 \to G_5$. $W_4(G_1) = 8$, $W_4(G_2) = 9$, $W_4(G_3) = 10$, $W_4(G_4) = 9$, $W_4(G_5) = 5$.

Let $h(p) = 2(2-k)(1-\frac{1}{p}) + \frac{n-2-p(k-2)}{p^2}$. Then the first derivative equals

$$f'(p) = (n-2-p(k-2))h(p)$$

By (4) we have $f'(p) = 0$ if and only if $p = \hat{p}$, where

$$\hat{p} = \frac{1}{4} + \frac{1}{4}\sqrt{\frac{8n+k-18}{k-2}} \tag{8}$$

Similarly $f'(p) > 0$ if and only if $h(p) > 0$. This is equivalent to the inequality

$$g(p) = 2p^2 - p - \frac{n-2}{k-2} < 0.$$

So $g(p) < 0$ if and only if $p < \hat{p}$ .
Let

$$s = 4\hat{p} = 1 + \sqrt{\frac{8n+k-18}{k-2}}.$$

Then

$$\frac{1}{\hat{p}} = \frac{\sqrt{(k-2)(8n+k-18)} - (k-2)}{2n-4} = \frac{(k-2)(s-2)}{2n-4}.$$

By (6) we can write

$$f(\hat{p}) = \left(n - 2 - \frac{1}{4}(k-2)s\right)^2 \left(1 - \frac{(k-2)(s-2)}{2n-4}\right).$$

Then

$$f(\hat{p}) = \left((n-2)^2 - \frac{(n-2)(k-2)}{2}s + \frac{(k-2)^2}{16}s^2\right) \cdot \left(1 - \frac{(k-2)(s-2)}{2n-4}\right). \tag{9}$$

We are interested in the case with $\hat{p} \geq 3$. By (8) we get $n \geq 15k - 28$.

**Example 1:**
By the formula (9) for $k = 6$ we get

$$f(\hat{p}) = \left((n-2)^2 - 2(n-2)\left(1+\sqrt{2n-3}\right) + \left(1+\sqrt{2n-3}\right)^2\right) \cdot \left(1 - \frac{2\sqrt{2n-3}-2}{n-2}\right).$$

Let us set

$$n = 2t^2 + 2 \geq 15k - 28 = 62. \tag{10}$$

By (8) for even $t$ we have

$$\lfloor \hat{p} \rfloor = \left\lfloor \frac{1}{4} + \frac{1}{4}\sqrt{4t^2+1} \right\rfloor = \left\lfloor \frac{1}{4} + \frac{t}{2} \right\rfloor = \frac{t}{2}. \tag{11}$$

Note that by (7)

$$f(\lfloor \hat{p} \rfloor) = 4t(t-1)^2(t-2), \tag{12}$$

and

$$f(\lceil \hat{p} \rceil) = 4t(t^2-t-2)^2 \frac{1}{t+2} > f(\lfloor \hat{p} \rfloor),$$

for $t > 2$.

We can note that by the formula (6) we get extremal 2-trees for the case

$$W_6(G) = \frac{1}{2} f(\lfloor \hat{p} \rfloor).$$

Now we compare this value with $W_k(G)$ for $p > 2$. By the formula (3) for $p = 2$ we get

$$W_6(G) \le (t^2+1)^2 - 5(2t^2+2) + 25 = t^4 - 8t^2 + 16.$$

So we get the following inequality

$$\frac{1}{2} f(\lfloor \hat{p} \rfloor) > t^4 - 8t^2 + 16.$$

By the formula (12) we get

$$2t(t-2)(t-1)^2 > t^4 - 8t^2 + 16. \tag{13}$$

The inequality (13) is equivalent to the following one

$$2t(t-1)^2 > (t-2)^2(t+2). \tag{14}$$

Suppose now that $t = 6$, then by (10) we have $n = 2 \cdot 6^2 + 2 = 74$ and by (9) we have $\lfloor \hat{p} \rfloor = 3$. The inequality (14) holds in this case. So we obtained the maximum $W_6(G) = 3 \cdot 20^2$ for the 2-tree $G$ with parameters $n = 74,\ k = 6,\ p = 3$ and $|A_i| = (n-14)/3 = 20$.

An extremal 2-tree is presented below in Fig. 2.

**Example 2:**

By the formula (9) for $k = 4$ we get

$$f(\hat{p}) = \left( (n-2)^2 - (n-2)\left(1 + \sqrt{4n-7}\right) + \frac{1}{4}\left(1 + \sqrt{4n-7}\right)^2 \right) \cdot \left(1 - \frac{\sqrt{4n-7} - 1}{n-2}\right).$$

We have:

$$n = t^2 + 2 \ge 15k - 28 = 15 \cdot 4 - 28 = 32. \tag{15}$$

By (8) for even $t$ we have

$$\lfloor \hat{p} \rfloor = \left\lfloor \frac{1}{4} + \frac{1}{4}\sqrt{4t^2+1} \right\rfloor = \left\lfloor \frac{1}{4} + \frac{t}{2} \right\rfloor = \frac{t}{2}. \tag{16}$$

and then by (7)

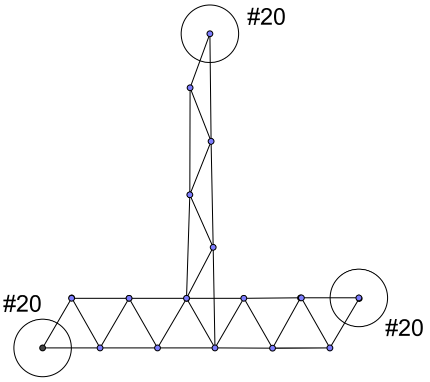

Fig. 2. An extremal graph of order $n = 74$ with $k = 6$ and three groups $|A_i| = 20,\ i = 1, 2, 3$.

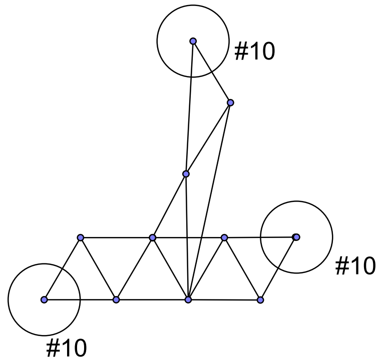

Fig. 3. An example of extremal graph for $k = 4$.

$$f(\lfloor \hat{p} \rfloor) = t(t-2)(t-1)^2,$$

and

$$f(\lceil \hat{p} \rceil) = t(t^2 - t - 2)^2 \frac{1}{t+2},$$

We can note that by the formula (6) we get

$$W_4(G) = \frac{1}{2} f(\lfloor \hat{p} \rfloor).$$

By the formula (3) for $p = 2$ and $k = 4$ we get $W_4(G) = \frac{1}{4}t^4 - 2t^2 + 4$.

Now we get the following inequality

$$f(\lfloor \hat{p} \rfloor) = t(t-2)(t-1)^2 > t(t^2 - t - 2)^2 \frac{1}{t+2} = f(\lceil \hat{p} \rceil).$$

The above inequality is equivalent to the following one

$$(t+2)(t-2)(t-1)^2 > (t^2 - t - 2)^2. \tag{17}$$

Suppose now that $t = 6$, then by (15) we have $n = 6^2 + 2 = 38 > 32$ and $\lfloor \hat{p} \rfloor = 3$. So the inequality (17) holds in this case and we have the maximum $W_4(G) = 3 \cdot 10^2$ for the 2-tree $G$ with parameters $n = 38,\ k = 4,\ \hat{p} = 3$ and $|A_i| = (n-8)/3 = 10, i = 1, 2, 3$.

An extremal 2-tree is presented in Fig. 3.

In general case we have the following result.

Let $p_- = \lfloor \hat{p} \rfloor$ and $p_+ = \lceil \hat{p} \rceil$ where $\hat{p}$ is defined in (8) . We present a theorem for 2-trees of order $n$ equal to $g(k)$, where $g(k)$ is some function defined in the proof.

**Theorem 1.** *Let $n$ and $k$ be integers. For each even integer $k \ge 4$ there exists a 2-tree $G$ of order $n$ with extremal generalized Wiener polarity index $W_k(G)$ and with $p_- \ge 3$ or $p_+ \ge 3$ groups of pendant vertices for $n = g(k)$ where $g(k)$ is some function in variable $k$. Then we have an infinite family of such 2-trees.*

**Proof:** By (7) and (8) we have $p_- \le \hat{p} \le p_+$ and $W_k(G) = \frac{1}{2}\max\{f(p_+), f(p_-)\}$, where

$$f(p_-) = \left((n-2)^2 + p_-^2(k-2)^2\right)\left(1 - \frac{1}{p_-}\right) - 2(k-2)(n-2)(p_- - 1).$$

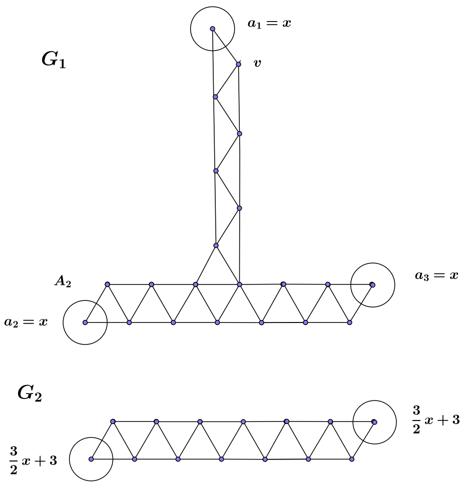

Fig. 4. Examples of 2-trees of the same order with diameter $k = 7$, where $W_7(G_1) > W_7(G_2)$ for even $x \geq 12$.

We get the inequality

$$\frac{1}{2}f(p_-) > \left\lfloor\frac{n}{2}\right\rfloor\left\lceil\frac{n}{2}\right\rceil - (k-1)(n-(k-1)).$$

Hence

$$p_-^3(k-2)^2 - p_-^2(k-2)(2n+k-6) + p_-\left((n-2)^2 - 2\left\lfloor\frac{n}{2}\right\rfloor\left\lceil\frac{n}{2}\right\rceil + 4kn - 6n - 2k^2 + 6\right) - (n-2)^2 > 0.$$

Similarly we can compare

$$\frac{1}{2}f(p_+) > \left\lfloor\frac{n}{2}\right\rfloor\left\lceil\frac{n}{2}\right\rceil - (k-1)(n-(k-1)).$$

This two above inequalities are equivalent to the following one:

$$n^2 - n(12((p-2)k - 2p) + 52) + 52 - 12k^2 + 6p((p-2)(k-2)^2 + (k-2)(k+2)) > 0$$

where $p = p_+$ or $p = p_-$.

By solving this inequality we can construct 2-trees $G$ with $p_- \geq 3$ or $p_+ \geq 3$ groups of pendant vertices with extremal generalized Wiener polarity index $W_k(G)$. It is enough to take $g(k) = 2 + p(k - 2 + a)$, where $a = |A_i|$ for each integer $a \geq (k-2)\max\{11, 2(p-1)\}$ and $i = 1, ..., p$ with $p = p_-$ or $p = p_+$. It follows by formula (8). This is the end of the proof.

In the theorem we are presenting the results for even $k$. Note that for odd $k$ the generalized Wiener polarity index $W_k(G)$ for 2-trees of order $n$ with two groups of pendant vertices in general case is not greater than such index for 2-trees of order $n$ with $p = 3$ groups of pendant vertices.
An infinite number of such examples of 2-trees is presented in Fig. 4.

In this paper we proved Theorem 1 for 2-trees of order $n$ with an extremal $W_k(G)$ for given $n$ and $k$. In the future work we wish to find an efficient algorithm for counting $W_k(G)$ for the considered family of graphs.

***Abstract*—The physical model of Water Capsule Flight is relatively simple but analytically unsolvable. The input data includes the mass of the capsule, velocity, altitude, aerodynamic coefficients of the capsule, and horizontal and vertical winds. The ABC optimization is focused on those attributes. This article is a part of the series dedicated to Inspired by Nature Methods of AI and their implementation in the mechatronic systems. A bag filled with water is an excellent source of explosion-produced water spray which can be used for extinguishing large fires or for other purposes. The paper presents theoretical models of flight of a bag filled with water, dropped from an aircraft moving horizontally. Results of numerical computations based on this model are compared with results of measurements for the trajectory of a bag dropped from a helicopter. A description of the experimental and numerical setup for this experiment are also discussed.**

## I. Introduction

BEHAVIOR of many animal species in nature is similar to the swarm behavior. Shoals of fish, flocks of birds and flocks of land animals are created as a result of the biological drive to live in a group. Specific individuals belonging to a flock or a shoal are characterized by higher survival probability because predators or raptors usually attack only one individual. Group movement is characteristic for flocks of birds and other animals as well as shoals of fish. Flocks of land animals react quickly to changes of movement direction and velocity of neighboring individuals. Herd behavior is also one of the main characteristic features of insects living in colonies (bees, wasps, ants, termites) Communication between individual insects of the swarm of social insects has already been thoroughly studied and is still subject of studies. The systems of communication between individual insects contribute to creation of "collective intelligence" of swarms of social insects [4], [11]. Thus the term "Swarm intelligence" emerged, meaning the above mentioned "collective intelligence" [6], [10], [9], [15], [16]. The swarm intelligence is part of the Artificial Intelligence as per examination of activities performed by separate individuals in decentralized systems [14]. The Artificial Bee Colony (ABC) metaheuristics has been introduced quite recently as a new trend in the Swarm intelligence domain [17][13][2]. Artificial bees represent agents solving complex combinatorial optimization problems. This article presents proposed optimization of water capsule flight using ABC method [10][9]. Data obtained from real water capsule flights developed for firefighting was used here. A very efficient way of water spray formation is explosion method consisting in detonation of an explosive placed in a water container [19]. Water sufficiently eliminates undesired consequences of detonation, which provides potential possibility for applications of that method. Water spray can be used, e.g. to extinguish fire and to neutralize contaminated areas [12][5]. Water capsule suspended under a helicopter or another aircraft enables fast transport of water to the area of airdrop. Described system allows automatic release of the water capsule at such a distance from the target so that, after some time of its free fall, it is located over the target at the specified altitude and then detonated to generate spray which covers specified area of the ground [5][18].

## II. Physical methodology of the water capsule flight analysis

In principle the problem of delivering a water capsule to a given point on the ground is very similar to the problem of hitting a surface target by a bomber with an unguided bomb. There are, however, two problems that make difficult a direct

978-83-60810-66-8/$25.00©2015, IEEE

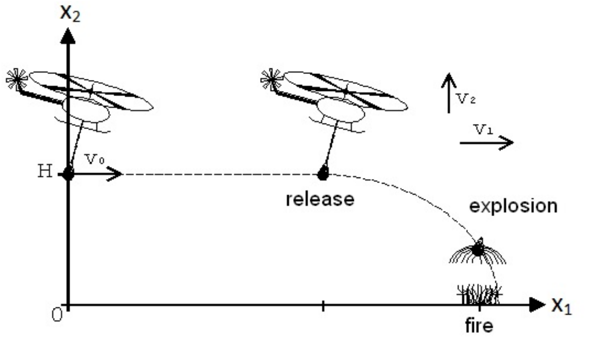

Fig. 1. Schematic view of the procedure of delivering water-capsule to a designed point.

application of the procedures used by military aviation. The first follows from the fact that such procedures, as majority of procedures used by the military are either classified as a whole or comprise classified crucial components [1] [7]. The second problem is connected with much higher safety standards that must be observed in the case of placing water-capsule "in target". It seems then more reasonable to develop procedures from the very beginning than to try to adopt non-classified components of similar military procedures. The ultimate objective consists in developing a high precision system of delivering by an aircraft (presumably a helicopter) a water-capsule to a defined point where it should be exploded in order to generate cloud of water-spray playing role of the fire-extinguishing agent. A scheme of such procedure is shown in Fig. 1.

Designing a suitable system must be based on theoretical models that can serve as a foundation of numerical programs. The models are founded on the assumption that the water-capsule moves in the air under the influence of a constant and vertical gravitational force and of the Bernoulli drag (pressure drag) that acts against its motion with respect to the air and is proportional to the square of the velocity of this motion. After denoting the velocity by $\overrightarrow{v}$ one can write the following formula the drag force.

$$\overrightarrow{O} = \frac{c\rho A}{2} v \overrightarrow{v}, \tag{1}$$

where $v = |\overrightarrow{v}| = \sqrt{v_1^2 + v_2^2}$,
$c$ is the drag coefficient depending on the shape of the moving body, $\rho$ denotes density of the air, and A is the frontal cross-section of the body.

### A. Equations describing flight of a water capsule

A water capsule dropped from a horizontally moving aircraft (e.g. helicopter) falls down under composite action of the drag force that has both vertical and horizontal components and the gravitational force that acts all time vertically. Introducing Cartesian coordinates: the horizontal one $x_1$ and the vertical one $x_2$, one can write equations of motion in the form

$$\dot{v_1} = -\frac{c_1\rho A_1}{2M}\sqrt{v_1^2 + v_2^2}v_1, \dot{v_2} = -\frac{c_2\rho A_2}{2M}\sqrt{v_1^2 + v_2^2}v_2 - g \tag{2}$$

where $v_1$ and $v_2$ are the horizontal and vertical coordinates of the capsule's velocity respectively, $M$ is its mass and $g$ denotes gravitational acceleration. One has to do with a set of ordinary, first order, nonlinear differential equation with respect to the Cartesian coordinates of capsules velocity. Having these equations solved, one can obtain coordinates of the capsule by simple integration coordinates of velocity with respect to time. Unfortunately, the equations (2) cannot be solved analytically without far going simplifications. It is so due to the coupling square root term. As such, one has to apply numerical methods for solving the equations.

### B. Numerical solutions

In this case the standard fourth order Runge-Kutta method was used, and numerical computations were performed inside the MATLAB environment. In practice some additional work aimed, e.g., on optimization of the length of the step of integration, had to be done, but we will not go into technical details [14].

The solution is obtained for standard initial conditions given by the equations

$$v_1(0) = v_0, v_2(0) = v_0 \tag{3}$$

which corresponds to horizontal motion of the water-capsule at the moment of release. Provided the value of the drag coefficient $c$ is known, one can obtain both components of capsule's velocity as functions of time. Since the main objective consists in computing trajectory of the capsule, one has to compute its horizontal and vertical component using integrals

$$\begin{aligned} x_1(t) &= \int_0^t v_1(\tau)d\tau + x_1(0), \\ x_2(t) &= \int_0^t v_2(\tau)d\tau + x_2(0) \end{aligned} \tag{4}$$

that, in general, have to be computed numerically since the functional form of $v_1$ and $v_2$ with respect to time are not known. The numerical solution of equations for the components $v_1$ and $v_2$ of the capsule's velocity has one more advantage. After some modifications such a procedure can be applied to the problem of flight in the air moving with respect to the ground. In fact, equations (2) describe velocity of the capsule with respect to the ground under the assumption that the air is still. If, however, velocities of wind and that of ascending or descending current are considerable, the equations have to be modified

$$\dot{v_1} = -\frac{c_1 \rho A_1}{2M} \sqrt{\tilde{v_1}^2 + \tilde{v_2}^2} \tilde{v_1}$$
$$\dot{v_2} = -\frac{c_2 \rho A_2}{2M} \sqrt{\tilde{v_1}^2 + \tilde{v_2}^2} \tilde{v_2} - g \tag{5}$$

where

$$\tilde{v_i} = \tilde{v_i} - \tilde{V_i}, i = 1, 2 \tag{6}$$

are coordinates of the capsule's velocity with respect to the air; $V_1$ denotes velocity of wind and $V_2$ velocity of vertical current (a further generalization, we will not discuss here, would be taking into account the fact that strong and random winds make the problem 3-dimensional instead of 2-dimensional planar problem of a flight in the still air).

Numerical solution of equation of motion requires inserting numerical data from the very beginning. Some of them like the mass $M$ of the capsule or the density of the air are at hand, but the drag coefficients $k_1 = cA_1$and $k_2 = cA_2$, appearing in (2) and (5) have to be determined from experimental data.

## III. ABC APPLICATION TO OPTIMIZATION OF FUEL CONSUMPTION OF A HELICOPTER

### A. Numerical solutions

Artificial bee colony (ABC) is a model proposed in 2005 by a Turkish scientist Dervis Karaboga [10][3][9]. Like other algorithms described herein, it is also based on herd behavior of honey bees. It differs from other algorithms in the application of higher number bee types in a swarm. After the initialization phase, the algorithm consists of the following four stages repeated by iteration until the number of repetitions specified by the used is competed:

- Employed Bees stage,
- Onlooker Bees stage,
- Scout Bees stage,
- storage of the best solution so far.

The algorithm starts with initialization of the food source vectors $x_m$, where $m = 1...SN$, while $SN$, is the population size. Each of those vectors stores $n$ values $x_m, i = 1...n$, that shall be optimized during execution of that method. The vectors are initialized using the following formula:

$$x_{mi} = l_i + rand(0, 1)x(u_i - l_i) \tag{7}$$

where:

$l_i$-lower limit of the searched range,

$u_i$- upper limit of the searched range,

Bees adapted to different tasks participate in each stage of the algorithm operation. In case of ABC, there are 3 types of objects involved in searching:

- Employed Bees - bees searching points near points already stored in memory,
- Onlooker Bees - objects responsible for searching neighborhood of points deemed the most attractive,
- Scout Bees - (also referred to as scouts) this kind of bees explores random points not related in any way to those discovered earlier.

Once initialization is completed, Employed Bees start their work. They are sent to places in the neighborhood of already known food sources to determine the amount of nectar available there. Results of the Employed Bees work are used by Onlooker Bees. Onlooker Bees randomly select a potential food source using the following relationship:

$$v_i = x_{mi} + \varphi_{mi}(x_{mi} + x_{ki}) \tag{8}$$

where:

$v_i$-vector of potential food sources,

$x_k$- randomly selected food source,

$\varphi_{mi}$- random number from the range [-a,a] Once the vector is determined its fitting is calculated based on the formula dependent on the problem being solved and the fitting $v_m$ is compared with $x_m$. If the new vector fits better than the former one, then the new replaces the old one. Another phase of the algorithm operation is the Onlooker Bees stage. Those bees are sent to food sources classified as the best ones and in those very points the amount of available nectar is determined. The probability of the $x_m$ source selection is expressed with the formula:

$$p_m = \frac{fit_m(x_m)}{\sum_{k=1}^{SN} fit_k(x_k)} \tag{9}$$

where:

$fit_m(x_m)$- value of fitting functions for a given source.

Obviously, when onlooker bees gather information on the amount of nectar, such data is compared with results obtained so far and if the new food sources are better, they replace the old ones in the memory. The last phase of this algorithm operation is exploration by scouts. Bees of that type select random points from the search space and then check nectar volumes available there. If newly found volumes are higher than the volumes stored so far, they replace the old volumes. The activity of those bees makes it possible to explore the space unavailable for the remaining types of bees thus allowing to omit any extremes.

### B. Application of ABC

The reach of the capsule flight is calculated so that the distance from the helicopter does not exceed 140 m and then the initial velocity V0 and the altitude Z are optimized. The fuel consumption at the power of 2225KM - 292 g /KMh (i.e. 292 g of fuel per horse power per hour) is assumed as the cost. At the moment the program estimates the results only approximately, but author believes that he shall be able to make the results more real in the near future.

```
Random selection of the initial altitude and velocity of the helicopter;
REPEAT
The selected altitude is put into the water capsule flight reach formula;
The selected velocity is put into the water capsule flight reach formula;
```

*Then we calculate the function of the cost of rising the*
*helicopter to the specified altitude and accelerating it to*
*the specified velocity so that the capsule is dropped not further than 140 m*
*away from the target;*
*Sources;*
*The verified velocity and altitude are replaced by new values;*
*The best velocity and altitude are stored in the memory;*
*UNTIL (the conditions are met)*

The main underlying idea of the optimization is to select such altitude and velocity of the helicopter that shall enable the capsule to reach the target. The path covered by the capsule falling from the helicopter to the vicinity of fire depends on the altitude from which the capsule was dropped. It is obvious that increase of altitude or velocity depends directly on helicopter rotor power. The power to be generated influences specific fuel consumption. As illustrated in the graph, vertical climb of the helicopter at zero horizontal velocity generates huge power demand. One can significantly reduce power needed to climb the helicopter to the specified altitude by increasing its horizontal velocity. This relationship results from the way of generating aerodynamic lift by the helicopter [8]. However, too high horizontal velocity can significantly increase power demand causing increased specific fuel consumption.

## IV. Conclusion

Obviously, the power required during forward flight will also be the function of GTOW (Gross Takeoff Weight). Representative results illustrating the effect of GTOW on the rotor power required are provided in Fig. 2 for a sample helicopter at sea-level (SL) conditions. It should be noted that with increasing GTOW, the excess power available decreases gradually, this phenomenon applies in particular at lower airspeed where the induced power requirement is a higher percentage of the total power. In the subject case, the power available at SL is 2800 hp and for a gas turbine this remains relatively constant versus airspeed. The airspeed value at the intersection of the power required curve and the power available curve indicates the maximum level flight speed. However, the maximum velocity is limited by probable onset of rotor stall and compressibility effects before this point is reached. Multi-objective optimization of a helicopter flight carrying a water capsule is a non-trivial problem. ABC algorithm application enables efficient optimization of fuel costs. Due to high complexity of that problem, one must bear in mind that optimization results may deviate from real results. These can be caused by the fact that wind drag and direction were skipped. The distance at which the helicopter must approach the fire can have significant impact on the final result while the air temperature can significantly influence the fuel demand of the helicopter engine. There is also an issue of the angle at which the capsule is dropped. That aspect can also be taken into account in further studies on ABC application to fuel consumption optimization and as a consequence, on reduction fire extinguishing cost using that method. Summing up, that problem is very complex, which makes it a good example of ABC application.

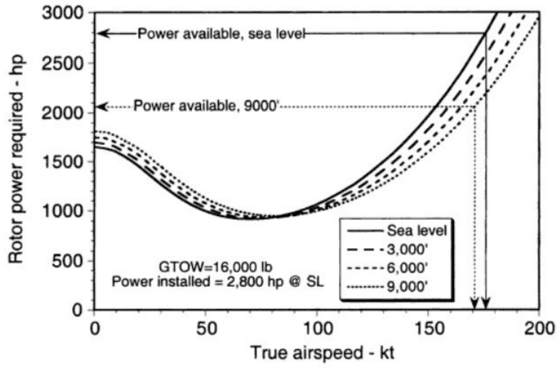

Fig. 2. The graph of fuel consumption versus the velocity and altitude of the helicopter flight.

***Abstract*—We propose a variant on the well-known Ant Colony Optimization (ACO) general framework where we introduce the environment to play an important role during the optimization process. Together with diversification and intensification, the environment is introduced with the aim of avoiding the search to get stuck at local optima. In this work, the environment is simulated by means of the Logistic map, that is used in ACO for perturbing the update of the pheromone trails. Our preliminary experiments show that our environmental ACO (*e*ACO), with variable environment, outperforms the standard ACO on a set of instances of the GPS Surveying Problem (GSP).**

## I. Introduction

GLOBAL optimization consists in finding the global optimum of a given objective function which is generally subject to a given number of constraints. Many real-life problems can be formulated as a global optimization problem where the objective function often contains several local optima. A major issue in solving such problems is to "escape" from local optima for converging towards the global optimum of the objective function [12].

Meta-heuristics are general-purpose methods for global optimization. They are usually based on the simulation of animal or natural behaviors. They consist in a list of actions (generally repetitive) to be performed for finding an approximation of the global optimum of a given (and generally hard) optimization problem [23]. In recent years, several meta-heuristic approaches have been proposed in the scientific literature. A classical example is the Simulating Annealing (SA) proposed in the 80s, which is still used in some applications, such as the ones where it is necessary to deal with biological molecules [16]. Other well-known examples of meta-heuristics are the Genetic Algorithms (GAs), Differential Evolution (DE), the Tabu Search (TS), the Variable Neighborhood Search (VNS), etc. In this paper, we consider the Ant Colony Optimization (ACO) approach (see Section II-A). For a quick survey on meta-heuristics and the main references for the meta-heuristics mentioned above, the reader can refer, for example, to [17].

Every meta-heuristic is developed in order to find the best trade-off between two main concepts: *diversification* and *intensification* [23]. While the former tries to widely extend the search in the domain of the optimization problem, the latter improves candidate solutions by focusing on local neighbors of the current best known solutions. In ACO, diversification is guaranteed by the simulation of the typical ant behavior, while intensification is performed by applying a local search to a set of candidate solutions.

In this work, we introduce the *environment* in our ACO implementation. Pheromone updates are not supposed to be performed only on the basis of found solutions, but also on the basis of the current environment "surrounding" the ants. As an example, particular real-life environment conditions, such as strong wind, may alter the perception of the deposited pheromone. We will simulate environment changes by employing the Logistic map [25]. This simulation will help our artificial ants to escape from local optima, which may otherwise focus on firstly discovered paths and completely skip better ones. We warn the reader that the Logistic map has already been employed in optimization for performing chaotic searches [3], [26]. However, its use is different from the one considered in this work for the simulation of environment changes.

This paper is organized as follows. In Section II, we will extend the classic ACO approach for managing environment changes, which will affect the fitness values used in the pheromone updating rule during the execution of ACO. We will refer to our extended ACO as "environmental ACO" (*e*ACO). In Section III, we will describe the problem we consider in our preliminary computational experiments: the GPS Surveying Problem (GSP). Computational experiments will be presented in Section IV: they show that our *e*ACO, with environment changes, outperforms the standard ACO on the set of considered instances. Finally, conclusions will be given in Section V.

## II. ACO WITH ENVIRONMENT CHANGES

We propose an extension of ACO for managing variable environments during the execution of the meta-heuristic. In Section II-A, we give a brief overview of this meta-heuristic search, and the reader who is interested in additional details is referred to the references given in the same section. In our ACO implementation, the pheromone updating rule is modified in order to take into consideration the current environment, and not only the objective function values of obtained solutions. Section II-B shows how to simulate environment changes in ACO. The environment is simulated by means of the Logistic map.

### *A. Ant Colony Optimization*

Ants foraging for food deposit a substance named pheromone on the paths they follow. An isolated ant would just move randomly. Ants encountering previously laid pheromone marks are however stimulated to follow the same paths. This way, the pheromone trails are reinforced around the optimal ones, so that the probability for the other ants to follow optimal paths increases with time. The repetition of this mechanism represents the auto-catalytic behavior of ant colonies in nature [1], [6].

Ant Colony Optimization (ACO) is inspired by this ant behavior. A colony of artificial ants working into a mathematical space is simulated. These ants search for candidate solutions of a given optimization problem, while possible paths are marked by artificial pheromone for guiding other ants in the regions of the search space where good-quality solutions were already found. In ACO, therefore, the artificial ants generally create a sort of environment by themselves, by depositing the pheromone on marked paths. As explained in details in Section II-B, we will perturb this environment by means of the Logistic map.

The ants' search space is represented by the so-called *construction graph*, which is a weighted graph $G_C = (S_C, E_C, \eta)$ where vertices in $S_C$ are solution components and edges in $E_C$ indicate the possibility to combine the two connected components for obtaining a partial solution. The weight $\eta : (u,v) \in E_C \longrightarrow \Re$ associated to each edge $(u,v)$ is named heuristic information, whose equation is generally tailored to the problem at hand. A path on $G_C$ allows to combine several partial solutions and to construct one complete solution.

Alg. 1 is a sketch of the ACO-based meta-heuristic. The transition probability $p_{uv}$, necessary in the algorithm when the ants need to decide on which edge $(u,v)$ to walk, is based on the heuristic information $\eta_{uv}$ and on the current pheromone level $\tau_{uv}$:

$$p_{uv} = \tau_{uv}^{\alpha}\eta_{uv}^{\beta}\left[\sum_{(u,w)\in E_S : w \not\subset X}\left(\tau_{uw}^{\alpha}\eta_{uw}^{\beta}\right)^{-1}\right], \tag{1}$$

where $\alpha$ and $\beta$ are transition probability parameters. When the algorithm starts, small positive values are given to every $\tau_{uv}$, which represent the current pheromone values on the edges $(u,v) \in E_C$. Then, every time a new solution is identified, the edges considered by the ants are marked with a new level of pheromone. In ACO, one possible updating rule (for a minimization problem) is the following:

$$\tau_{uv} = \tau_{uv} + \frac{1}{f(X)}, \tag{2}$$

where $X$ is the current solution, and $f$ is the objective function of the considered problem.

**Algorithm 1** Ant Colony Optimization

```
1: ACO  (in: $N$, $G_C$, $\alpha$, $\beta$;  out: $X_{best}$)
2: let $X_{best} = \emptyset$;
3: while (stopping criteria not satisfied) do
4:    for ($k = 1$, $N$) do
5:       place $k^{th}$ ant on a random vertex $u \in S_C$;
6:       let $X = \{u\}$;
7:       while ($X$ is incomplete) do
8:          select the vertex $v$ in the star of $u$ having higher
            probability $p_{uv}$ (see equ. (1));
9:          let $X = X \cup \{v\}$;
10:         let $u = v$;
11:      end while
12:      update pheromone (see equ. (2));
13:      apply local search starting from $X$ (optional);
14:      if ($X$ is better than $X_{best}$) then
15:         let $X_{best} = X$;
16:      end if
17:   end for
18: end while
```

In ACO, the general ant behavior allows to perform a wide search on the search domain (diversification), while the local search (see line 13 in Alg. 1) from constructed solutions $X$ allows to focus on promising neighbors (intensification). Our implementation of ACO makes use of MaxMin Ant System (MMAS). The reader is referred to the paper [22] for a wider explanation of the ACO implementation considered in this work.

### *B. Simulating the environment*

The Logistic map is a quadratic dynamical equation proposed in 1938 as a demographic model [25]. It is a rather simple quadratic polynomial

$$x_{n+1} = rx_n(1 - x_n), \qquad n > 0, \tag{3}$$

where $x_n$ represents the population size at time $n$ and $r$ is a constant, named growth coefficient. Given $x_0 \in [0,1]$ and a value for $r \in [0,4]$, this dynamical equation can either converge or be chaotic. In the first case, given any $x_0 \in [0,1]$, $x_n$ tends to the so-called "attraction domain". In the second case, $x_n$ never converges, but it can rather take, in an apparent random way, any possible value in the range $[0,1]$.

Fig 1 shows the behavior of the Logistic map for different values of $r$ in the range $[2,4]$ (its behavior is linear in the range $[0,2]$). On the $x$-axis, we consider a discrete subset of 3000 equidistant values for $r$ between 2 and 4; on the $y$-axis,

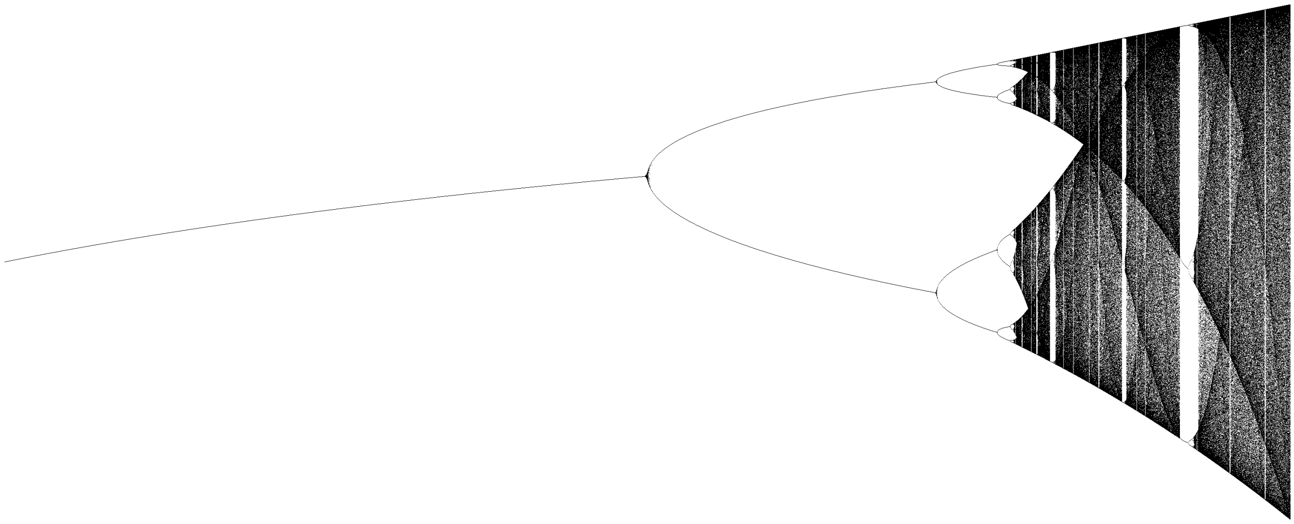

Fig. 1. The behavior of the Logistic map for different values of $r$ (on the $x$-axis, for $r = 2$ to 4 in the figure). The attraction domain can be either regular or chaotic.

for every considered value for $r$, we report the corresponding attraction domain. In order to identify the attraction domains, we take 1500 equidistant points in the interval $[0,1]$ and we apply equation (3) 1000 times for each of them. For small values of $r$, the Logistic map always converges to one single point, i.e. the attraction domain consists of one point only. The first bifurcation appears when $r = 3$, where the attraction domain consists of 2 points; then there is another bifurcation when $r = 1 + \sqrt{6}$, where the attraction domain consists of 4 points. For larger values for $r$, the Logistic map experiences other bifurcations, and it can be chaotic for some subintervals of $r$. However, in these chaotic regions, it is still possible to identify regular attraction domains. For example, in Fig 2, the same graphic reported in Fig. 1 is zoomed in the region $r = [3.901, 3.908]$, where this phenomenon is clearly shown. Regular regions, that can be glimpsed in Fig. 1, still contain bifurcations. Moreover, we can notice that the whole graphic in Fig. 1 reappears in our zoomed region. Other regular attraction domains can be identified by looking at tighter subintervals of $r$, as well as other copies of the entire graphic. The graphic in Fig. 1 is in fact a fractal, because of its self-similarity [7], [19].

We simulate regular and chaotic changes of environment in ACO by introducing the Logistic map in equation (2), which is used in ACO for updating the pheromone trails. In the hypothesis the objective function of the considered problem is positive and greater than 1, the term $1/f(X)$ in equation (2) has always values ranging between 0 and 1. It can therefore take the place of $x_0$ in the Logistic map, so that a perturbed value $x_1$ can be computed, for a given value of $r$ in $[0,4]$. The equation for updating the pheromone therefore becomes:

$$\tau_{uv} = \tau_{uv} + r \cdot \frac{1}{f(X)} \cdot \left(1 - \frac{1}{f(X)}\right). \tag{4}$$

With this simple change in the rule for updating the pheromone, we artificially perturb the environment of the ants, which would otherwise only depend on the solution fitness values. Different values for $r$ can produce different environment changes, depending on the behavior of the Logistic map. For values of $r$ for which the Logistic map converges, the pheromone levels added to $\tau_{uv}$ tend to be constant, reducing in this way the effects of good-quality solutions, that might mislead the ants towards a local optimum. For values of $r$ for which the Logistic map behaves instead chaotically, the environment is dominant on the choices of the ants, as the pheromone update mostly depend on the simulated environment, rather than on the actual fitness value.

We refer to ACO with environment changes as *environmental* ACO (*e*ACO). In this work, we present some preliminary experiments (see Section IV) where *e*ACO is employed for solving the GSP (see next section).

## III. GPS SURVEYING

The Global Positioning System (GPS) was originally developed in the US for military purposes, even if it was soon after used as well for civil applications [11]. It consists of a certain number of satellites that constantly orbit around earth and that are provided with sensors able to communicate with machines located on earth. The power that is necessary for establishing a satellite-earth communication allows for estimating the distance between the two communicating machines. Since the machine located on earth lies over a sphere that does not contain the satellite, a very precise information about the distance between the earth surface and the satellite would allow for determining the precise location of the machine on earth [15]. Moreover, the precision in locating sensor machines on earth can still be high when the distance information is not very precise, but the communication with more than one satellite can be established [14].

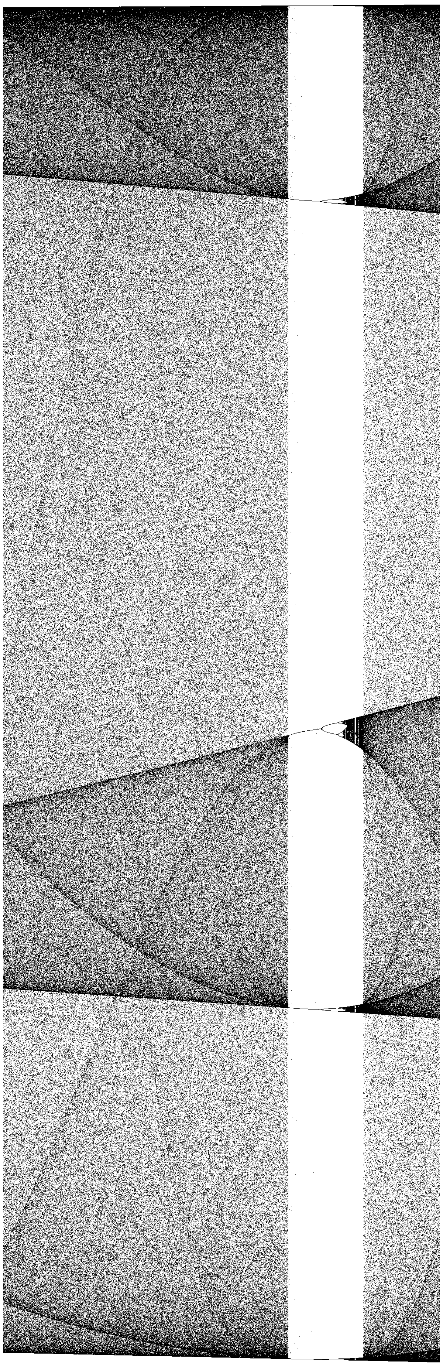

Fig. 2. The behavior of the Logistic map for values of $r$ in the interval $[3.901, 3.908]$. This region of the Logistic map is generally chaotic, but regular attraction domains (with the typical bifurcations) can still be identified.

GPS technology can in fact provide very accurate locations for all sensors forming a given sensor network. The related costs can however be too high when it is necessary to deal with large networks. For this reason, over the last years, researchers have been trying to design and install local ground networks having the task of recording satellite signals with the aim of decreasing the overall network functioning cost [5], [20]. A network is composed by a certain number of *receivers* working at different *stations* in different moments. Therefore, given a certain number of *sessions*, representing the temporarily assignment of a given number of receivers to a set of distinct stations, the problem is to find a suitable *order* for such sessions for reducing the overall cost. This cost is in fact strictly related to the order of the sessions, because receivers need to be moved from one station to another when stepping from one session to another. Therefore, the distance between two involved stations is important for the computation of the costs. However, there are also additional costs that we might need to consider: if the number of working days necessary to perform the operation is more than one, then the need of planning an over-night stop at a company office can make the cost of the operation increase. The session order is also named *session schedule*. Generally, in order to alleviate the impact of measurement errors in the data, at least two receivers per session are considered [24].

The GPS Surveying Problem (GSP) can be formalized as follows. Let

$$S = \{s_1, s_2, \ldots, s_n\}$$

be a set of stations, and let

$$R = \{r_1, r_2, \ldots, r_m\}$$

be a set of receivers, with $m < n$. Sessions can be defined by a function $\sigma : R \longrightarrow S$ that associates one receiver to one station. Considering that no more than one receiver should be assigned to the same station, $\sigma$ can be represented by an $m$-vector $(\varsigma_1, \varsigma_2, \ldots, \varsigma_m)$ containing, for each of the $m$ receivers, the labels of the chosen stations. Since $m < n$ (and generally fixed to 2 or 3 in the applications), the number of permutations of $m$ objects from $n$ distinguishable ones is $n!/(n-m)!$, which can be huge when the network is large. Notice, however, that not all permutations may actually be possible, depending on the problem at hand.

Let $C$ be an $n \times n$ matrix providing the costs $c(\varsigma_u, \varsigma_v)$ for moving one receiver from the station $\varsigma_u$ to the station $\varsigma_v$. This matrix can be symmetric when moving between $\varsigma_u$ and $\varsigma_v$ is independent from the directionality; the non-symmetric case is however more realistic.

An instance of the GSP can be represented by a weighted undirected multigraph $G = (V, E, c)$ where vertices represent sessions $\sigma_v$ and arcs $(\sigma_u, \sigma_v)$ indicate the possibility to switch from session $\sigma_u$ to session $\sigma_v$. The upper bound on the cardinality of $V$ is $n!/(n-m)!$, which corresponds to the maximum number of possible sessions. The weight associated

TABLE I
COMPARISON BETWEEN ACO AND *e*ACO ON A SET OF GSP INSTANCES.

to the arcs provides the cost $c(\sigma_u, \sigma_v)$ for moving every receiver from the station $\varsigma_{u,i}$ to the station $\varsigma_{v,i}$, for each $i$:

$$c(\sigma_u, \sigma_v) = \sum_{i=1}^{m} c(\varsigma_{u,i}, \varsigma_{v,i}).$$

The graph $G$ is not simple in general, because it might be feasible to switch from session $\sigma_u$ to session $\sigma_v$, as well as from $\sigma_v$ to $\sigma_u$, but with a different total cost. The problem consists in finding an optimal path on $G$, i.e. a path for which all selected arcs give the minimal total cost, while covering the entire vertex set $V$ [5].

The GSP can be seen as the classic Traveling Salesman Problem (TSP), which asks for determining the optimal route for a salesman to visit a given number of cities while minimizing the traveled distance [13]. If the two cities are replaced with sessions $\sigma_v$ and the distances are replaced with the weights associated to the arcs $(\sigma_u, \sigma_v)$ of our graph $G$, the equivalence between the two problems becomes evident. More precisely, since the weights on the arcs $(\sigma_u, \sigma_v)$ and $(\sigma_v, \sigma_u)$ are generally different, GSP better fits with the Asymmetric TSP (ATSP), where distances between the cities depend upon the order in which the cities are reached. Finally, we also remark that the necessity of an over-night office stop can be formalized by adding a fictive session in $G$ where receivers come back to base offices. This special session might need to be "traveled" more than once: we can therefore say that, in general, the GSP can be seen as a Multiple Asymmetric TPS (MATSP) [2]. The TSP and these variants are NP-hard [18]. Therefore, the GSP is NP-hard as well.

First attempts for solving the GSP were based on the idea of transforming GSP instances into instances of the class of TSP-like problems, and to employ existing methods and algorithms. In [4], a branch-and-bound approach was employed, which is actually able to find the optimal solutions for small GSP instances. As the size of the networks increases, the complexity grows and the time necessary for a branch-and-bound to converge becomes prohibitive. On the other side, in real-life applications, there is generally the need to obtain GSP solutions as fast as possible, even if only approximated ones. Therefore, heuristic approaches particularly developed for this application have been proposed over the last years for identifying optimal or near-optimal session orders [8], [9], [20]. In this work, we consider a set of instances of the GSP for testing our ACO approach with environment changes described in Section II.

## IV. COMPUTATIONAL EXPERIMENTS

We apply our *e*ACO (see Section II) for solving instances of the GSP (see Section III). In this application, the construction graph $G_C$ corresponds to the weighted undirected multigraph $G$ where vertices are sessions $\sigma_u$ and edges indicate the possibility to switch from one session to another. As test cases, we consider data from two real networks: Malta [20], composed by 38 sessions, and Seychelles [21], composed by 71 sessions. We also consider larger instances designed for testing the ATSP, which are freely available on the Internet.[1]

Our *e*ACO implementation is based on Alg. 1, where the transition probability $p_{uv}$ is computed by equation (1), and the pheromone update is performed by applying equation (4). The heuristic information $\eta_{uv}$ is given by the formula:

$$\eta_{uv} = \frac{1}{c(\sigma_u, \sigma_v)},$$

where $c(\sigma_u, \sigma_v)$ is the total cost for switching from session $\sigma_u$ to session $\sigma_v$ (see Section III). Finally, the values for the transition probability parameters $\alpha$ and $\beta$ are fixed to 1 and 2, respectively. These values were identified in previous works as the optimal ones for ACO when solving instances of the GSP [10]. In the following experiments, we will focus on the quality of the found solutions, rather than on the algorithms' performances. In fact, the increase in complexity for using equation (4), rather than equation (2), can be neglected when considering the overall algorithms' complexity. We do not compare our results to the best results currently known for the considered instances. In the present work, our aim is not to improve those results, but only to give a preliminary validation to the usefulness of the presented idea.

Table I shows some computational experiments for different values of $r$. Average values over 30 runs are reported in the table. *e*ACO is able to identify better quality solutions in all experiments and for almost all used values for $r$. This shows that, in fact, a variable environment for the ants, instead of a constant one, gives benefits to the search. For values of $r$ equal to 1, 2 and 3, the Logistic map converges to one unique value; it is instead chaotic for $r = 4$. It seems therefore that

[1] http://www.informatik.uni-heidelberg.de/groups/comopt/software/TSLIB95/ATSP.html

the best results can be achieved when the environment tends to homogenize the pheromone trails. Notice, however, that only one experiment with $r = 4$, when the environment is chaotic, was not able to provide a better solution (w.r.t the one provided by the standard ACO).

## V. Conclusions

We introduced a variant of ACO where the ant environment is not constant but it is rather subject to change over time. This way, in our ACO implementation, there are less chances for the meta-heuristic search to be trapped at a local optimum. In this work, we have tested this idea on instances of the GSP. In order to simulate the environment in our *e*ACO, we employed the well-known Logistic map, which can have either a regular or a chaotic behavior, depending on the values assigned to its parameter $r$.

We believe this is the first research contribution where an "environment" is introduced in a meta-heuristic search. In this work, we showed that this novel idea seems to be promising when working with ACO. Evidently, the idea still needs to be studied in details from a theoretical point of view, as well as from a practical one. The effect of a suitable environment should be studied in conjunction with other meta-heuristic frameworks. Moreover, a much wider experimental analysis should be performed, on a larger set of instances of the GSP, as well as on instances of other known hard problems. This will be our main direction for future works.

***Abstract*—In this paper we apply an approach based on the apparatus of the Index Matrices and the Intuitionistic Fuzzy Sets – namely InterCriteria Analysis. The main idea is to use the InterCriteria Analysis to establish the existing relations and dependencies of defined parameters in non-linear model of an *E. coli* fed-batch cultivation process. Moreover, based on results of series of identification procedures we observe the mutual relations between model parameters and considered optimization techniques outcomes, such as execution time and objective function value. Based on InterCriteria Analysis we examine the obtained identification results and discuss the conclusions about existing relations and dependencies between defined, in terms of InterCriteria Analysis, criteria.**

*Index Terms*—InterCriteria Analysis; Index matrices; Intuitionistic Fuzzy Sets; Genetic Algorithm; chromosomes; parameter identification; *E. coli*; fed-batch cultivation process.

## I. Introduction

THE InterCriteria Analysis (ICA) is developed with the aim to gain additional insight into the nature of the criteria involved and discover on this basis existing relations between the criteria themselves [8]. It is based on the apparatus of the Index Matrices (IM) [10], [11], and the Intuitionistic Fuzzy Sets [12] and can be applied for decision making in different areas of science and practice. The approach has been discussed in a several papers [10], [14], [15], [16]. In [8] a possibility of the ICA method for criterion value prediction, proposing two algorithms, is presented. In [16] a discussion on the threshold values in the ICA was further elaborated. But, up to now, considering ICA application, the only applications reported are in one area: namely, EU member states competitiveness analysis [14], [15]. Encouraging results of these first applications of the ICA provoke us to use the method for establishing and identifying the relations between parameters of the mathematical model of an *E. coli* fed-batch cultivation process. The model parameters are further considered as criteria in terms of ICA.

In the case of modelling of cultivation processes ICA approach could be very useful. Cultivation processes are characterized with complex, non-linear dynamic and their modelling is a hard combinatorial optimization problem. On the one hand, the parameter identification is of key importance for modelling process and additional knowledge about the model parameters relations will be extremely useful to improve the model accuracy. On the other hand, the information may be used to improve the performance of the used optimization algorithms if, for instance, some algorithm outcomes are added to the considered criteria. Thus, the relations between model parameters and optimization algorithm performance will be established.

In this paper we applied the ICA to establish the basic relations between the parameters in the model of an *E. coli* fed-batch cultivation process. The existing relations are identified based on results of a series of parameters identification procedures. The use of meta-heuristic techniques such as Genetic Algorithms (GAs) has received more and more attention [3]. These methods offer good solutions, even global optima, within reasonable computing time [17], so we choose to use genetic algorithms for estimation of the model parameters.

The paper is organized as follows. The background of InterCriteria Analysis is given in Section 2. The problem formulation is described in Section 3. The numerical results and a discussion are presented in Section 4. Conclusion remarks are done in Section 5.

## II. InterCriteria Analysis

Here we expand on the idea proposed in [8]. Following [8] and [12] we will obtain an Intuitionistic Fuzzy Pair (IFP) as the degrees of “agreement” and “disagreement” between two criteria applied on different objects. We remind briefly that an IFP is an ordered pair of real non-negative numbers $\langle a, b\rangle$ such that:

$$a + b \leq 1.$$

978-83-60810-66-8/$25.00©2015, IEEE

For clarity, let us be given an IM (see [10]) whose index sets consist of the names of the criteria (for rows) and objects (for columns). The elements of this IM are further supposed to be real numbers (in the general case, this is not required). We will obtain an IM with index sets consisting of the names of the criteria (for rows and for columns) with elements IFPs corresponding to the "agreement" and "disagreement" of the respective criteria.

Two things are further supposed (which are not always guaranteed in practice and, when not fulfilled, present an interesting direction for new research in themselves):

1) All criteria provide an evaluation for all objects (i.e. there are no inapplicable criteria for a given object) and all these evaluations are available (no missing evaluations).
2) All the evaluations of a given criteria can be compared amongst themselves.

Further by $O$ we denote the set of all objects $O_1, O_2, \ldots, O_n$ being evaluated, and by $C(O)$ the set of values assigned by a given criteria $C$ to the objects, i.e.

$$\begin{aligned} O &\stackrel{\text{def}}{=} \{O_1, O_2, \ldots, O_n\}, \\ C(O) &\stackrel{\text{def}}{=} \{C(O_1), C(O_2), \ldots, C(O_n)\}. \end{aligned}$$

Let:

$$C^*(O) \stackrel{\text{def}}{=} \{\langle x, y\rangle |\ x \neq y\ \&\ \langle x, y\rangle \in C(O) \times C(O)\}.$$

In order to compare two criteria we must construct the vector of all internal comparisons of each criteria, which fulfill exactly one of three relations $R$, $\overline{R}$ and $\tilde{R}$. In other words, we require that for a fixed criterion $C$ and any ordered pair $\langle x, y\rangle \in C^*(O)$ it is true:

$$\langle x, y\rangle \in R \Leftrightarrow \langle y, x\rangle \in \overline{R}, \tag{1}$$

$$\langle x, y\rangle \in \tilde{R} \Leftrightarrow \langle x, y\rangle \notin (R \cup \overline{R}), \tag{2}$$

$$R \cup \overline{R} \cup \tilde{R} = C^*(O). \tag{3}$$

From the above it is seen that we need only consider a subset of $C(O) \times C(O)$ for the effective calculation of the vector of internal comparisons (denoted further by $V(C)$) since from (1), (2) and (3) it follows that if we know what is the relation between $x$ and $y$ we also know what is the relation between $y$ and $x$. Thus we will only consider lexicographically ordered pairs $\langle x, y\rangle$. Let, for brevity:

$$C_{i,j} = \langle C(O_i), C(O_j)\rangle.$$

Then for a fixed criterion $C$ we construct the vector:

$$\begin{aligned} V(C) = \{&C_{1,2}, C_{1,3}, \ldots, C_{1,n}, C_{2,3}, C_{2,4}, \ldots, \\ &C_{2,n}, C_{3,4}, \ldots, C_{3,n}, \ldots, C_{n-1,n}\}. \end{aligned}$$

It can be easily seen that it has exactly $\frac{n(n-1)}{2}$ elements. Further, to simplify our considerations, we replace the vector $V(C)$ with $\hat{V}(C)$, where for each $1 \leq k \leq \frac{n(n-1)}{2}$ for the $k$-th component it is true:

$$\hat{V_k}(C) = \begin{cases} 1 \text{ iff } V_k(C) \in R, \\ -1 \text{ iff } V_k(C) \in \overline{R}, \\ 0 \text{ otherwise.} \end{cases}$$

Then when comparing two criteria we determine the "degree of agreement" between the two as the number of matching components (divided by the length of the vector for normalization purposes). This can be done in several ways, e.g. by counting the matches or by taking the complement of the Hamming distance. The "degree of disagreement" is the number of components of opposing signs in the two vectors (again normalized by the length). This also may be done in various ways. A pseudocode of the algorithm used in this study for calculating the degrees of agreement and disagreement between two criteria $C$ and $C'$ is presented below.

**Algorithm 1** Calculating "agreement" and "disagreement" between two criteria

```
Require: Vectors $\hat{V}(C)$ and $\hat{V}(C')$

function DEGREE OF AGREEMENT($\hat{V}(C), \hat{V}(C')$)
    $V \leftarrow \hat{V}(C) - \hat{V}(C')$
    $\mu_{C,C'} \leftarrow 0$
    for $i \leftarrow 1$ to $\frac{n(n-1)}{2}$ do
        if $V_i = 0$ then
            $\mu_{C,C'} \leftarrow \mu_{C,C'} + 1$
        end if
    end for
    $\mu_{C,C'} \leftarrow \frac{2}{n(n-1)}\mu_{C,C'}$
    return $\mu_{C,C'}$
end function

function DEGREE OF DISAGREEMENT($\hat{V}(C), \hat{V}(C')$)
    $V \leftarrow \hat{V}(C) - \hat{V}(C')$
    $\nu_{C,C'} \leftarrow 0$
    for $i \leftarrow 1$ to $\frac{n(n-1)}{2}$ do
        if abs($V_i$) = 2 then                ▷ abs: absolute value
            $\nu_{C,C'} \leftarrow \nu_{C,C'} + 1$
        end if
    end for
    $\nu_{C,C'} \leftarrow \frac{2}{n(n-1)}\nu_{C,C'}$
    return $\nu_{C,C'}$
end function
```

It is obvious (from the way of calculation) that for $\mu_{C,C'}$, $\nu_{C,C'}$, we have:

$$\mu_{C,C'} = \mu_{C',C}, \nu_{C,C'} = \nu_{C',C}.$$

Also, $\langle \mu_{C,C'}, \nu_{C,C'}\rangle$ is an IFP.

## III. Problem Formulation

Let us use the following non-linear differential equation system to describe the *E. coli* fed-batch cultivation process [1], [4]:

$$\frac{dX}{dt} = \mu X - \frac{F_{in}}{V}X, \tag{4}$$

$$\frac{dS}{dt} = -q_S X + \frac{F_{in}}{V}(S_{in} - S), \tag{5}$$

$$\frac{dV}{dt} = F_{in}, \tag{6}$$

where

$$\mu = \mu_{max}\frac{S}{k_S + S}, \quad q_S = \frac{1}{Y_{S/X}}\mu \tag{7}$$

and $X$ is the biomass concentration, [g/l]; $S$ is the substrate concentration, [g/l]; $F_{in}$ is the feeding rate, [l/h]; $V$ is the bioreactor volume, [l]; $S_{in}$ is the substrate concentration in the feeding solution, [g/l]; $\mu$ and $q_S$ are the specific rate functions, [1/h]; $\mu_{max}$ is the maximum value of the $\mu$, [1/h]; $k_S$ is the saturation constant, [g/l]; $Y_{S/X}$ is the yield coefficient, [-].

For the model (Eq. (4)-Eq. (7)) the parameters that will be identified are $\mu_{max}, k_S$ and $Y_{S/X}$.

Let $Z_{\text{mod}} \overset{\text{def}}{=} [X_{\text{mod}}\ S_{\text{mod}}]$ (model predictions for biomass and substrate) and $Z_{\text{exp}} \overset{\text{def}}{=} [X_{\text{exp}}\ S_{\text{exp}}]$ (known experimental data for biomass and substrate). Then putting $Z = Z_{\text{mod}} - Z_{\text{exp}}$, we define the objective function as:

$$J = \|Z\|^2 \to \min, \tag{8}$$

where $\|\|$ denotes the $\ell^2$-vector norm.

For the model parameters identification we use experimental data for biomass and glucose concentration of an *E. coli* MC4110 fed-batch fermentation process. The detailed description of the process condition and experimental data are presented in [2].

To estimate the model parameters we applied consistently 14 differently tuned GA. We use various population sizes – from 5 to 200 chromosomes in the population. The number of generations is fixed to 200. The main GA operators and parameters are summarized in Table I. Because of the stochastic nature of the applied algorithms we perform series of 30 runs for each population size. Thus, we obtain the average, best and worst estimate of the parameters, as well as of the algorithm execution time and value of objective function. The detailed description of identification procedure is given in [7].

To perform ICA three IMs are constructed – the IM $A_1$ (Eq. 9) with the obtained average results, the IM $A_2$ (Eq. 10) with the best obtained results and IM $A_3$ (Eq. 11) with the worst obtained results. In addition to the presented in [7] results here the average, worst and best estimates for the tree model parameters in all 14 cases are given too. Thus, five criteria are considered – $C_1$ is parameter $\mu_{max}$, $C_2$ is parameter $k_S$, $C_3$ is parameter $Y_{S/X}$, $C_4$ is objective function value $J$ and $C_5$ is resulting execution time $T$.

TABLE I
Main GA Operators and Parameters

| **Operator** | **Type** |
|---|---|
| fitness function | linear ranking |
| selection function | roulette wheel selection |
| crossover function | simple crossover |
| mutation function | binary mutation |
| reinsertion | fitness-based |
| **Parameter** | **Value** |
| generation gap | 0.97 |
| crossover probability | 0.75 |
| mutation probability | 0.01 |
| number of generations | 200 |

## IV. Numerical Results and Discussion

Computer specification to run all identification procedures are Intel Core i5-2329 3.0 GHz, 8 GB Memory, Windows 7 (64bit) operating system.

Based on the presented **Algorithm 1** the ICA is implemented in the Matlab 7.5 environment. We obtain IMs that determine the degrees of "agreement" ($\mu_{C,C'}$) and "disagreement" ($\nu_{C,C'}$) between criteria for the three cases.

*1) Case of average results:*

Resulting degrees of "agreement" ($\mu_{C,C'}$) are as follows:

$$\text{IM}_1 = \begin{array}{c|ccccc} & C_1 & C_2 & C_3 & C_4 & C_5 \\ \hline C_1 & \mathbf{1} & 0.91 & 0.41 & 0.74 & 0.26 \\ C_2 & 0.91 & \mathbf{1} & 0.36 & 0.78 & 0.27 \\ C_3 & 0.41 & 0.36 & \mathbf{1} & 0.55 & 0.38 \\ C_4 & 0.74 & 0.78 & 0.55 & \mathbf{1} & 0.11 \\ C_5 & 0.26 & 0.27 & 0.38 & 0.11 & \mathbf{1} \end{array}$$

Resulting degrees of "disagreement" ($\nu_{C,C'}$) are as follows:

$$\text{IM}_2 = \begin{array}{c|ccccc} & C_1 & C_2 & C_3 & C_4 & C_5 \\ \hline C_1 & \mathbf{0} & 0.08 & 0.58 & 0.26 & 0.74 \\ C_2 & 0.08 & \mathbf{0} & 0.62 & 0.21 & 0.71 \\ C_3 & 0.58 & 0.62 & \mathbf{0} & 0.44 & 0.60 \\ C_4 & 0.26 & 0.21 & 0.44 & \mathbf{0} & 0.89 \\ C_5 & 0.74 & 0.71 & 0.60 & 0.89 & \mathbf{0} \end{array}$$

*2) Case of worst results:*

Resulting degrees of "agreement" ($\mu_{C,C'}$) are as follows:

$$\text{IM}_5 = \begin{array}{c|ccccc} & C_1 & C_2 & C_3 & C_4 & C_5 \\ \hline C_1 & \mathbf{1} & 0.79 & 0.34 & 0.88 & 0.14 \\ C_2 & 0.79 & \mathbf{1} & 0.18 & 0.84 & 0.22 \\ C_3 & 0.34 & 0.18 & \mathbf{1} & 0.33 & 0.64 \\ C_4 & 0.88 & 0.84 & 0.33 & \mathbf{1} & 0.07 \\ C_5 & 0.14 & 0.22 & 0.64 & 0.07 & \mathbf{1} \end{array}$$

Resulting degrees of "disagreement" ($\nu_{C,C'}$) are as follows:

$$A_1(average) =$$

$$\begin{array}{c|cccccccccccccc}

C_5 & 0.86 & 0.77 & 0.35 & 0.93 & \mathbf{0}
\end{array}$$

*3) Case of best results:*

Resulting degrees of "agreement" ($\mu_{C,C'}$) are as follows:

$$\mathrm{IM}_3 = \begin{array}{c|ccccc}
 & C_1 & C_2 & C_3 & C_4 & C_5 \\
\hline
C_1 & \mathbf{1} & 0.74 & 0.49 & 0.63 & 0.36 \\
C_2 & 0.74 & \mathbf{1} & 0.35 & 0.53 & 0.51 \\
C_3 & 0.49 & 0.35 & \mathbf{1} & 0.71 & 0.30 \\
C_4 & 0.63 & 0.53 & 0.71 & \mathbf{1} & 0.25 \\
C_5 & 0.36 & 0.51 & 0.30 & 0.25 & \mathbf{1}
\end{array}$$

Resulting degrees of "disagreement" ($\nu_{C,C'}$) are as follows:

$$\mathrm{IM}_4 = \begin{array}{c|ccccc}
 & C_1 & C_2 & C_3 & C_4 & C_5 \\
\hline
C_1 & \mathbf{0} & 0.19 & 0.44 & 0.33 & 0.59 \\
C_2 & 0.19 & \mathbf{0} & 0.59 & 0.44 & 0.46 \\
C_3 & 0.44 & 0.59 & \mathbf{0} & 0.26 & 0.68 \\
C_4 & 0.33 & 0.44 & 0.26 & \mathbf{0} & 0.75 \\
C_5 & 0.59 & 0.46 & 0.68 & 0.75 & \mathbf{0}
\end{array}$$

Let us consider the following scheme for defining the consonance and dissonance between each pair of criteria (see Table III).

TABLE II
CRITERIA RELATIONS SORTED BY $\mu_{C,C'}$ VALUES

| **Criteria relation** | **Obtained $\langle \mu_{C,C'}, \nu_{C,C'} \rangle$ values in case of** | | |
|---|---|---|---|
| | **average results** | **worst results** | **best results** |
| $C_1 \leftrightarrow C_2$ | $\langle 0.91, 0.08 \rangle$ | $\langle 0.79, 0.20 \rangle$ | $\langle 0.74, 0.19 \rangle$ |
| $C_2 \leftrightarrow C_4$ | $\langle 0.78, 0.21 \rangle$ | $\langle 0.84, 0.15 \rangle$ | $\langle 0.53, 0.44 \rangle$ |
| $C_1 \leftrightarrow C_4$ | $\langle 0.74, 0.26 \rangle$ | $\langle 0.88, 0.12 \rangle$ | $\langle 0.63, 0.33 \rangle$ |
| $C_3 \leftrightarrow C_4$ | $\langle 0.55, 0.44 \rangle$ | $\langle 0.33, 0.66 \rangle$ | $\langle 0.71, 0.26 \rangle$ |
| $C_1 \leftrightarrow C_3$ | $\langle 0.41, 0.58 \rangle$ | $\langle 0.34, 0.65 \rangle$ | $\langle 0.49, 0.44 \rangle$ |
| $C_3 \leftrightarrow C_5$ | $\langle 0.38, 0.60 \rangle$ | $\langle 0.64, 0.35 \rangle$ | $\langle 0.30, 0.68 \rangle$ |
| $C_2 \leftrightarrow C_3$ | $\langle 0.36, 0.62 \rangle$ | $\langle 0.18, 0.80 \rangle$ | $\langle 0.35, 0.59 \rangle$ |
| $C_2 \leftrightarrow C_5$ | $\langle 0.27, 0.71 \rangle$ | $\langle 0.22, 0.77 \rangle$ | $\langle 0.51, 0.46 \rangle$ |
| $C_1 \leftrightarrow C_5$ | $\langle 0.26, 0.74 \rangle$ | $\langle 0.14, 0.86 \rangle$ | $\langle 0.36, 0.59 \rangle$ |
| $C_4 \leftrightarrow C_5$ | $\langle 0.11, 0.89 \rangle$ | $\langle 0.07, 0.93 \rangle$ | $\langle 0.25, 0.75 \rangle$ |

In the case of the average values of the examined criteria, in accordance with the scale presented in Table III, we found the following pair dependencies:

- There is no observed strong positive consonance or strong negative consonance between any of the ten criteria pairs. Since the observed values depend on the number of objects if we can expand their number, it is possible to

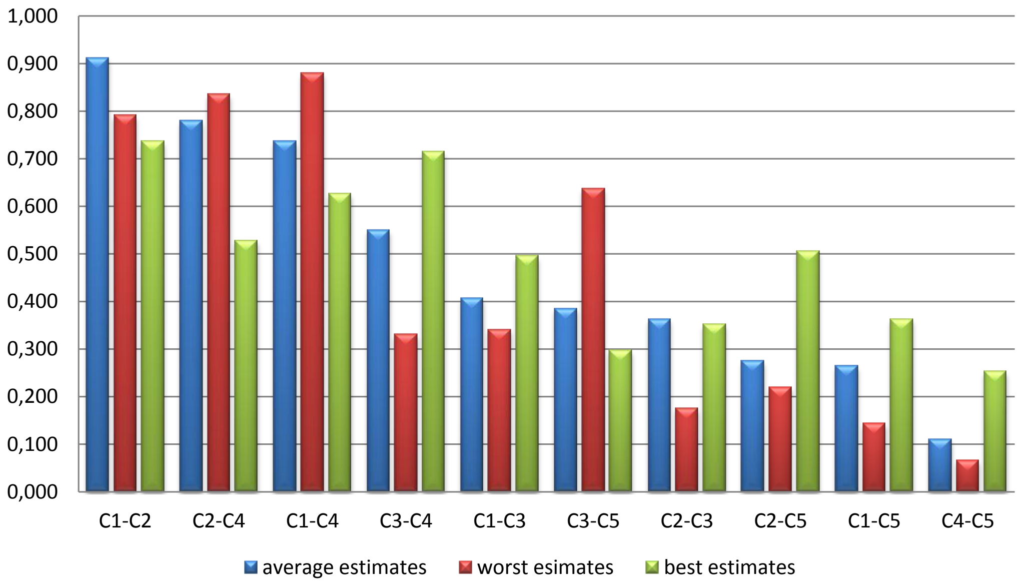

Fig. 1. Degrees of "agreement" ($\mu_{C,C'}$ values) for all cases

TABLE III
CONSONANCE AND DISSONANCE SCALE

| **Interval of** $\mu_{C,C'}$, % | **Meaning** |
|---|---|
| [0-5] | strong negative consonance |
| (5-15] | negative consonance |
| (15-25] | weak negative consonance |
| (25-33] | weak dissonance |
| (33-43] | dissonance |
| (43-57] | strong dissonance |
| (57-67] | dissonance |
| (67-75] | weak dissonance |
| (75-85] | weak positive consonance |
| (85-95] | positive consonance |
| (95-100] | strong positive consonance |

obtain values in these intervals.

- For the pair $C_4 \leftrightarrow C_5$ (i.e., $T \leftrightarrow J$) a negative consonance is identified. Such dependence is logical – for a large number of algorithm iterations (i.e., greater execution time $T$) it is more likely to find a more accurate solution, i.e. smaller value of $J$.
- The pairs $C_2 \leftrightarrow C_5$ (i.e., $k_S \leftrightarrow T$) show identical results – these criteria are in weak dissonance. The third model parameter $Y_{S/X}$ and $T$ are in dissonance. The conclusion is that the total execution time is not dependent solely on one of the model parameters. Logically the triple of these parameters should be in consonance with $T$.
- For the pairs $C_1 \leftrightarrow C_3$ (i.e., $\mu_{max} \leftrightarrow Y_{S/X}$) and $C_2 \leftrightarrow C_3$ (i.e., $k_S \leftrightarrow Y_{S/X}$) a dissonance is observed. Considering the physical meaning of the model parameters [1] it is clear that there is no dependence between these criteria. A strong correlation is expected between criteria $C_1 \leftrightarrow C_2$ (i.e., $\mu_{max} \leftrightarrow k_S$) [1]. The results confirmed these expectation – these criteria are in a positive consonance.
- The observed low value of $\mu_{C_3,C_4}$, i.e., strong dissonance between $Y_{S/X} \leftrightarrow J$ show the low sensitivity of this model parameter. According to [18] the parameter $Y_{S/X}$ has lower sensitivity compared to parameter $\mu_{max}$.
- Due to the established strong correlation between criteria $C_1 \leftrightarrow C_2$ (i.e., $\mu_{max} \leftrightarrow k_S$) we observe that $C_1 \leftrightarrow C_4$ (i.e., $\mu_{max} \leftrightarrow J$) and $C_2 \leftrightarrow C_4$ (i.e., $k_S \leftrightarrow J$) are in, respectively weak dissonance and weak positive consonance. Similarly to the relations with $T$ the conclusion is that the accuracy of the criterion is not dependent solely on one of the model parameters. Logically the triple of these parameters should be in consonance (or strong consonance) with the criterion value. Moreover, taking into account the parameters sensitivity it is clear that the more sensitive parameter will be more linked to the value of $J$.

Due to stochastic nature of considered here GA we observed some different criteria dependences in the rest two cases – case of worst and case of best results:

- In the case of the worst results we found weaker relation between $C_1 \leftrightarrow C_2, C_3 \leftrightarrow C_4, C_2 \leftrightarrow C_3, C_1 \leftrightarrow C_5, C_2 \leftrightarrow C_5$ and $C_4 \leftrightarrow C_5$. For the pairs $C_1 \leftrightarrow C_4, C_2 \leftrightarrow C_4$ and $C_3 \leftrightarrow C_5$ we observed higher value of $\mu_{C,C'}$. Compared to the case of average results there are no large, strongly manifested discrepancies. In case

of discrepancy, the considered criteria pair appears in an adjacent scale according to Table III. For example, pair $C_1 \leftrightarrow C_2$ in case of average results are in positive consonance, while in case of worst results – in weak positive consonance.
- In the case of the best results we identify the same results – in case of discrepancy the considered criteria pair appears in an adjacent scale. However, in this case we observed some larger discrepancies. Taking into account the nature of the GA we consider that the results in case of average criteria values have the highest significance.

## V. Conclusion

In this paper based on the apparatus of the Index Matrices and the Intuitionistic Fuzzy Sets, InterCriteria Analysis of a model parameters identification using Genetic Algorithm is performed. A non-linear model of an *E. coli* fed-batch cultivation process is considered. Series of model identification procedures using Genetic Algorithms are done. The InterCriteria Analysis is applied to explore the existing relations and dependencies of defined model parameters and Genetic Algorithms outcomes – execution time and objective function value. Three case studies are examined – considering average, worst and best results for the obtained model parameters, execution time and objective function value. Applying the InterCriteria Analysis we establish relations and dependencies between the defined criteria. Based on the used scale for defining the consonance and dissonance between each pair of criteria, we discuss which criteria are in consonance and dissonance, as well as the degree of their dependence.

***Abstract*—Many practical problems are modeled with networks and graphs. Their exploration is of significant importance, and several graph-exploration algorithms already exist. In this paper, we focus on a type of vertex equivalence, called *exploratory equivalence*, which has a great potential to speed up such algorithms. It is an equivalence based on graph automorphisms and can, for example, help us in solving the subgraph isomorphism problem, which is a well-known $NP$-hard problem. In particular, if a given pattern graph has nontrivial automorphisms, then each of its nontrivial exploratory equivalent classes gives rise to a set of constraints to prune the search space of solutions. In the paper, we define the maximum exploratory equivalence problem. We show that the defined problem is at least as hard the graph isomorphism problem. Additionally, we present a polynomial-time algorithm for solving the problem when the input is restricted to tree graphs. Furthermore, we show that for trees, a maximum exploratory equivalent partition leads to a globally optimal set of subgraph isomorphism constraints, whereas this is not necessarily the case for general graphs.**

## I. Introduction

Searching for patterns in structured data is one of the most ubiquitous applications of computer algorithms in various scientific areas. Such data is often modeled with graphs, which efficiently represent diverse types of entities (modeled by graph vertices) and relations between them (modeled by graph edges) and also enable a more general and global view on the data. In the era of ever-growing, even planetary-wide (social, citation, traffic, etc.) networks [1], all of which can be naturally modeled by graphs, graph representation and also algorithms on graphs are becoming increasingly important. Applications of graphs arise in various areas, ranging from chemistry [2], [3], economy [4], politics [5], to popular culture [6].

In this paper, we focus on a general technique for speeding up algorithms that search for patterns in graphs. The main idea of our technique is to exploit symmetries of a graph, i.e., to find equivalent vertices in such a way that if two vertices are equivalent then the search algorithm could process only one (and deduce the information about the other one).

The problem of finding equivalent vertices of a graph has already appeared in the literature; see, for example, papers on regular and structural equivalence [7], [8]. To the best of our knowledge, our definition introduces a new form of equivalence. We call it *exploratory equivalence* ($EE$), since its primary intent is to be utilized in graph search algorithms; see [9] for the introductory paper. Nevertheless, the exploitation of symmetries of a problem to reduce the amount of time for exploring the solution search space is not new. See, for example, a method for solving 0/1 integer linear programs having a large symmetry [10] or [11] for a similar method. Another equivalence similar to ours, defined in [12], can also be used for pruning the search space. However, our equivalence is more general and, hence, has a greater pruning power.

To find the symmetries in a graph, the usual approach is to find all graph isomorphisms ($GI$), i.e., structure preserving mappings. In particular, given two graphs, the graph isomorphism problem asks whether they are the same. Similarly, the graph automorphism problem asks whether a graph can be (non-trivially) mapped to itself. The $GI$ problem has a special place in the complexity theory, as it is a canonical example of a possible candidate for an $NP$-intermediate problem. Ladner's theorem [13] tells us that if $P$ is not equal to $NP$, then the class of $NP$-intermediate problems is not empty. As a result, a polynomial-time algorithm is unlikely for the $GI$ problem. Nevertheless, in practice, there are several efficient algorithms and software packages for finding automorphisms of graphs, e.g., NAUTY [14], [15], BLISS [16], [17], SAUCY [18], [19], [20], and NISHE [21]. For some special cases of graphs, e.g., tree graphs [22], polynomial-time algorithms exist.

Based on automorphisms, one could define *automorphic equivalence*, where two vertices are equivalent if and only if there exists an automorphism that maps one to another. Such equivalence classes are also called *orbits*. Notice that exploratory equivalence is similar but not the same as *automorphic equivalence*. Indeed, exploratory equivalence is more restrictive.

In our preceding paper [9], we already presented the definition of exploratory equivalences and the corresponding problem of finding maximum exploratory equivalent partition of graph vertices, i.e., the MAXEXPLOREQ problem. In this paper, we show that the MAXEXPLOREQ is $GI$-hard, which means that a polynomial-time algorithm (in terms of the number of graph vertices) is unlikely to exist. Hence, it is reasonable to restrict the input to MAXEXPLOREQ to selected subclasses of graphs. As the second contribution of this paper, we present a polynomial-time algorithm for solving MAXEXPLOREQ on an arbitrary tree. Thereby we show that the restriction of MAXEXPLOREQ to trees is in $P$. Additionally, we also show that for trees, a maximum exploratory equivalent partition leads to a globally optimal set of subgraph isomorphism search constraints. In particular, when searching for a given tree in a given host graph using the constraints derived from a maximum exploratory equivalent partition of the tree, each of the occurrences of the tree in the host graph will be discovered exactly once. For general graphs, this is not necessarily the case.

The rest of this paper is structured as follows. In the next section, we present mathematical notions needed for the rest of the paper. In Section III, we present a motivational example (based on the subgraph isomorphism problem) for exploratory

978-83-60810-66-8/$25.00©2015, IEEE

equivalence. The definition of the MaxExploreEq problem is presented in Section IV. In Section V, we show that the MaxExploreEq problem is $GI$-hard. In Section VI, we present a polynomial-time algorithm for solving the MaxExploreEq problem on trees and determine its computational complexity. Section VII presents an empirical demonstration of the presented algorithm on the set of all small trees. In Section VIII, we elaborate on the connection between exploratory equivalence and subgraph isomorphism, with a particular emphasis on trees. Finally, Section IX concludes the paper.

## II. Preliminaries

Let $G = (V, E)$ denote a simple undirected graph, where $V = \{1, 2, \ldots, n\}$ is a set of vertices and $E \subseteq V \times V$ is a set of edges. The graph can be labeled; let $\Sigma$ denote a set of labels, and let $\ell_V \colon V \to \Sigma$ and $\ell_E \colon E \to \Sigma$ denote the functions that assign labels to individual vertices and edges, respectively. An unlabeled graph can be viewed as a labeled graph where all vertices and edges have the same label. A *tree* is a connected acyclic undirected graph.

A (graph) *homomorphism* from a graph $G = (V, E)$ to a graph $H = (U, F)$ is a mapping $h \colon V \to U$ such that for each $(i, j) \in E$ it also holds that $(h(i), h(j)) \in F$. To simplify notation, the homomorphism $h \colon V \to U$ will be denoted $h \colon G \to H$. An *endomorphism* is a homomorphism whose domain is equal to its codomain, i.e., $h \colon G \to G$.

An *isomorphism* is a bijective homomorphism, i.e., a mapping $h \colon G \to H$ such that $(i, j) \in E$ if and only if $(h(i), h(j)) \in F$. We write $G \simeq H$ if there exists an isomorphism from $G$ to $H$; such graphs $G$ and $H$ are called isomorphic. A *subgraph isomorphism* $G \to H$ is an isomorphism between the graph $G$ and a subgraph of the graph $H$. A subgraph in $H$ that is isomorphic to $G$ is called an *occurrence* of $G$ in $H$.

An *automorphism* is both an endomorphism and an isomorphism, i.e., a mapping $h \colon G \to G$ such that $(i, j) \in E$ if and only if $(h(i), h(j)) \in E$. Note that every automorphism is a permutation. The set of all automorphisms of a graph $G$ can be defined as

$$\mathrm{Aut}(G) = \{a \in \Pi[n] \mid G \simeq a(G)\} \tag{1}$$

where $\Pi[P]$ denotes the set of all permutations of a set $P$ and $\Pi[n] \equiv \Pi[\{1, 2, \ldots, n\}]$. For example, the set of automorphisms of the graph $G$ in Fig. 1 can be denoted as $\{123456, 123465, 124356, 124365, 215634, 215643, 216534, 216543\}$, where, e.g., 215643 denotes an automorphism $h$ such that $h(1) = 2$, $h(2) = 1$, $h(3) = 5$, $h(4) = 6$, $h(5) = 4$, and $h(6) = 3$.

Given a (finite) set $S$, a family $\{P_1, P_2, \ldots, P_s\}$ of nonempty subsets of $S$ is a *partition* of $S$ if every element in $S$ is exactly in one of the subsets, i.e., $P_i \subseteq S$ and $P_i \neq \emptyset$, where $1 \leq i \leq s$, $\bigcup_{1 \leq i < s} P_i = S$, and $P_i \cap P_j = \emptyset$ for all $1 \leq i, j \leq s$ with $i \neq j$. When the partition $\{P_1, P_2, \ldots, P_s\}$ is given explicitly, we usually use $\{i \in P_1 \mid i \in P_2 \mid \ldots \mid i \in P_s\}$ as a short form, e.g., $\{\{1, 2\}, \{3\}, \{4\}\}$ is shortened to $\{1, 2 \mid 3 \mid 4\}$. In what follows, the order of the sets in a partition is often important. To denote such an *ordered partition*, we use the form $\langle i \in P_1 \mid i \in P_2 \mid \ldots \mid i \in P_s \rangle$, e.g., $\langle 1, 2 \mid 3 \mid 4 \rangle$.

## III. Motivation

Given a pattern graph and a host graph, the goal of the *subgraph isomorphism problem* is to find all (or at least one, depending on the definition) occurrences of the pattern graph in the host graph, i.e., the subgraphs of the host graph that are isomorphic to the pattern graph.

Unfortunately, the decision version of the subgraph isomorphism problem is $NP$-complete [23], while its counting version is $\#P$-complete, since the counting version of the clique problem is $\#P$-complete [24]. Furthermore, not only that it is unlikely that a polynomial-time algorithm exists, but so far no exponential-time algorithm with a lower bound better than what can be achieved by the naive enumeration of the occurrences has been devised [25]. Most algorithms are therefore based on a backtracking approach (e.g., [26], [27]). In particular, the vertices of the pattern graph are matched with those of the host graph until a match is found, using the vertex neighborhood information to prune the search space.

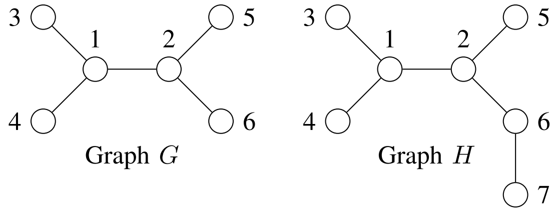

Fig. 1. A sample pattern graph $G$ and host graph $H$.

Let us assume that a given pattern graph $G$ has $m$ nontrivial automorphisms. When searching for the occurrences of $G$ in a given host graph $H$, a search algorithm that establishes all valid matches between $G$ and subgraphs of $H$ discovers *each* of $G$'s occurrences $m$ times, because the vertices of $G$ can be isomorphically mapped to the vertices of each of $G$'s occurrences in $m$ different ways. As an example, consider the pattern graph $G$ and the host graph $H$ in Fig. 1. An algorithm that is unaware of the eight automorphisms of $G$ will find the single occurrence of $G$ in $H$ eight times. In other words, it will establish eight subgraph isomorphisms $h \colon G \to H$:

| $i$ | $h_i(1)$ | $h_i(2)$ | $h_i(3)$ | $h_i(4)$ | $h_i(5)$ | $h_i(6)$ |
|---|---|---|---|---|---|---|
| 1 | 1 | 2 | 3 | 4 | 5 | 6 |
| 2 | 1 | 2 | 3 | 4 | 6 | 5 |
| 3 | 1 | 2 | 4 | 3 | 5 | 6 |
| 4 | 1 | 2 | 4 | 3 | 6 | 5 |
| 5 | 2 | 1 | 5 | 6 | 3 | 4 |
| 6 | 2 | 1 | 5 | 6 | 4 | 3 |
| 7 | 2 | 1 | 6 | 5 | 3 | 4 |
| 8 | 2 | 1 | 6 | 5 | 4 | 3 |

However, by imposing the constraints $h(1) < h(2)$, $h(3) < h(4)$, and $h(5) < h(6)$ while performing the exhaustive subgraph isomorphism search, the sole occurrence of the graph $G$ in the graph $H$ will be discovered exactly once, and this *regardless of the numbering of H's vertices*.

Motivated by this observation, we recently introduced the so-called *exploratory equivalence* [9], on the basis of which such constraints can be defined and safely imposed during the subgraph isomorphism search. Exploratory equivalence is an automorphisms-based equivalence relation on the vertices of a given graph; an *exploratory equivalent partition* (EE partition) is a partition of the graph vertex set into a set of exploratory equivalence classes. Every EE partition can be directly translated into a safe set of search constraints, where 'safe' means that the constraints never lead the algorithm to miss any occurrence, regardless of the numbering of the host graph vertices. In particular, an EE partition $\{u_{11}, \ldots, u_{1k_1} \mid u_{21}, \ldots, u_{2k_2} \mid \ldots \mid u_{s1}, \ldots, u_{sk_s}\}$ (the vertices $u_{11}$, …, $u_{1k_1}$ constitute the first equivalence class, etc.) gives rise to the constraint set $\{h(u_{11}) < \ldots < h(u_{1k_1})$, $h(u_{21}) < \ldots < h(u_{2k_2})$, …, $h(u_{s1}) < \ldots < h(u_{sk_s})\}$. In the example of Fig. 1, one of the EE partitions of the graph $G$ is $\{1, 2 \mid 3, 4 \mid 5, 6\}$, and it leads to the above-mentioned set of constraints.

If a graph $G$ has nontrivial automorphisms, it has several nontrivial EE partitions. All of them lead to a safe set of search constraints. However, of particular interest is one that gives rise to the set of constraints that results in the largest speedup when searching for the occurrences of $G$. Such an EE partition is called a *maximum EE partition* ('a' instead of 'the' because there can be several of them), and the problem of finding such a partition for a given graph is denoted MAXEXPLOREQ. In our previous paper [9], we defined the problem and showed two algorithms, both of which are polynomial only in the number of automorphisms, rather than in the number of graph vertices. Besides that, the algorithms fail to find a maximum EE partition for all graphs, although counterexamples appear to be very rare; for example, the second algorithm finds a maximum EE partition for all but 2 graphs out of 261080 connected unlabeled undirected 9-vertex graphs.

## IV. PROBLEM DESCRIPTION

Since the MAXEXPLOREQ problem is defined and thoroughly explained in our FedCSIS 2014 paper [9], we provide a relatively brief review of the main definitions.

*Definition 1 (cover):* A set of permutations $A \subseteq \Pi[n]$ *covers* a set $P \subseteq \{1, \ldots, n\}$ if for every permutation $\sigma$ of the set $P$ there exists a permutation $a \in A$ such that $a(i) = \sigma(i)$ for all $i \in P$:

$$\text{cover}(A, P) \equiv \forall \sigma \in \Pi[P]\ \exists a \in A\ \forall i \in P\colon \sigma(i) = a(i). \quad (2)$$

For example, the set Aut($G$) for the graph $G$ of Fig. 1 covers the set $\{3, 5\}$, since it contains both an automorphism for which $a(3) = 3$ and $a(5) = 5$ (12**3**4**5**6) and an automorphism for which $a(3) = 5$ and $a(5) = 3$ (21**5**6**3**4). For the graph $G'$ of Fig. 2, the set Aut($G'$) covers the set $\{1, 3, 5\}$, since it contains an automorphism for each of the 3! permutations of the set $\{1, 3, 5\}$ (**1**2**3**4**5**6 for the permutation 135, **1**6**5**4**3**2 for the permutation 153, **3**2**1**6**5**4 for the permutation 315, etc.)

*Definition 2 (stabilizer):* The *stabilizer* of a set $A \subseteq \Pi[n]$ with respect to a set $P \subseteq \{1, \ldots, n\}$ is the set of all permutations in $A$ that fix all elements of $P$:

$$\text{Stab}(A, P) = \{a \in A \mid \forall i \in P\colon a(i) = i\}. \quad (3)$$

For the graph $G$ of Fig. 1, we have Stab(Aut($G$), $\{1, 2\}$) $=$ {**12**3456, **12**3465, **12**4356, **12**4365}, Stab(Aut($G$), $\{3, 4\}$) $=$ {12**34**56, 12**34**65}, and Stab(Aut($G$), $\{3, 5\}$) $=$ {12**3**4**5**6}.

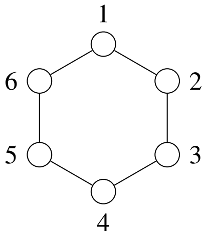

Fig. 2. A sample graph $G'$.

*Definition 3 (EE ordered partition):* For a given graph $G = (V, E)$, an ordered partition $\langle P_1, P_2, \ldots, P_s\rangle$ of $V$ is *exploratory equivalent* if for all $i \in \{1, \ldots, s\}$ we have

$$\text{cover}(A_{i-1}, P_i) \text{ and } A_i = \text{Stab}(A_{i-1}, P_i),$$

where $A_0 = \text{Aut}(G)$.

For the graph $G$ of Fig. 1, one of the EE ordered partitions is $\langle 1, 2 \mid 3, 4 \mid 5, 6\rangle$; the corresponding stabilizers are $A_1 = \{123456, 123465, 124356, 124365\}$, $A_2 = \{123456, 123465\}$, and $A_3 = \{123456\}$.

*Definition 4 (EE partition):* For a given graph $G = (V, E)$, a partition $\langle P_1, P_2, \ldots, P_s\rangle$ of $V$ is *exploratory equivalent* if there exists an exploratory equivalent ordered partition $\langle P_{i_1}, P_{i_2}, \ldots, P_{i_s}\rangle$ for a set of distinct indices $i_j \in \{1, \ldots, s\}$.

Figure 3 shows all EE partitions of the graph $G$ in Fig. 1.

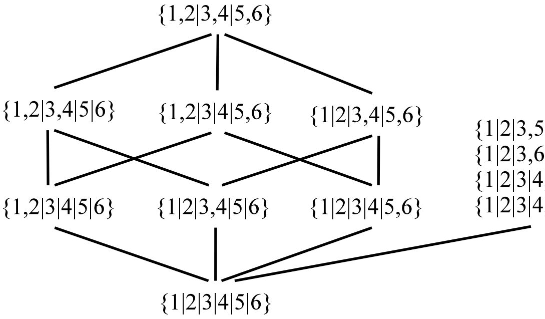

Fig. 3. The Hasse diagram of all EE partitions of the graph $G$ of Fig. 1. (The four partitions on the right-hand side are actually four separate vertices in the diagram.)

As we mentioned in the introduction, an EE partition determines a set of subgraph isomorphism search constraints. For example, the EE partition $\{1 \mid 2 \mid 3, 4 \mid 5, 6\}$ determines the constraints $h(3) < h(4)$ and $h(5) < h(6)$, which can be safely used when searching for subgraph isomorphisms $h\colon G \to H$ in an arbitrary host graph $H$. Since an EE partition set with $k$ vertices represents $k!$ permutations of those vertices, the corresponding constraint reduces the number of discoveries of each occurrence of $G$ in $H$ by a factor of $k!$. The score of an EE partition can thus be defined as follows:

*Definition 5 (score of an EE partition):* The *score* of an EE partition $\{P_1, \ldots, P_s\}$ is $\prod_{i=1}^{s} |P_i|!$.

The goal of the MAXEXPLOREQ problem is to find a maximum EE partition, i.e., one with the highest score:

*Definition 6 (*MaxExploreq*):* Given a graph $G$, find an EE partition with the maximum score.

The sole maximum EE partition of the graph $G$ of Fig. 1 is $\{1, 2 \mid 3, 4 \mid 5, 6\}$, with the score of $2!\,2!\,2! = 8$. One of the two maximum EE partitions of the graph $G'$ of Fig. 2 $\{1, 3, 5 \mid 2 \mid 4 \mid 6\}$, with the score of $3!\,1!\,1!\,1! = 6$. The other is $\{2, 4, 6 \mid 1 \mid 3 \mid 5\}$. Note that $\{1, 3, 5 \mid 2, 4, 6\}$ is *not* an EE partition, since $\mathrm{Stab}(\mathrm{Aut}(G'), \{1, 3, 5\}) = \{123456\}$ and the resulting set of automorphisms covers only singletons.

For convenience, let us also define an exploratory equivalent set and exploratory equivalent vertices:

*Definition 7 (EE set):* For a graph $G = (V, E)$, a set $P \subseteq V$ is *exploratory equivalent* if there exists an EE partition that contains $P$.

For example, in the graph $G$ of Fig. 1, the sets $\{3, 5\}$, $\{5, 6\}$, and $\{3, 6\}$ are all exploratory equivalent. However, the set $\{3, 5, 6\}$ is not.

*Definition 8 (EE vertices):* Vertices $v_1$, …, $v_k$ are *exploratory equivalent* if the set $\{v_1, \ldots, v_k\}$ is exploratory equivalent.

We will now present an alternative interpretation of exploratory equivalence that will be used in some proofs. Let $V' = \{v_1, v_2, \ldots, v_k\} \subseteq V$ be a subset of vertices of an unlabeled graph $G = (V, E)$, and let $Z_1$, $Z_2$, …, $Z_k$ be mutually distinct labels. Let $G^j$ denote a copy of the graph $G$ in which the vertex $v_i$ (for $i \in \{1, \ldots, k\}$) is labeled $\sigma_j(Z_i)$, where $\sigma_j$ (for $j \in \{1, \ldots, k!\}$) represents the $j$-th permutation of the set $\{Z_1, \ldots, Z_k\}$. Now, the set $V'$ is exploratory equivalent if the graphs $G^1$, …, $G^{k!}$ are all mutually isomorphic. For instance, in the case of the graph $G'$ of Fig. 2, the set $\{1, 3, 5\}$ is exploratory equivalent because all 3! graphs in Fig. 4 are mutually isomorphic.

Let $\mathcal{P} = \langle P_1, P_2, \ldots, P_s\rangle$ with $P_i = \{v_{i1}, v_{i2}, \ldots, v_{ik_i}\}$ be an ordered partition of the vertex set of an unlabeled graph $G$, and let $Z_{11}$, $Z_{12}$, …, $Z_{1k_1}$, $Z_{21}$, $Z_{22}$, …, $Z_{2k_2}$, …, $Z_{s1}$, $Z_{s2}$, …, $Z_{sk_s}$ be mutually distinct labels that do not occur at any vertex in the graph $G$. Let $G^{r,j}$ $(1 \leq r \leq s)$ denote a copy of the graph $G$ in which the vertices $v_{i1}$, $v_{i2}$, …, $v_{ik_i}$ (for $i \in \{1, \ldots, r-1\}$) are labeled $Z_{i1}$, $Z_{i2}$, …, $Z_{ik_i}$, respectively, while the vertices $v_{r1}$, $v_{r2}$, …, $v_{rk_r}$ are labeled $\sigma_j(Z_{r1})$, $\sigma_j(Z_{r2})$, …, $\sigma_j(Z_{rk_r})$, respectively, where $\sigma_j$ (for $j \in \{1, \ldots, k_r!\}$) represents the $j$-th permutation of the set $\{Z_{r1}, \ldots, Z_{rk_r}\}$. Now, the partition $\mathcal{P}$ is exploratory equivalent if we have $G^{i,1} \simeq G^{i,2} \simeq \ldots \simeq G^{i,k_i!}$ for each $i \in \{1, \ldots, s\}$. For instance, in the case of the graph $G$ of Fig. 1, the ordered partition $\langle 1, 2 \mid 3, 4 \mid 5, 6\rangle$ is exploratory equivalent because we have $G^{1,1} \simeq G^{1,2}$, $G^{2,1} \simeq G^{2,2}$, and $G^{3,1} \simeq G^{3,2}$ for the graphs of Fig. 5.

Alternatively, the partition $\mathcal{P} = \langle P_1, P_2, \ldots, P_s\rangle$ is exploratory equivalent if the set $P_1$ is exploratory equivalent and if for each $i \in \{2, \ldots, s\}$, the set $P_i$ remains exploratory equivalent after the labels of the vertices of the sets $P_j$ (for all $1 \leq j < i$) have been fixed to $Z_{j1}$, …, $Z_{jk_j}$.

## V. The Complexity of MaxExploreq

In this section, we show that MaxExploreq is at least as hard as the graph isomorphism problem. We have the following theorem:

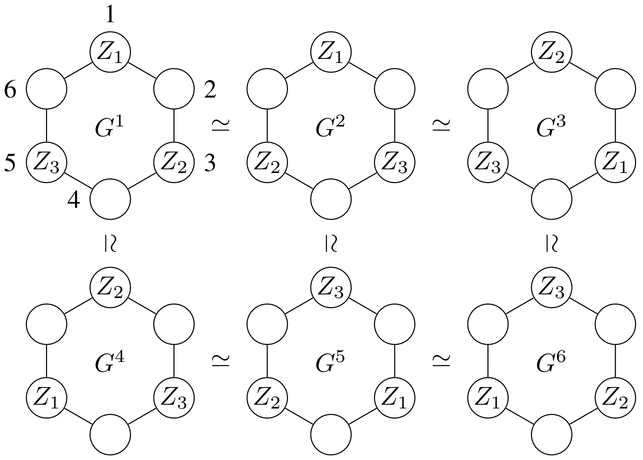

Fig. 4. These 6 isomorphic graphs prove that the set $\{1, 3, 5\}$ is exploratory equivalent for the graph $G'$ of Fig. 2.

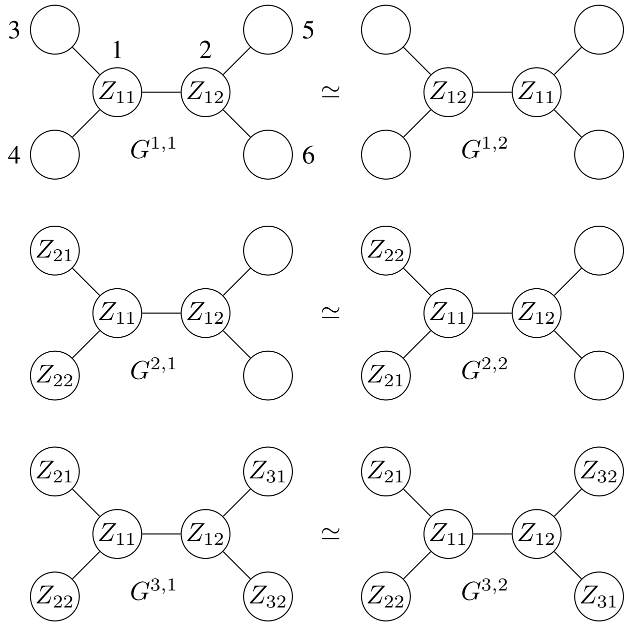

Fig. 5. The three pairs of isomorphic graphs proving that the ordered partition $\langle\{1, 2\}, \{3, 4\}, \{5, 6\}\rangle$ is exploratory equivalent for the graph $G$ of Fig. 1.

*Theorem 1:* The MaxExploreq problem is $GI$-hard.

*Proof:* The theorem can be proved by a polynomial-time reduction of the graph isomorphism problem to the MaxExploreq problem. Let $G$ and $H$ be graphs for which one would like to determine whether they are isomorphic. Let us form a graph $G'$ by adding a vertex $u_0$ to the graph $G$ and connecting it with all the vertices of $G$. In an analogous way, let us form a graph $H'$ from the graph $H$ (we call the added vertex $v_0$). Now we solve the MaxExploreq problem on the graph $G' \cup H'$, i.e., on the disjoint union of the graphs $G'$ and $H'$. We claim that the graphs $G$ and $H$ are isomorphic if and only if any maximum EE partition contains a set with at least one vertex from $G'$ and at least one vertex from $H'$. Let us prove this.

(If) If a maximum EE partition for the graph $G' \cup H'$ contains a set with vertices $u \in V(G')$ and $v \in V(H')$, then there exists an automorphism that maps $u$ to $v$ and $v$ to $u$. Since the graphs $G'$ and $H'$ are both connected, such an automorphism can exist only if the graphs are isomorphic. This implies that the graphs $G$ and $H$ are isomorphic, too.

(Only if) If the graphs $G$ are $H$ isomorphic, then an EE partition for the graph $G' \cup H'$ cannot be maximum unless it contains at least one set with at least one vertex from both $G'$ and $H'$. Indeed, in an EE partition that contains no such set, one can always join the singletons $\{u_0\}$ and $\{v_0\}$ into an EE set $\{u_0, v_0\}$ and thus obtain an EE partition with a higher score, since the vertices $u_0$ and $v_0$, owing to their degree, can only be exploratory equivalent with each other (and they are, if the graphs $G'$ and $H'$, and of course also $G$ and $H$, are isomorphic). ■

Because of its $GI$-hardness, the MAXEXPLOREQ problem for general graphs is unlikely to be solvable in polynomial time. In the rest of this paper, we therefore restrict the problem to trees.

## VI. SOLVING THE MAXEXPLOREQ PROBLEM ON TREES

### A. Prerequisites

Let a graph $T = (V, E)$ be an arbitrary tree. For the sake of simplicity, let us assume that the tree is unlabeled; the algorithm could be fairly straightforwardly generalized to labeled trees. Since $T$ is an arbitrary unrooted tree, we will only speak of *leaves* (vertices with degree 1) but not of the root, parents, and children. Before showing an algorithm for finding a maximum EE partition on $T$, let us present some auxiliary definitions and claims.

*Definition 9 (distance):* The *distance* between vertices $u$ and $v$ in a tree (denoted $d(u, v)$) is the number of edges on the (unique) path from $u$ to $v$.

*Definition 10 (neighborhood):* In a tree, the *neighborhood* of a vertex $u$ at a distance $d$ is the subtree composed of all vertices $v$ such that $d(u, v) \leq d$.

*Definition 11 (eccentricity, center):* The *eccentricity* of a vertex $u$ in a tree is the maximum distance between $u$ and any other vertex, i.e., $e(u) = \max_{v \in V} d(u, v)$. A *center* of the tree is a vertex with minimum eccentricity.

*Theorem 2:* Any tree has either one or two centers. If it has two, they are adjacent.

*Proof:* Let us focus on a longest path (several such paths are possible) in the tree, and let $u$ and $v$ be the two extreme vertices on that path. The distance between $u$ and $v$ is therefore the greatest possible in the tree. The eccentricity of any vertex $w$ on the path is $e(w) = \max\{d(u, w), d(v, w)\}$; it obviously cannot be lower, but if it were greater, we could form a strictly longer path in the tree (passing through $w$, one of $u$ and $v$, and the most remote vertex from $w$), contradicting our assumption. Any center $c$ of the tree has to be located somewhere on the path from $u$ to $v$, for if we had, say, a putative center $c'$ outside of that path, then $e(c') = \max\{d(u, c'), d(v, c')\}$ would be greater than $e(c) = \max\{d(u, c), d(v, c)\}$. Since a center is a vertex with the lowest eccentricity, we have only two possibilities:

- If $d(u, v)$ is odd, the tree has exactly one center $c$, and it is located halfway between $u$ and $w$, such that $d(c, u) = d(c, v)$.
- If $d(u, v)$ is even, the tree has two adjacent centers $c_1$ and $c_2$ such that $d(c_1, u) = d(c_2, v)$.

■

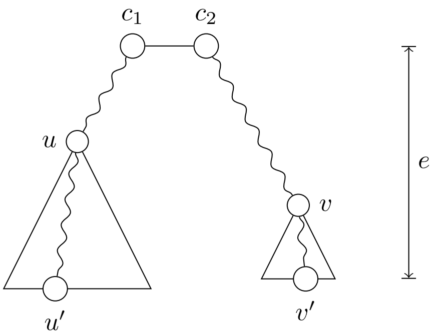

Fig. 6. An illustration of the proof of Lemma 3.

*Lemma 3:* Let $c_1$ and $c_2$ be the center(s) of the tree (by Theorem 2, we may have $c_1 = c_2$). If vertices $u$ and $v$ are exploratory equivalent, we have $d(u, c_1) = d(v, c_2)$.

*Proof:* Let us assume that $d(u, c_1) \neq d(v, c_2)$. Without loss of generality, we may further assume that $d(u, c_1) < d(v, c_2)$. Consider Fig. 6. Let $u'$ be a leaf such that $d(c_1, u') = e(c_1) = e(c_2) = e$ (since $c_1$ is a center, such a leaf must exist). Likewise, let $v'$ be a leaf such that $d(c_2, v') = e$. Since $d(u, c_1) < d(v, c_2)$, we have $d(u, u') > d(v, v')$. This means that there is a leaf at the distance of $d(u, u')$ from $u$, but there cannot be any leaf at the same distance from $v$. The neighborhoods of $u$ and $v$ at the distance $d(u, u')$ are therefore non-isomorphic, which implies that the vertices $u$ and $v$ cannot be automorphically mapped to each other. Consequently, the vertices $u$ and $v$ are not exploratory equivalent. ■

*Definition 12 (centrifugal subtree):* Let $u$ be a vertex connected with vertices $v_1, \ldots, v_k$, and let $v_i$, for some $i \in \{1, \ldots, k\}$, be the sole vertex on the path from $u$ to the center(s) of the tree. The *centrifugal subtree* of the vertex $u$ is the tree composed of the vertex $u$ and of all vertices on the paths starting at $u$, passing through $v_1, \ldots, v_{i-1}, v_{i+1}, \ldots, v_k$, respectively, and finishing at leaves.

Informally, the centrifugal tree of a given vertex $u$ contains the vertex $u$ and all vertices 'below' it in the direction away from the center(s). The triangles in Fig. 6 represent the centrifugal subtrees of the vertices $u$ and $v$.

*Lemma 4:* If vertices $u$ and $v$ of the tree $T$ are exploratory equivalent, they have isomorphic centrifugal subtrees.

*Proof:* If the centrifugal subtrees are not isomorphic, the vertices $u$ and $v$ cannot be automorphically mapped to each other, since there exists some distance $d$ at which their neighborhoods are not isomorphic. Therefore, the vertices cannot be exploratory equivalent. ■

*Lemma 5:* If vertices $v_1, \ldots, v_k$ of the tree $T$ are connected to the same vertex and all their centrifugal subtrees are mutually disjoint and isomorphic, then the vertices $v_1$, …, $v_k$ are exploratory equivalent.

*Proof:* It is easy to see that the vertices $v_1$, …, $v_k$ (and with them the entire corresponding centrifugal subtrees) can be automorphically mapped to each other in all $k!$ possible ways, which means that they are exploratory equivalent. ■

*Lemma 6:* Let the tree have two distinct centers, $c_1$ and $c_2$. If the centrifugal subtrees of $c_1$ and $c_2$ are isomorphic, then the centers $c_1$ and $c_2$ are exploratory equivalent.

*Proof:* Here, the same argument applies as in the proof of Lemma 5. ■

*Lemma 7:* Let $\mathcal{P} = \langle P_1, \ldots, P_s \rangle$ be an ordered partition of the vertex set $V$ such that the following holds:

- The set $P_1$ is exploratory equivalent in the sense of Lemma 5 or Lemma 6.
- Every set $P_i$ with $i > 1$ is exploratory equivalent in the sense of Lemma 5.
- If the vertices of $P_j$, together with their common neighbor, all belong to the centrifugal subtree of some vertex $v \in P_i$, then $j > i$.

If all the above conditions are met, the partition $\mathcal{P}$ is exploratory equivalent.

*Proof:* By Lemmas 5 and 6, the set $P_1 = \{u_{11}, \ldots, u_{1k_1}\}$ is exploratory equivalent. Let us fix the labels of $u_{11}$, …, $u_{1k_1}$ to $Z_{11}$, …, $Z_{1k_1}$. Is the set $P_2 = \{u_{21}, \ldots, u_{2k_1}\}$ still exploratory equivalent? Yes, owing to the third condition in the lemma, it holds that for each vertex $u_{1i}$ ($i \in \{1, \ldots, k_1\}$) the centrifugal subtrees of the vertices $u_{21}, \ldots, u_{2k_2}$ are either disjoint from the centrifugal tree of $u_{1i}$ or completely contained within it. In both cases, the vertices $u_{21}$, …, $u_{2k_2}$ (and with them the entire centrifugal subtrees) can be automorphically mapped to each other in all $k_2!$ possible ways, even if the vertices $u_{11}$, …, $u_{1k_1}$ have distinct unique labels. The second case is illustrated in Fig. 7. Since the same reasoning applies all the way to the set $P_s$, we can conclude that the partition is indeed exploratory equivalent. ■

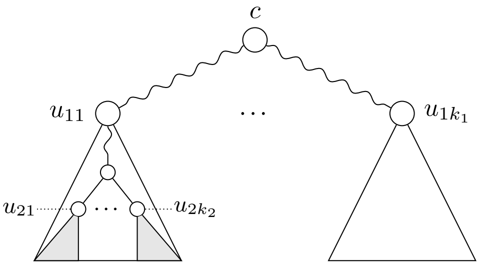

Fig. 7. An illustration of the second case in the proof of Lemma 7. The subtrees represented by the two large triangles are isomorphic, and so are those represented by the two small ones.

For the tree of Fig. 8, an ordered EE partition in the sense of Lemma 7 is $\langle 17 \mid 15, 16 \mid 11 \mid 12 \mid 13 \mid 14 \mid 1, 2, 3 \mid 4, 5 \mid 6, 7 \mid 8, 9, 10 \rangle$. Non-singleton sets are represented by different colors.

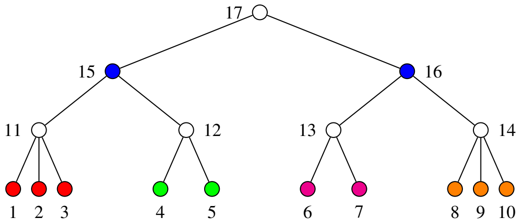

Fig. 8. A sample tree.

*Lemma 8:* If $u$ and $v$ are EE vertices at a distance greater than 2, then there also exist EE vertices $u'$ and $v'$ at a distance of at most 2.

*Proof:* Let us first assume that $d = d(u, v)$ is even. Let $w$ be the sole vertex such that $d(u, w) = d(v, w) = d/2$. Now let $u'$ and $v'$ be the neighbors of $w$ on the paths from $w$ to $u$ and $w$ to $v$, respectively. The distance between $u'$ and $v'$ is therefore 2. We claim that the vertices $u'$ and $v'$ are exploratory equivalent if so are $u$ and $v$. Indeed! The automorphism that maps $u$ to $v$ and vice versa maps the entire centrifugal subtree of $u'$ to the centrifugal subtree of $v'$ and vice versa. In particular, $u'$ is mapped to $v'$ and vice versa, which means that $u'$ and $v'$ are exploratory equivalent, too. (However, note that the sets $\{u, v\}$ and $\{u', v'\}$ cannot *both* be part of the same EE partition!)

If $d(u, v)$ is odd, then it follows from Lemma 3 that the tree $T$ has two distinct centers, $c_1$ and $c_2$, and that $d(u, c_1) = d(v, c_2)$. An automorphism that maps $u$ to $v$ (and $v$ to $u$) also maps $c_1$ to $c_2$ (and $c_2$ to $c_1$), implying that the vertices $c_1$ and $c_2$ are exploratory equivalent, too. ■

*Lemma 9:* If $u_1$, …, $u_k$ are EE vertices, then there also exist EE vertices $u'_1$, …, $u'_k$ such that $d(u_i, u_j) \leq 2$ for all distinct pairs $i, j \in \{1, \ldots, k\}$. Furthermore, if $k > 2$, then $d(u_i, u_j) = 2$ for all distinct pairs $i, j \in \{1, \ldots, k\}$.

*Proof:* The first part of the lemma is a straightforward generalization of Lemma 8. As for the second part, observe that if distinct vertices $u$, $v$, and $w$ are exploratory equivalent, we cannot have $d(u, v) = d(v, w) = 1$ and $d(u, w) = 2$; such vertices would then form a 3-vertex line subgraph $u - v - w$, which can never have more than 2 automorphisms, but a set of three vertices can be exploratory equivalent only if at least 3! automorphisms exist. The case $d(u, v) = d(u, w) = d(v, w) = 1$ is clearly impossible in a tree, and so $d(u, v) = d(u, w) = d(v, w) = 2$ remains as the only possibility. ■

*Lemma 10:* There exists a maximum EE partition $\mathcal{P} = \{P_1, \ldots, P_s\}$ of the tree $T$ such that for each $i \in \{1, \ldots, s\}$ the distance between each pair of vertices in $P_i$ is at most 2.

*Proof:* Let $\mathcal{R} = \{R_1, \ldots, R_s\}$ be a maximum EE partition such that a set $R \in \mathcal{R}$ does not conform to the conditions in the lemma. By Lemma 9, the set $R$ can be replaced by the corresponding EE set $R'$ of vertices at a distance of at most 2. We now claim that the partition $\mathcal{R}' = \mathcal{R} \setminus \{R\} \cup \{R'\}$ is also exploratory equivalent. To see this, consider the operation performed in the proof of Lemma 8. Let $v$ be the vertex such that $d(v, u_1) = \ldots = d(v, u_k)$. (If $k = 2$, such a vertex might not exist, but then we have $d(c_1, u_1) = d(c_2, u_2)$, and the same logic applies.) By replacing the EE set $R = \{u_1, \ldots, u_k\}$ with the EE set $R' = \{u'_1, \ldots, u'_k\}$ (where $u'_1, \ldots, u'_k$ are the neighbors of $v$ on the paths from $v$ to $u_1, \ldots, u_k$, respectively), the resulting partition remains exploratory equivalent, since an automorphism that maps $u_i$ to $u_j$ also maps the entire path from $v$ to $u_i$ to the path from $v$ to $u_j$ and since the selection of $R$ into an EE partition precludes the selection of any other set containing vertices on different paths from $v$ to $u_1, \ldots, u_k$. However, the opposite is not necessarily the case. While the choice of $R'$ does, of course, preclude the selection of $R$, it might not rule out everything 'between' $R'$ and $R$. For instance, in the example shown in Fig. 8, it would be unwise to select the EE set $R_1 = \{1, 8\}$ into an EE partition, since the most we could then possibly attain would be the partition $\{1, 8 \mid 2, 3 \mid 4, 5 \mid 6, 7 \mid 9, 10 \mid \text{singletons}\}$. However, if we instead choose the set $R'_1 = \{15, 16\}$, we can obtain the clearly better (and indeed maximum) partition $\{15, 16 \mid 1, 2, 3 \mid 4, 5 \mid 6, 7 \mid 8, 9, 10 \mid \text{singletons}\}$. ■

The above lemma tells us that when searching for a maximum EE partition, we may safely ignore any pairs of vertices at the distance greater than 2. This important fact is the basis for the algorithm we show below.

### *B. The algorithm*

We are now ready to present a polynomial-time algorithm that constructs a maximum EE partition for a given tree. The algorithm is shown as Alg. 1. At the beginning, the algorithm assigns the so-called *ornament* $*$ to each leaf of the given tree; all other vertices are assigned the ornament $\epsilon$. The algorithm then proceeds in a reverse breadth-first fashion: in each iteration, the vertices connected to the (current) leaves that have at most one $\epsilon$-ornamented neighbor receive their ornaments, constructed from the ornaments of their leaf neighbors. Simultaneously, the leaves are removed from the tree. The output of the algorithm is a partition of the vertex set of the original tree.

Figures 9 and 10 provide two examples for Alg. 1. The numbers beside the vertices indicate the order in which the ornaments are assigned to the vertices (of course, the order within each iteration is arbitrary), while the boxes show the ornaments. The vertices with the same non-white color belong to the same set in the returned partition. For the tree of Fig. 9, the algorithm thus produces the partition $\langle 9, 10 \mid 7, 8 \mid 5, 6 \mid 4 \mid 3 \mid 2 \mid 1\rangle$. The partition for the tree of Fig. 10 is $\langle 8 \mid 6, 7 \mid 1 \mid 5 \mid 4 \mid 3 \mid 2\rangle$.

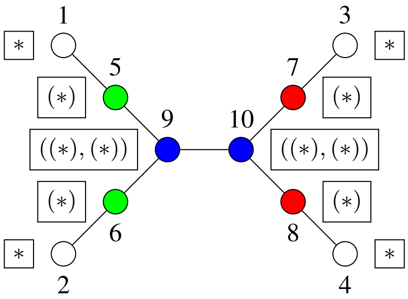

Fig. 9. The execution of Alg. 1 on a sample tree.

**Algorithm 1** An algorithm for solving the MAXEXPLOREQ problem on a given tree $T$.

```
function FINDMAXPARTITION($T = (V, E)$)
    for all $v \in V$ do $\mathrm{orn}(v) \leftarrow \epsilon$
    $L \leftarrow$ the set of leaves of $T$
    for all $v \in L$ do $\mathrm{orn}(v) \leftarrow *$
    $t \leftarrow 0$
    while $|V| > 2$ do
        $W = \{w \in V \mid (\exists v \in L\colon (w, v) \in E)$ and
            only one neighbor $w'$ of $w$ has $\mathrm{orn}(w') = \epsilon\}$
        for all $w \in W$ do
            $\langle r_1, \ldots, r_m\rangle \leftarrow$ the leaves connected to $w$,
                lexicographically sorted by their ornaments
            $\mathrm{orn}(w) \leftarrow (\mathrm{orn}(r_1), \ldots, \mathrm{orn}(r_m))$
            $R \leftarrow \{r_1, \ldots, r_m\}$
            while $R \neq \emptyset$ do
                $r \leftarrow$ any vertex from $R$
                $t \leftarrow t + 1$
                $P_t \leftarrow \{r' \in R \mid \mathrm{orn}(r') = \mathrm{orn}(r)\}$
                $R \leftarrow R \setminus P_t$
                remove each vertex in $P_t$ from $T$
        $L \leftarrow$ the set of leaves of $T$
    if $|V| = 1$ then return $\langle V, P_t, P_{t-1}, \ldots, P_1\rangle$
    else
        $\{u, v\} \leftarrow V$
        if $\mathrm{orn}(u) = \mathrm{orn}(v)$ then return $\langle V, P_t, \ldots, P_1\rangle$
        else return $\langle \{u\}, \{v\}, P_t, \ldots, P_1\rangle$
```

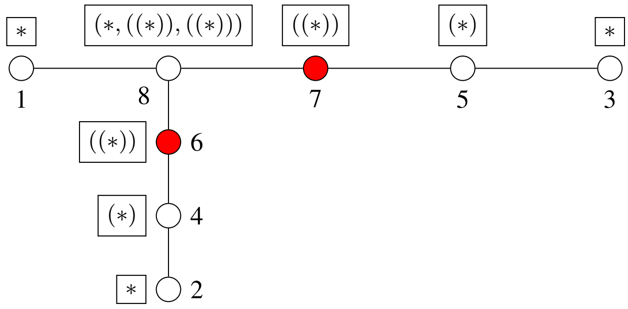

Fig. 10. The execution of Alg. 1 on a sample tree.

*Lemma 11:* In each iteration, the algorithm removes from the current tree all vertices that are farthest from the center(s) of the current tree.

*Proof:* In each iteration, the algorithm removes all leaves except those whose neighbor is connected to at least two non-leaves. However, such leaves cannot be at the greatest distance from the center(s). ■

*Corollary 12:* After each iteration, the center(s) of the resulting tree are coincident with those of the original tree.

*Corollary 13:* The (at most two) vertices that remain in the set $V$ after the main loop of the algorithm are exactly the center(s) of the tree.

*Lemma 14:* At the end of the algorithm, two vertices have equal ornaments if and only if their centrifugal subtrees are isomorphic.

*Proof:* Since the algorithm proceeds from the leaves towards the centers, it builds the ornaments of individual vertices from the ornaments of their centrifugal subtrees. By construction, the ornament of a vertex reflects the structure of its centrifugal subtree. The lexicographical ordering ensures that two vertices with isomorphic centrifugal subtrees also have equal ornaments. As for the 'only if' part, consider that vertices with non-isomorphic centrifugal subtrees cannot possibly have equal ornaments; any valid ornament takes the form $(s_1, s_2, \ldots, s_k)$, where $s_1, \ldots, s_k$ are individual subornaments, and there is exactly one way to split a valid ornament into valid constituents. Therefore, it cannot happen that two non-isomorphic subtrees 'accidentally' receive equal ornaments. ■

*Lemma 15:* For a given tree, the ordered partition produced by the algorithm is exploratory equivalent.

*Proof:* First, the properties from Lemmas 5, 6, and 14 ensure that each set from the EE partition is *individually* exploratory equivalent. Indeed, the algorithm adds a non-singleton set to the partition only if all vertices from that set have the same neighbor and isomorphic centrifugal subtrees. Second, does the returned ordered partition $\langle P_s, P_{s-1}, \ldots, P_1 \rangle$ (where $s = t + 1$ or $t + 2$, depending on the situation after the main loop) conform to the conditions in Lemma 7, which guarantee 'EE-ness'? It does! The first two conditions are clearly met; the two centers, if they exist and if they are exploratory equivalent, constitute the set $P_s$. As for the third condition, consider that the algorithm 'peels' the tree from the leaves towards the centers and that the EE sets are stacked into the partition in the reverse order. These facts ensure that the centrifugal subtree of a vertex in $P_j$ can be a subtree of the centrifugal subtree of a vertex in $P_i$ only if $j > i$. ■

*Lemma 16:* The EE partition produced by the algorithm contains all possible EE sets $P = \{u_1, \ldots, u_k\}$ such that for each distinct pair $i, j \in \{1, \ldots, k\}$ we have $d(u_i, u_j) \leq 2$.

*Proof:* By Lemma 3, the vertices $\{u_1, \ldots, u_k\}$ of an EE set all have the same distance from the center. If the distance between each pair of them is at most 2, then they must be connected with the same vertex or, if $k = 2$, the vertices $u_1$ and $u_2$ can also be the two centers of the tree. By Lemma 3, EE vertices are always located at the same distance from the tree center(s); by Lemma 4, they must also have isomorphic centrifugal subtrees. The algorithm produces *all* such sets that fulfill these conditions: (1) it considers all sets of vertices that have the pairwise distance of exactly 2 and are located at the same distance from the tree center(s); (2) if the tree has two centers, the algorithm will, at the very end, certainly check whether they have the same ornaments; (3) the algorithm adds each such set of vertices to the output partition provided that the vertices have isomorphic centrifugal subtrees. ■

*Theorem 17:* For a given tree, Alg. 1 produces a maximum exploratory equivalent (ordered) partition.

*Proof:* By Lemma 15, the partition is exploratory equivalent. By Lemma 10, every tree has a *maximum* EE partition such that all pairwise distances in each EE set are at most 2. Since, by Lemma 16, the algorithm constructs an EE partition out of *all* such EE sets in the input tree, and since each of these sets contains as many vertices as possible (owing to line 17 in Alg. 1), the output EE partition certainly has the maximum score. ■

We have just proved that the algorithm indeed solves the MAXEXPLOREQ problem for trees. To get an estimate on the algorithm's complexity, we proceed as follows. For each vertex of the tree, one has to sort the signatures of its children (the neighbors of that vertex in its centrifugal subtree). Each vertex has $O(n)$ children, and the length of each ornament is $O(n)$, giving $O(n^2 \log n)$ to sort the signatures of the children of each vertex. Since there are $O(n)$ vertices, the total complexity of the algorithm is $O(n^3 \log n)$. We have the following theorem:

*Theorem 18:* Algorithm 1 is a polynomial-time algorithm for tree graphs.

## VII. MAXEXPLOREQ ON SMALL TREES

In order to give us some insight into the problem, we performed a small empirical study of MAXEXPLOREQ on the set of small trees. This analysis will show us how the symmetries (that we can detect and exploit with MAXEXPLOREQ) are present in the studied set of trees.

Since trees are a ubiquitous structure, there are a lot of applications that can benefit from the symmetries found with our algorithm. An application that directly relates to the set of small trees is graphlet counting. In [28], the authors present a method for counting graphlets by exploiting many symmetries of small graphs (up to 5 nodes). Their method is currently considered one of the best, and with the use of MAXEXPLOREQ some of those symmetries could also be used to count larger graphlets much faster than with the straightforward approach.

For the analysis of this set of trees, we generated all nonisomorphic unlabeled trees of sizes 2 to 20 (let us call the set $T_2^{20}$) and computed MAXEXPLOREQ on every generated tree. Table I gives the number of trees for each size; in parentheses, we give the number of trees that have only the trivial automorphism, i.e., all sets in the MAXEXPLOREQ partition are singletons. Figure 11 shows the distribution of MAXEXPLOREQ score in $T_2^{20}$. This histogram shows that maximum EE partitions are non-trivial in a vast majority of trees.

To view the potential of MAXEXPLOREQ in more detail, let us examine trees of different sizes separately. For each separate set, we computed the median MAXEXPLOREQ score. The resulting chart is shown in Fig. 12. From this chart, we can see the potential speedup of at least half of the trees in the set of all trees with the same size. For example, for the trees of size 15, half of the trees have the potential speedup of 12, and for larger trees the median value is even larger, implying an almost exponential growth of the median value.

The two charts shown above demonstrate features of the MAXEXPLOREQ score, but they do not show the structure of individual partitions in any way. To show a feature of the MAXEXPLOREQ partitions, we measured the frequencies of the largest set in the partition (for each tree in $T_2^{20}$). Figure 13 shows the frequencies of these sets. In this histogram, we can see that most of the partitions are composed of pairs and triplets; the frequency of other partitions drops exponentially.

TABLE I. NUMBER OF NONISOMORPHIC TREES OF A SPECIFIED SIZE. IN PARENTHESES, THE NUMBER OF TREES WITHOUT AUTOMORPHISMS IS GIVEN.

## VIII. EXPLORATORY EQUIVALENCE AND THE SUBGRAPH ISOMORPHISM PROBLEM

We motivated exploratory equivalence by its application to the subgraph isomorphism problem. In this section, we will establish the relationship between these two concepts in more depth. First, note that there is a bijection between the set of automorphisms of a pattern graph $G$ and the set of isomorphisms between $G$ and each occurrence of $G$ in an arbitrary host graph $H$:

*Lemma 19:* If $G'$ is an occurrence of a graph $G$ in a graph $H$, then for each automorphism of $G$ there exists an isomorphism $G \to G'$, and vice versa.

*Proof:* A subgraph isomorphism between the graphs $G$ and $H$ is an isomorphism between two copies of the graph $G$ ($G$ and $G'$ in our case). An automorphism of $G$ can be interpreted in exactly the same way: as an isomorphism between two copies of $G$. ■

*Lemma 20:* Let $G = (V, E)$ be a pattern graph, and let $G'$ be its occurrence in a host graph $H$. If a set $\{v_1, v_2, \ldots, v_k\} \subseteq V$ is exploratory equivalent, then there exists an isomorphism $h' \colon G \to G'$ such that $h'(v_1) < h'(v_2) < \ldots < h'(v_k)$.

*Proof:* Without loss of generality, we may assume that the graph $G'$ consists of the vertices $u_1, u_2, \ldots, u_k$ such that $u_1 < u_2 < \ldots < u_k$. Let $h_0 \colon G \to G'$ be an isomorphism such that $h_0(v_i) = u_{\sigma(i)}$ (for each $i \in \{1, \ldots, k\}$), where $\sigma$ is some permutation of the set $\{1, \ldots, k\}$. Since the set $\{v_1, v_2, \ldots,$

$v_k\}$ is exploratory equivalent, there exists an automorphism of $G$ for each of the $k!$ permutations of the set. One of those automorphisms (e.g., $h$) has the property that $h(v_i) = v_{\sigma^{-1}(i)}$ for each $i \in \{1, \ldots, k\}$. Now, let us define the isomorphism $h' = h_0 \circ h$. For each $i \in \{1, \ldots, k\}$, we have $h'(v_i) = h_0(h(v_i)) = h_0(v_{\sigma^{-1}(i)}) = u_i$ and hence $h'(v_1) < h'(v_2) < \ldots < h'(v_k)$. ∎

*Theorem 21:* Let $G$ be a pattern graph, and let $G'$ be its occurrence in a host graph $H$. If $\mathcal{P} = \langle P_1, \ldots, P_s\rangle$ (where $P_i = \{v_{i1}, \ldots, v_{ik_i}\}$ for $i \in \{1, \ldots, s\}$) is an EE ordered partition, then there exists an isomorphism $h' \colon G \to G'$ such that $h'(v_{i1}) < h'(v_{i2}) < \ldots < h'(v_{ik_i})$ for all $i \in \{1, \ldots, s\}$.

*Proof:* Since $P_1 = \{v_{11}, \ldots, v_{1k_1}\}$ is an EE set, Lemma 20 ensures the existence of an isomorphism $h_1 \colon G \to G'$ with the property $h_1(v_{11}) < h_1(v_{12}) < \ldots < h_1(v_{1k_1})$. Now, the fact that $\mathcal{P}$ is an EE ordered partition implies that the set $P_2$ remains exploratory equivalent even if we assign unique labels to the vertices in $P_1$. In other words, even if the set of all possible isomorphisms $h \colon G \to G'$ is restricted to those that satisfy $h(v_{11}) < h(v_{12}) < \ldots < h(v_{1k_1})$, there will still exist an isomorphism $h_2 \colon G \to H$ such that $h_2(v_{21}) < h_2(v_{22}) < \ldots < h_2(v_{2k_2})$ (in addition to $h_2(v_{11}) < \ldots < h_2(v_{1k_1})$). The same reasoning applies for $P_3$, $P_4$, etc., up to $P_s$. Therefore, there exists an automorphism $h'$ such that $h'(u_{i1}) < \ldots < h'(u_{ik_i})$ for all $i \in \{1, \ldots, s\}$. ∎

From Theorem 21, it follows that if $\mathcal{P} = \{P_1, \ldots, P_s\}$ is an EE partition of a pattern graph $G$, we can safely impose the constraints $h(v_{i1}) < \ldots < h(v_{ik_i})$ (for each $i \in \{1, \ldots, s\}$) while searching for subgraph isomorphisms $h \colon G \to H$ in an arbitrary host graph $H$. However, these constraints are not necessarily optimal in the sense of redundancy elimination: they might not reduce the number of residual isomorphisms between $G$ and each of its occurrences in $H$ to 1. For example, consider the graphs $G$ and $H$ in Fig. 14. The set of automorphisms of $G$ (and simultaneously the set of $G$-to-$H$ isomorphisms) is $\{1234,\ 2341,\ 3412,\ 4123,\ 4321,\ 3214,\ 2143,\ 1432\}$, and the maximum EE partition is $\{1, 3 \mid 2, 4\}$, giving the set of constraints $\{h(1) < h(3),\ h(2) < h(4)\}$. However, these constraints still retain two isomorphisms, 1234 and 2143. (In fact, two isomorphisms would remain regardless of how the vertices of $H$ were numbered.) This means that in this case, the set of constraints resulting from the maximum EE partition does *not* eliminate the entire redundancy in subgraph isomorphism search and hence cannot be regarded as optimal. Incidentally, the optimal set of constraints is $\{h(1) < h(3) < h(4)\}$, but the partition $\{1, 3, 4 \mid 2\}$ is not exploratory equivalent.

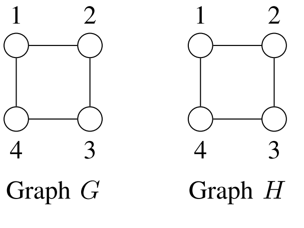

Fig. 14. A sample pattern graph $G$ and host graph $H$.

In the case of general graphs, a maximum EE partition might lead to a suboptimal set of constraints because the number of automorphisms might be greater than the score of a maximum EE partition. In a tree, however, these two values are exactly the same.

We will state the following lemma without a formal proof. We can employ the same techniques as in the proofs of lemmas and theorems of Section VI. In addition, note that the set of automorphisms forms a group: if $h$ and $h'$ are automorphisms, then $h \circ h'$ and $h' \circ h$ are automorphisms, too.

*Lemma 22:* For any tree $T$, the following properties hold:

- If $T$ contains an automorphism that maps a vertex $u$ to a vertex $v$, then the vertices $u$ and $v$ are exploratory equivalent.
- Let $c_1$ and $c_2$ be the centers of the tree (we may also have $c_1 = c_2$). If the tree has an automorphism $h$ such that $h(u) = v$, then (1) $d(u, c_1) = d(v, c_2)$ and (2) the centrifugal subtrees of $u$ and $v$ are isomorphic.
- For each nontrivial tree automorphism $h$, there exists a pair of vertices $u$ and $v$ such that $1 \le d(u, v) \le 2$ and $h(u) = v$.
- Let the set $P = \{v_1, \ldots, v_k\}$ be exploratory equivalent. Let $h$ and $h'$ be automorphisms such that $h(v_1) = h'(v_1) = \sigma(v_1)$, …, $h(v_k) = h'(v_k) = \sigma(v_k)$ for some permutation $\sigma$ of the set $P$. If, on top of that, $h(u) = w_1$ and $h'(u) = w_2$ with $\{u, w_1, w_2\} \cap \{v_1, \ldots, v_k\} = \emptyset$ and $w_1 \neq w_2$, then the set $W = \{w_1, w_2\}$ is exploratory equivalent independently of the set $P$, which means that the sets $P$ and $W$ can both be part of the same EE partition.
- If the sets of tree vertices $P = \{u_1, \ldots, u_p\}$ and $Q = \{v_1, \ldots, v_q\}$ are both exploratory equivalent and if they cannot be extended by any other vertices without becoming non-EE, then the number of distinct automorphisms permuting the sets $P$ and $Q$ is equal to $p!\,q!$ only if (1) the centrifugal subtrees of the vertices in $P$ are all pairwise disjoint from the centrifugal subtrees of the vertices in $Q$ or (2) the vertices $v_1, \ldots,$ $v_q$ are all part of the centrifugal subtree of a vertex $u_i$ for some $i \in \{u_1, \ldots, u_p\}$ (or vice versa). Otherwise, the number of distinct automorphisms permuting the sets $P$ and $Q$ is $p! = q!$. In this case, we must have $p = q$, and each of the vertices of $Q$ is located in the centrifugal subtree of a different vertex of $P$ (or the other way around).

*Theorem 23:* Let $\mathcal{P} = \langle P_1, P_2, \ldots, P_s\rangle$ be the maximum EE ordered partition obtained by Alg. 1 for a given tree $T$. Then the number of automorphisms of $T$ is $|P_1|! \ldots |P_s|!$.

*Proof:* If $s = 1$, the vertices of $P_1$ can be mapped to each other in all $|P_1|!$ ways, which means that there are at least $|P_1|!$ automorphisms. However, the number of automorphisms is exactly $|P_1|!$. Suppose there were two automorphisms, $h$ and $h'$, for the same permutation of the set $P_1$. In particular, if $P_1 = \{v_1, \ldots, v_k\}$, suppose that $h(v_i) = h'(v_i) = \sigma(v_i)$ for all $i \in \{1, \ldots, k\}$ and for some permutation $\sigma$ of $P_1$. For $h$ and $h'$ to be distinct, we must have, say, $h(u) = w_1$ and $h'(u) = w_2$ with $w_1 \neq w_2$ and $u, w_1, w_2 \in V \setminus P_1$. However, in this case, the set $\{w_1, w_2\}$ is exploratory equivalent independently of the set $P_1$ (Lemma 22) and is therefore part of the same maximum EE partition as the set $P_1$.

Now, let us assume that the theorem holds for some $s > 1$, and let us verify that it also holds for $s + 1$. Indeed: for any fixed permutation of the vertices in the set $P_1 \cup \ldots \cup P_s$, there are exactly $|P_{s+1}|!$ automorphisms, one for each permutation of the set $P_{s+1}$, which, together with the inductive assumption, gives the property stated in the theorem. The number of automorphisms cannot possibly be more than that; if it were, that would imply the exploratory equivalence of some set not present in $\mathcal{P}$ (independently of the sets in $\mathcal{P}$) or the fact that the set $P_s$ is not at the bottom of the centrifugal subtree containment hierarchy (which would, in turn, imply that $\mathcal{P}$ is not an EE ordered partition). ■

Theorem 23 implies the optimality of the subgraph isomorphism constraints derived from a maximum EE partition for an arbitrary tree. In the search for occurrences of a pattern tree $T$ in an arbitrary host graph $H$, the use of these constraints reduces the number of generated isomorphisms between $T$ and each of its occurrences in $H$ to 1, thus eliminating the automorphism-induced redundancy completely.

## IX. Conclusion

Recently, we defined the so-called MaxExplorEq problem, the goal of which is to find a maximum exploratory equivalent (EE) partition of the vertex set of a given graph $G$. This problem is closely related to the problem of finding occurrences of a graph $G$ in a graph $H$ (the subgraph isomorphism problem), since every EE partition of $G$ determines a set of redundancy reduction constraints that can be safely imposed during the subgraph isomorphism search. In the MaxExplorEq problem, we try to find an EE partition that gives rise to the optimal set of constraints in terms of redundancy elimination in subgraph isomorphism search.

In this paper, we proved that MaxExplorEq is $GI$-hard, which means that it is unlikely to be solvable in polynomial time. For this reason, we restricted the MaxExplorEq problem to an important subclass of graphs — the class of trees. By devising a polynomial-time algorithm, we showed that the restricted MaxExplorEq problem belongs to the complexity class $P$. Our algorithm finds a maximum EE partition in time $O(n^3 \log n)$, where $n$ is the number of vertices of the input tree. Note that in contrast to the algorithms presented in our previous paper [9], Alg. 1 does not require or enumerate the set of automorphisms of the given tree. If it did, it could not possibly run within polynomial-time bounds, since the number of automorphisms for a tree with $n$ vertices can be up to $(n-1)!$.

Besides that, we showed that the score of the maximum EE partition is equal to the number of automorphisms in the case of trees, but not necessarily in the case of general graphs. For any tree, a maximum EE partition thus gives rise to an optimal set of subgraph isomorphism search constraints.

To demonstrate the large potential of MaxExplorEq, we performed a small empirical study on the set of all trees of sizes 2 to 20. The study demonstrates that large speedups could be obtained in various search algorithms, especially for finding tree-shaped patterns in larger structures. The automorphisms on trees have been, of course, well known for a long time; however, our algorithm finds the partition of nodes that can be completely interchanged in search algorithms, and thus we give an explicit recipe on how to exploit these symmetries.

Could we apply the approach presented in this paper to general graphs? The $GI$-hardness of the MaxExplorEq problem does not offer much hope to find a polynomial-time algorithm for arbitrary graphs. Nevertheless, the lemmas and theorems of Section VI — if, of course, they could really be extended to arbitrary graphs in some way — might at least give rise to a relatively efficient branch-and-bound algorithm for finding a maximum EE partition. However, a number of problems will have to be solved before arriving at a viable algorithm. A general graph might have an arbitrary number of centers, and it is not yet clear whether the concepts such as ‘centrifugal subtree’ could be generalized at all.

***Abstract*—In this paper a new formulation of the robust graph coloring problem (RGCP) is proposed. In opposition to classical GCP defined for the given graph *G(V,E)* not only elements of E but also Ē can be subject of color conflicts in edge vertices. Conflicts in Ē are assigned penalties 0<P(e)<1. In addition to satisfying constraints related to the number of colors and/or a threshold of the acceptable sum of penalties for color conflicts in graph complementary edges (rigidity level), a new bound called the relative robustness threshold (RRT) is proposed. Then two metaheuristics – SA, TS and their parallel analogues PSA and PTS – for that version of RGCP are presented and experimentally compared. For comparison we use DIMACS graph coloring instances in which a selected percentage of graph edges E is randomly moved to Ē. Since graph densities and chromatic numbers of DIMACS GCP instances are known in advance, the RGCP instances generated on their basis are more suitable for testing algorithms than totally random instances used so far. The results of the conducted experiments are presented and discussed.**

## I. Introduction

The classical graph $k$-colorability problem belongs to the class of NP-hard combinatorial problems [9]. This decision problem is defined for an undirected graph $G=(V,E)$ and positive integer $k \leq |V|$ : is there an assignment of available $k$ colors to graph vertices, providing that adjacent vertices receive different colors? In optimization version of the basic problem called GCP, a conflict-free coloring with minimum number of colors $k$ is searched.

Many particular colorings of graph vertices and/or edges represent solutions of variety of practical problems that can be modeled by graphs with specific constraints put on the elements of the sets $V$ and $E$. With additional assumptions many variants of the coloring problem can be defined such as equitable coloring, sum coloring, contrast coloring, harmonious coloring, circular coloring, consecutive coloring, list coloring, total coloring etc. [14], [18].

One of the most interesting variants of GCP is the robust graph coloring problem (RGCP) [24]. It models a class of vertex coloring problems in which adjacency relation between graph vertices is not “stable”. In certain circumstances nonadjacent vertices $u$ and $v$ can become adjacent and the edge $(u,v)$ is assigned a penalty $0<P(u,v)<1$ when there is a color conflict : $c(u)=c(v)$. If all penalties $P(u,v)$ are known it is possible to define requirements for solution feasibility. A conflict-free coloring of all vertices in $E$ is required, while a number of penalized color conflicts in the set of complementary edges $\bar{E}$ , not exceeding certain threshold (f.i. rigidity level) can be tolerated. Given a number of colors $k$, the coloring with a lower rigidity level is more robust. In general, feasibility conditions can be expressed in terms of the maximum number of colors used and an upper bound on a cost function.

Similarly as GCP also RGCP is known to be NP-hard [26]. Therefore, application of approximate algorithms and metaheuristics for solving this problem is reasonable [1], [10], 11]. In literature no r-approximation algorithms for RGCP were reported so far. Research conducted in this area contains a number of algorithms and metaheuristics for RGCP [2], [19], [20], [24], [25] a new formulation of specific robust coloring problems [4] and a combination of system robustness and fuzziness [8], [12]. Research results were gathered and summarized in [24]. Other recent papers on system robustness are [7] and [23].

In research papers [19], [20] there appears a problem in experimental verification of the investigated metaheuristic methods. How to measure quality of the solution, when nothing is known about chromatic properties of the given graph? How to validate the assumed penalty threshold for a feasible solution? In our approach RGCP is redefined in order to allow the system designer to use a new cost function - the relative robustness of the solution, which can be expressed by a percentage – the relative robustness $RR=100\%$ means a conflict-free vertex coloring in both edges $E$ and complementary edges $\bar{E}$ with $P(e)>0$. This view is very natural and meets common expectations of system designers. For experimental verification two metaheuristics - Tabu Search (TS), Simulated Annealing (SA) and their parallel versions – PTS and PTA – are used. In standard and parallel versions they were applied earlier in similar research [3], [6], [16], [17], [19], [20], [21], [22]. As input graphs we used DIMACS graph coloring instances [27], [28], [29] in

978-83-60810-66-8/$25.00©2015, IEEE

which a constant percentage of graph edges *E*, denoted by *E'* is assigned penalties *0<P(e)<1*. Since graph densities and chromatic numbers of DIMACS GCP instances are known in advance [15], the RGCP instances generated on their basis are more suitable for testing algorithms than totally random instances used so far. The presented results justify both theoretical assumptions and application of parallel metaheuristics for solving RGCP problem.

In the next section RGCP problem is defined together with its new formulation. TS/PTS and SA/PSA algorithms and their parameters are presented in sections III. Then, in section IV, computer experiments are described and their results discussed. In conclusion some general suggestions related to the obtained results and future research in this area are derived.

## II. Robust Graph Coloring Problem

GCP is defined for an undirected graph *G(V,E)* as an assignment of available colors {*1, . . . , k*} to graph vertices providing that adjacent vertices receive different colors and the number of colors *k* is minimal. The resulting coloring *c* is called conflict–free and *k* is called graph chromatic number *χ(G)*.

### A. RGCP – a simple formulation

RGCP is defined for undirected weighted graph *G(V,E)* with function *w(e)*= $p_{uv} \in [0,1]$, as an assignment of available colors {*1, . . ., k*} to graph vertices, providing that

$$\forall (u,v) \in E \ : (p_{uv} = 1) \Rightarrow \ c(u) \neq c(v) \qquad (1)$$

and rigidity level for $\bar{E}$ is minimum

$$RL(c) = \sum_{((u,v)\in\overline{E})\wedge(c(u)=c(v))\wedge(p(u,v)>0)} p_{uv} \qquad (2)$$

In some cases weight (penalty) $p_{uv}$ may be considered as a probability of edge existence; in the classical vertex coloring $p_{uv} \in \{0,1\}$.

For most practical problems it suffices, that

$$RL(c) \leq T \qquad (3)$$

where :

*T* – is an assumed threshold.

The question is what value of *T* is reasonable for the modeled problem? How it reflects system robustness? What level of *T* should be guaranteed for the given system? In order to answer such questions an alternative formulation of RGCP problem is proposed. The alternative formulation of RGCP does not change the nature of the problem, but allows the system designer to apply the relative robustness level instead of the absolute robustness level which is not known in advance.

### B. RGCP – an alternative formulation

Let us characterize system robustness more precisely. The robustness threshold is given by the following formula

$$RT(c) = \frac{\mathrm{RRT(c)}}{100\%} \sum_{(e\in\overline{E})\wedge(p((u,v))>0)} p_{uv} \ , \qquad (4)$$

where:

*RRT(c)* – is a relative robustness threshold set up by the designer and expressed in [%].

Thus, our optimization goal is to find a coloring *c* satisfying equation (1) and inequalities (5) and (6):

$$\sum_{((u,v)\in\overline{E})\wedge(c(u)\neq c(v))\wedge(p(u,v)>0)} p_{uv} \geq RT(c) \qquad (5)$$

$$\frac{\sum_{((u,v)\in\overline{E})\wedge(c(u)\neq c(v))\wedge(p(u,v)>0)} p_{uv}}{\sum_{((u,v)\in\overline{E})\wedge(p(u,v)>0)} p_{uv}} \cdot 100\% \geq RRT(c) \qquad (6)$$

### C. Generation of RGCP instances

Parametrized RGCP instances can be generated by a random modification of GCP instances: a percentage of *E'ϵ E* is moved to $\bar{E}$ with weights *0<p(u,v)<1*. In Fig. 1 three out of seven edges are selected at random and assigned new values *p(u,v)*.

### D. Cost function for RGCP

In problem formulation the priority is given to conflict-free coloring of edges with *P(u,v)=1* . Otherwise, the solution is not feasible. Feasible solutions have the cost function:

$$cf(c) = \sum_{(u,v)\in E\cup\overline{E}} q_{uv} \qquad (7)$$

where:

$$q_{uv} = \left| \begin{array}{ll} 1, & if\,(c(u)=c(v)\, and\ p_{uv}=1 \\ p_{uv} & if\,(c(u)=c(v)\, and\ p_{uv}<1 \\ 0 & if\,(c(u)\neq c(v)) \end{array} \right. \qquad (8)$$

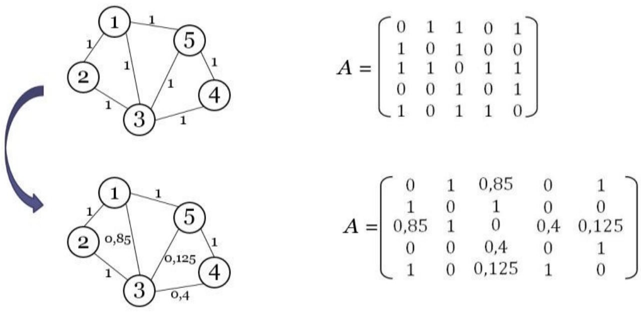

Fig. 1 Generation of RGCP graph instances from GCP instances (42,86% of *E* moved to $\bar{E}$; $\bar{E}$ percentage increased from 30 to 60%).

## III. PTS AND PSA METAHEURISTICS

The applications of basic metaheuristics for RGCP was reported in [19]. The first parallel metaheuristic for RGCP – Parallel Evolutionary Algorithm – was presented in [5]. In the present paper we deal with two other popular parallel metaheuristics PTS and PSA. The details of implementation are skipped here for the sake of brevity. In order to determine their parameters at first we investigate algorithms TS and SA.

### *A. Parameters for Tabu Search Algorithm*

Tabu Search metaheuristic presented in [19] is adapted for parallelization. PTS algorithm includes three TS processes that periodically exchange information when 1/3 and 2/3 of the required RR is obtained. There are at least two key parameters of TS/PTS algorithms that have to be set [6]: tMAX and MaxTenure. This parameters were found experimentally. The results of conducted experiments are shown in Table I and Table II.

The values of parameters recommended for TS and PTS algorithms are as follows: tMAX=10 and MaxTenure=15. As a selection criterion majority of optimum solutions with respect to relative robustness RR was used.

### *B. Parameters for Simulated Annealing Algorithm*

A Simulated Annealing metaheuristic for RGCP presented in [19] is adapted for parallelization. There are three important parameters of SA and PSA algorithms that have to be set [21]: MinIteration, ControlFactor (speed of convergence) and Tmax. These parameters were also found experimentally. The results of conducted experiments are shown in Tables III, IV, and V. We can assume Tmin=0,25.

PSA algorithm includes also three SA processes that periodically exchange information when 1/3 and 2/3 of the required RR is obtained. All processes resume computations with new best solution. The values of parameters recommended for PSA are the following: MinIteration=5, ControlFactor=0,9 and Tmax=10.

Table I Efficiency of TSA with tMax (MaxTenure=10)

| Graphs | tMax : 5 | | | **tMax : 10** | | | tMax : 15 | | |
|---|---|---|---|---|---|---|---|---|---|
| | c.f. | time [s] | RR [%] | c.f. | time [s] | RR [%] | c.f. | time [s] | RR [%] |

|---|---|---|---|---|---|---|---|---|---|
| | c.f. | time [s] | RR [%] | c.f. | time [s] | RR [%] | c.f. | time [s] | RR [%] |
| queen5.5_40<br>χ(g)=5<br>dens.=54% | 14 | **0,2** | 79,3 | **6,4** | 0,3 | **90,9** | 7,9 | 0,5 | 88,9 |
| games120_4<br>χ(g)=9<br>dens.=9% | 104 | **18,3** | 96,1 | **4,1** | 28,7 | **98,5** | 6,4 | 57,3 | 97,6 |
| myciel7_40<br>χ(g)=8<br>dens.=13% | 2k | **75,2** | - | 13,8 | 119 | 98,8 | **5,4** | 240 | **99,5** |

Table V Efficiency of SA algorithm with Tmax (Tmin=0,25; MinIteration=5; ControlFactor=0,9)

| Graphs | Tmax : 5 | | | **Tmax : 10** | | | Tmax : 15 | | |
|---|---|---|---|---|---|---|---|---|---|
| | c.f. | time [s] | RR [%] | c.f. | time [s] | RR [%] | c.f. | time [s] | RR [%] |
| queen5.5_40<br>χ(g)=5<br>dens.=54% | 10 | **0,2** | 85,8 | **9,5** | 0,3 | **86,6** | 12,0 | 0,3 | 83,1 |
| games120_4<br>χ(g)=9<br>dens.=9% | **4,0** | **24,2** | **98,5** | 5,4 | 29,8 | 98,0 | 6,9 | 30,7 | 97,4 |
| myciel7_40<br>χ(g)=8<br>dens.=13% | 19 | **94,1** | 98,3 | **14,5** | 122 | **98,7** | 18,1 | 137 | 98,3 |

Similarly, as a selection criterion for a given parameter the majority of optimum solutions with respect to relative robustness RR was used.

SA/PSA algorithm has SA2/PSA2 version with automatic computation of Tmax (the initial temperature), cf. [21].

The computed parameters of TS and SA metaheuristics were used for parallel versions of both iterative methods.

## IV. Experimental Results

The application has been written in C++, while GUI in C#, accordingly. Microsoft Visual Studio 2008 v.9.0 was used. All computer experiments we performed on a machine with Intel Core 2 Duo, CPU P8400, 2,27 GHz, 4,00 GB of RAM memory.

### *A. Goals of optimization and algorithms*

The main purpose of optimization was obtaining the best available robustness with minimum number of colors used. It is possible to:

a. compute maximal RR for the given number of colors (algorithms: TS, SA, SA2)

b. compute the above in parallel (algorithms: PTS, PSA2)

c. find a robust coloring with minimal number of colors for the given RR (algorithms TS, SA$^C$, SA2$^C$)

d. compute the above in parallel (algorithms PTS$^C$, PSA2$^C$)

The program solves RGCP problem providing value of cost function, relative robustness RR and the number of colors. There is a pool of algorithm's variants to choose from, including sequential and parallel versions.

In next subsections a number of experiments performed with the help of that program is reported.

### *B. TS versus SA*

The first experiment was devoted to efficiency comparison of sequential versions of the two basic metaheuristics. For comparison 9 DIMACS graphs were selected the number of colors was set up to *k*= *χ(G)*. The results are shown in Fig. 2. For most combinations of test graphs and the size of the set *E'* the TS outperforms SA in terms of relative robustness RR of the modeled system. Typically, TS was able to achieve 100% RR and never less than 95%. SA issued a bit worse results: for only three graphs maximum RR=100% was obtained. In majority of cases RR was within the range 91–99%. In a single case when SA algorithm failed to achieve a conflict-free coloring for a graph with density 46%, the value *k* was incremented. Basically, more dense graph are more difficult to color. SA is simpler than TS, much faster for bigger graphs and its power relies on randomization in a higher degree than TS which is more precise in searching for a good solution, checking all color combinations for all vertices in each iteration. Regardless of *E'* size both algorithms delivered solutions with similar values of cost function and RR. However, when *E'* size is bigger the number of iterations required to obtain a conflict-free coloring decreases in both methods and the speed of TS decreases. The graph density is more essential than the graph size.

### *C. TS$^C$ versus SA$^C$ and SA2$^C$*

Three subsequent experiments were based on eight graphs instances with the percentage of *E'* equal 60%. The number of colors was computed that allows to achieve the given level of system relative reliability RR on the levels 70%, 85%, and 95% respectively.

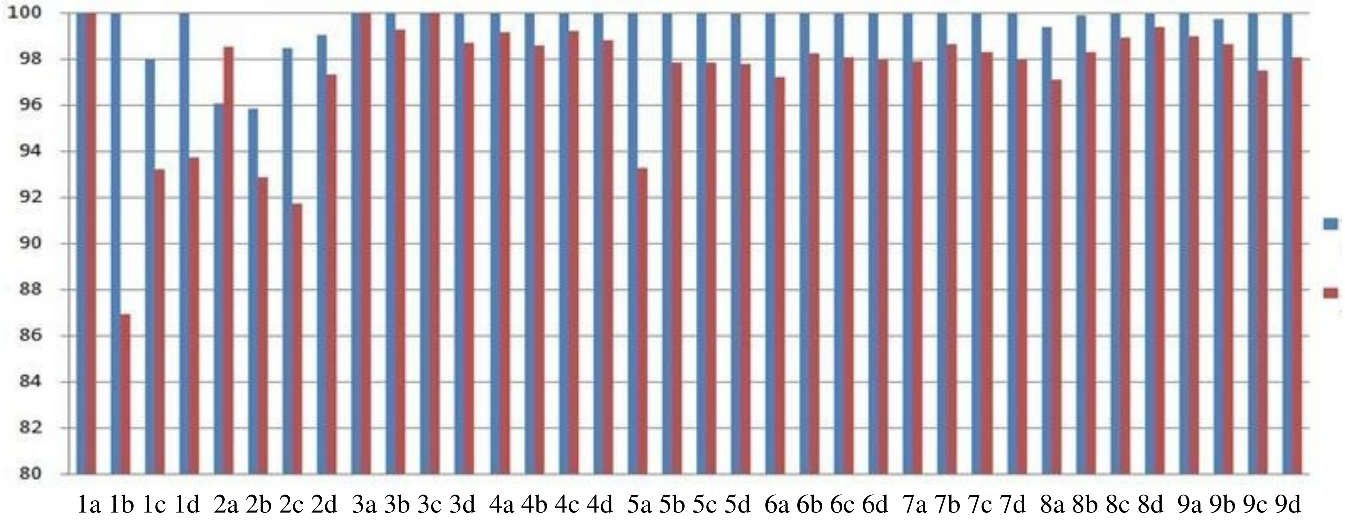

Fig. 2 Relative robustness *RR* [TS-blue, SA-red]. Graphs: 1-queen5.5, 2-queen6.6, 3-myciel, 4-huck, 5-david, 6-games120, 7-anna, 8-mulsol.i.4, 9-myciel7. *E'* : a=10%, b=20%, c=40%, d=60%. Number of colors k= *χ(G)*.

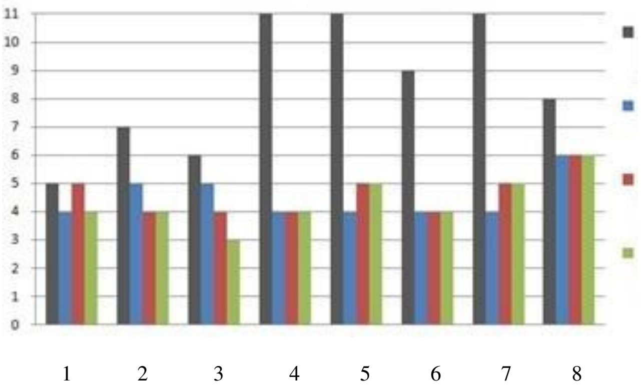

Fig. 3 Number of colors required for *RR*=70%, [$\chi(G)$,TS$^C$,SA$^C$,SA2$^C$]. Basic graphs: 1-queen5.5, 2-queen6.6, 3-myciel, 4-huck, 5-david, 6-games120, 7-anna, 8-myciel7; *E'* – 60%.

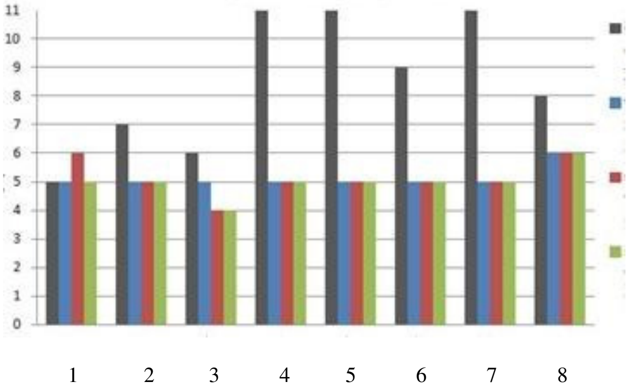

Fig. 4 Number of colors required for *RR*=85%, [$\chi(G)$,TS$^C$,SA$^C$,SA2$^C$]. Graphs: 1-queen5.5, 2-queen6.6, 3-myciel, 4-huck, 5-david, 6-games120, 7-anna, 8-myciel7; *E'* – 60%.

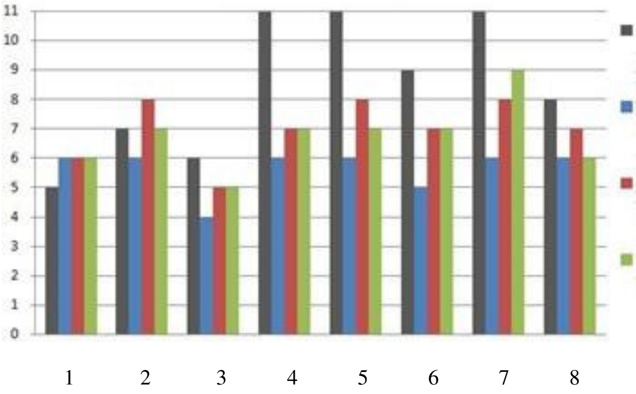

Fig. 5 Number of colors required for *RR*=95%, [$\chi(G)$,TS$^C$,SA$^C$,SA2$^C$]. Graphs: 1-queen5.5, 2-queen6.6, 3-myciel, 4-huck, 5-david, 6-games120, 7-anna, 8-myciel7; *E'* – 60%.

In Fig. 3-5 the order of bars characterizing experiments for the given input graph is as follows: $\chi(G)$, TS$^C$, SA$^C$ and SA2$^C$. The results depicted in Fig. 3 present the number of colors used by the corresponding methods for the set of all 8 graphs with RR=70%. The average number of colors used is as follows : TS$^C$=4,5 , SA$^C$=4,625 and SA2$^C$=4,375 , with the average sum of $\chi(G)$ equal 8,5.

Similarly, the results depicted in Fig. 4 can be characterized in short by average number of colors used by the corresponding methods for the set of all 8 graphs RR=85% : TS$^C$=5,125 , SA$^C$=5,125 and SA2$^C$=5,0 with the same sum of $\chi(G)$.

Finally, the general results depicted in Fig. 5 can be summarized by average number of colors used by the corresponding methods for the set of all 8 graphs with RR=95%: TS$^C$=5,625 , SA$^C$=7,0 and SA2$^C$=6,75 with respect to the sum of $\chi(G)$ as above.

### *D. PTS$^C$ versus PSA2$^C$*

The experiment reported in subsection C was then repeated for parallel metaheuristics PTS$^C$ and PSA2$^C$ (with an automatic computing of initial temperature Tmax).

Three subsequent experiments were based on eight graphs instances with the percentage of *E'* equal 60%. The number of colors was computed that allows to achieve the given level of system relative reliability RR on the levels 70%, 85%, and 95% respectively

Results of the research concerning minimization of colors in a conflict free robust graph coloring with fixed RR level can be summarized by the average number of colors used by the corresponding sequential and parallel methods for the set of all eight graphs from subsection C: PTS$^C$=5,5, TS$^C$=5,625, PSA2$^C$=6,625 and SA2$^C$=6,75 when the average $\chi(G)$ is 8,5. As expected , the results obtained by parallel metaheuristics are slightly improved in comparison to classical metaheuristics.

In addition total computation time of sequential and parallel versions of both metaheuristics was compared for the set of all eight graphs from subsection C. Average processing time of PTS$^C$ is 666,8 [s] while TS$^C$ 693,2 [s]. The average processing time of PSA2$^C$ is 674,8 [s] while SA2$^C$ 435,9 [s]. Solutions generated by PTS$^C$ are often repeatable while PSA2$^C$ results are less stable and with similar quality as those from SA2$^C$ .

## V. Conclusions

In this paper new formulation of RGCP problem is given that seems to be more appropriate for designers of robust systems. Relative robustness is a versatile measure for characterization of any robust system modeled by a graph. For experimental verification two popular parallel metaheuristics TS/PTS and SA/PSA were used.

We proposed a new method of test instance generation by random modification of a given percentage *E'* of graph edges *E*. DIMACS hard-to-color graph instances were used for modification. The results confirm that the proposed approach and the used tools can be efficiently used for practical applications.

An interesting goal of the future research is to apply to RGCP – and verify experimentally – more metaheuristics like Parallel Evolutionary Algorithm (PEA), Parallel

Immune Algorithm (PIA), Ant Colony Optimization (ACO), Particle Swarm Optimization (PSO) and others [10], [11]. For particular applications the robustness measures can be modified to reflect specific properties of the given system.

***Abstract*—Evolution strategies are powerful evolutionary algorithms for continuous optimization. The main search operator is mutation. Its extend is controlled by the covariance matrix and must be adapted during a run. Modern Evolution Strategies accomplish this with covariance matrix adaptation techniques. However, the quality of the common estimate of the covariance is known to be questionable for high search space dimensions. This paper introduces a new approach by changing the coordinate system and introducing sparse covariance matrix techniques. The results are evaluated in experiments.**

## I. Introduction

EVOLUTIONARY COMPUTATION has a long research tradition. The field comprises today the main classes genetic algorithms, genetic programming, evolution strategies, evolutionary programming, and differential evolution. Evolution strategies (ESs), on which the research presented in this paper focuses, are primarily used for optimizing continuous functions. The function is not required to be analytical.

Evolution strategies rely on mutation, i.e., on the random perturbation of candidate solutions to navigate the search space. The process must be controlled in order to achieve good performance. For this, modern ESs apply covariance matrix adaptation in several variants [1]. Nearly all approaches take the sample covariance matrix into account. This estimator is known to be problematic in the case of small sample sizes compared to the search space dimensionality. Since the population size in evolution strategies is typically considerably smaller, this paper argues that the adaptation process may profit from the introduction of different estimators.

So far, evolutionary algorithms or related approaches have only seldom considered statistical estimation methods targeted at high-dimensional spaces. The reason may be twofold: The improved quality of the estimators induces increased computational costs which may lower the convergence velocity of the algorithm. In addition, the estimators are developed and analyzed for samples of independently, identically distributed random variables. Since evolutionary algorithms deploy selection based on rank or fitness, the assumption of the same distribution is not valid. This may be the reason as to why the literature research has resulted in only one previous approach [2]. There, the authors considered Gaussian based estimation of distribution algorithms. The problem they were faced with concerned a non-positive definiteness of the estimated covariance matrix. Therefore, Dong and Yao augmented the algorithm with a shrinkage procedure to guarantee positive definiteness. Shrinkage is one of the common methods to improve the quality of the sample covariance, see e.g. [3]. While the approach in [2] resembles the Ledoit-Wolf estimator [3], it adapted the shrinkage intensity during the run.

This paper extends the work presented in [4], [5], where Ledoit-Wolf shrinkage estimators were analyzed, combined with a maximum entropy approach, and integrated into evolution strategies. While the results were promising, the question remained how to adapt the parameter of the estimator. Therefore, in this paper, another computational simple estimation method is investigated: thresholding.

The paper is structured as follows. First, modern evolution strategies with covariance adaptation are introduced. Afterwards, a short motivation as to why we think that the covariance computation in ESs may profit from estimation theory for high-dimensional spaces is provided. The next section describes the new approach developed and is followed by the experimental section which compares the new approach against the original ES. Conclusions and a discussion of potential future research constitute the last part of the paper.

### A. Modern Evolution Strategies

This section provides a short introduction into evolutionary algorithms focussing on evolution strategies and covariance matrix adaptation. Evolutionary algorithms (EAs) [6] in general are population-based stochastic search and optimization algorithms used when only direct function measurements are possible.

Their iterative search process requires the definition of termination criteria and stops if these are fulfilled. In each generation, a series of operations is performed: selection for reproduction, followed by offspring creation, i.e. recombination and mutation processes, and finally survivor selection. The initial population of candidate solutions is either drawn randomly from the permissable search space or is initialized based on information already obtained. First of all, the offspring population has to be created. For this, a subset of the parents is determined during *parent selection*. The creation

978-83-60810-66-8/$25.00©2015, IEEE

of the offspring is based on recombination and mutation. Recombination combines traits from two or more parents resulting in one or more intermediate offspring. In contrast, mutation is an unary operator changing the components of an individual randomly. After the offspring have been created, survivor selection is performed to determine the next parent population. The different variants of evolutionary algorithms adhere to the same principles in general, but they may differ in the representation of the solutions and how the selection, recombination, and mutation processes are realized.

*a) Evolution Strategies:* Evolution strategies (ESs) [7], [8] are used for continuous optimization $f : \mathbb{R}^N \rightarrow \mathbb{R}$. Several variants have been introduced see e.g. [9], [1]. In many cases, a population of $\mu$ parents is used to create a set of $\lambda$ offspring, with $\mu \leq \lambda$. For recombination, $\rho$ parents are chosen uniformly at random without replacement and are then recombined. Recombination usually consists of determining the (weighted) mean or centroid of the parents [9]. The result is then mutated by adding a normally distributed random variable with zero mean and covariance matrix $\sigma^2\mathbf{C}$. While there are ESs that operate without recombination, the mutation process is seen as the essential process. It is often interpreted as the main search operator. After the offspring have been created, the individuals are evaluated using the function to be optimized or a derived function which allows an easy ranking of the population. Only the rank of an individual is important for the selection. In the case of continuous optimization, the old parent population is typically discarded with the selection considering only the $\lambda$ offspring of which the $\mu$ best are chosen.

The covariance matrix which is central to the mutation must be adapted during the run: Evolution strategies with ill-adapted parameters converge only slowly or may even fail in the optimization. Therefore, research on methods for adapting the scale factor $\sigma$ or the full covariance matrix has a long research tradition in ESs dating back to their origins [7]. The next section describes one of the current approaches.

*b) Updating the Covariance Matrix:* To our knowledge, covariance matrix adaptation comprises two main classes: one applied in the *covariance matrix adaptation evolution strategy* (CMA-ES) [10] and an alternative used in the *covariance matrix self-adaptation evolution strategy* (CMSA-ES) [11]. Both consider information from the present population combining it with information from the search process so far. The CMA-ES is one of the most powerful evolution strategies and often referred to as the standard in ESs. However, as pointed out in [11], its scaling behavior with the population size may not be good. Beyer and Sendhoff [11] showed that the CMSA-ES performs comparably to the CMA-ES for smaller populations but that is less computational expensive for larger population sizes.

Therefore, the present paper focuses on the CMSA-ES leaving the CMA-ES for future research. The CMSA-ES uses weighted intermediate recombination, in other words, the weighted centroid $\mathbf{m}^{(g)}$ of the $\mu$ best individuals of the population is computed. To create the offspring, random vectors are drawn from the multivariate normal distribution $\vec{\mathcal{N}}(\mathbf{m}^{(g)}, (\sigma^{(g)})^2\mathbf{C}^{(g)})$. The notation of covariance matrix as $(\sigma^{(g)})^2\mathbf{C}^{(g)}$ illustrates that the actual covariance matrix is interpreted as the combination of a general scaling factor (or step-size or mutation strength) with a rotation matrix. Following the usual practice in literature on evolution strategies the latter matrix $\mathbf{C}^{(g)}$ is referred to as *covariance matrix* in the remainder of the paper.

The covariance matrix update is based upon the common estimate of the covariance using the newly created population. Instead of considering all offspring for deriving the estimates, though, it introduces a bias towards good search regions by taking only the $\mu$ best individuals into account. Furthermore, it does not estimate the mean anew but uses the weighted mean $\mathbf{m}^{(g)}$. Following [10],

$$\mathbf{z}_{m:\lambda}^{(g+1)} := \frac{1}{\sigma^{(g)}}\left(\mathbf{x}_{m:\lambda}^{(g+1)} - \mathbf{m}^{(g)}\right) \tag{1}$$

are determined with $\mathbf{x}_{m:\lambda}$ denoting the $m$th best of the $\lambda$ particle according to the fitness ranking. The rank-$\mu$ update then obtains the covariance matrix as

$$\mathbf{C}_{\mu}^{(g+1)} \;:=\; \sum_{m=1}^{\mu} w_m \mathbf{z}_{m:\lambda}^{(g+1)} (\mathbf{z}_{m:\lambda}^{(g+1)})^{\mathrm{T}} \tag{2}$$

which is usually a positive semi-definite matrix since $\mu \ll N$. The weights $w_m$ should fulfill $w_1 \geq w_2 \geq \ldots \geq w_\mu$ with $\sum_{m=1}^{\mu} w_i = 1$. To derive reliable estimates larger population sizes are required which would lower the algorithm's speed. Therefore, past covariance matrices are taken into account via the convex combination of (2) with the sample covariance being shrunk towards the old covariance

$$\mathbf{C}^{(g+1)} \;:=\; (1 - \frac{1}{c_\tau})\mathbf{C}^{(g)} + \frac{1}{c_\tau}\mathbf{C}_{\mu}^{(g+1)} \tag{3}$$

with the weights usually set to $w_m = 1/\mu$ and

$$c_\tau = 1 + \frac{N(N+1)}{2\mu}, \tag{4}$$

see [11]. As long as $\mathbf{C}^{(g)}$ is positive semi-definite, (3) will result in a positive definite matrix.

*c) Step-Size Adaptation:* The CMSA implements the step-size using *self-adaptation* first introduced in [7] and developed further in [8]. Here, evolution is used for fitting the strategy parameters of the mutation process. In other words, the scaling parameter or in its full form, the complete covariance matrix, undergoes recombination, mutation, and indirect selection processes. The working principle is based on an indirect stochastic linkage between good individuals and appropriate parameters: Well adapted parameters should result more often in better offspring than too large or too small values or misleading directions. Although self-adaptation has been developed to adapt the whole covariance matrix, it is applied today mainly to adapt the step-size or a diagonal covariance matrix. In the case of the mutation strength, usually a log-normal distribution

$$\sigma_l^{(g)} \;=\; \sigma_{\text{base}}\exp(\tau\mathcal{N}(0,1)) \tag{5}$$

is used for mutation. The parameter $\tau$ is called the *learning rate* and is usually chosen to scale with $1/\sqrt{2N}$. The baseline $\sigma_{\text{base}}$ is either the mutation strength of the parent or if recombination is used the recombination result. For the step-size, it is possible to apply the same type of recombination as for the positions although different forms – for instance a multiplicative combination – could be used instead. The self-adaptation of the step-size is referred to as *$\sigma$-self-adaptation* ($\sigma$SA) in the remainder of this paper.

The newly created mutation strength is then directly used in the mutation of the offspring. If the resulting offspring is sufficiently good, the scale factor is passed to the next generation.

Self-adaptation with recombination has been shown to be "robust" against noise [12] and is used in the CMSA-ES as the update rule for the scaling factor.

### B. Concerning the Covariance Matrix Adaptation ...

In the case of $\lambda > 1$, the sample covariance (2) appears in nearly any adaptation process. Disregarding the distortion due to selection, the sample covariance as the maximum likelihood estimator of the true covariance matrix is known as a good and reliable estimate if $\mu \gg N$. Evolution strategies typically operate with $\mu < N$, however. For example, following [13] the sizes of the parent and offspring populations in the standard CMA-ES should be chosen as $\lambda = \lfloor \log(3N) \rfloor + 4$ and $\mu = \lfloor \lambda/2 \rfloor$.

Unfortunately, $\mu < N$ leads to problems with respect to the covariance estimation. This is a well-known problem in statistics [14], [15], giving raise to a broad range on literature on alternative estimators e.g. [15], [16], [17], [18], [19], [20], [21], [22], [23]. The quality of a maximum likelihood estimate may be insufficient – especially for high-dimensional spaces, see e.g. [16]. For example, Marčenko and Pastur showed that if $N/\mu \not\to 0$ but $N/\mu \in (0,1)$, instead, the eigenvalues of the covariance matrix are distributed in the interval $((1-\sqrt{N/\mu})^2, (1+\sqrt{N/\mu})^2)$ in the case of the standard normal distribution [17].

Equation (3) actually attempts to counteract the singularity of the population covariance matrix by using the well-known concept of shrinking. However, some distinctive differences are present. First of all, the target is a full covariance matrix whereas shrinkage typically considers simpler regulation forms as e.g. a diagonal matrix. Secondly, the parameter is usually determined via optimizing a performance measure.

Seeing that evolution strategies already apply some kind of shrinkage, some questions arise: Can we improve the estimator further by not only "shrinking" the population or sample covariance matrix but by applying further concepts stemming from the estimation of high-dimensional covariance matrices? And considering that (3) is one regulation technique among several, is it possible to find another well-performing substitute? Or did research in evolution strategies already happen upon the best technique possible?

## II. A Sparse Covariance Matrix Adaptation

This section introduces the new covariance adaptation technique which uses thresholding to transform the population covariance matrix. The decision for thresholding is based upon the comparatively computational efficiency of the approach.

### A. Space Transformation

The ideal covariance matrix for the search depends on the function landscape which is unknown in practical applications. Considering the smooth test functions of typical black-box optimization suites, shows that the Hessians of several functions, as e.g. the separable functions, can be classified as sparse or approximately sparse matrices following the definitions introduced later.

Therefore, sparse structures of the covariance matrix suffice which is exemplified by the separable CMA-ES [24] which restricts the covariance to a diagonal matrix in case of separability to allow fast progress to the optimal solution. For the general case, a spare structure may not be suitable, however.

For this reason, the paper does not require sparseness of the original covariance matrix, although it would be interesting to see how such a variant would perform on the test suites. Instead, it considers a transformation. As argued in [25], an change of the coordinate system may improve the performance of an evolution strategy. Therefore, an adaptive encoding was introduced. In each iteration, the covariance matrix is adapted following the rules of the CMA-ES. Its spectral decomposition is used to change the basis. The creation of new search points is carried out in the eigenspace of the current covariance matrix and the main search parameters of the CMA-ES are updated there. After selection, the covariance matrix is adapted and utilized for a renewed decoding and encoding.

This paper also addresses a change of the coordination system. However, we address the covariance matrix adaptation and estimation itself which in [25] occurs in the original space. Here, we argue that a switch to the eigenspace of the old covariance matrix $\mathbf{C}^{(g)}$ may be beneficial for the estimation of the covariance matrix itself.

Let the covariance matrix $\mathbf{C}^{(g)}$ be a symmetric, positive definite $N \times N$ matrix. The condition holds for the original adaptation since (3) combines a positive definite with a positive semi-definite matrix. As we will see below, in the case of thresholding the condition may not always be fulfilled. Assuming a positive definite matrix allows carrying out a spectral decomposition: Let $\mathbf{v}_1, \dots, \mathbf{v}_N$ denote the $N$ eigenvectors with the eigenvalues $\lambda_1, \dots, \lambda_N$, $\lambda_j > 0$. Note, the eigenvectors form a orthonormal basis of $\mathbb{R}^N$, i.e., $\mathbf{v}_i^{\mathrm{T}}\mathbf{v}_i = 1$ and $\mathbf{v}_i^{\mathrm{T}}\mathbf{v}_j = 0$, if $i \neq j$. We define $\mathbf{V} := (\mathbf{v}_1, \dots, \mathbf{v}_N)$ as the modal matrix. It then holds that $\mathbf{V}^{-1} = \mathbf{V}^{\mathrm{T}}$. Switching to the eigenspace of $\mathbf{C}^{(g)}$ results in the representation of the covariance matrix

$$\Lambda^{(g)} = \mathbf{V}\mathbf{C}^{(g)}\mathbf{V}^{\mathrm{T}} \tag{6}$$

as a diagonal matrix with the eigenvalues as the diagonal entries. Diagonal matrices are sparse matrices, thus for the estimation of the covariance matrix the more efficient procedures for sparse structures could be used. However, it is not the goal to re-estimate $\mathbf{C}^{(g)}$ but to estimate the true covariance matrix of the distribution indicated by the sample $\mathbf{z}_{1;\lambda},\ldots,\mathbf{z}_{\mu;\lambda}$.

Before continuing, it should be noted that several definitions of sparseness exist. Usually, it is demanded that the number of non-zero elements in a row may not exceed a predefined limit $s_0(N) > 0$, i.e.,

$$\max_i \sum_{j=1}^{N} \delta(|a_{ij}| > 0) \leq s_0(N), \tag{7}$$

which should grow only slowly with $N$. The indicator function $\delta$ fulfills $\delta(\cdot) = 1$ if the condition is met and is zero otherwise. This definition can, however, be relaxed to a more general definition of sparseness, also referred to as approximate sparseness. Cai and Liu [22] consider the following uniformity class of sparse matrices

**Definition 1.** *Let $s_0(N) > 0$ and let $\cdot \succ 0$ denote positive definiteness. Then a class of sparse covariance matrices is defined as*

$$\begin{aligned}\mathcal{U}_q^* :=& \mathcal{U}_q^*(s_0(N)) \\ =& \left\{\Sigma : \Sigma \succ 0, \max_i \sum_{j=1}^{p} (\sigma_{ii}\sigma_{jj})^{\frac{(1-q)}{2}} |\sigma_{ij}|^q \leq s_0(N)\right\}\end{aligned} \tag{8}$$

*for some $0 \leq q < 1$.*

Definition 1 requires the entries of the covariance matrix to lie within a weighted $l_q$ ball. The weight is given by the variances. Cai and Liu [22] introduce a thresholding estimator that requires the assumption above. Its convergence rate towards the true covariance depends on $s_0(N)(\log(N)/\mu)^{(1-q)/2}$. Therefore, the number $s_0(N) > 0$ should again grow only "slowly" for $N \to \infty$.

Definition 1 leads to the main assumption of the paper. Consider an evolution strategy in the search space. The new sample that is the offspring population has been created with the help of the old covariance matrix. The covariance matrix of the selected sample differs from the previous. The deviations of from its structure stem from finite sampling characteristics and rank-based selection. Assuming that the form of the covariance matrix will not change considerably in one iteration, the new underlying covariance matrix should be sparse in the eigenspace of the old covariance, however.

**Assumption 1.** *Let $\Sigma^{(g+1)}$ denote the true covariance matrix of the selected offspring. Consider the old covariance $\mathbf{C}^{(g)}$ with its modal matrix $\mathbf{V}$. Then $\hat{\Lambda} = \mathbf{V}\Sigma^{(g+1)}\mathbf{V}^{\mathrm{T}}$ is approximately sparse, i. e. $\hat{\Lambda} \in \mathcal{U}_q^*$ for some $0 \leq q < 1$.*

Assuming the validity of the assumption, we change the coordinate system in order to perform the covariance matrix estimate. Reconsider the normalized (apart from the covariance matrix) mutation vectors $\mathbf{z}_{1;\lambda},\ldots,\mathbf{z}_{\mu;\lambda}$ that were associated with the $\mu$ best offspring. Their representation in the eigenspace reads

$$\hat{\mathbf{z}}_{m;\lambda} \quad = \quad \mathbf{V}^{\mathrm{T}}\mathbf{z}_{m;\lambda} \text{ for } m = 1,\ldots,\mu. \tag{9}$$

The transformed population covariance is then estimated as

$$\hat{\mathbf{C}}_\mu = \sum_{m=1}^{\mu} w_m \hat{\mathbf{z}}_{m;\lambda}\hat{\mathbf{z}}_{m;\lambda}^{\mathrm{T}}. \tag{10}$$

The estimate (10) will be used to compute the final estimator. In the next section, we discuss potential estimators for sparse covariance matrices.

### B. Sparse Covariance Matrix Estimation

In recent years, covariance matrix estimation in high-dimensional spaces has received a lot of attention. In the case of sparse covariance matrices, banding, tapering, and thresholding can be applied, see e.g. [26] All three make use of the fact that many entries of the matrix that shall be estimated are actually zero or at least very small. Banding and tapering differ from thresholding in that they assume a specific matrix structure in other words they assume an ordering of the variables which is for instance often the case in time-series analysis. Banding and tapering approaches typically lead to consistent estimators if $\log(N)/\mu \to 0$.

Thresholding does not assume a natural order of the variables. Instead, it discards entries which are smaller than a given threshold $\epsilon > 0$. For a matrix $\mathbf{A}$, the thresholding operator $T_\epsilon(\mathbf{A})$ is defined as

$$T_\epsilon(\mathbf{A}) := (a_{ij}\delta(|a_{ij}| \geq \epsilon))_{N\times N}. \tag{11}$$

The choice of the threshold is critical for the quality of the resulting estimate.

Equation (11) represents a example of universal thresholding with a hard thresholding function. Equation (11) can be extended in several ways. On the one hand, the threshold may depend on the entry itself, and on the other hand, instead of the hard threshold applied, a generalized shrinkage function $s_\lambda(\cdot)$ can be used. Following [22] , the function $s_\lambda(\cdot)$ should have the following properties

i) $\exists c > 0$: $s_\lambda(x) \leq c|y|$ $\forall\, x, y$ which satisfy $|x - y| \leq \lambda$,
ii) $s_\lambda(x) = 0$ $\forall x \leq \lambda$,
iii) $|s_\lambda(x) - x| \leq \lambda$ $\forall x \in \mathbb{R}$.

Several functions have been introduced that fulfill i)-iii), as e.g. the soft-thresholding

$$s_\lambda(x) = \operatorname{sign}(x)(|x| - \lambda)_+ \tag{12}$$

or the Lasso

$$s_\lambda(x) = |x|(1 - |\frac{\lambda}{x}|^\eta)_+ \tag{13}$$

with $(x)_+ := \max(0, x)$. In this paper, the threshold $\lambda_{ij}$ is defined component-wise and not universal. Since its correct choice is difficult to decide a priori, adaptive thresholding is applied as in [22], setting

$$\lambda_{ij} := \lambda_{ij}(\delta) = \delta\sqrt{\frac{\hat{\theta}_{ij}\log N}{\mu}} \tag{14}$$

with $\delta > 0$ can be either chosen as a constant or adapted data driven. The variable $\hat{\theta}_{ij}$ that appears in (14) is obtained as

$$\hat{\theta}_{ij} = \frac{1}{\mu}\sum_{m=1}^{\mu} [(\hat{z}_{mi} - \overline{Z^i})((\hat{z}_{mj} - \overline{Z^j}) - \hat{c}_{ij}^{\mu}]^2 \tag{15}$$

```
Require: $\lambda$, $\mu$, $\mathbf{C}^{(0)}$, $\mathbf{m}^{(0)}$, $\sigma^{(0)}$, $\tau$, $c_\tau$

```

Fig. 1. The CMSA-ES with thresholding. The generation counter $g$ is sometimes left out in order to simplify the notation. The symbol *spectral* stands for the spectral decomposition of the matrix into the modal matrix $\mathbf{V}$ and the diagonal matrix containing the eigenvalues $\mathbf{D}$. Rank-based deterministic selection of the $\mu$ best offspring is performed in line 8 based on the fitness $f$.

with $\hat{c}_{ij}^{\mu}$ denoting the $(i,j)$-entry of $\hat{\mathbf{C}}_\mu^{(g+1)}$, $\hat{z}_{mi}$ the $i$th component of $\hat{\mathbf{z}}_{m:\lambda}$, and $\overline{Z^i} := (1/\mu) \sum_{m=1}^{\mu} \hat{z}_{mi}$. Other thresholds have been introduced, see e.g. [27] and will be considered in future work.

While thresholding respects symmetry and non-negativeness properties, it results only in asymptotically positive definite matrices. Thus, for finite sample sizes, it does neither preserve nor induce positive definiteness in general. This holds for hard thresholding as well as for most cases of potential thresholding functions. As shown in [28], a positive semi-definiteness can only be guaranteed for a small class of functions for general matrices. In the case that the condition number of the matrix is sufficiently small, the group of functions that preserve positive definiteness can be widened to include also polynomials. In [27], procedures are discussed that result in positive definite matrices. As this paper aims for a proof of concept, it does not consider repair mechanisms.

### C. Evolution Strategies with Sparse Covariance Adaptation

Component-wise adaptive thresholding can be integrated readily into evolution strategies. Figure 1 illustrates the main points of the algorithm. There are several ways to design the operator $T_{S_{\lambda_{ij}}}$. The first choice concerns the thresholding function $s_{\lambda_{ij}}(\cdot)$. The second question concerns whether thresholding should be applied to all entries of the covariance matrix (11) or only to the off-diagonal elements. This question is difficult to decide beforehand in the application context considered. Therefore, two variants are investigated

1) CMSA-Thres-ES (abbreviated to Thres): An evolution strategy with CMSA which applies thresholding in the eigenspace of the covariance, using the operator

$$T_{S_{\lambda_{ij}}}(\mathbf{A})_{ij} = s_{\lambda_{ij}}(a_{ij}) \qquad (16)$$

and

2) CMSA-Diag-ES (abbreviated to Diag): An ES with covariance matrix adaptation which uses thresholding in the eigenspace of the covariance and excepts the diagonal elements with

$$T_{S_{\lambda_{ij}}}(\mathbf{A})_{ij} = \begin{cases} a_{ij} & \text{if } i = j \\ s_{\lambda_{ij}}(a_{ij}) & \text{if } i \neq j \end{cases}. \qquad (17)$$

In statistics, thresholding is often applied only to the off-diagonal entries. Keeping the diagonal unchanged may however result in a too strong reliance on the structure of the old covariance matrix in our case. This may make a change of the search directions difficult. Therefore, both variants are taken into account.

## III. Experiments

The experiments are performed for the search space dimensions $N = 10$ and 20. Since we aim for a general approach, the performance of the new techniques should also be analyzed for lower dimensional spaces. The maximal number of fitness evaluations is set to $\mathrm{FE}_{\max} = 2 \times 10^5 N$. The start position of the algorithms is randomly chosen from $[-4, 4]^N$. The population size were chosen as $\lambda = \lfloor \log(3N) + 8 \rfloor$ and $\mu = \lceil \lambda/2 \rceil$. The weights $w_m$ were set to $w_m = 1/\mu$.

A run terminates before reaching the maximal number of evaluations, if the difference between the best value obtained so far and the optimal fitness value $|f_{\mathrm{best}} - f_{\mathrm{opt}}|$ is below a predefined target precision set to $10^{-8}$. For each fitness function and dimension, 15 runs are used in accordance to the practice of the black box optimization workshops, see below. If the search stagnates, indicated by changes of the best values being below $10^{-8}$ for $10 + \lceil 30N/\lambda) \rceil$ generations, the ES is restarted. The Lasso thresholding function (13) with $\eta = 4$ was chosen as the thresholding function and by performing a preliminary series of experiments the scaling factor $\delta$ in (15) was set to $\delta = 2\max(\hat{\mathbf{C}}_\mu)$. Both choices can be probably improved. Since the paper strives for a first proof of concept, a detailed investigation of good parameter settings will be performed in future research.

### A. Test Suite

For the experiments, the algorithms were implemented in MATLAB. The paper uses black box optimization benchmarking (BBOB) software framework and the test suite introduced for the black box optimization workshops, see [29]. The goal of the workshop is to benchmark and to compare metaheuristics and other direct search methods for continuous optimization. The framework[1] allows the plug-in of algorithms adhering to a common interface and provides a comfortable way of generating the results in form of tables and figures.

TABLE I
SOME OF THE TEST FUNCTIONS USED FOR THE COMPARISON OF THE ALGORITHMS.

The test suite contains noisy and noise-less functions with the position of the optimum changing randomly from run to run. This paper focuses on the noise-less test suite which contains 24 functions [30]. They can be divided into four classes: separable functions (function ids 1-5), functions with low/moderate conditioning (ids 6-9), functions with high conditioning (ids 10-14), and two groups of multimodal functions (ids 15-24). Among the unimodal functions with only one optimal point, there are separable functions given by the general formula

$$f(\mathbf{x}) = \sum_{i=1}^{N} f_i(x_i) \qquad (18)$$

which can be solved by optimizing each component separately. The simplest member of this class is the (quadratic) sphere with $f(\mathbf{x}) = \|\mathbf{x}\|^2$. Other functions include ill-conditioned functions, like for instance the elliposoidal function, and multimodal functions (Rastrigin) which represent particular challenges for the optimization (Table I). The variable $\mathbf{z}$ denotes a transformation of $\mathbf{x}$ in order to keep the algorithm from exploiting certain particularities of the function, see [30].

### *B. Performance Measure*

The following performance measure is used in accordance to [29]. The expected running time (ERT) gives the expected value of the function evaluations ($f$-evaluations) the algorithm needs to reach the target value with the required precision for the first time, see [29]. In this paper, we use

$$\text{ERT} = \frac{\#(FEs(f_{\text{best}} \geq f_{\text{target}}))}{\#succ} \qquad (19)$$

as an estimate by summing up the fitness evaluations $FEs(f_{\text{best}} \geq f_{\text{target}})$ of each run until the fitness of the best individual is smaller than the target value, divided by all successfull runs.

### *C. Results and Discussion*

The findings are interesting – indicating advantages for thresholding in many but not in all cases. The result of the comparison depends on the function class. In the case of the separable functions with ids 1-5, the strategies behave on the whole very similar in the case of both dimensionalities 10D and 20D. This can be seen in the empirical cumulative distribution functions plots in Fig. 2 and Fig. 3 for example.

Concerning the particular functions, differences are revealed as Tab. II and Tab. III show for the expected running time (ERT) which is provided for several precision targets. The expected running time is provided relative to the best results achieved during the black-box optimization workshop in 2009. The first line of the outcomes for each function reports the ERT of the best algorithm of 2009. However, not only the ERT values but also the number of successes is important. The ERT can only be measured if the algorithm achieved the respective target in the run. If the number of trials where is the full optimization objective has been reached is low then the remaining targets should be discussed with care. If only a few runs contribute to the result, the findings may be strongly influenced by initialization effects. To summarize, only a few cases end with differences that are statistically significant. To achieve this, the algorithm has to perform significantly better than both competing methods – the other thresholding variant and the original CMSA-ES.

In the case of the sphere (function with id 1), slight advantages for the thresholding variants are revealed. A similar observation can be made for the second function, the separable ellipsoid. Here, both thresholded ESs are faster, with the one that only shrinks the off-diagonal elements significantly (Tab. III). This is probably due to the enforced more regular structure.

No strategy is able to reach the required target precision in the case of the separable Rastrigin (id 3) and the separable Rastrigin-Bueche (id 4). Since all strategies only achieve the lowest target precision of $10^1$, a comparison is not performed. The linear slope is solved fast by all, with the original CMSA-ES the best strategy.

In the case of the function class containing test functions with low to moderate conditioning, different findings can be made for the two search space dimensionalities. This is also shown by the empirical cumulative distribution functions plots in Fig. 2 and Fig. 3, especially for $N = 10$. Also in the case of $N = 10$, Table II shows that the strategies with thresholding achieve a better performance in a majority of cases. In addition, thresholding that is not applied to the diagonal appears to lead to a well-performing strategy with the exception of f9, the rotated Rosenbrock function, where it lead to the largest expected running times.

The results for f6, the so-called attractive sector, in 10D are astonishing. While the original CMSA-ES could only reach the required target precision in six of the 15 runs, the thresholding variants were able to succeed 14 times (CMSA-Thres-ES) and 13 times (CMSA-Diag-ES). The latter achieved lower expected running times, though. This does not transfer to 20D. Here, only a minority of runs were successfull for all strategies. Experiments with a larger number of fitness evaluations must be conducted in order to investigate the findings more closely.

The same holds for the step ellipsoid (id 7) which cannot be solved with the target precision required by any strategy. Concerning the lower precision targets, sometimes the CMSA-ES and sometimes the CMSA-Diag-ES appears superior. However, more research is required, since the number of runs entering the data for some of the target precisions is low and

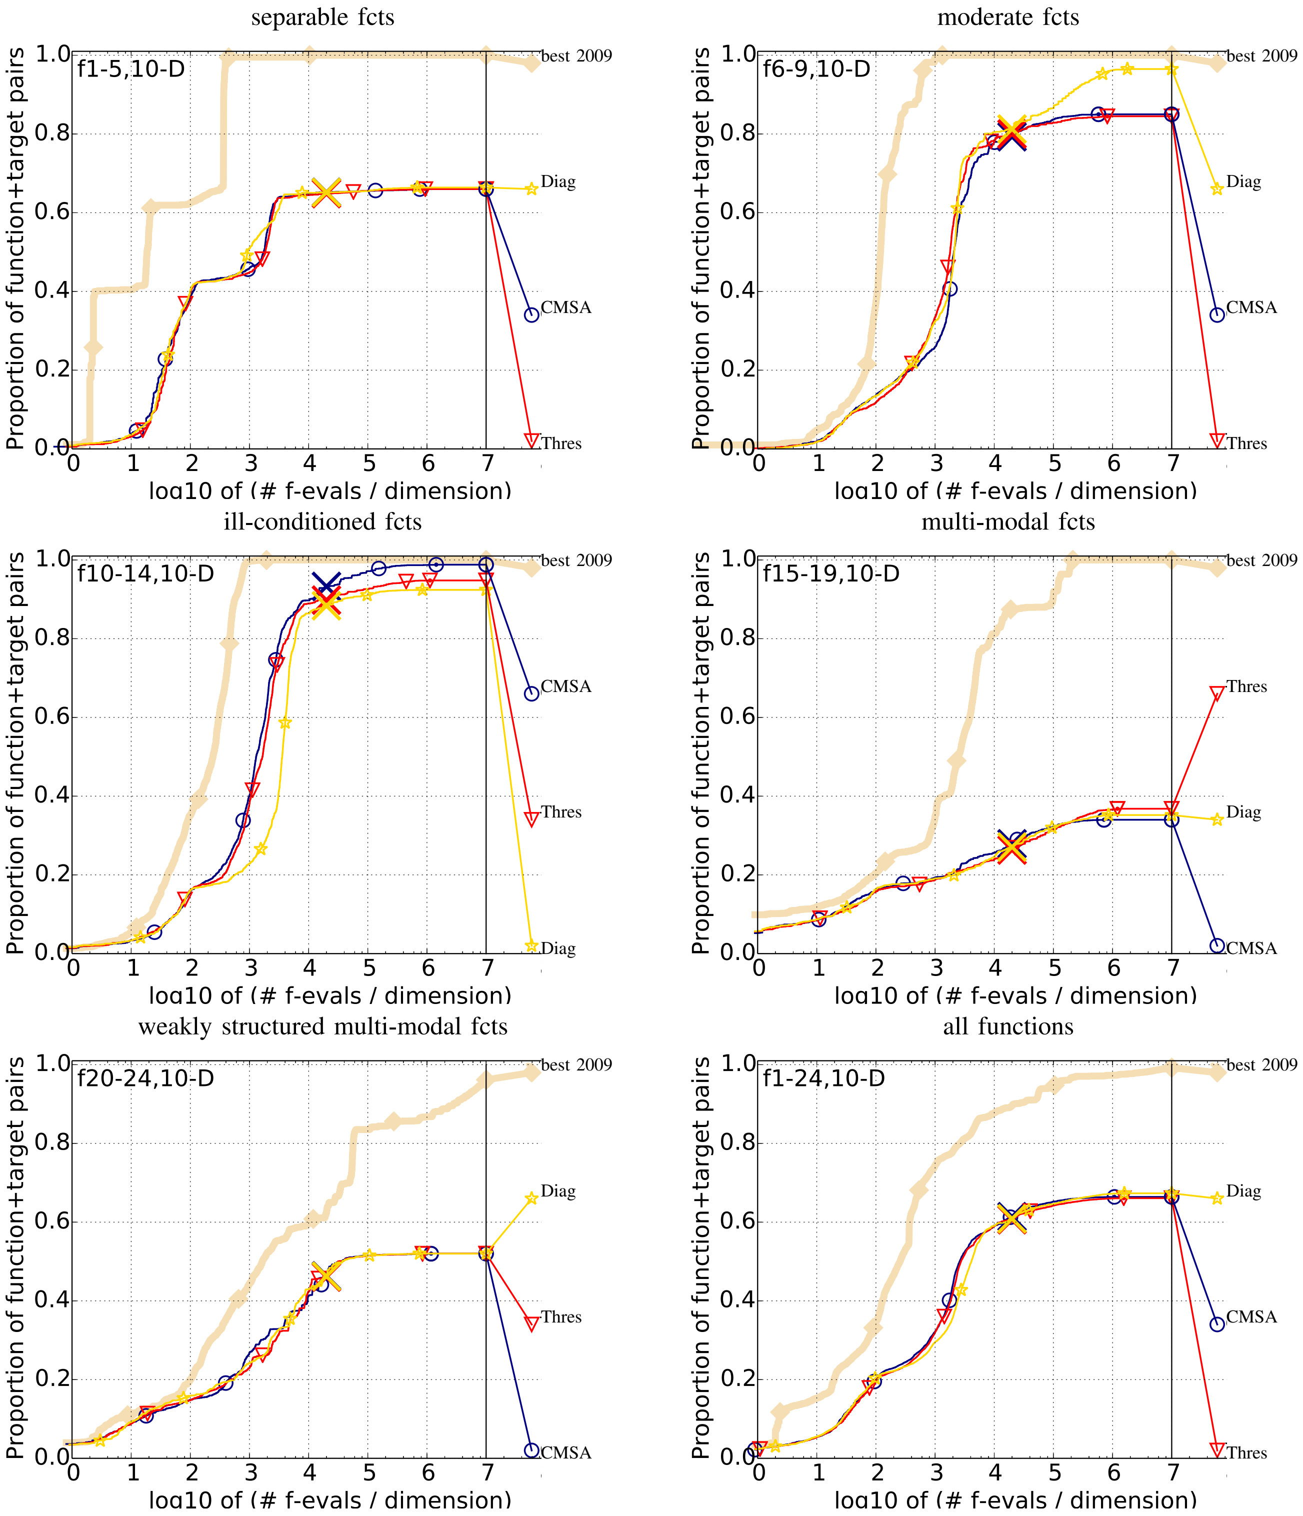

Fig. 2. Bootstrapped empirical cumulative distribution of the number of objective function evaluations divided by dimension (FEvals/DIM) for 50 targets in $10^{[-8..2]}$ for all functions and subgroups in 10-D. The "best 2009" line corresponds to the best ERT observed during BBOB 2009 for each single target.

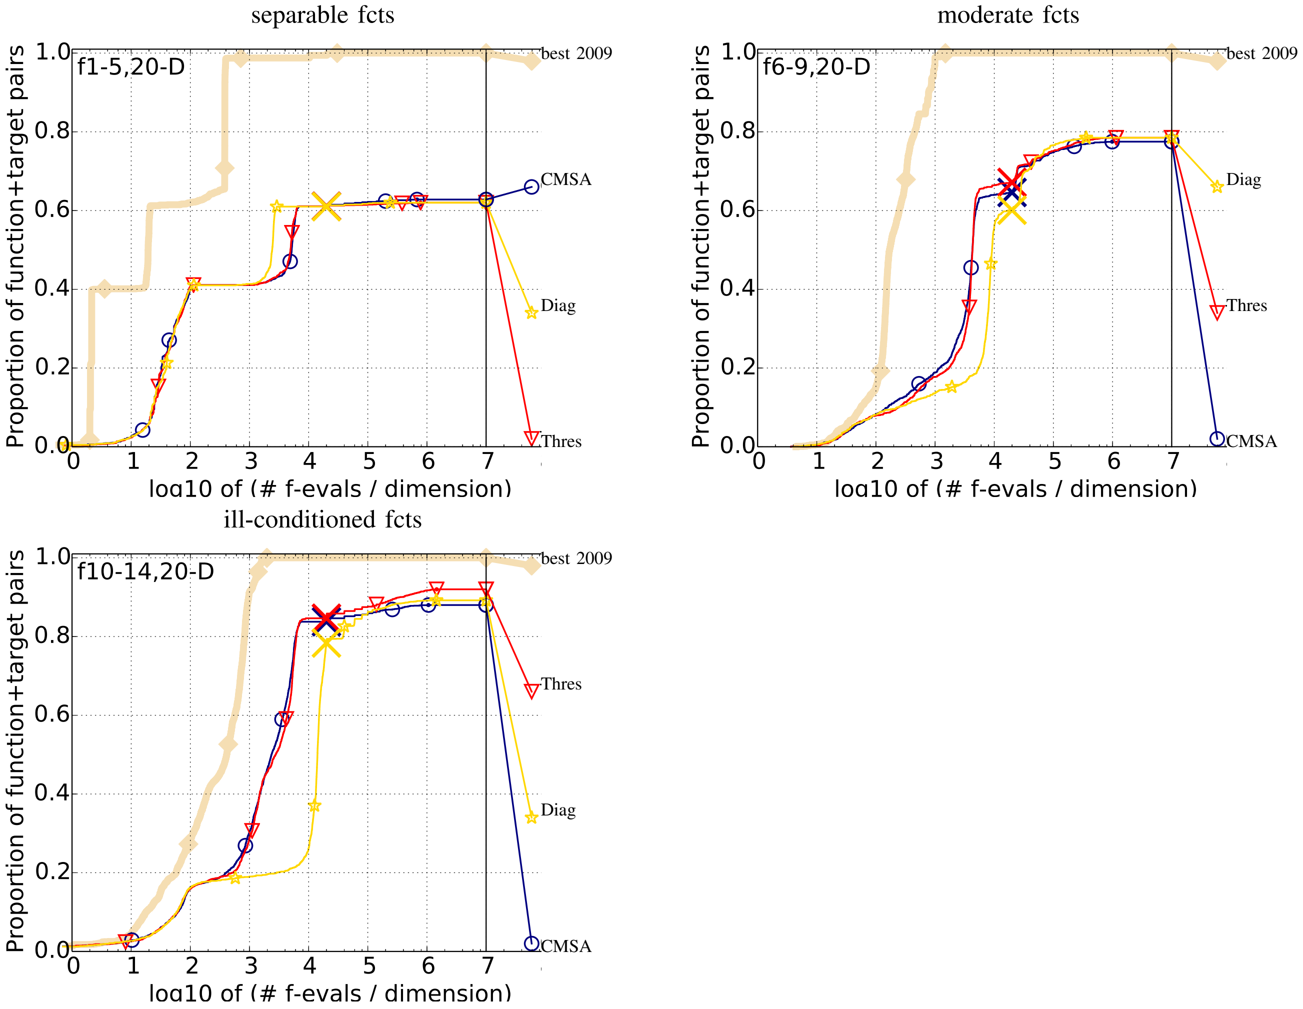

Fig. 3. Bootstrapped empirical cumulative distribution of the number of objective function evaluations divided by dimension (FEvals/DIM) for 50 targets in $10^{[-8..2]}$ for all functions and subgroups in 20-D. The "best 2009" line corresponds to the best ERT observed during BBOB 2009 for each single target.

initial positions may be influential.

On the original Rosenbrock function (id 8), the CMSA-ES and the CMSA with thresholding show a similar behavior with the CMSA-ES performing better. In contrast, the thresholding variant that leaves the diagonal unchanged exhibits larger expected running times. The roles of the original CMSA-ES and the CMSA-Thres-ES reverse for the rotated Rosenbrock (id 9). Here, the best results can be observed for the thresholding variant. Again, the CMSA-Diag-ES performs worst.

In the case of ill-conditioned functions, the findings are mixed. In general, thresholding without including the diagonal does not appear to improve the performance. The strategy performs worst of all – an indicator that keeping the diagonal unchanged may be sometimes inappropriate due to the space transformation. However, since there are interactions with the choice of the thresholding parameters which may have resulted in comparatively too large diagonal elements, we need to address this issue further before coming to a conclusion. First of all for $N = 10$, all strategies are successfull in all cases for the ellipsoid (id 10), the discus (id 11), the bent cigar (id 12), and the sum of different powers (id 14). Only the CMSA-ES reaches the optimization target in the case of the sharp ridge (id 13). This, however, only twice. The reasons for this require further analysis. Either the findings may be due to a violation of the sparseness assumption or considering that this is only a weak assumption the choice of the thresholding parameters and the function should be reconsidered.

All strategies exhibit problems in the case of the group of multi-modal functions, Rastrigin (id 15), Weierstrass (id 16), Schaffer F7 with condition number 10 (id 17), Schaffer F7 with condition 1000 (id 18), and Griewank-Rosenbrock F8F2 (id 19). Partly, this may be due to the maximal number of fitness evaluations permitted. Even the best performing methods of the 2009 BBOB workshop required more evaluations than we allowed in total. Thus, experiments with larger values for the maximal function evaluations should be conducted in future research. Concerning the preliminary targets with lower precision, the CMSA-ES achieves the best results in a majority of cases. However, the same argumentation as for the step ellipsoid applies.

In the case of $N$ = 20, the number of function evaluations that were necessary in the case of the best algorithms of 2009 to reach even the lower precision target of $10^{-1}$ exceeds the budget chosen here. Therefore, the function group is excluded from the analysis for $N$ = 20 and not shown in Figure 3 and Table III.

The remaining group consists of multi-modal functions with weak global structures. Here, especially the functions with numbers 20 (Schwefel $x \sin(x)$), 23 (Kaatsuuras), and 24 (Lunacek bi-Rastrigin) represent challenges for the algorithms. In the case of $N$ = 10, they can only reach the first targets of $10^1$ and $10^0$. Again, the maximal number of function evaluations should be increased to allow a more detailed analysis on these functions. For the case of the remaining functions, function 21, Gallagher 101 peaks, and function 22, Gallagher 21 peaks, the results indicate a better performance for the CMSA-ES versions with thresholding compared with the original algorithm. Again due to similar reasons as for the first group of multi-modal functions, the results are only shown for $N$ = 10.

## IV. Conclusions and Outlook

This paper adressed covariance matrix adaptation techniques for evolution strategies. The original versions are based on the sample covariance – an estimator known to be problematic. Especially in high-dimensional search spaces, where the population size does not exceed the search space dimensionality, the agreement of the estimator and the true covariance may be low. Therefore, thresholding, a comparably computationally simple estimation technique, has been integrated into the covariance adaptation process. Thresholding stems from estimation theory for high-dimensional spaces and assumes an approximately sparse structure of the covariance matrix. The matrix entries are therefore thresholded, meaning a thresholding function is applied. The paper considered adaptive entry-wise thresholding. Since the covariance matrix cannot be assumed to be sparse in general, a basis transformation was carried out and the thresholding process was performed in the transformed space. The performance of the resulting new covariance matrix adapting evolution strategies was compared to the original variant on the black-box optimization benchmarking test suite. Two main variants were considered: A CMSA-ES which subjected the complete covariance to thresholding and a variant which left the diagonal elements unchanged. While the latter is more common in statistics, it is not easy to justify its preferation in optimization. The first findings were interesting with the new variants performing better for several function classes. While this is promising, more experiments and analyses are required and will be performed in future research. This concerns e.g. which variant to use since it depended on the function which of the two performed best. Open questions concern among others the choice of the thresholding function and the scaling parameter for the threshold. In this paper, it was selected by a small series of experiments. Making the parameter completely data driven and thus depending on the current sample is the goal of ongoing research.

If the assumption that the representation of true covariance $\Sigma^{(g+1)}$ of the offspring population in the eigenspace of the previous covariance $C^{(g)}$ is approximately sparse should be violated in some cases, then it may be worthwhile to take a closer look at the convex combination of the new and the old covariance matrix. Further work will thus also consider applying thresholding to the traditionally obtained covariance.

TABLE III

EXPECTED RUNNING TIME (ERT IN NUMBER OF FUNCTION EVALUATIONS) DIVIDED BY THE RESPECTIVE BEST ERT MEASURED DURING BBOB-2009 IN DIMENSION 20. THE ERT AND IN BRACES, AS DISPERSION MEASURE, THE HALF DIFFERENCE BETWEEN 90 AND 10%-TILE OF BOOTSTRAPPED RUN LENGTHS APPEAR FOR EACH ALGORITHM AND TARGET, THE CORRESPONDING BEST ERT IN THE FIRST ROW. THE DIFFERENT TARGET $\Delta f$-VALUES ARE SHOWN IN THE TOP ROW. #SUCC IS THE NUMBER OF TRIALS THAT REACHED THE (FINAL) TARGET $f_{\mathrm{opt}} + 10^{-8}$. THE MEDIAN NUMBER OF CONDUCTED FUNCTION EVALUATIONS IS ADDITIONALLY GIVEN IN *italics*, IF THE TARGET IN THE LAST COLUMN WAS NEVER REACHED. ENTRIES, SUCCEEDED BY A STAR, ARE STATISTICALLY SIGNIFICANTLY BETTER (ACCORDING TO THE RANK-SUM TEST) WHEN COMPARED TO ALL OTHER ALGORITHMS OF THE TABLE, WITH $p = 0.05$ OR $p = 10^{-k}$ WHEN THE NUMBER $k$ FOLLOWING THE STAR IS LARGER THAN 1, WITH BONFERRONI CORRECTION BY THE NUMBER OF INSTANCES.

***Abstract*—Given an undirected weighted connected graph $G = (V, E)$ with vertex set $V$ and edge set $E$ and a designated vertex $r \in V$, we consider the problem of constructing a spanning tree in $G$ that balances both the minimum spanning tree and the shortest paths tree rooted at $r$. Formally, for any two constants $\alpha, \beta \geq 1$, we consider the problem of computing an $(\alpha, \beta)$-balanced spanning tree $T$ in $G$, in the sense that, (i) for every vertex $v \in V$, the distance between $r$ and $v$ in $T$ is at most $\alpha$ times the shortest distance between the two vertices in $G$, and (ii) the total weight of $T$ is at most $\beta$ times that of the minimum tree weight in $G$. It is well known that, for any $\alpha, \beta \geq 1$, the problem of deciding whether $G$ contains an $(\alpha, \beta)$-balanced spanning tree is NP-complete [15]. Consequently, given any $\alpha \geq 1$ (resp., $\beta \geq 1$), the problem of finding an $(\alpha, \beta)$-balanced spanning tree that minimizes $\beta$ (resp., $\alpha$) is NP-complete. In this paper, we present efficient genetic algorithms for these problems. Our experimental results show that the proposed algorithm returns high quality balanced spanning trees.**

***Index Terms*—Minimum Spanning Tree, Shortest Paths Tree, Balanced Spanning Tree, Genetic Algorithms, Graph Algorithms**

## I. Introduction

LET $G = (V, E)$ be an undirected edge-weighted connected graph with vertex set $V$ and edge set $E$ such that $|V| = n$ and $|E| = m$.

For any vertex $r$ in $G$, a spanning tree $T$ rooted at $r$ is a shortest paths tree if, for every vertex $v \in V$, the distance between $r$ and $v$ in $T_s$ equals the shortest distance between the two vertices in $G$. Dijkstra's algorithm is one of the well known polynomial time algorithms for computing shortest path tree in weighted graphs [22].

Note that, there exist weighted graphs in which the total weight of a shortest path tree may be much more than that of a minimum spanning tree, and vertices that are close to the designated root can be far away from the root in a minimum spanning tree (see [15] for an illustrative example). In this paper, we aim to find a spanning tree in weighted graphs that balances a minimum spanning tree and a shortest path tree, that is, a rooted tree of total weight at most a constant times the minimum tree weight, and the distance between the root and any vertex in the tree is at most a constant times the shortest distance between the two vertices in the graph. A formal definition of the problem can be described as follows.

*Definition 1:* [15] For any $\alpha, \beta \geq 1$, a rooted spanning tree $T$ of $G$ is called $(\alpha, \beta)$-balanced spanning tree if it satisfies the following two conditions:

1) For every vertex $v$, the distance between the root and $v$ in $T$ is at most $\alpha$ times the shortest distance between the two vertices in $G$.
2) The total weight of $T$ is at most $\beta$ times the minimum tree weight in $G$.

The shortest paths tree and minimum spanning tree are widely used in network routing. In particular, the shortest paths tree minimizes the delay from the source to every destination through a routing tree, and the minimum spanning tree minimizes the total routing cost along a tree. See [7], [14], [17], [21] and the references therein. Thus, balanced spanning tree is an appropriate routing tree for networks with the above two objectives.

Given any $\alpha \geq 1$, Awerbuch et al. [4] proposed an algorithm that approximates a minimum spanning tree and a shortest paths tree in edge-weighted graphs.

This work is partially supported by Alexander von Humboldt foundation

978-83-60810-66-8/$25.00©2015, IEEE

Namely, they modified the algorithm described in [3], [9] to compute an $(\alpha, 1+\frac{4}{\alpha-1})$-balanced spanning tree in $O(m+n\log n)$ time. Afterwards, Khullar et al. [15] improved the above result and presented a constructive linear time algorithm that outputs an $(\alpha, 1+\frac{2}{\alpha-1})$-balanced spanning tree. In other words, for any $\gamma > 0$, the algorithm of Khullar et al. [15] outputs an $(1+\sqrt{2}\gamma, 1+\frac{\sqrt{2}}{\gamma})$-balanced spanning tree in linear time.

For any $\alpha, \beta \geq 1$, the problem of deciding whether $G$ contains an $(\alpha, \beta)$-balanced spanning tree is NP-complete [15]. Consequently, given any $\alpha \geq 1$, the problem of finding an $(\alpha, \beta)$-balanced spanning tree that minimizes $\beta$ is NP-complete. Analogously, given any $\beta \geq 1$, the problem of finding an $(\alpha, \beta)$-balanced spanning tree that minimizes $\alpha$ is also NP-complete. In this paper, we present efficient genetic algorithms for these two problems. Our experimental results show that the proposed algorithm returns high quality balanced spanning trees.

The rest of this paper is organized as follows. Section II reviews some results on related problems. Section III presents the proposed genetic algorithm. Section IV evaluates our algorithm by applying it to randomly generated instances of the balanced spanning tree problem. Section V makes some concluding remarks.

## II. Related Work

In this section, we present results on related problems.

Bharath-Kumar and Jaffe [5] studied the problem of finding a rooted tree in the underlying graph such that the total distances from the root to all vertices is at most a constant times the minimum total distances from the root to all vertices.

For each graph $G$, the greatest distance between any two vertices in $G$ is called the diameter of $G$. A tree in a graph $G$ is called shallow-light tree if its diameter is at most a constant (greater than or equal 1) times the diameter of $G$ and with total weight at most a constant times the minimum tree weight. Awerbuch et al. [3] proved that each graph has a shallow-light tree.

Cong et al. [9] proposed a model of timing-driven global routing for cell-based design to improve the construction of a shallow-light tree based on the idea of finding minimum spanning trees with bounded radius. They designed an algorithm to find, for any constant $\epsilon > 0$, a spanning tree with radius $(1+\epsilon)\cdot R$ (using an analog of the classical Prim's minimum spanning tree structure), where $R$ is the minimum possible tree radius. They find a smooth trade-off between the radius and the cost of the tree. Afterwards, they proposed a new method [10] to improve their previous algorithm based on a provably good algorithm that simultaneously minimizes both total weight and longest interconnection path length of the tree. More specifically, their algorithm produced a tree with radius at most $(1+\epsilon)\cdot R$ and of total weight at most $(1+\frac{2}{\epsilon})$ times the minimum tree weight.

## III. Genetic Algorithm

In this section, we propose genetic algorithms to the two variants of the balanced spanning tree problem described in Section I. To avoid duplication, we present an algorithm for only one of these problems; the other variant of the problem can be described analogously. Namely, throughout this section, we focus on the problem in which we are given a constant $\alpha \geq 1$ and the objective is to compute an $(\alpha, \beta)$- balanced spanning tree that minimizes $\beta$.

We first introduce some terminologies that will be used throughout this section. Let $G'$ be a subgraph of $G$. The sets $V(G')$ and $E(G')$ denote the set of vertices and edges of $G'$, respectively. The shortest distance between two vertices $u$ and $v$ in $G'$ is denoted by $d_{G'}(u,v)$. We use $w(G')$ to denote the sum $\sum_{e\in E(G')} w(e)$ of weights of all edges in $G'$. For two subgraphs $G_1$ and $G_2$ of $G$, let $G_1 \cup G_2$, $G_1 \cap G_2$, and $G_1 - G_2$ denote the subgraph induced by $E(G_1)\cup E(G_2)$, $E(G_1)\cap E(G_2)$, and $E(G_1)-E(G_2)$, respectively. For any edge $e$ in $G$, let $Adj(e)$ denote the set of all adjacent edges to $e$ in $G$, where two edges of $G$ are called adjacent if they share a common vertex.

### A. Algorithm Overview

The Genetic Algorithm (GA) is an iterative optimization approach based on the principles of genetics and natural selection [2]. The first step of genetic algorithms is to determine a suitable data structure to represent individual solutions (chromosomes), and then construct an initial population (first generation) of prescribed cardinality $pop-size$. A typical intermediate iteration of genetic algorithms can be outlined as follows. Starting with the current generation, we use a predefined selection technique to repeatedly choose a pair of individuals (parents) in the current generation to reproduce, with probability $p_c$, a new set of individuals (offsprings) by applying crossover operation to the selected pair. To keep an appropriate diversity among different generations, we apply mutation operation with specific probability $p_m$ to genes of individuals of the current generation to get more offsprings. A new generation is then selected from both the offspring and the current generation based on their fitness values (the more suitable solutions have more chances to reproduce). The algorithm terminates when it meets prescribed stopping criteria.

A formal description of the proposed genetic algorithm is given in Algorithm 1.

In genetic algorithms, determining representation method, population size, selection technique, crossover and mutation probabilities, and stopping criteria are crucial since they mainly affect the convergence of the algorithm (see [1], [13], [18], [19], [20]).

The rest of this section is devoted to describe steps of Algorithm 1 in details.

### *B. Representation*

Let $G = (V, E)$ be a given undirected graph such that $V = \{1, 2, \ldots, n\}$. Note that, each edge $e \in E$ with end points $i$ and $j$ can be defined by an unordered pair $\{i, j\}$, and consequently, any subgraph $G'$ of $G$ is uniquely defined by the set of unordered pairs of all its edges. In particular, any spanning tree $T$ in $G$ is induced by a set of exactly $n-1$ pairs corresponding to its edges since $T$ is a subgraph of $G$ that spans all vertices in $V$ and has no cycles. Therefore, each chromosome (spanning tree) can be represented as a sequence of ordered pairs of integers each of which represent a gene (edge) in the chromosome.

### *C. Initial Population*

Before initializing the first generation of the genetic algorithm, we have to first decide its size $pop-size$. As mentioned before, this decision on population size affect the convergence of the algorithm. In particular, small population size may lead to weak solutions, while, large population size increases the space and time complexity of the algorithm. Many literatures studied the influence of the population size to the performance of genetic algorithms (see [19] and the references therein). In this paper, we discuss the effect of the population size on the convergence time of the algorithm (cf. Section IV).

**Algorithm 1** Genetic Algorithm for the Balanced Spanning Tree Problem

```
Input: An edge-weighted graph $G$, a population size $pop - size$, a maximum number of generations
    $maxgen$, a crossover probability $p_c$, a mutation probability $p_m$, a shortest paths tree $T_s$,
    a minimum spanning tree $T_m$, and a real number $\alpha \geq 1$.
Output: An $(\alpha, \beta)$-balanced spanning tree that minimizes $\beta$.
1. Compute an initial population $I_0$ (cf. Section III-C).
2. $gen \leftarrow 1$.
3. While ($gen \leq maxgen$) do
4.    For $i = 1$ to $pop - size$ do
5.       Select a pair of chromosomes from $I_{gen-1}$ (cf. Section III-D).
6.       Apply crossover operator with probability $p_c$
         to the selected pair of chromosomes to get
         two offsprings (cf. Section III-E).
7.    Endfor
8.    For each chromosome in $I_{gen-1}$, apply mutation
      operator with probability $p_m$ to get an offspring
      (cf. Section III-F).
9.    Extend $I_{gen-1}$ with valid offsprings output from
      lines 6 and 8.
10.   Find the minimum total weight chromosome
      $T_{gen-1}$ in $I_{gen-1}$.
11.   If $gen \geq 2$ and $w(T_{gen-2}) = w(T_{gen-1}) =$
      $w(T_{gen})$, then break.
12.   Select $pop - size$ chromosomes from $I_{gen-1}$ to
      form $I_{gen}$ (cf. Section III-D).
13.   $gen \leftarrow gen + 1$.
14. Endwhile
15. Output $T_{gen}$.
```

We apply random initialization to generate an initial population. Namely, we compute each chromosome in the initial population by repeatedly applying the following simple procedure as long as the length of the chromosome (number of edges) is less than $n - 1$. Let $T$ denote the tree constructed so far by the procedure (initially, $T$ consists of a random vertex from $V(G)$). We first select a random vertex $v \notin V(T)$ from the set of the neighbors of all vertices in $T$, and then add the the edge $e = (u, v)$ to $T$, where $u$ is the neighbor of $v$ in $T$. It is easy to verify that the above procedure returns a tree after exactly $n-1$ iterations. The generated tree $T$ is added to the initial population only if it is valid, where a tree $T$ is said to be a valid chromosome if, for every vertex $v$ in $T$, it holds that $d_T(r,v) \leq \alpha \cdot d_G(r,v)$.

The above algorithm is repeated as long as the number of constructed population is less than $pop-size$.

### *D. Selection Process*

In this paper, we apply four common selection techniques: random selection, roulette wheel selection, stochastic universal sampling selection, and tournament selection. All these techniques, except the random selection, are called fitness-proportionate selection techniques since they are based on a predefined fitness function used to evaluate the quality of individual chromosomes. Here, the objective function of the underlying balanced spanning tree problem (i.e., the ratio of the the minimum weight tree to the total weight of the chromosome) is used as the fitness function of each chromosome. We assume that the same selection technique is used throughout the execution of the algorithm. The rest of this section is devoted to briefly describe these selection techniques.

**Random Selection (RS):** [2] It is the simplest selection operator, where each chromosome has the same probability to be selected. That is, from a population of size $q$, each chromosome has the chance to be chosen with probability $1/q$.

**Roulette Wheel Selection (RWS):** [2], [8] In the roulette wheel technique, the probability of selecting a chromosome is based on its fitness value. More precisely, each chromosome is selected with the probability that equals to its normalized fitness value, i.e., the ratio of its fitness value to the total fitness values of all chromosomes in the set from which it will be selected.

**Stochastic Universal Sampling Selection (SUS):** [6], [8] It is a single phase sampling; instead of a single selection pointer used in roulette wheel approach, SUS uses $h$ equally spaced pointers, where $h$ is the number of chromosomes to be selected from the underlying population. All chromosomes are represented in number line randomly and a single pointer $ptr \in (0, \frac{1}{h}]$ is generated to indicate the first chromosome to be selected. The remaining $h-1$ individuals whose fitness spans the positions of the pointers $ptr + i/h$, $i = 1, 2, \ldots, h-1$ are then chosen.

**Tournament Selection (TRWS):** [2], [6] In this approach, we first select a set of $k < pop-size$ chromosomes randomly from the current population. From the selected set, we choose the required number of chromosomes by applying the roulette wheel selection approach.

### *E. Crossover Process*

In each iteration of the algorithm we repeatedly select a pair of chromosomes (parents) from the current generation and then apply crossover operator with probability $p_c$ to the selected chromosomes to get new chromosomes (offsprings). Simulations and experimental results of the literatures show that a typical crossover probability lies between $0.75$ and $0.95$. There are two common crossover techniques: single-point crossover and multi-point crossover. Many researchers studied the influence of crossover approach and crossover probability to the efficiency of the whole genetic algorithm, see for example [17], [20] and the references therein. In this paper, we use a multi-point crossover approach by exchanging a randomly selected set of edges between the two parents. In particular, for each selected pair of chromosomes $T_1$ and $T_2$, we generate a random number $s \in (0,1]$. If $s < p_c$ holds, we apply crossover operator to $T_1$ and $T_2$ as follows.

Define the two sets $E_1 = E(T_1) - E(T_2)$ and $E_2 = E(T_2) - E(T_1)$ ($|E_1| = |E_2|$ holds). Let $t = |E_1| = |E_2|$, and generate a random number $k$ from $[1,t]$. We first choose a random subset $E_1'$ of cardinality $k$ from $E_1$, and then add $E_1'$ to $T_2$ to get a subgraph $T'$ (i.e., $T' = T_2 \cup E_1'$). Clearly, $T'$ contains $k$ cycles each of which contains a distinct edge from $E_1'$. For every edge $e = (u,v)$ in $E_1'$, we apply the following procedure to fix a cycle containing $e$. Let $\widetilde{T}$ be the current subgraph (initially, $\widetilde{T} = T'$). We first find a path $P_{\widetilde{T}}(u,v)$ between $u$ and $v$ in $\widetilde{T} - \{e\}$. We then choose an edge $\widetilde{e}$ in $P_{\widetilde{T}}(u,v)$ by applying the selection technique used in the algorithm to the set of all edges in $P_{\widetilde{T}}(u,v)$, assuming that the weight of each edge is its fitness value. Finally, we delete $\widetilde{e}$ from subgraph $\widetilde{T}$. Note that, edges of large weights in $P_{\widetilde{T}}(u,v)$ have more chances to be deleted, and hence it is more likely that the current subgraph $\widetilde{T}$ attains total weight less than that of $T' - \{e\}$. In general, it is more likely that offsprings output from the crossover operation attains total weights less than that of its parents.

Similarly, we apply the above crossover technique by interchanging the roles of $T_1$ and $T_2$ one more offspring. Finally, we add each of the resulting spanning trees to the set of generated offsprings if it is valid.

### F. Mutation Process

Mutation is a genetic operator that intends to maintain the diversity among different generations of the population by altering some random genes (edges) in a chromosome. This may allow the algorithm to get better solutions by avoiding local minimum. Many results analyzed the role of mutation operator in genetic algorithms [1], [13], [17].

For a chromosome $T$ in the current population, we apply mutation operator such that each edge in $T$ is mutated with probability $p_m$. The standard range of $p_m$ lies between $1/\ell$ and $0.5$, where $\ell$ is the length (number of edges) of the chromosome. With $p_m = 1/\ell$, at least one gene (edge) on average should mutate. On the other hand, with $p_m = 0.5$, half of the edges should mutate on average, and consequently a random offspring is generated. In particular, for each edge $e$ in $T$, we generate a random number $s \in (0, 1]$, and then mutate $e$ if $s < p_m$ holds by replacing $e$ with a random edge from $Adj(e) - E(T)$. Let $T'$ denote the subgraph obtained after applying mutation operator to $T$. If $T'$ is disconnected, then we discard it. Otherwise, $T'$ is a spanning tree.

Finally, we add the resulting spanning tree to the set of generated offsprings only if it is valid.

## IV. Experimental Results

In this section, we evaluate the proposed genetic algorithms by applying it to several random instances of both variants of the balanced spanning tree problem. In particular, we generate a random graph $G$ of $n$ nodes by applying Erdos and Renyi [11] approach in which an edge is independently included between each pair of nodes of $G$ with probability $p$. Here, we generate random graphs with sizes 6, 10, 15, and 20, and a randomly chosen probability $p$. Moreover, all edge weights of the generated graphs are set to random integers from the range $[1, 100]$.

For each of the generated graphs, we apply the proposed algorithm with different selection techniques and different values of $\alpha$ (resp., $\beta$). We set the population size $pop-size = 30$, the maximum number of iterations the genetic algorithm executes $maxgen = 300$, the crossover probability $p_c = 0.9$, and the mutation probability $p_m = 0.01$. The algorithm terminates if either the number of iterations exceeds $maxgen$ or the solution does not change for three consecutive iterations. All obtained solutions are compared with the corresponding optimal solutions obtained by considering all possibilities of valid spanning trees in the underlying graphs. There are many algorithms for finding all spanning trees in undirected graphs, see for example [12].

We discuss the effect of the values of $\alpha$ (resp., $\beta$) on the convergence of the algorithm. It is seen that the running time of the algorithm decreases as the the value of $\alpha$ (resp., $\beta$) increases, see Figures 1-2 (resp. Figures 5-6).

We also study the effect of the population size $pop-size$ to the convergence of the algorithm. From the experimental results, we observe that a constant fraction of the number of nodes $n$ is an appropriate value for the population size, see Figures 3-4 and Figures 7-8.

All results presented in this section were performed in MATLAB R2014b on a computer powered by a core i7 processor and 16 GB RAM.

### A. Minimizing $\beta$

In this section, we present our experimental results for the problem in which $\alpha$ is given and the objective is to minimize $\beta$. We apply our algorithm with different values of $\alpha$ from the range $[1, 2]$. The results of applying our genetic algorithm to random graphs with sizes $n = 6$, $n = 10$, $n = 15$, and $n = 20$, are shown in Table I, Table II, Table III, and Table IV, respectively. In particular, Tables I-IV compare the values of $\beta$ returned by the algorithm with the corresponding optimal value of $\beta$. It is seen that the proposed algorithm outputs optimal balanced spanning tree for all the instances the algorithm applies to.

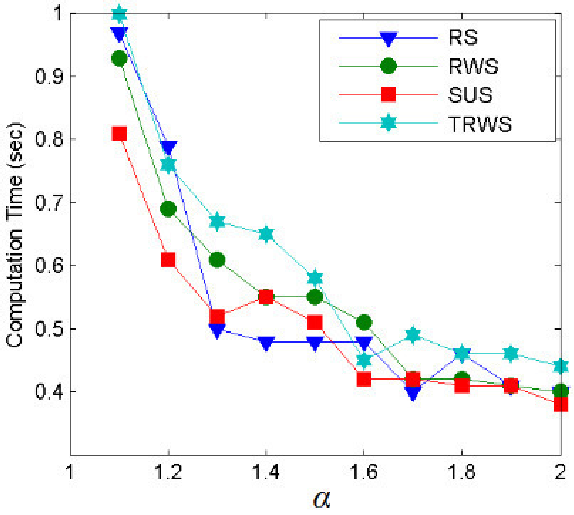

Fig. 1. The influence of $\alpha$ on the running time of the algorithm ($n = 15$)

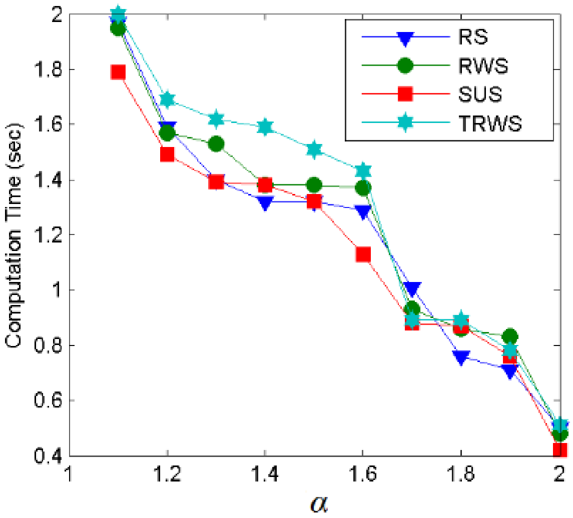

Fig. 2. The influence of $\alpha$ on the running time of the algorithm ($n = 20$)

Figures 1-2 show the influence of the value of $\alpha$ and the used selection technique on the execution time of the algorithm for graphs of $n = 15$ and $n = 20$, respectively. It is expected that the number of valid offsprings obtained in each iteration increases by relaxing the value of $\alpha$, and consequently it is more likely that the execution time of the algorithm decreases as the value of $\alpha$ increases.

We also evaluate the influence of the population size on the convergence of the proposed genetic algorithm. For a graph of $n$ nodes, we apply the algorithm with population sizes $n/3$, $2n/3$, $n$, $4n/3$, and $2n$. Figures 3-4 illustrate the running time of the algorithm applied to graphs of sizes $n = 15$, and $n = 20$, respectively, for fixed value $\alpha = 1.3$. We observe that the execution time of the algorithm increases as the population size increases, and the algorithm attains the least running time when the population size is set to a constant fraction of the graph size $n$.

### B. *Minimizing $\alpha$*

In this section, we present our experimental results for the problem in which $\beta$ is given and the objective is to

to graphs of sizes $n = 15$, and $n = 20$, respectively, for fixed value $\beta = 1.3$. We observe that the algorithm attains the least running time when the population size is set to a constant fraction of the graph size $n$.

## V. Conclusion

In this paper, we have studied the problem of finding a tree that balances a shortest path tree and a minimum spanning tree in undirected edge-weighted graphs. In particular, we have focused on two NP-complete variants of the problem in which we are given a bound on how far the required tree is from the shortest path tree (resp., minimum spanning tree), and the objective is to find the closest tree to the minimum spanning tree (resp., shortest path tree) under this bound. We have designed genetic algorithms for these problems. We have evaluated our algorithm by applying it to random graph instances. The algorithm outputs optimal balanced spanning tree for all instances it has been applied to. It will be interesting to relax our model to balanced subgraphs instead of balanced trees, that is, the problem of finding a minimum weight subgraph such that the distance between any two vertices $u$ and $v$ in the subgraph is at most a given constant times the shortest distance between the two vertices in the underlying graph (this problem is known as $t$-spanner problem in the literatures). See [23], [24], [25], [26] and the references therein.

***Abstract*—Fuzzy cognitive map (FCM) is a soft computing methodology that allows to describe the analyzed problem as a set of nodes (concepts) and connections (links) between them. In this paper a new Structure Optimization Genetic Algorithm (SOGA) for FCMs learning is presented for modeling complex decision support systems. The proposed approach allows to automatic construct and optimize the FCM model on the basis of historical multivariate time series. The SOGA defines a new learning error function with an additional penalty for highly complexity of FCM understood as a large number of concepts and a large number of connections between them. The aim of this study is the analysis of usefulness of the Structure Optimization Genetic Algorithm for fuzzy cognitive maps learning. Comparative analysis of the SOGA with other well-known FCM learning algorithms (Real-Coded Genetic Algorithm and Multi-Step Gradient Method) was performed on the example of prediction of rented bikes count. Simulations were done with the ISEMK (Intelligent Expert System based on Cognitive Maps) software tool. The obtained results show that the use of SOGA allows to significantly reduce the structure of the FCM model by selecting the most important concepts and connections between them.**

## I. Introduction

FUZZY cognitive map (FCM) [16] is a soft computing methodology combining the advantages of fuzzy logic and artificial neural networks. It allows to visualize and analyze problem as a set of nodes (concepts) and links (connections between them). One of the most important aspect connected with the use of fuzzy cognitive maps is their ability to learn on the basis of historical data [22]. Supervised [14], [15], [25] and population-based [1], [7], [8], [20], [28] methods allow to evaluate the weights of connections.

Fuzzy cognitive maps are an effective tool for modeling dynamic decision support systems [18]. They were applied to many different areas, such as prediction of pulmonary infection [19], scenario planning for the national wind energy sector [2] or integrated waste management [4]. Carvalho discussed possible use of FCM as tool for modeling and simulating complex social, economic and political systems [5]. The use of FCMs as pattern classifiers is presented in [23]. An innovative method for forecasting artificial emotions and designing an affective decision system on the basic of fuzzy cognitive map is proposed in [26]. The application of fuzzy cognitive maps to univariate time series modeling is discussed in [13], [12], [17]. Prediction of work of complex and imprecise systems on the basis of FCM is described in [27].

In practical applications to solve certain classes of problems (e.g. data analysis, prediction or diagnosis), finding the most significant concepts and connections plays an important role. It can be based on expert knowledge at all stages of analysis: designing the structure of the FCM model, determining the weights of the relationships and selecting input data. Supervised and population-based algorithms allow the automatic construction of fuzzy cognitive map on the basis of data selected by the experts or all available input data. However, modeling of complex systems can be difficult task due to the large amount of the information about analyzed problem. Fuzzy cognitive maps with the large number of concepts and connections between them can be difficult to interpret and impractical to use as the number of parameters to be established grows quadratically with the size of the FCM model [13]. In [12] nodes selection criteria for FCM designed to model univariate time series are proposed. Also some simplifications strategies by posteriori removing nodes and weights are presented [13].

In [21] the Structure Optimization Genetic Algorithm allowing selection of the crucial connections is proposed. In this paper, we present an extension of this algorithm that allows to significantly reduce the size of FCM by automatic selection not only the most important connections but also the most important concepts from all possible nodes. The proposed approach enables fully automatic construction of the FCM model by selection of crucial concepts and determining the relationships between them on the basis of available historical data. The SOGA is compared with well-known methods: the Multi-Step Gradient Method (MGM) [14] and the Real-Coded Genetic Algorithm (RCGA) [28] on the example of system for prediction of count of rented bikes. Learning and

978-83-60810-66-8/$25.00©2015, IEEE

testing of FCMs are based on historical multivariate time series, taken from the UCI Machine Learning Repository [6]. Simulations are accomplished with the use of the developed ISEMK (Intelligent Expert System based on Cognitive Maps) software tool [24].

The aims of this paper are:

- to introduce a new FCM learning algorithm that allows to automatic optimize the structure of fuzzy cognitive map by finding the most important concepts and connections between them on the basic of historical data,
- to perform a comparative analysis of the proposed method of FCM learning with other well-known algorithms on the example of system for prediction of count of rented bikes.

The paper is organized as follows. In Section II fuzzy cognitive maps are described. Section III introduces the proposed method for fuzzy cognitive maps learning. Section IV describes the developed software tool ISEMK. Section V presents selected results of simulation analysis of the proposed approach. The last Section contains a summary of the paper.

## II. Fuzzy Cognitive Maps

The structure of FCM is based on a directed graph:

$$< X, W > , \tag{1}$$

where $X = [X_1, ..., X_n]^T$ is the set of the concepts significant for the analyzed problem, $W$ is weights matrix, $W_{j,i}$ is the weight of the connection between the $j$-th concept and the $i$-th concept, taking on the values from the range $[-1, 1]$. Value of $-1$ means full negative influence, 1 denotes full positive influence and 0 means no causal effect [16].

Concepts obtain values in the range between $[0, 1]$ so they can be used in time series prediction. The values of concepts can be calculated according to the formula:

$$X_i(t+1) = F\left(X_i(t) + \sum_{j \neq i} W_{j,i} \cdot X_j(t)\right) , \tag{2}$$

where $t$ is discrete time, $t = 0, 1, 2, ..., T$, $T$ is end time of simulation, $X_i(t)$ is the value of the $i$-th concept, $i = 1, 2, ..., n$, $n$ is the number of concepts, $F(x)$ is a transformation function, which can be chosen in the form:

$$F(x) = \frac{1}{1 + e^{-cx}} , \tag{3}$$

where $c > 0$ is a parameter.

Fuzzy cognitive map can be automatic constructed with the use of supervised and population-based learning algorithms. In the next section, selected methods of FCMs learning are described.

## III. Fuzzy Cognitive Maps Learning

The aim of the FCM learning process is to estimate the weights matrix $W$. In the paper a new population-based approach for fuzzy cognitive maps learning is analyzed. Performance of the Structure Optimization Genetic Algorithm is compared with the Real-Coded Genetic Algorithm and the Multi-Step Gradient Method. Description of these methods is presented below.

### A. Real-Coded Genetic Algorithm

Real-Coded Genetic Algorithm defines each chromosome as a floating-point vector, expressed as follows [28]:

$$W' = [W_{1,2}, ..., W_{1,n}, W_{2,1}, W_{2,3}, ..., W_{2,n}, ..., W_{n,n-1}]^T , \tag{4}$$

where $W_{j,i}$ is the weight of the connection between the $j$-th and the $i$-th concept.

Each chromosome in the population is decoded into a candidate FCM and its quality is evaluated on the basis of a fitness function according to the objective [9]. The aim of the analyzed learning process is to optimize the weights matrix with respect to the prediction accuracy. Fitness function can be described as follows:

$$fitness_p(J_l) = \frac{1}{a \cdot J(l) + 1} , \tag{5}$$

where $a$ is a parameter, $a > 0$, $p$ is the number of chromosome, $p = 1, ..., P$, $P$ is the population size, $l$ is the number of population, $l = 1, ..., L$, $L$ is the maximum number of populations, $J(l)$ is the learning error function, described as follows:

$$J(l) = \frac{1}{(T-1)n_o} \sum_{t=1}^{T-1} \sum_{i=1}^{n_o} (Z_i^o(t) - X_i^o(t))^2 , \tag{6}$$

where $t$ is discrete time of learning, $T$ is the number of the learning records, $Z(t) = [Z_1(t), ..., Z_n(t)]^T$ is the desired FCM response for the initial vector $Z(t-1)$, $X(t) = [X_1(t), ..., X_n(t)]^T$ is the FCM response for the initial vector $Z(t-1)$, $n$ is the number of the all concepts, $n_o$ is the number of the output concepts, $X_i^o(t)$ is the value of the $i$-th output concept, $Z_i^o(t)$ is the reference value of the $i$-th output concept.

Each population is assigned a probability of reproduction. According to the assigned probabilities parents are selected and new population of chromosomes is generated. Chromosomes with above average fitness tend to receive more copies than those with below average fitness [9]. The basic operator of selection is a roulette wheel method. For each chromosome in population the probability of including a copy of such chromosome into the next population can be calculated according to the formula [11]:

$$P(p) = \frac{fitness_p(J_l)}{\sum\limits_{i=1}^{P} fitness_i(J_l)} , \tag{7}$$

where $p$ is the number of the chromosome, $P$ is the population size.

The population is mapped onto a roulette wheel, where each chromosome $p$ is represented by a space that proportionally corresponds to $P(p)$. In the analysis a more effective ranking method of selection was used [3]. Selecting a copy of the chromosome into the next population is based on ranking by fitness [9].

The crossover operator is a method for sharing information between parents to form new chromosomes. It can be applied to random pairs of chromosomes and the likelihood of crossover depends on probability defined by the crossover probability $P_c$. The popular crossover operators are the single-point crossover and the uniform crossover [11].

The mutation operator modifies elements of a selected chromosome with a probability defined by the mutation probability $P_m$. The use of mutation prevents the premature convergence of genetic algorithm to suboptimal solutions [11]. In the analysis Mühlenbein's and random mutation were used. To ensure the survival of the best chromosome in the population, elite strategy was applied. It retains the best chromosome in the population [9].

The learning process stops when the maximum number of populations $L$ is reached or the condition (8) is met.

$$fitness_{best}(J_l) > fitness_{max}\ , \tag{8}$$

where $fitness_{best}(J_l)$ is the fitness function value for the best chromosome, $fitness_{max}$ is a parameter.

### B. Structure Optimization Genetic Algorithm

In this paper a new Structure Optimization Genetic Algorithm is proposed, which allows to select the most important for prediction task concepts and connections between them. SOGA defines each chromosome as a floating-point vector type (4) and a binary vector expressed as follows:

$$C' = [C_1, C_2, ..., C_n]^T\ , \tag{9}$$

where $C_i$ is the information about including the $i$-th concept to the candidate FCM model, whereas $C_i$ =1 means that the candidate FCM model contains the $i$-th concept, $C_i$ =0 means that the candidate FCM model does not contain the $i$-th concept.

The quality of each population is calculated based on an original fitness function, described as follows:

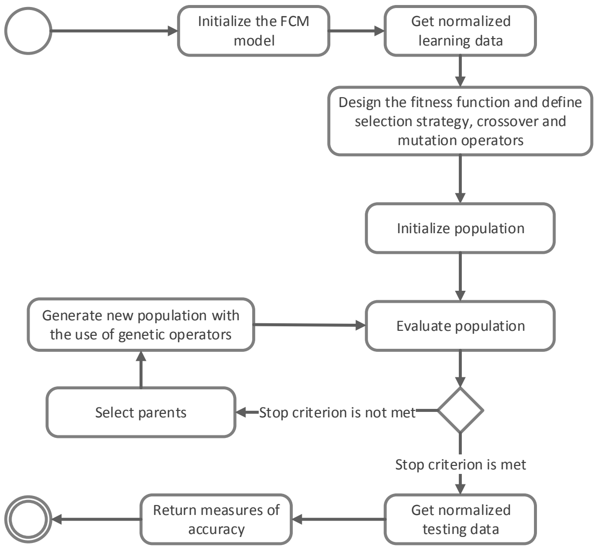
$$fitness_p(J'_l) = \frac{1}{a \cdot J'(l) + 1}\ , \tag{10}$$

where $a$ is a parameter, $a > 0$, $p$ is the number of the chromosome, $l$ is the number of population, $l = 1, ..., L$, $L$ is the maximum number of populations, $J'(l)$ is the new learning error function with an additional penalty for highly complexity of FCM understood as a large number of concepts and non-zero connections between them [10]:

$$J'(l) = J(l) + b_1 \cdot \frac{n_r}{n^2} \cdot J(l) + b_2 \cdot \frac{n_c}{n} \cdot J(l)\ , \tag{11}$$

where $t$ is discrete time of learning, $T$ is the number of the learning records, $b_1, b_1$ are the parameters, $b_1 > 0$, $b_2 > 0$, $n_r$ is the number of the non-zero weights of connections, $n_c$ is the number of the concepts in the candidate FCM model, $n$ is the number of the all possible concepts, $J(l)$ is the learning error function type (11).

Fig. 1 illustrates the steps of the learning and analysis of the FCM in modeling prediction systems with the use of population-based algorithms (SOGA and RCGA).



Initialize the FCM model
Get normalized learning data
Design the fitness function and define selection strategy, crossover and mutation operators
Initialize population
Evaluate population
Generate new population with the use of genetic operators
Select parents
Stop criterion is not met
Stop criterion is met
Get normalized testing data
Return measures of accuracy

Fig. 1. Activity diagram for population-based learning algorithm

In the paper the proposed algorithm was compared with the Real-Coded Genetic Algorithm and also with supervised learning based on Multi-Step Gradient Method.

### C. Multi-Step Gradient Method

Multi-step algorithms of FCM learning are some kind of generalization of known one-step methods. Effectiveness of these methods in modeling of decision support systems was presented in [15], [25]. Multi-step supervised learning based on gradient method is described by the equation [14]:

$$W_{j,i}(t+1) = P_{[-1,1]}(\sum_{k=0}^{m_1} \alpha_k \cdot W_{j,i}(t-k)+ \sum_{l=0}^{m_2}(\beta_l \cdot \eta_l(t) \cdot (Z_i(t-l) - X_i(t-l)) \cdot y_{j,i}(t-l)))\ , \tag{12}$$

where $\alpha_k, \beta_l, \eta_l$ are learning parameters, $k = 1, ..., m_1; l = 1, ..., m_2$, $m_1, m_2$ are the number of the steps of the method, $t$ is a time of learning, $t = 0, 1, ..., T-1$, $T$ is end time of learning, $X_i(t)$ is the value of the $i$-th concept, $Z_i(t)$ is the reference value of the $i$-th concept, $y_{j,i}(t)$ is a sensitivity function, $P_{[-1,1]}(x)$ is an operator of design for the set [-1,1], described as follows:

$$P_{[-1,1]}(x) = \frac{1 - e^{-x}}{1 + e^{-x}}\ , \tag{13}$$

Sensitivity function $y_{j,i}(t)$ is described by the equation:

$$\begin{aligned} y_{j,i}(t+1) = (y_{j,i}(t) + X_j(t)) \cdot F'(X_i(t) \\ + \textstyle\sum_{j \neq i} W_{j,i} \cdot X_j(t))\ , \end{aligned} \tag{14}$$

where $F'(x)$ is derivative of the stabilizing function.

Termination criterion can be expressed by the formula:

$$J(t) = \frac{1}{n} \sum_{i=1}^{n} (Z_i(t) - X_i(t))^2 < e\ , \tag{15}$$

where $e$ is a level of error tolerance.

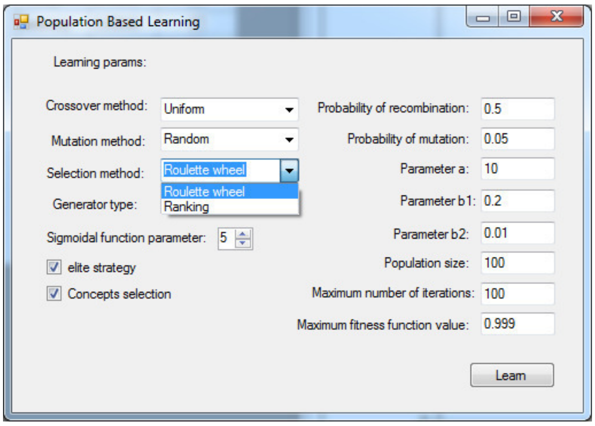
Simulation analysis of the presented algorithms performance was done with the use of ISEMK software tool. The basic features of ISEMK are described below.

## IV. ISEMK Software Tool

ISEMK is a universal tool for modeling decision support systems based on FCMs [24]. It allows to:

- initialize the structure of the FCM model historical data (reading from .data files),
- visualize the structure of the FCM model,
- learn the FCM model based on Multi-Step Gradient Method and historical data (reading from .data files),
- learn the FCM model with the use of population-based learning algorithms (RCGA, SOGA) and historical data (reading from .data files),
- test the accurace of the learned FCMs operation based on historical data (reading from .data files) by calculating Mean Squared Error measure,
- export the results of learning and testing to .csv files,
- visualize the results of learning and testing in the form of charts.

Figure 2 shows an exemplary initialization of SOGA. Figure 3 shows an exemplary visualization of testing of the learned FCM operation.



Population Based Learning

Learning params:

Crossover method: Uniform

Mutation method: Random

Selection method: Roulette wheel

Generator type:

Sigmoidal function parameter: 5

☑ elite strategy

☑ Concepts selection

Probability of recombination: 0.5

Probability of mutation: 0.05

Parameter a: 10

Parameter b1: 0.2

Parameter b2: 0.01

Population size: 100

Maximum number of iterations: 100

Maximum fitness function value: 0.999

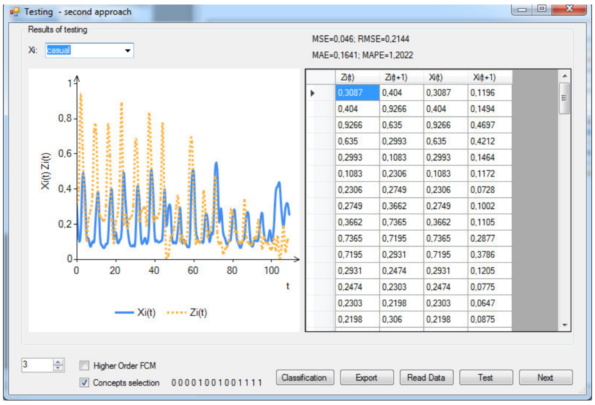
## V. Simulation Results

To evaluate the proposed Structure Optimization Genetic Algorithm, historical data taken from the UCI Machine Learning Repository [6] were used. The dataset contains bike sharing counts aggregated on daily basis (731 days) and has the following fields:

- season (1:springer, 2:summer, 3:fall, 4:winter),
- year (0: 2011, 1:2012),
- month ( 1 to 12),
- hour (0 to 23),
- holiday : weather day is holiday or not,
- weekday : day of the week,
- working day : if day is neither weekend nor holiday is 1, otherwise is 0,



Testing - second approach

□ Higher Order FCM

☑ Concepts selection 0 0 0 0 1 0 0 1 0 0 1 1 1 1

Fig. 3. Exemplary visualization of testing of learned FCM

- weather situation (1: Clear, Few clouds, Partly cloudy, Partly cloudy, 2: Mist + Cloudy, Mist + Broken clouds, Mist + Few clouds, Mist, 3: Light Snow, Light Rain + Thunderstorm + Scattered clouds, Light Rain + Scattered clouds, 4: Heavy Rain + Ice Pallets + Thunderstorm + Mist, Snow + Fog),
- temperature (normalized temperature in Celsius),
- feeling temperature (normalized feeling temperature in Celsius),
- humidity (normalized humidity),
- wind speed (normalized wind speed),
- casual (count of casual users),
- registered (count of registered users),
- count (count of total rented bikes including both casual and registered).

The core data set is related to the two-year historical log corresponding to years 2011 and 2012 from Capital Bikeshare system, Washington D.C., USA (http://capitalbikeshare.com/system-data). The corresponding weather and seasonal information (http://www.freemeteo.com) were added. Normalization of the available data in the $[0, 1]$ range is needed in order to use the FCM model. Conventional min-max normalization (16) can be used.

$$f(x) = \frac{x - min}{max - min} , \tag{16}$$

where $x$ is an input numeric value, $min$ is the minimum of the dataset, $max$ is the maximum of the dataset.

The aim of the study is one-step-ahead prediction of daily count of rented bikes based on the current values, environmental and seasonal settings. The dataset was divided into two subsets: learning (621 records) and testing (110 records) data. The learning process was accomplished with the use of Multi-Step Gradient Method, Real-Coded Genetic Algorithm and Structure Optimization Genetic Algorithm. Mean Squared Error for the output concepts (17) was used to estimate the performance of the FCM learning algorithms.

$$MSE = \frac{1}{n_o(T-1)} \sum_{t=1}^{T-1} \sum_{i=1}^{n_o} \left( Z_i^o(t) - X_i^o(t) \right)^2 , \tag{17}$$

where $t$ is time of testing, $t = 0, 1, ..., T-1$, $T$ is the number of the test records, $Z(t) = [Z_1(t), ..., Z_n(t)]^T$ is the desired FCM response for the initial vector $Z(t-1)$, $X(t) = [X_1(t), ..., X_n(t)]^T$ is the FCM response for the initial vector $Z(t-1)$, $X_i^o(t)$ is the value of the $i$-th output concept, $Z_i^o(t)$ is the reference value of the $i$-th output concept, $n_o$ is the number of the output concepts.

The learning process was accomplished for various learning parameters, determined using experimental trial and error method. Optimal parameters of all analyzed algorithms were chosen based on minimization of the objective function, described as follows:

$$f_c = f(MSE, n_r, n_c) = 10000MSE + n_r + 10n_c \ , \quad (18)$$

where $n_r$ is the number of the non-zero weights of the connections, $n_c$ is the number of the concepts.

The best results of all three approaches were selected. Fig. 4 presents the structure of the FCM learned with the use of MGM (for the following parameters: $m_1 = 1$, $m_2 = 0$, $\alpha_0 = 1.5$, $\alpha_1 = -0.5$, $\beta_0 = 50$, $\lambda_0 = 100$, $e = 0.001$, $c = 3$). Table I shows the weights matrix for this map. Fig. 5 presents the structure of the FCM learned with the use of RCGA (for the following parameters: $P = 100$, $L = 200$, ranking selection, uniform crossover, Mühlenbein's mutation, $a = 10$, $h_{max} = 0.999$, $c = 3$). Table II shows the weights matrix for this map. Fig. 6 presents the structure of the FCM learned with the use of SOGA (for the following parameters: $P = 100$, $L = 500$, ranking selection, uniform crossover, random mutation, $a = 100$, $h_{max} = 0.999$, $c = 5$, $b_1 = 0.1$, $b_2 = 0.01$). Table III shows the weights matrix for this map.

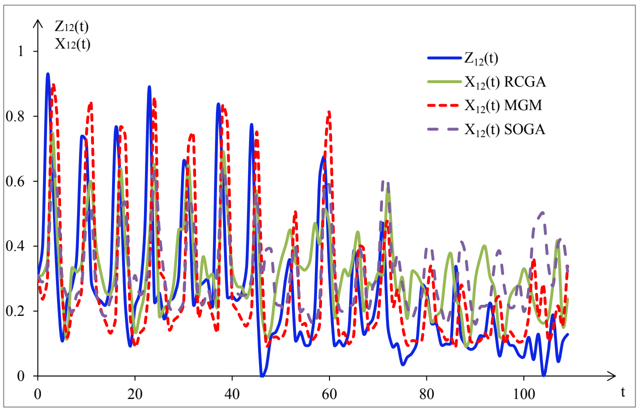

Fig. 7. Obtained values $X_{12}(t)$ and the desired values $Z_{12}(t)$ during testing

The lowest values of the objective function were obtained for the FCMs learned with the use of the Structure Optimization Genetic Algorithm. The minimum of $f_c = 471$ was achieved for the following parameters: $P = 100$, $L = 200$, ranking selection, uniform crossover, Mühlenbein's mutation, $a = 10$, $h_{max} = 0.999$, $c = 3$, $b_1 = 0.1$, $b_2 = 0.01$. Moreover, the second case of SOGA gives value of $MSE$ lowest than Multi-Step Gradient Method and very similar to Real-Coded Genetic Algorithm. Also, from the fig. 6, we can say that bike-sharing rental process is highly related to holiday, day of the week, feeling temperature, humidity and wind speed. The results show the superiority of the SOGA. It allows to significantly simplify the FCM model by selecting the most important for prediction task concepts (e.g. 8 out of 14 possible) and connections (e.g. 41 out of 182 possible) with keeping the low values of $MSE$.

TABLE IV

## VI. CONCLUSION

In this paper we present a new approach for fuzzy cognitive maps learning allowing selection of the most important for the analyzed tasks concepts and connections between them. The proposed Structure Optimization Genetic Algorithm is described together with well-known methods for FCM learning. Comparative analysis of SOGA, RCGA and MGM was performed on the example of prediction of count of rented bikes. Simulation research was done in ISEMK. Selected results of simulation analysis of the developed algorithms performance are presented. The obtained results show that the proposed approach can significantly reduce the size of FCM by selecting the most important concepts and connections between them. The SOGA algorithm seems to be promising and effective method for modeling complex decision support systems based on fuzzy cognitive maps. There are plans of further analysis of the use of the Structure Optimization Genetic Algorithm.

***Abstract*—Innovative algorithm for forming graph minimum convex hulls using the GPU is proposed. High speed and linear complexity of this method are achieved by distribution of the graph's vertices into separate units and their filtering. The key factor for improving the performance of innovative algorithm is the massively-parallel implementation of local hulls formation using video accelerators. A computational process is controlled by means of auxiliary matrices. A number of experimental studies of the algorithm have been carried out, and its suitability for application in the hull processing for large-scale problems has been demonstrated. The speed of the new method is 10 – 20 times higher compared to using functions of the professional mathematical package Wolfram Mathematica.**

***Index Terms*—Minimum convex hull, CPU+GPU hybrid system, GPGPU technology, High-performance computing, CUDA, Graph**

## I. Introduction

FINDING the minimum convex hull (MCH) of the graph's vertices is a fundamental problem in many areas of modern research [7]. The solution of this task involves the formation of the minimum convex set containing all the nodes present in the graph (Fig. 1a). It is known that MCH is a common tool in computer-aided design and computer graphics packages [21]. For example, Bezier's curves used in *Adobe Photoshop*, *GIMP* and *CorelDraw* for modeling smooth lines fully lie in the convex hull of their control nodes (Fig. 1b). This feature greatly simplifies finding the points of intersection between curves and allows their transformation (moving, scaling, rotating, etc.) by appropriate control nodes [23]. The formation of some fonts and animation effects in the *Adobe Flash* package also uses splines composed of quadratic Bezier's curves [8].

It should be noted that convex hulls are used in *Geographical Information Systems* and routing algorithms in determining the optimal ways for avoiding obstacles. The paper [1] offers the methods for solving complex optimization problems using them.

Last decades are associated with rapid data volume growth in research processed by the information systems [19]. According to IBM, about 15 petabytes of new information are created daily in the world [14]. Therefore, in modern science, there is a separate area called *Big Data* related to the study of large data sets [13]. However, most of the known algorithms for MCH construction have time complexity $O(nlogn)$, making them useless when forming solutions to large-scale graphs. Therefore, there is a need to develop efficient algorithms with the complexity close to linear $O(n)$.

TABLE I
COMPARISON OF THE COMMON ALGORITHMS FOR MCH CONSTRUCTION

| **Algorithm** | **Complexity** | **Parallel versions** | **Multidimensional cases** |
|---|---|---|---|
| Jarvis's march | $O(nh)$, where $h$ is a number of points on MCH | + | + |
| Graham's Scan | $O(nlogn)$ | - | - |
| QuickHull | $O(nlogn)$, in the worst case – $O(n^2)$ | + | + |
| Divide and Conquer | $O(nlogn)$ | + | + |

It is known that Wolfram Mathematica is one of the most powerful mathematical tools for the high performance computing. Features of this package encapsulate a number of algorithms and, depending on the input parameters of the problem, select the most productive ones [20]. Therefore, Wolfram Mathematica 9.0 is used to track the performance of the algorithm proposed in this article.

In recent years, CPU+GPU hybrid systems (GPGPU technology) allowing for a significant acceleration of computations have become widespread. Unlike CPU, consisting of several cores, the graphics processor is a multicore structure and the number of its components is measured in hundreds [16]. In this case, the sequential steps of algorithm are executed on the CPU, while its parallel parts are implemented on the GPU [20]. For example, the latest generation of NVIDIA Fermi GPUs contains 512 computing cores, allowing for the introduction of new algorithms with large-scale parallelism [9]. Thus, the usage of NVIDIA GPU ensures the conversion of standard workstations to powerful supercomputers with cluster performance [17].

The paper goal is to develop a high-speed algorithm for finding the minimum convex hulls using GPU. The time complexity of the proposed method is close to linear. The optimal values of algorithm's parameters, with which the usage of GPU resources is the most effective, are established in this paper.

## II. A REVIEW OF ALGORITHMS FOR FINDING THE MINIMUM CONVEX HULLS

Despite intensive research, which lasted for the past 40 years, the problem of developing efficient algorithms for MCH formation is still open. The main achievement is the development of numerous methods based on the extreme points determination of the original graph and the link establishment among them [6]. These techniques include the *Jarvis's march* [15], *Graham's Scan* [11], *QuickHull* [4], *Divide and Conquer* algorithm and many others. The main features of their practical usage are given in Table I.

For parallelization the *Divide and Conquer* algorithm is the most suitable. It provides a random division of the original vertex set into subsets, formation of partial solutions and their connection to the general hull [21]. Although the hull connection phase has linear complexity, it leads to a significant slowdown of the algorithm, and as a result, to the unsuitability of its application in the hull processing for large-scale graphs.

Chan's algorithm, which is a combination of slower algorithms, has the lowest time complexity $O(nlogh)$. However, it can work by the known number of vertices contained in the hull [3]. Therefore, currently, its usage in practice is limited [5].

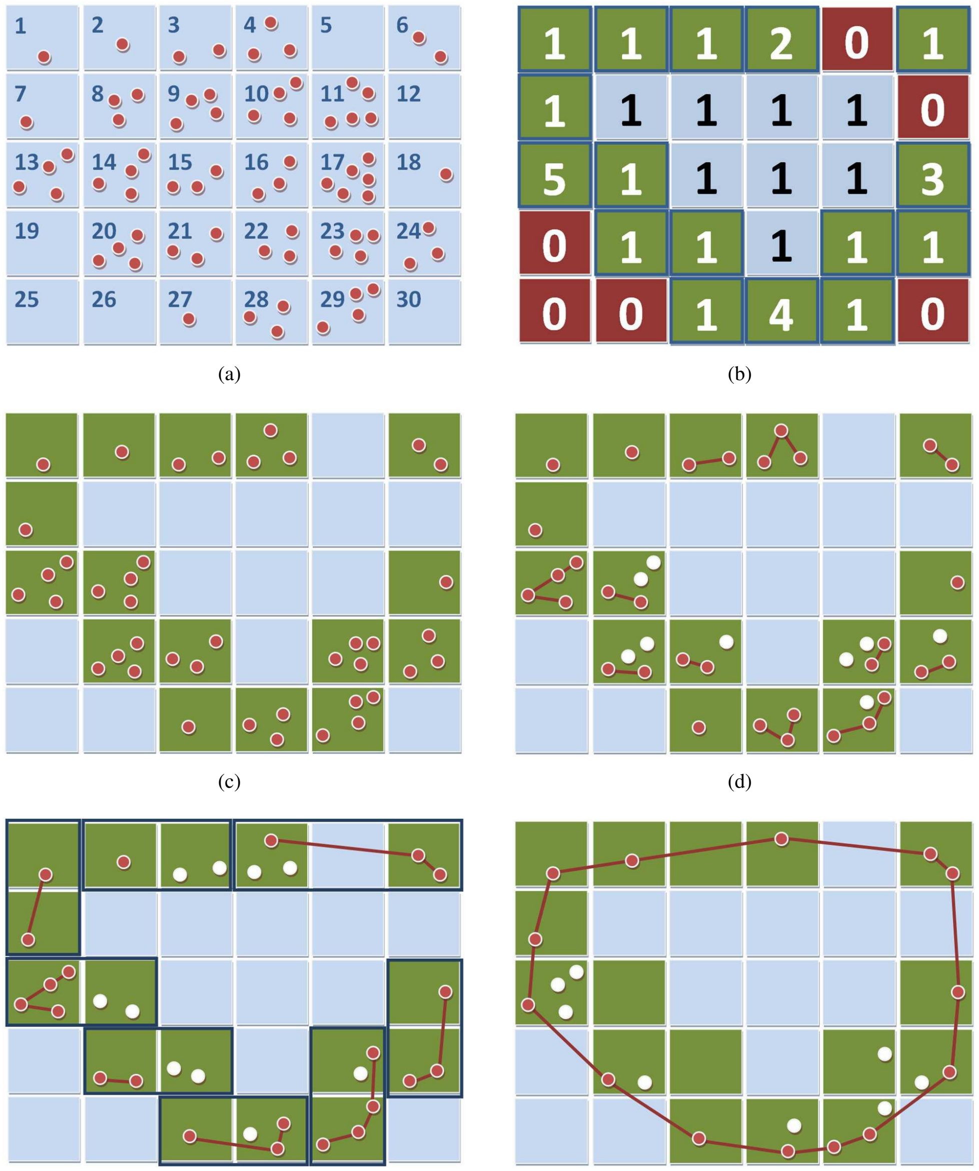
Study [2] gives a variety of acceleration tools for known MCH formation algorithms by cutting off the graph's vertices falling inside an octagon or rectangle and appropriate reducing the dimensionality of the original problem. The paper [12] suggests numerous methods of convex hull approximate formation, which have linear complexity. Such algorithms are widely used for tasks where speed is a critical parameter. But linearithmic time complexity of the fastest exact algorithms demonstrates the need for the introduction of new high-speed methods of convex hulls formation for large-scale graphs.

## III. INNOVATIVE ALGORITHM FOR FORMATION OF THE CONVEX HULLS

We shall consider non-oriented graph $G = (V, E)$. The new algorithm provides a division of the original graph's vertex set into a set of output units $U = \langle U_1, U_2, ..., U_n \rangle$, $U_i \subseteq V$. However, unlike the *Divide and Conquer* method, this division is not random, but it is based on the spatial distribution of vertices. All nodes of the graph should be distributed by the formed subsets, i.e. $\bigcup_{i=1}^{n} U_i = V$. This allows the presence of empty units, which do not contain vertices. Additionally, the condition of orthogonality division is met, i.e. one vertex cannot be a part of the different blocks: $U_i \cap U_j = \varnothing$, $\forall i \neq j$. Fig. 2a shows an example of division taking into account the above requirements.

The next stage of the proposed algorithm involves the formation of an auxiliary matrix based on the distribution of nodes by units. The purpose of this procedure is the primary filtration of the graph's vertices, which provides a significant decrease in the original problem dimensionality. In addition, the following matrices define the sets of blocks for the calculation in the subsequent stages of the algorithm and the sequence of their connection to the overall result. An auxiliary matrix formation involves the following operations:

1) Each block of the original graph must be mapped to one cell of the supporting matrix. Accordingly, the dimension of this matrix is $n \times m$, where $n$ and $m$ are the numbers of blocks allocated by the relevant directions.
2) The following operations provide the necessary coding of matrix's cells. Thus, the value of cell $c_{i,j}$ is zero if the corresponding block $U_{i,j}$ of original graph contains no vertices. Coding of blocks that contain extreme nodes (the highest, rightmost, lowest and leftmost points) of



(a) (b)

(c) (d)

(e) (f)

Fig. 2. Example of the algorithm execution

a given set is important for the algorithm. Appropriate cells are filled with numbers from 2 to 5. Other units that are filled, and contain no extreme peaks, shall be coded with ones in auxiliary matrix.

3) Further, primary filtration of allocated blocks is carried out using the filled matrix. Empty subsets thus shall be excluded from consideration. Blocks containing extreme vertices shall determine the graph division into parts for which the filtration procedure is applied. We shall consider the example of the block selection for the section limited with cells 2 – 3. If $c_{i,j} = 2$, then the next non-zero cell is searched by successive increasing of $j$. In their absence, the next matrix's row $i + 1$ is reviewed. Selection of blocks is completed, if the value of another chosen cell is $c_{i,j} = 3$. The study of the other graph's parts is based on a similar principle.

Partial solutions are formed for selected blocks. Such operations require the formation of fragments rather than full-scale hulls that provides secondary filtration of the graph's vertices. The last step of the algorithm involves the connection of partial solutions to the overall result. Thus the sequential merging of local fragments is done on a principle similar to *Jarvis's march*. It should be noted that at this stage filtration mechanism leads to a significant reduction in the dimensionality of the original problem. Therefore, when processing the hulls for large graphs, combination operations constitute about 0.1% of the algorithm total operation time.

We shall consider the example of this algorithm execution. Let the set of the original graph's vertices have undergone division into 30 blocks (Fig. 2a). Auxiliary matrix calculated for this case is given in Fig. 2b. After application of primary filtration, only 57% of the graph's nodes were selected for investigation at the following stages of the algorithm (Fig. 2c). The next operations require the establishment of local hulls (Fig. 2d) and their aggregations are given in Fig. 2e. After performing of pairwise connections, this operation is applied repeatedly until a global convex hull is obtained (Fig. 2f).

## IV. The development of hybrid CPU-GPU algorithm

We know that the video cards have much greater processing power compared to the central processing elements. GPU computing cores work simultaneously, enabling to use them to solve problems with the large volume of data. CUDA (*Compute Unified Device Architecture*), the technology created by NVIDIA, is designed to increase the productivity of conventional computers through the usage of video processors computing power [22].

CUDA architecture is based on SIMD (*Single Instruction Multiple Data*) concept, which provides the possibility to process the given set of data via one function. Programming model provides for consolidation of threads into blocks, and blocks – into a grid, which is performed simultaneously. Accordingly, the key to effective usage of GPU hardware capabilities is algorithm parallelization into hundreds of blocks performing independent calculations on the video card [24].

It is known that GPU consists of several clusters. Each of them has a texture unit and two streaming multiprocessors, each containing 8 computing devices and 2 superfunctional units [10]. In addition, multiprocessors have their own distributed memory resources (16 KB) that can be used as a programmable cache to reduce delays in data accessing by computing units [22]. From these features of CUDA architecture, it may be concluded that it is necessary to implement massively-parallel parts of the algorithm on the video cards, while sequential instructions must be executed on the CPU. Accordingly, the stage of partial solutions formation is suitable for implementation on the GPU since the operations for each of the numerous blocks are carried out independently.

It is known that function designed for executing on the GPU is called a kernel. The kernel of the innovative algorithm contains a set of instructions to create a local hull of any selected subset. In this case, distinguishing between the individual subtasks is realized only by means of the current thread's number. Thus, the developed hybrid algorithm has the following execution stages:

1) Auxiliary matrix is calculated on the CPU. The program sends cells' indexes that have passed the primary filtration procedure and corresponding sets of vertices to the video card.
2) Based on the received information, particular solutions are formed on the GPU, recorded to its global memory and sent to the CPU.
3) Further, the procedure of their merging is carried out and the overall result is obtained.

It should be noted that an important drawback of hybrid algorithms is the need to copy data from the CPU to the GPU and vice versa, which leads to significant time delays [16], [18]. Communication costs are considerably reduced by means of filtration procedure.

When developing high-performance algorithms for the GPU it is important to organize the correct usage of the memory resources. It is known that data storage in the global video memory is associated with significant delays in several hundred GPU cycles. Therefore, in the developed algorithm, the global memory is used only as a means of communication between the processor and video card. The results of intermediate calculations for each of the threads are recorded in the shared memory, access speed of which is significantly higher and is equal to 2 – 4 cycles.

## V. Experimental studies of the proposed algorithm

In the current survey, experimental tests were run on a computer system with an Intel Core i7-3610QM processor (2.3 GHz), 8 GB RAM and DDR3-1600 NVIDIA GeForce GT 630M video card (2GB VRAM). This graphics accelerator contains 96 CUDA kernels, and its clock frequency is 800 MHz.

It is known that the number of allocated blocks increases linearly with enhancing of processed graphs dimensionality. The complexity of calculating the relevant auxiliary matrices grows by the same principle. The stages of multi-step filtration and local hulls construction provide a significant simplification of final connection procedure. Thus, the complexity of the developed algorithm is linear $O(n)$ for uniformly distributed data.

MCH instances composed of all graph's vertices are the worst for investigation. In this case, the filtration operations do not provide the required acceleration and the algorithm complexity is equal to $O(nlogn)$. However, these examples have purely theoretical significance and almost never occur in practice.

Fig. 3 shows the dependence of the innovative algorithm execution time on the graph dimensionality and the number of vertices in the selected blocks. These results confirm the linear complexity of the proposed method. In addition, it is important to set the optimal dimensionality of the subsets allocated in the original graph. A selection of smaller blocks (up to 1000 nodes) leads to a dramatic increase in the algorithm operation time.

This phenomenon is caused by the significant enhancing of the auxiliary matrices dimensionality, making it difficult to control the computing process (Fig. 4). Per contra, the allocation of large blocks (over 5000 vertices) is associated with the elimination of the massive parallel properties, mismanagement of the video card resources, and as a consequence, increasing of the algorithm execution time. Thus, the highest velocity of the proposed method is observed for intermediate values of

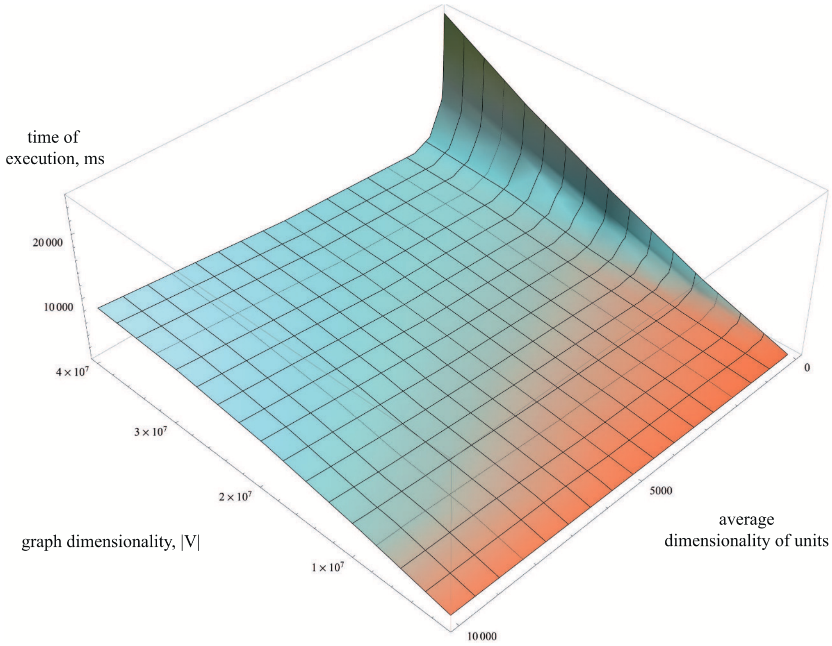


Fig. 3. Dependence of the innovative algorithm performance on the graph dimensionality and the number of vertices in the selected blocks

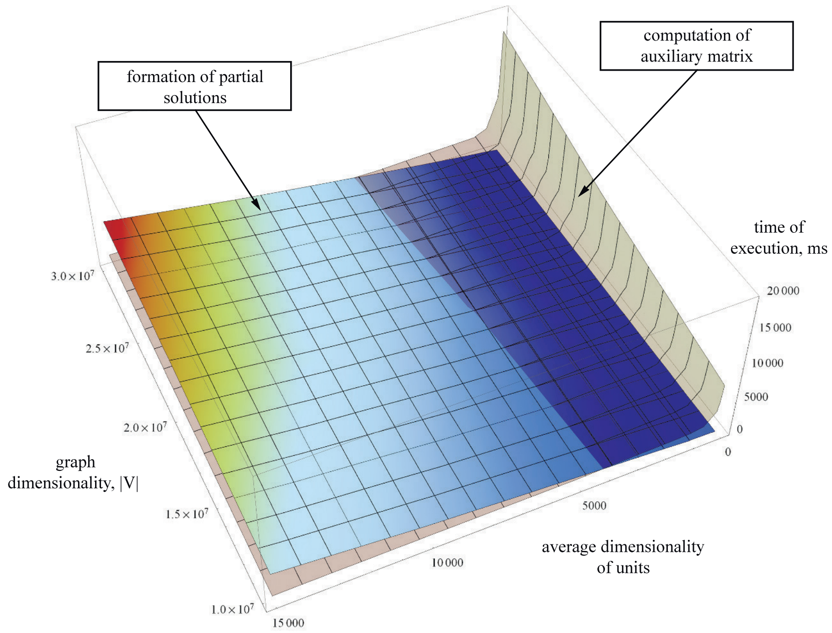

Fig. 4. Dependences of the various stages performance on the graph dimensionality and the number of vertices in the selected blocks

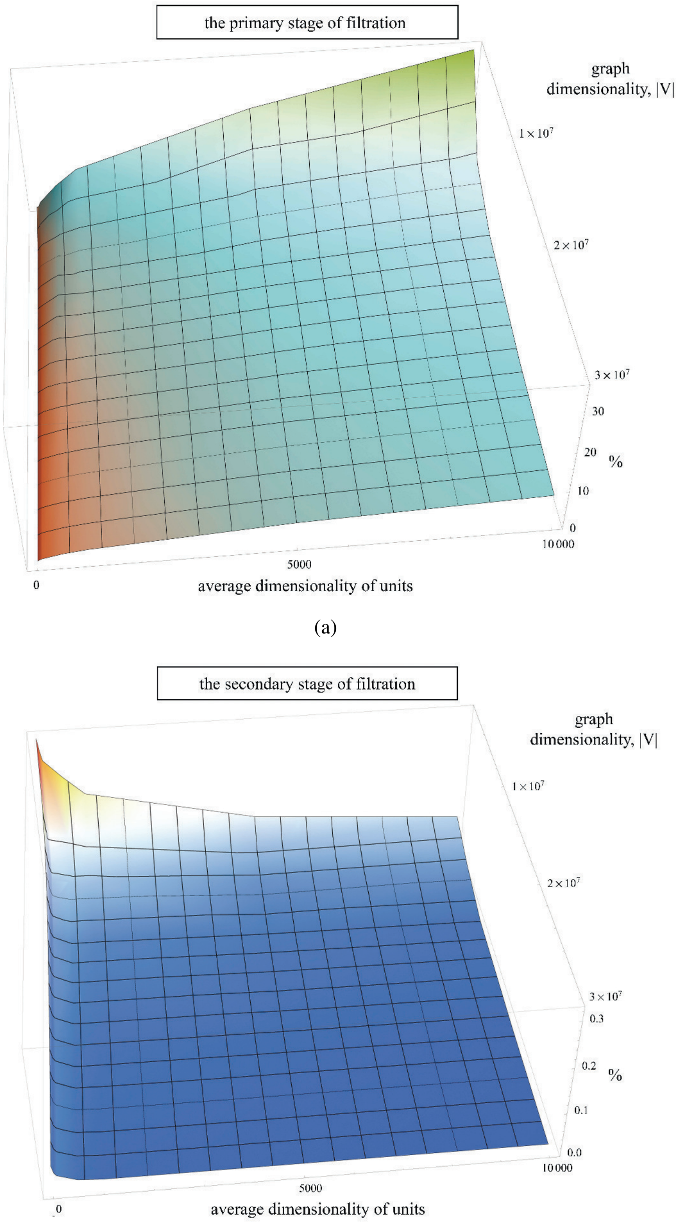
the blocks dimensionality (1000 – 5000 vertices). In this case, auxiliary matrices are relatively small, and the second stage of the algorithm preserves the properties of massive parallelism.

One of the most important means to ensure the algorithm's high performance is the multi-step filtration of the graph's vertices. Fig. 5a shows the dependence of the primary selection quality on the dimensionality of the original problem and allocated subsets. These results show that such filtration is the most efficient with the proviso that the graph's vertices are distributed into small blocks. Furthermore, the number of selected units increases with the raising of the problem's size, providing rapid solutions to graphs of extra large dimensionality. By virtue of a riddance from the discarded blocks, the following operations of the developed algorithm are applied only to 1 – 3% of the initial graph's vertices.

However, the results of the secondary filtration (Fig. 5b) are the opposite. In this case, the highest quality of the selection is obtained on the assumption that the original



(a)

(b)

Fig. 5. The influence of filtration procedure over the reduction in the problem's size

vertices are grouped into large subsets. Withal, the secondary filtration is much slower than the primary procedure, so the most effective selection occurs at intermediate values of the blocks dimensionality. As a result of these efforts, only 0.05 – 0.07% of the initial graph's vertices are involved in the final operations of the proposed algorithm.

In order to determine the efficiency of the developed algorithm, its execution time has been compared with the built-in tools of the mathematical package *Wolfram Mathematica 9.0*. All choice paired comparison tests were conducted for randomly generated graphs. The MCH formation in *Mathematica* package is realized by the instrumentality of *ConvexHull[]* function, while the *Timing[]* expression is used to measure the obtained performance. The results of the performed comparison are given in Fig. 6. They imply that the new algorithm computes the hulls up to 10 – 20 times faster than *Mathematica's* standard features.

## VI. Conclusions

The paper suggests an innovative algorithm for finding the minimum convex hulls, which is based on the GPGPU technology and uses graphic accelerators. Unlike its predecessors, this algorithm is adapted to fast solving of the large-scale problems and, therefore, is suitable for using with respect to *Big Data*

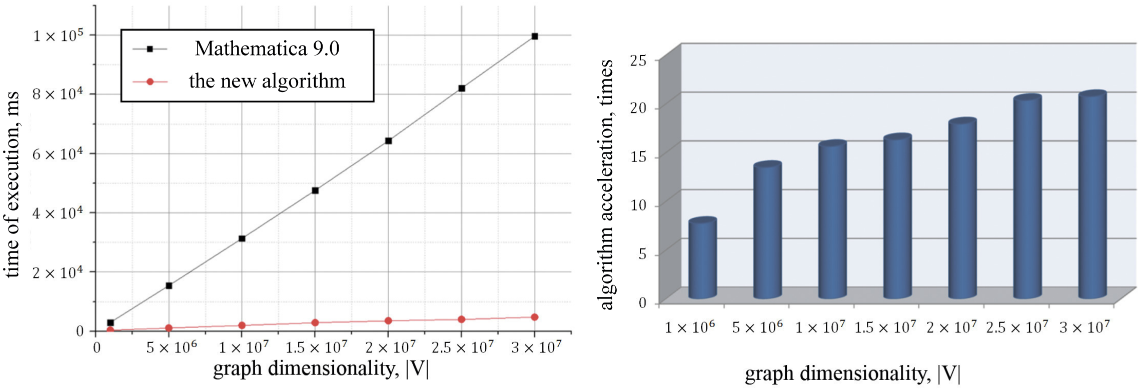


Fig. 6. A performance comparison between the new algorithm and built-in tools of the mathematical package Wolfram Mathematica 9.0

direction. Compared to the classical methods it has a number of the following benefits:

1) **High speed of operation and linear complexity.** Algorithm performance is increased by the steps of vertices' distribution into blocks, filtration and using of the auxiliary matrices. As a result, the speed of the new method is 10 – 20 times higher in contrast to the usage of professional mathematical package *Mathematica*.
2) **Massive parallelism.** Formation of partial hulls is carried out independently, which contributes to the implementation of these calculations by using graphics processors.
3) **The ability of hulls' dynamic adjustment.** When adding new vertices to the initial set, calculations are executed only for units that have undergone modification. These operations require only local updating of the convex hulls, because the results for intact parts of the original graph are invariable.
4) **The ability of generalization for the multidimensional problem instances.** In these cases, the selected subsets are the $n$-dimensional cubes to which operations of the developed method are applied.

These advantages may be the basis for the inclusion of the innovative algorithm in the professional mathematical packages to promote the high-performance computations among their users. A further direction of research is related to the development of hybrid CPU+GPU versions of this algorithm for complex systems with many processors and video cards.

***Abstract*—Let $\mathcal{H} = (V, \mathcal{E})$ be a 3-uniform linear hypergraph with one hypercycle $\mathcal{C}_3$. We consider a blow-up hypergraph $\mathcal{B}[\mathcal{H}]$.**

**We are interested in the following problem. We have to decide whether there exists a blow-up hypergraph $\mathcal{B}[\mathcal{H}]$ of the hypergraph $\mathcal{H}$, with hyperedge densities satisfying special conditions, such that the hypergraph $\mathcal{H}$ appears in a blow-up hypergraph as a transversal. We present an efficient algorithm to decide whether a given set of hyperedge densities ensures the existence of a 3-uniform linear hypergraph $\mathcal{H}$ with hypercycle $\mathcal{C}_3$ in the blow-up hypergraph $\mathcal{B}[\mathcal{H}]$.**

**Moreover, we state some relations between roots of the multivariate matching polynomial and the inhomogeneous density Turán problem.**

***Index Terms*—blow-up hypergraph; density; Turán density problem; unicyclic hypergraph.**

## I. Introduction

Let $\mathcal{H} = (V, \mathcal{E})$ be a simple, connected and finite hypergraph with the vertex set $V$ and hyperedge set $\mathcal{E}$ (see [2]). Turán [13] stated the first results in extremal graph theory. Then many authors extended this subject and formulated similar and new Turán density problems. Many interesting results for some families of simple graphs were published in [1], [6], [7], [9], [11], [12] and [14] obtained.

In this paper we present some algorithm for testing whether a hypergraph with a given set of hyperedge densities is a factor (a transversal) of a blow-up hypergraph for some unihypercyclic hypergraphs. Our algorithm has the time complexity at most $\mathcal{O}(n^2)$, where $n$ is the number of hyperedges of the hypergraph.

Ealier Csikvári and Nagy [8] discovered an interesting algorithm for testing whether a tree with a given set of edge densities is a factor of a blow-up graph. Some generalization of their algorithm is presented in [4]. In this paper we extend this ideas to create a respective algorithm for the family of 3-uniform linear unihypercyclic hypergraphs with a hypercycle $\mathcal{C}_3$.

First we define some notions and notations. Other definitions one can find in [2], [5] and [10].

A hypergraph $\mathcal{H}$ is called *linear* if any two hyperedges intersect in at most one vertex. A hypergraph $\mathcal{H}$ is called $r$-*uniform* if each hyperedge consists of $r$ vertices.

A subhypergraph $\mathcal{P}_t$ of $\mathcal{H}$ is called *a linear hyperpath of length* $t$ if the hyperedges of $\mathcal{P}_t$ can be labelled by $e_i, 0 \leq i \leq t-1$ such that the sequence $(e_0, e_1, .., e_{t-1})$ satisfies the condition: $|e_i \cap e_j| = 1$ if and only if $|i-j| = 1$ and $e_i \cap e_j = \emptyset$ if and only if $|i-j| > 1$, where $e_i \in \mathcal{E}(\mathcal{H})$ (see Fig. 1(a)).

A subhypergraph $\mathcal{C}_t$ of $\mathcal{H}$, $t \geq 3$, is called *a linear hypercycle of length* $t$ if the hyperedges of $\mathcal{C}_t$ can be labelled by $e_i, 0 \leq i \leq t-1$ such that the sequence $(e_0, e_1, .., e_{t-1})$ satisfies the condition: $|e_i \cap e_j| = 1$ if and only if $|i-j| = 1$ or $i = 0$ and $j = t-1$ and $e_i \cap e_j = \emptyset$, $i \neq j$, in the opposite case, where $e_i \in \mathcal{E}(\mathcal{H})$ (see Fig. 2).

A 3-*uniform linear unihypercyclic hypergraph* $\mathcal{H}$ is a connected linear 3-uniform hypergraph with one hypercycle $\mathcal{C}_3$ (see Fig. 3).

The degree of the vertex $v$ in the hypergraph $\mathcal{H}$ is the number of hyperedges containing this vertex. Each vertex of degree 1 in a hypergraph $\mathcal{H}$ is called *the leaf*. We say that the hypergraph $\mathcal{H}$ is $r$-*regular* if each vertex of $\mathcal{H}$ has degree $r$. A hyperedge $e \in \mathcal{E}(\mathcal{H})$ is called *a pendant hyperedge* if it contains exactly one vertex of degree $> 1$.

A set $S \subset V(\mathcal{H})$ is called *the independent vertex set* if the subhypergraph of $\mathcal{H}$ induced by $S$ has empty set of hyperedges. The set $M \subseteq \mathcal{E}(\mathcal{H})$ is called *the matching* (or *independent hyperedge set*) in the hypergraph $\mathcal{H}$ if the subhypergraph of $\mathcal{H}$ induced by $M$ is 1-regular.

Let $\mathcal{H}$ be a 3-uniform linear hypergraph. For each vertex $i \in V(\mathcal{H})$ we associate *a cluster* $A_i$, as a set of new, independent vertices.

For a hypergraph $\mathcal{H}$ we define *a blow-up hypergraph* $\mathcal{B}[\mathcal{H}]$ of the hypergraph $\mathcal{H}$ as follows. First we replace each vertex $i \in V(\mathcal{H})$ by a cluster $A_i$ and next we create some hyperedges between the clusters $A_i$, $A_j$ and $A_k$ if $\{i, j, k\}$ is a hyperedge in $\mathcal{H}$, $i, j, k \in V(\mathcal{H})$. Equivalently each hyperedge in $\mathcal{B}[\mathcal{H}]$ has exactly one vertex from the clusters.

978-83-60810-66-8/$25.00©2015, IEEE

For any three clusters we define *a density* between them by the following formula

$$d(A_i, A_j, A_k) = \frac{e(A_i, A_j, A_k)}{|A_i||A_j||A_k|}, \tag{1}$$

where $e(A_i, A_j, A_k)$ denotes the number of hyperedges with one element of each of the clusters $A_i$, $A_j$ and $A_k$.

The hypergraph $\mathcal{H}$ is *a transversal* of $\mathcal{B}[\mathcal{H}]$ if $\mathcal{H}$ is a subhypergraph of $\mathcal{B}[\mathcal{H}]$ such that we have a homomorphism

$$\phi : V(\mathcal{H}) \to V(\mathcal{B}[\mathcal{H}])$$

for which $\phi(i) \in A_i$ for all $i \in V(\mathcal{H})$. Other terminology: $\mathcal{H}$ is *a factor* of $\mathcal{B}[\mathcal{H}]$ (see Fig. 1(b)).

A hyperedge $e = \{i, j, k\}$ of the hypergraph $\mathcal{H}$ we denote shortly by $e = ijk$.

*The homogeneous density Turán problem for* 3*-uniform linear hypergraphs* can be defined as follows. Let us determine the critical hyperedge density, denoted by $d_{crit}(\mathcal{H})$, which ensures the existence of the subhypergraph $\mathcal{H}$ of $\mathcal{B}[\mathcal{H}]$ as a transversal. Precisely, assume that all hyperedges $e = \{i, j, k\}$ in the hypergraph $\mathcal{H}$ satisfy the condition

$$d(A_i, A_j, A_k) > d_{crit}(\mathcal{H}),$$

where $i, j, k \in V(\mathcal{H})$. Then, no matter how we construct the blow-up hypergraph $\mathcal{B}[\mathcal{H}]$, it contains the hypergraph $\mathcal{H}$ as a transversal. On the other words, for any value $d < d_{crit}(\mathcal{H})$ there exists a blow-up hypergraph $\mathcal{B}[\mathcal{H}]$ such that

$$d(A_i, A_j, A_k) > d$$

for all hyperedges $ijk \in \mathcal{E}(\mathcal{H})$ which does not contain $\mathcal{H}$ as a transversal.

Moreover, we define *the inhomogeneous density Turán problem for* 3*-uniform linear hypergraphs* as follows. Let us assume that for every hyperedge $e \in \mathcal{E}(\mathcal{H})$ a density $\gamma_e$ is given. Now our task is to decide if the set of densities $\{\gamma_e\}_{e\in\mathcal{E}(\mathcal{H})}$ ensure the existence of the hypergraph $\mathcal{H}$ as a transversal or we can construct a blow-up hypergraph $\mathcal{B}[\mathcal{H}]$ such that

$$d(A_i, A_j, A_k) \geq \gamma_{ijk},$$

$\{i, j, k\} \in \mathcal{E}(\mathcal{H})$, but it does not induce the hypergraph $\mathcal{H}$ as a transversal.

This two problems has been studied in [8], [12] for simple graphs which are 2-uniform linear hypergraphs. We extend some of those results to 3-uniform linear hypergraphs with the hypercycle $\mathcal{C}_3$.

Let us recall the definition of *the multivariate matching polynomial* of the hypergraph.

Let $\mathcal{H}$ be a hypergraph and let $\underline{x_e}$ be the vector of variables $x_e$, for $e \in \mathcal{E}(\mathcal{H})$. We define *the multivariate matching polynomial* $F_{\mathcal{H}}(\underline{x_e}, t)$ of the hypergraph $\mathcal{H}$ as follows

$$F_{\mathcal{H}}(\underline{x_e}, t) = \sum_{M\in\mathcal{M}} \left( \prod_{e\in M} x_e \right) (-t)^{|M|}, \tag{2}$$

where the summation goes over all matchings of the hypergraph $\mathcal{H}$, including the empty matching (see Example 1 ).

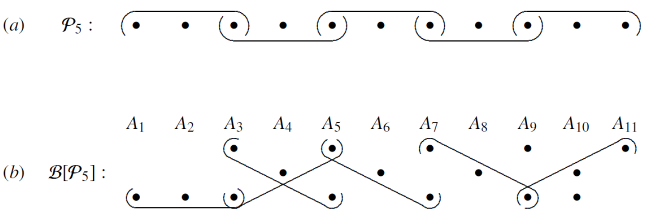

Fig. 1. A 3-uniform linear hyperpath on 5 hyperedges and a blow-up hypergraph $\mathcal{B}[\mathcal{P}_5]$ without the factor $\mathcal{P}_5$. Let $|A_i| = 1$ for $i \in \{1, 2, 4, 6, 8, 11\}$ and $|A_i| = 2$ for $i \in \{3, 5, 7, 9, 10\}$. We obtain the following densities between the clusters in $\mathcal{B}[\mathcal{P}_5]$: $d(A_1, A_2, A_3) = d(A_3, A_4, A_5) = \frac{1}{2}$, $d(A_5, A_6, A_7) = d(A_7, A_8, A_9) = d(A_9, A_{10}, A_{11}) = \frac{1}{4}$ and 0 for others. If we add the new hyperedge between clusters $A_7, A_8, A_9$, we get $d(A_7, A_8, A_9) = \frac{1}{2}$ and $\mathcal{P}_5$ as a factor.

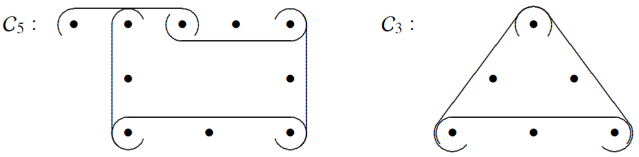

Fig. 2. A 3-uniform linear hypercycles $\mathcal{C}_5$ and $\mathcal{C}_3$.

The polynomial is the useful tool for the proofs of our results. In particular, we state some relations between roots of the multivariate matching polynomial and the inhomogeneous density Turán problem for 3-uniform linear hypergraphs with the hypercycle $\mathcal{C}_3$ which are presented in Theorem 4.

**Example 1.** *Let us consider the* 3*-uniform linear hypergraph* $\mathcal{H}$ *with* 7 *hyperedges as in Fig. 3. Assume that variables* $x_e$ *are given for hyperedges* $e \in \mathcal{E}(\mathcal{H})$ *as follows*

$$x_1 = x_4 = x_7 = 2,\ x_2 = x_6 = 1 \text{ and } x_3 = x_5 = 3.$$

*Then the multivariate matching polynomial of the hypertree* $\mathcal{H}$ *is presented below*

$$\begin{aligned} F_{\mathcal{H}}(\underline{x_e}, t) &= 1 - t(x_1 + x_2 + x_3 + x_4 + x_5 + x_6 + x_7) \\ &+ t^2(x_1x_5 + x_1x_6 + x_1x_7 + x_2x_4 + x_2x_5 \\ &+ x_2x_6 + x_2x_7 + x_3x_5 + x_3x_6 + x_3x_7 + \\ &x_4x_6 + x_4x_7 + x_6x_7) - t^3(x_1x_6x_7 + x_2x_4x_6 \\ &+ x_2x_4x_7 + x_2x_6x_7 + x_3x_6x_7 + x_4x_6x_7) \\ &+ t^4x_2x_4x_6x_7 = 1 - 14t + 44t^2 - 22t^3 + 4t^4. \end{aligned}$$

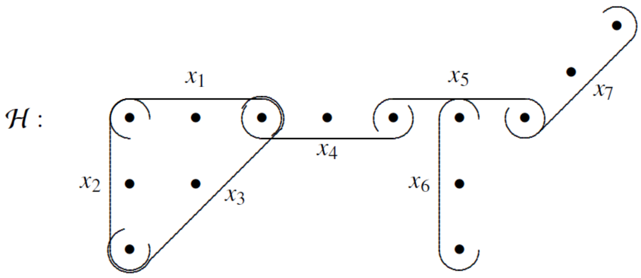

Fig. 3. A 3-uniform linear hypergraph $\mathcal{H}$ with hypercycle $\mathcal{C}_3$, where $|V(\mathcal{H})| = 14$ and $|\mathcal{E}(\mathcal{H})| = 7$, with variables $x_e$ assigned to hyperedges $e \in \mathcal{E}(\mathcal{H})$.

## II. The inhomogeneous density Turán problem for 3-uniform linear unihypercyclic hypergraphs with hypercycle $\mathcal{C}_3$

In this section we study the inhomogeneous density Turán problem for 3-uniform linear hypergraphs $\mathcal{H}$ with one hypercycle $\mathcal{C}_3$, where a hyperedge density $\gamma_e$ is given for each hyperedge $e \in \mathcal{E}(\mathcal{H})$. We extend some results presented in [8], where authors studied the inhomogeneous problem for trees and proved the following theorem.

**Theorem 1.** *(Csikvári, Nagy [8]) Let $T$ be a tree of order $n$ and let $v$ be a leaf of $T$. Assume that for each edge of $T$ a density $\gamma_e = 1 - r_e$ is given. Let $T^{'}$ be a tree obtained from $T$ by deleting the leaf $v$ and the edge $uv$, where $u$ is the unique neighbour of $v$. Let the edge densities $\gamma_e^{'}$ in $T^{'}$ be defined as follows*

$$\gamma_e^{'} = \begin{cases} \gamma_e = 1 - r_e, & \text{if } e \text{ is not incident to } u \text{ in } T', \\ 1 - \frac{r_e}{1 - r_{uv}}, & \text{if } e \text{ is incident to } u \text{ in } T'. \end{cases}$$

*Then the set of densities $\{\gamma_e\}_{e \in E(T)}$ ensures the existence of the factor $T$ if and only if all $\gamma_e^{'} \in (0,1]$ and the set of densities $\{\gamma_e^{'}\}_{e \in E(T')}$ ensures the existence of the factor $T^{'}$.*

Theorem 1 provides authors of [8] with an efficient algorithm (Algorithm $T$) to decide whether a given set of edge densities in a tree ensures the existence of a transversal or does not ensure. Their algorithm is cited on the next page.

We show that their algorithm can be extended for 3-uniform linear hypergraphs with hypercycle $\mathcal{C}_3$. This extension is presented in Algorithm $\mathcal{HC}_3$, which is presented in the second half of this paragraph.

**Proposition 1.** *The Algorithm $\mathcal{HC}_3$ stops in at most $\mathcal{O}(n^2)$ steps, where $n$ is the number of hyperedges of the input hypergraph.*

*Proof.* Execution time for checking of the property described in *Step 0* is at most $\mathcal{O}(n)$, where $n$ is the number of hyperedges of the input hypergraph. Similarly, execution time for checking the first property described in *Step 2* is at most $\mathcal{O}(n)$. In the worst case *Step 1* is executed at most $\mathcal{O}(n)$, similarly, *Step 2*, so the time complexity of our algorithm is at most $\mathcal{O}(n^2)$. □

The correctness of the Algorithm $\mathcal{HC}_3$ follows from the following theorem.

**Theorem 2.** *Let $\mathcal{H}$ be a 3-uniform linear hypergraph with the hypercycle $\mathcal{C}_3$. If $|\mathcal{E}(\mathcal{H})| > 3$ let $u, v \in V(\mathcal{H})$ be two leaves from a pendant hyperedge $e = \{u, v, w\} \in \mathcal{E}(\mathcal{H})$ for some $w \in V(\mathcal{H})$. Assume that for each hyperedge of $\mathcal{H}$ the density $\gamma_e = 1 - r_e$ is given. Let $\mathcal{H}^{'}$ be a hypergraph obtained from $\mathcal{H}$ by deleting vertices $u$ and $v$ with the hyperedge $uvw$. Let the hyperedge densities $\gamma_e^{'}$ in $\mathcal{H}^{'}$ be defined as follows*

$$\gamma_e^{'} = \begin{cases} \gamma_e = 1 - r_e, & \text{if } e \text{ is not incident to } w \text{ in } \mathcal{H}^{'}, \\ 1 - \frac{r_e}{1 - r_{uvw}}, & \text{if } e \text{ is incident to } w \text{ in } \mathcal{H}^{'}. \end{cases}$$

*If $|\mathcal{E}(\mathcal{H})| = 3$ (with hyperedge set $\mathcal{E} = \{ayb, axc, bzc\}$), then let $\mathcal{H}^{'}$ be a hypertree obtained from $\mathcal{H}$ by deleting a vertex of degree 2, say vertex $a$, with incident hyperedges $ayb$ and $axc$. $\mathcal{H}^{'}$ is a hyperpath $\mathcal{P}_{bzc}$. Let the density $\gamma_{czb}^{'}$ in $\mathcal{H}^{'}$ be defined as follows*

$$\gamma_{bzc}^{'} = 1 - \frac{r_{bzc}}{(1 - r_{ayb})(1 - r_{axc})}.$$

*Then the set of densities $\{\gamma_e\}_{e \in \mathcal{E}(\mathcal{H})}$ ensures the existence of a factor $\mathcal{H}$ if and only if all $\gamma_e^{'} \in (0,1]$ and the set of densities $\{\gamma_e^{'}\}_{e \in \mathcal{E}(\mathcal{H}')}$ ensures the existence of a factor $\mathcal{H}^{'}$.*

*Proof.* Let $\mathcal{H}$ be a 3-uniform linear hypergraph with one hypercycle $\mathcal{C}_3$ and let a density $\gamma_e = 1 - r_e$ be given for each $e \in \mathcal{E}(\mathcal{H})$.

($\Rightarrow$) First we prove the following statement: if all $\gamma_e^{'}$ are indeed densities and they ensure the existence of a factor $\mathcal{H}^{'}$, then the original densities $\gamma_e$ ensure the existence of a factor $\mathcal{H}$.

Let $\mathcal{B}[\mathcal{H}]$ be a blow-up hypergraph of the hypergraph $\mathcal{H}$ such that the density between clusters $A_i$, $A_j$ and $A_k$ is at least $\gamma_{ijk}$, where $A_i, A_j, A_k$ are clusters of the vertices and $i, j, k \in V(\mathcal{H})$. We show that $\mathcal{B}[\mathcal{H}]$ contains a factor $\mathcal{H}$.

Assume that $|\mathcal{E}(\mathcal{H})| > 3$. Let $u, v, w \in V(\mathcal{H})$ and $\{u, v, w\} \in \mathcal{E}(\mathcal{H})$, where $u, v$ are leaves. Define $R_{u,v,w}$ as the subset of $A_w$ in the following way (see Fig. 4)

$$R_{u,v,w} = \{x \in A_w \mid \exists_{u' \in A_u, v' \in A_v} \{u^{'}, v^{'}, x\} \in \mathcal{E}(\mathcal{B}[\mathcal{H}])\}.$$

Note that by (1)

$$|R_{u,v,w}| \cdot |A_u| \cdot |A_v| \geq e(R_{u,v,w}, A_u, A_v) = e(A_u, A_v, A_w)$$
$$= \gamma_{uvw} |A_u| \cdot |A_v| \cdot |A_w|.$$

Hence

$$|R_{u,v,w}| \geq \gamma_{uvw} |A_w|.$$

Now we show the lower bound for the number of hyperedges incident to $R_{u,v,w}$. Let $k, z \in V(\mathcal{H})$ such that $\{k, z, w\} \in \mathcal{E}(\mathcal{H})$. By the inclusion - exclusion formula we count the lower bound for the number of hyperedges between $R_{u,v,w}$, $A_k$ and $A_z$ as follows

$$e(R_{u,v,w}, A_k, A_z) \geq$$
$$e(A_w, A_k, A_z) - (|A_w| - |R_{u,v,w}|) \cdot |A_k| \cdot |A_z| =$$

```
Algorithm $T$
  Step 0.
  Let there be given a tree $T^0$ and edge densities $\gamma_e^0$. Set $T := T^0$ and $r_e = 1 - \gamma_e^0$.

  Step 1.
  Consider $(T, r_e)$.
    • if $|V(T)| = 2$ and $0 \leq r_e < 1$ then
        STOP: the densities $\gamma_e^0$ ensure the existence of a factor $T^0$.
    • if $|V(T)| \geq 2$ and there exists an edge for which $r_e \geq 1$ then
        STOP: the densities $\gamma_e^0$ do not ensure the existence of a factor $T^0$.

  Step 2.
  if $|V(T)| \geq 3$ and $0 \leq r_e < 1$ for all edges $e \in E(T)$ then
  DO pick a vertex $v$ of degree 1 and let $u$ be its unique neighbour. Let $T^{'} := T - v$ and
      $r_e^{'} = \begin{cases} r_e, & \text{if } e \text{ is not incident to } u, \\ \frac{r_e}{1-r_{uv}}, & \text{if } e \text{ is incident to } u. \end{cases}$
  Jump to Step 1 with $(T, r_e) := (T^{'}, r_e^{'})$.
```

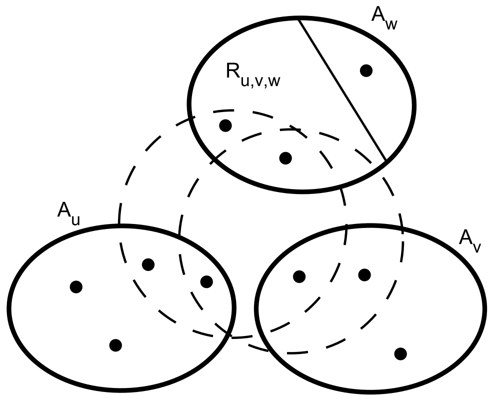

Fig. 4. Clusters $A_u, A_v$ and $A_w$ (bold line) with some hyperedge (broken line) and the set $R_{u,v,w}$

$$|R_{u,v,w}| \cdot |A_k| \cdot |A_z| + (\gamma_{wkz} - 1) \cdot |A_w| \cdot |A_k| \cdot |A_z| \geq$$

$$|R_{u,v,w}| \cdot |A_k| \cdot |A_z| + \frac{1}{\gamma_{uvw}}(\gamma_{wkz} - 1) \cdot |R_{u,v,w}| \cdot |A_k| \cdot |A_z| =$$

$$\left(1 - \frac{r_{wkz}}{1 - r_{uvw}}\right) \cdot |R_{u,v,w}| \cdot |A_k| \cdot |A_z| =$$

$$\gamma_{wkz}^{'} \cdot |R_{u,v,w}| \cdot |A_k| \cdot |A_z|.$$

Now, by deleting the vertex sets $A_u$, $A_v$ and $A_w \backslash R_{u,v,w}$ from $\mathcal{B}[\mathcal{H}]$, we obtain a hypergraph which is a blow-up hypergraph of $\mathcal{H}^{'}$ with the hyperedge densities ensuring the existence of the factor $\mathcal{H}^{'}$.

Moreover, by the definition of $R_{u,v,w}$ the factor $\mathcal{H}^{'}$ can be extended to a factor $\mathcal{H}$.

Now let us assume that $|\mathcal{E}(\mathcal{H})| = 3$, i.e. a hypergraph $\mathcal{H}$ is isomorphic to the hypercycle $\mathcal{C}_3$. Let $\mathcal{E}(\mathcal{H}) = \{ayb, axc, bzc\}$, where vertices $a, b, c$ have degree equal to 2 and vertices $x, y, z$ have degree equal to 1. Let $A_a$ be a cluster of the vertex $a$. Define sets $R_{a,y,b}$ and $R_{a,x,c}$ in the following way (see Fig. 5 )

$$R_{a,y,b} = \{v \in A_b \ |\exists_{a' \in A_a, y' \in A_y} \{a^{'}, y^{'}, v\} \in \mathcal{E}(\mathcal{B}[\mathcal{H}])\},$$

$$R_{a,x,c} = \{v \in A_c \ |\exists_{a' \in A_a, x' \in A_x} \{a^{'}, x^{'}, v\} \in \mathcal{E}(\mathcal{B}[\mathcal{H}])\}.$$

Note that by (1)

$$|R_{a,y,b}| \cdot |A_a| \cdot |A_y| \geq e(R_{a,y,b}, A_a, A_y) =$$

$$e(A_b, A_a, A_y) = \gamma_{ayb}|A_a| \cdot |A_y| \cdot |A_b|$$

and

$$|R_{a,x,c}| \cdot |A_a| \cdot |A_x| \geq e(R_{a,x,c}, A_a, A_x) =$$

$$e(A_c, A_a, A_x) = \gamma_{axc}|A_a| \cdot |A_x| \cdot |A_c|.$$

Hence we have the following lower bounds for the cardinalities of $R_{a,y,b}$ and $R_{a,x,c}$

$$|R_{a,y,b}| \geq \gamma_{ayb}|A_b|$$

```
Algorithm $\mathcal{HC}_3$ (for 3-uniform linear hypergraph with a hypercycle $\mathcal{C}_3$)
  Input: a 3-uniform linear hypergraph $\mathcal{H}$ with one hypercycle $\mathcal{C}_3$ with the set of hyperedge densities $\{\gamma_e\}_{e\in\mathcal{E}(\mathcal{H})}$.
  Output: a boolean value
      $D = \begin{cases} TRUE, & \text{the densities } \gamma_e \text{ ensure the existence of a factor } \mathcal{H}, \\ FALSE, & \text{the densities } \gamma_e \text{ does not ensure the existence of a factor } \mathcal{H}. \end{cases}$
  Consider a weighted hypergraph $(\mathcal{H}, r_e)$, where $r_e = 1 - \gamma_e$.

  Step 0.
  if $|E(\mathcal{H})| \ge 1$ and there exists a hyperedge $e \in \mathcal{E}(\mathcal{H})$ for which $r_e \ge 1$ then
      $D := FALSE$; STOP;

  Step 1.
  if $|E(\mathcal{H})| = 1$ (means $\mathcal{H}$ is a hyperpath $\mathcal{P}_1$) and $0 \le r_e < 1$ then
      $D := TRUE$; STOP;

  Step 2.
  if $|E(\mathcal{H})| > 3$ then
      pick two leaves $u, v$ from a pendant hyperedge $f = \{u, v, w\} \in \mathcal{E}(\mathcal{H})$. Let
      $\mathcal{H}' = (V(\mathcal{H}) - \{u, v\}, \mathcal{E}(\mathcal{H}) - \{\{u, v, w\}\})$ and for each hyperedge $e \in \mathcal{E}(\mathcal{H}')$ set
          $r_e^{'} = \begin{cases} r_e, & \text{if } e \cap f = \emptyset, \\ \frac{r_e}{1-r_{uvw}}, & \text{if } e \cap f = \{w\}; \end{cases}$

  if $|E(\mathcal{H})| = 3$ ($\mathcal{E}(\mathcal{H}) = \{ayb, axc, bzc\}$) then
      pick vertex of degree equal to 2, say vertex $a$, and let $\mathcal{H}' = (V(\mathcal{H}) - \{a, y, x\}, \mathcal{E}(\mathcal{H}) - \{ayb, axc\})$. For hyperedge
      $e = bzc \in \mathcal{E}(\mathcal{H}')$ set
          $r_e^{'} = r_{bzc}^{'} = \frac{r_{bzc}}{(1 - r_{ayb})(1 - r_{axc})};$

  if $r_e^{'} \ge 1$ for some hyperedge $e \in \mathcal{E}(\mathcal{H}')$ then
      $D := FALSE$; STOP;

  Go to Step 1 with $(\mathcal{H}, r_e) := (\mathcal{H}^{'}, r_e^{'})$.
```

and
$$|R_{a,x,c}| \ge \gamma_{axc}|A_c|.$$

Next let us show how many hyperedges are incident to the sets $R_{a,y,b}$ and $R_{a,x,c}$. By the inclusion - exclusion formula we count the lower bound for the number of hyperedges between $R_{a,y,b}$ and $R_{a,x,c}$

$$e(R_{a,y,b}, R_{a,x,c}, A_z) \ge e(A_b, A_c, A_z) -$$
$$(|A_b| - |R_{a,y,b}|) \cdot |A_c| \cdot |A_z| - (|A_c| - |R_{a,x,c}|) \cdot |A_b| \cdot |A_z| +$$
$$(|A_b| - |R_{a,y,b}|)(|A_c| - |R_{a,x,c}|) \cdot |A_z| = |R_{a,y,b}| \cdot |R_{a,x,c}| \cdot |A_z| +$$
$$(\gamma_{bcz} - 1) \cdot |A_b| \cdot |A_c| \cdot |A_z| \ge |R_{a,y,b}| \cdot |R_{a,x,c}| \cdot |A_z| +$$
$$(\gamma_{bcz} - 1) \frac{1}{\gamma_{ayb}} \frac{1}{\gamma_{axc}} \cdot |R_{a,y,b}| \cdot |R_{a,x,c}| \cdot |A_z| =$$
$$\left(1 - \frac{r_{bzc}}{(1 - r_{ayb})(1 - r_{axc})}\right) \cdot |R_{a,y,b}| \cdot |R_{a,x,c}| \cdot |A_z| =$$
$$\gamma_{bzc}^{'} |R_{a,y,b}| \cdot |R_{a,x,c}| \cdot |A_z|.$$

Now, by deleting the vertex sets $A_a$, $A_b \backslash R_{a,y,b}$ and $A_c \backslash R_{a,x,c}$ from $\mathcal{B}[\mathcal{H}]$, we obtain a hypergraph which is a blow-up hypergraph of $\mathcal{C}^{'} = \mathcal{P}_1$, where $V(\mathcal{P}_1) = \{b, z, c\}$, with the hyperedge density ensuring the existence of the factor $\mathcal{P}_2$.

Moreover, by the definition of $R_{a,y,b}$ and $R_{a,x,c}$ the factor $\mathcal{P}_1$ can be extended to a factor $\mathcal{C}_3$.

($\Leftarrow$) Note that if $\gamma_{wkz}^{'} < 0$ then $\gamma_{wkz} + \gamma_{uvw} < 1$. So there exists a construction of blow-up hypergraph which does not induce the linear hyperpath $\mathcal{P}_2$ with the consecutive vertices $u, v, w, k, z$ and hyperedges $\{u, v, w\}$, $\{w, k, z\}$, where $i \in A_i$

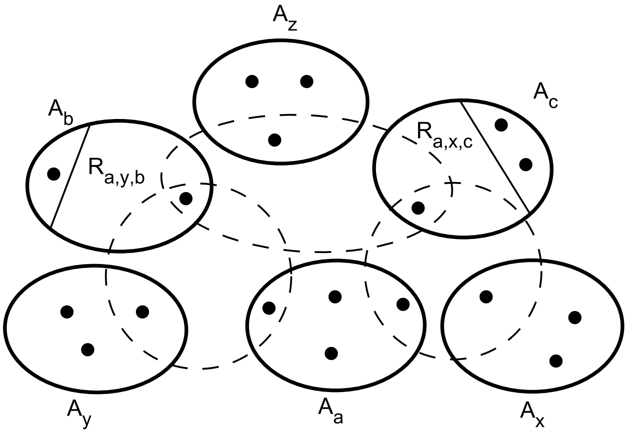

Fig. 5. Clusters $A_a, A_x$, $A_y$, $A_b$ and $A_c$ (bold line) with some hyperedges (broken line) and the sets $R_{a,y,b}$ and $R_{a,x,c}$.

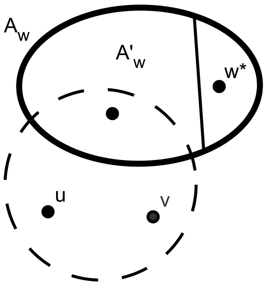

Fig. 6. We assume that $\mathcal{B}^{'}[\mathcal{H}^{'}]$ is without a factor $\mathcal{H}'$. The construction of the blow-up hypergraph $\mathcal{B}[\mathcal{H}]$ without factor $\mathcal{H}$ for the case where vertices $u, v$ are leaves in $\mathcal{H}$ and $\mathcal{H}' = (V(\mathcal{H}) - \{u, v\}, \mathcal{E}(\mathcal{H}) - \{uvw\})$. The cluster $A_w'$ is in $\mathcal{B}^{'}[\mathcal{H}^{'}]$. Let $A_w = \{w^*\} \cup A_w^{'}$, $A_u = \{u\}$ and $A_v = \{v\}$ be clusters in $\mathcal{B}[\mathcal{H}]$. Bold line - cluster, broken line - hyperedge.

for $i \in \{u, v, w, k, z\}$ in this case. Therefore, if some $\gamma_{wkz}^{'} < 0$ then there exists a construction for a blow-up hypergraph of the hypertree $\mathcal{H}$ without a factor $\mathcal{H}$.

Next assume that all the $\gamma_e^{'}$ are proper densities, but there is a construction of a blow-up hypergraph, say $\mathcal{B}^{'}[\mathcal{H}^{'}]$, with hyperedge densities at least $\gamma_e^{'}$, but which does not induce a factor $\mathcal{H}^{'}$. Thus we construct a blow-up hypergraph $\mathcal{B}[\mathcal{H}]$ of the hypertree $\mathcal{H}$ not inducing $\mathcal{H}$. We consider two cases. First, let $|\mathcal{E}(\mathcal{H})| > 3$ and $v, u$ be two leaves of $\mathcal{H}$ such that $uvw \in \mathcal{E}(\mathcal{H})$ for some vertex $w \in V(\mathcal{H})$. Let $\mathcal{H}' = (V(\mathcal{H}) - \{u, v\}, \mathcal{E}(\mathcal{H}) - \{uvw\})$. Set $A_w = \{w^*\} \cup A_w^{'}$, $A_u = \{u\}$ and $A_v = \{v\}$. We create hyperedges $uvw$ for all $w \in A_w^{'}$ but do not create $uvw^*$ without changing densities in $\mathcal{B}^{'}[\mathcal{H}^{'}]$ and with an appropriate density $\gamma_{uvw}$ (see Fig. 6 ).

Now assume that $\mathcal{H} = \mathcal{C}_3$ with hyperedge set $\mathcal{E}(\mathcal{H}) = \{ayb, axc, bzc\}$. Let $\mathcal{H}' = (V(\mathcal{H}) - \{a, y, c\}, \mathcal{E}(\mathcal{H}) - \{ayb, axc\})$, where $a$ is a vertex of $\mathcal{C}_3$ of degree 2. Set $A_b = \{b^*\} \cup A_b'$, $A_c = \{c^*\} \cup A_c'$, $A_a = \{a\}$, $A_x = \{x\}$ and $A_y = \{y\}$. We create hyperedges $ayb$ for all $b \in A_b^{'}$ and $axc$ for all $c \in A_c^{'}$ but do not create hyperedges $ayb^*$ and $axc^*$ without changing densities in $\mathcal{B}^{'}[\mathcal{H}^{'}]$ and with an appropriate densities $\gamma_{ayb}$ and $\gamma_{axc}$ (see Fig. 7). □

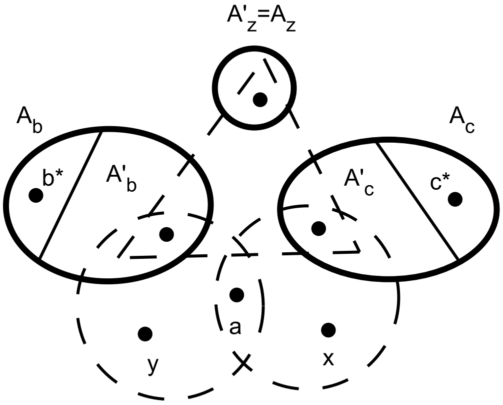

Fig. 7. We assume that $\mathcal{B}^{'}[\mathcal{H}^{'}]$ is without a factor $\mathcal{H}'$. The construction of the blow-up hypergraph $\mathcal{B}[\mathcal{H}]$ without factor $\mathcal{H} = \mathcal{C}_3$ for the case where vertex $a$ has degree 2 in $\mathcal{H}$ and $\mathcal{H}' = (V(\mathcal{H}) - \{a, x, y\}, \mathcal{E}(\mathcal{H}) - \{ayb, axc\})$. The clusters $A_b'$ and $A_c'$ are in $\mathcal{B}^{'}[\mathcal{H}^{'}]$. Let $A_b = \{b^*\} \cup A_b^{'}$, $A_c = \{c^*\} \cup A_c^{'}$, $A_a = \{a\}$, $A_x = \{x\}$ and $A_y = \{y\}$ be clusters in $\mathcal{B}[\mathcal{H}]$. Bold lines - clusters, broken lines - hyperedges.

**Example 2.** *Let us consider a* 3*-uniform linear hypergraph* $\mathcal{H}$ *with one hypercycle* $\mathcal{C}_3$*, such that* $|\mathcal{E}(\mathcal{H})| = 5$ *and* $|V(\mathcal{H})| = 10$ *, presented in Fig. 8 with two different sets of parameters* $\{r_e\}_{e\in\mathcal{E}(\mathcal{H})}$ *(in round brackets are given parameters* $r_e$ *from the second set of hyperedge densities). In Table I are presented two different sets of densities* $\{\gamma_e\}_{e\in\mathcal{E}(\mathcal{H})}$, $\gamma_e = 1 - r_e$, *and changes of parameters* $r_e$ *during the execution of the Algorithm* $\mathcal{HC}_3$.

*We are interested in whether these sets of hyperedge densities ensure an existence of the hypergraph* $\mathcal{H}$ *as a factor. To solve this problem we use Algorithm* $\mathcal{HC}_3$*. For each hyperedge* $e$ *a parameter* $r_e = 1 - \gamma_e$ *is assigned as in Fig. 8. Let run Algorithm* $\mathcal{HC}_3$*. All parameters satisfy the condition* $0 \leq r_e < 1$*, so we cut the hyperedge* $e_{fhi}$ *and modify parameters* $r_e$ *by proper formulas presented in the algorithm. We repeat this procedure untill we get a hypergraph with at least one hyperedge* $e^*$ *for which parameter* $r_{e^*} \geq 1$ *or one-hyperedge hyperpath (see Fig. 9-12). Notice that we get two different velues at the end. First set of densities* $\{\gamma_e\}$ *ensure the existence of* $\mathcal{H}$ *as a factor and the second set* $\{\gamma_e\}$ *does not ensure.*

Now we show some relations between roots of the multivariate matching polynomial and the inhomogeneous density Turán problem. This kind of relations for 3-uniform linear hypertrees have been studied in [4]. Authors of [4] obtained Theorem 3 cited for completeness of this paper. Ealier this subject has been studied by Csikvári and Nagy [8] for trees and in [3] for some family of connected unicyclic graphs.

**Theorem 3.** *(Bielak, Powroźnik [4]) Let* $\mathcal{T} = (V, \mathcal{E})$ *be a weighted* 3*-uniform linear hypertree. Let* $\gamma_e = 1 - tr_e$ *be densities assigned to each hyperedge* $e \in \mathcal{E}(\mathcal{T})$*, where* $r_e \in$

TABLE I
CHANGING OF PARAMETERS $r_e$ FOR HYPEREDGES $e \in \mathcal{E}(\mathcal{H})$ DURING THE EXECUTION OF THE ALGORITHM $\mathcal{HC}_3$ FOR TWO DIFFERENT SETS OF HYPEREDGE DENSITIES $\gamma_e$ OF THE HYPERGRAPH PRESENTED IN FIG. 8.

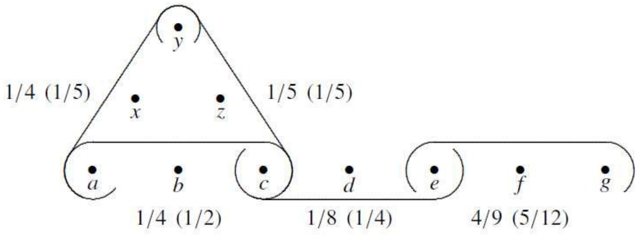

Fig. 9. The hypergraph $\mathcal{H}'$ obtained after the first execution of *Step 2* of Algorithm $\mathcal{HC}_3$ with the hypergraph $\mathcal{H}$ presented in Fig. 8, where the hyperedge $fhi$ was deleted and the parameter $r_{efg}$ was modyfied according to the first conditional instruction.

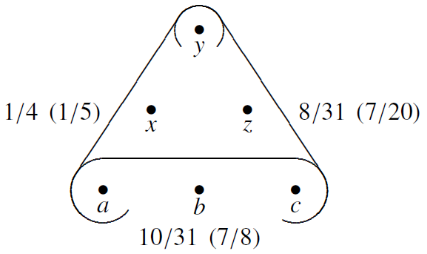

Fig. 11. The hypergraph $\mathcal{H}'$ obtained after the third execution of *Step 2* of Algorithm $\mathcal{HC}_3$ with the hypergraph $\mathcal{H}$ presented in Fig. 10, where the hyperedge $cde$ was deleted and the parameters $r_{abc}$ and $r_{yzc}$ were modyfied according to the first conditional instruction.

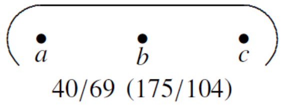

Fig. 12. The hypergraph $\mathcal{H}'$ obtained after the last execution of *Step 2* of Algorithm $\mathcal{HC}_3$ with the hypergraph $\mathcal{H}$ presented in Fig. 11, where the hyperedges $axy$ and $yzc$ were deleted and the parameter $r_{abc}$ was modyfied according to the second conditional instruction.

$[0, 1)$. *Assume that after running of Algorithm $\mathcal{T}$ we get a one-hyperedge hyperpath $\mathcal{P}_1$ with*

$$F_{\mathcal{P}_1}(\underline{r_e}, t) = 0.$$

*Then $t$ is a root of the multivariate matching polynomial $F_{\mathcal{T}}(\underline{r_e}, s)$ of the hypertree $\mathcal{T}$.*

In Theorem 4 we show similar relation between roots of the multivariate matching polynomial and the inhomogeneous density Turán problem for 3-uniform linear hypergraphs with a hypercycle $\mathcal{C}_3$.

**Theorem 4.** *Let $\mathcal{H} = (V, \mathcal{E})$ be a weighted 3-uniform linear unihypercyclic hypergraph with a hypercycle $\mathcal{C}_3$. Let $\gamma_e = 1 - tr_e$ be densities assigned to each hyperedge $e \in \mathcal{E}(\mathcal{H})$, where $r_e \in [0, 1)$. Assume that after running of Algorithm $\mathcal{HC}_3$ we get a hypercycle $\mathcal{C}_3$ with*

$$F_{\mathcal{C}_3}(\underline{r_e}, t) = 0.$$

*Then $t$ is a root of the multivariate matching polynomial $F_{\mathcal{H}}(\underline{r_e}, s)$ of the hypergraph $\mathcal{H}$.*

*Proof.* Let $\mathcal{H} = (V, \mathcal{E})$ be a weighted 3-uniform linear unihypercyclic hypergraph with hypercycle $\mathcal{C}_3$. Assume that $|\mathcal{E}(\mathcal{H})| = n$. To prove this theorem we use induction on the number of hyperedges of the hypergraph $\mathcal{H}$.

If this hypergraph consists of 3 hyperedges (i.e., $\mathcal{H}$ is isomorphic to $\mathcal{C}_3$, say with $\mathcal{E}(\mathcal{H}) = \{abc, cde, efa\}$), then

$$F_{\mathcal{H}}(\underline{r_e}, t) = 1 - t(r_{abc} + r_{cde} + r_{efa})$$

and the condition $F_{\mathcal{H}}(\underline{r_e}, t) = 0$ means that $t$ is a root of this multivariate matching polynomial of the hypergraph $\mathcal{H}$.

Assume that the statement of the theorem is true for each hypergraph on at most $n - 1$ hyperedges, where $n > 3$. Let $\mathcal{H}$ be a hypergraph with $n$ hyperedges and assume that we execute the Algorithm $\mathcal{HC}_3$ for a hyperedge $e = \{u, v, w\}$, shortly $uvw$, in the *Step 2*, where vertices $u, v$ are two leaves in $\mathcal{H}$. Let $\mathcal{H}^{'} = \mathcal{H} - \{u, v\}$ be a hypergraph obtained from hypergraph $\mathcal{H}$ by deleting $u$ and $v$ and the hyperedge $uvw$. Densities on hyperedges in hypergraph $\mathcal{H}^{'}$ are modyfied by formulas presented in Algorithm $\mathcal{HC}_3$. By executing the Algorithm $\mathcal{HC}_3$ with input $\mathcal{H}'$ we obtain a hypercycle $\mathcal{C}_3$ with $F_{\mathcal{C}_3}(\underline{r'_e}, t) = 0$. By induction we get that $F_{\mathcal{T}'}(\underline{r_e}^{'}, t) = 0$.

Now we apply the formula (2) for hypergraphs $\mathcal{H}'$ and $\mathcal{H}$.

We can expand $F_{\mathcal{H}'}$ according to whether a monomial contains $x_{wkz}$ (where $wkz \in \mathcal{E}(\mathcal{H}^{'})$) or not. Obviously, each monomial contains at most one of the variables $x_{wkz}$ where $wkz \in \mathcal{E}(\mathcal{H})$.

Thus

$$F_{\mathcal{H}'}(\underline{x_e}, s) = Q_0(\underline{x_e}, s) - \sum_{\{k,z,w\} \in \mathcal{E}(\mathcal{H}')} s x_{wkz} Q_{kz}(\underline{x_e}, s),$$

where $Q_0(\underline{x_e}, s)$ consists of those terms which do not contain $x_{wkz}$ and $-s x_{wkz} Q_{kz}(\underline{x_e}, s)$ consists of those terms which contain $x_{wkz}$ (i.e., these terms correspond to the matchings containing the hyperedge $wkz$).

We observe that

$$F_{\mathcal{H}}(\underline{x_e}, s) = (1 - s x_{uvw}) Q_0(\underline{x_e}, s) - \sum_{\{k,z,w\} \in \mathcal{E}(\mathcal{H}')} s x_{wkz} Q_{kz}(\underline{x_e}, s).$$

Since

$$0 = F_{\mathcal{H}'}(\underline{r'_e}, t) = Q_0(\underline{r_e}, t) - \sum_{\{k,z,w\} \in \mathcal{E}(\mathcal{H}')} t \frac{r_{wkz}}{1 - t r_{uvw}} Q_{kz}(\underline{r_e}, t)$$

we have

$$0 = (1 - t r_{uvw}) F_{\mathcal{H}'}(\underline{r'_e}, t) = (1 - t r_{uvw}) Q_0(\underline{r_e}, t) - \sum_{\{k,z,w\} \in \mathcal{E}(\mathcal{H}')} t r_{wkz} Q_{kz}(\underline{r_e}, t) = F_{\mathcal{H}}(\underline{r_e}, t).$$

So $t$ is a root of $F_{\mathcal{H}}(\underline{r_e}, s)$. The proof is done. □

To search more relations between roots of the multivariate matching polynomial and the inhomogeneous density Turán problem for 3-uniform linear hypergraphs with a hypercycle $\mathcal{C}_3$ we need analogue result to Lemma 1 presented below. According to our knowledge similar result for hypercycle $\mathcal{C}_3$ is not known.

**Lemma 1.** *(Bondy, et al. [6]) Let $\alpha$, $\beta$, $\gamma$ be the edge densities between the clusters of a blow-up graph of the triangle - a cycle $C_3$. If*

$$\alpha\beta + \gamma > 1, \beta\gamma + \alpha > 1, \gamma\alpha + \beta > 1,$$

*then the blow-up graph contains a triangle as a transversal.*

## III. Conclusion

In this paper we showed some results for the inhomogeneous density Turán problem of 3-uniform connected linear unihypercyclic hypergraphs with a hypercycle $\mathcal{C}_3$.

We presented Algorithm $\mathcal{HC}_3$ for testing whether the 3-uniform connected linear hypergraph $\mathcal{H}$ with a hypercycle $\mathcal{C}_3$ with a given set of hyperedge densities $\{\gamma_e\}_{e \in \mathcal{E}(\mathcal{H})}$ is a transversal of a blow-up hypergraph $\mathcal{B}[\mathcal{H}]$. The Algorithm $\mathcal{HC}_3$ has $\mathcal{O}(n^2)$ time complexity in the worst case, where $n$ is the number of hyperedges of $\mathcal{H}$. In this way we have the answer whether the hyperedge densities ensure the existence of the transversal or does not ensure.

Moreover, we stated Theorem 2 to prove the correctness of the Algorithm $\mathcal{HC}_3$.

Additionally, in Theorem 4, we stated some relation between roots of the multivariate matching polynomial and the inhomogeneous density Turán problem for 3-uniform linear hypergraphs with a hypercycle $\mathcal{C}_3$.

**Open problem:** In the future work we want to find relations between location of roots of the multivariate matching polynomial and the inhomogeneous density Turán problem for $r$-uniform linear hypergraphs with one hypercycle of length $t$, where $t \geq 3$. This problem for trees was studied in [8] and for some connected unicyclic graphs was studied in [3].

# Comparative Evaluation of the Stochastic Simplex Bisection Algorithm and the SciPy.Optimize Module

Christer Samuelsson
German Research Center for Artificial Intelligence
Email: christer.samuelsson@dfki.de

***Abstract*—The stochastic simplex bisection (SSB) algorithm is evaluated against the collection of optimizers in the Python SciPy.Optimize module on a prominent test set. The SSB algorithm greatly outperforms all SciPy optimizers, save one, in exactly half the cases. It does slightly worse on quadratic functions, but excels at trigonometric ones, highlighting its multimodal prowess. Unlike the SciPy optimizers, it sustains a high success rate. The SciPy optimizers would benefit from a more informed metaheuristic strategy and the SSB algorithm would profit from quicker local convergence and better multidimensional capabilities. Conversely, the local convergence of the SciPy optimizers is impressive and the multimodal capabilities of the SSB algorithm in separable dimensions are uncanny.**

## I. Introduction

Stochastic optimization [1], i.e., using randomness to guide search, is currently popular: genetic algorithms [2], particle swarm optimization [3], and ant-colony optimization [4] are celebrity approaches. These schemes are not only applied to discrete problems, but also to continuous ones, especially for objective functions where the gradient and Hessian are not readily available, e.g., where the function value is only obtainable by expensive simulation. They are also used to optimize highly multimodal functions.

We here compare the performance of the stochastic simplex bisection (SSB) algorithm [5] with that of the optimizers of the Python SciPy.optimize module [6]. The former employs a common stochastic optimization scheme, but unlike other stochastic approaches, it applies the scheme to search space regions, rather than to individual points. The latter are high-quality, local optimizers that are available with most Python distributions. The SSB algorithm has not previously been tested against other optimizers. We here seek to rectify this.

The rest of the article is organized as follows. Section II presents the stochastic simplex bisection algorithm. Section III describes the optimizers of the Python SciPy.Optimize module. Section IV details the experimental setup, and reports and analyses the findings. It also contains a short digression on the employed success criterion and its success regions.

## II. The Stochastic Simplex Bisection Algorithm

Consider the simple problem where we wish to minimize $f(x)$, which is strictly convex on $\mathbf{R}$. Assume further that we have found $x_1 < x_3 < x_5$, where $f(x_1) \geq f(x_3) \leq f(x_5)$, i.e., that we have found an interval that has an interior point $x_3$ with a smaller function value than its end points. [1]

**Algorithm for Convex Functions**

**Choose** $x_2 \in ]x_1, x_3[$ and $x_4 \in ]x_3, x_5[$, i.e., choose interior points $x_2$ and $x_4$.
**If** $f(x_2) \leq f(x_3)$, recurse on $x_1, x_2, x_3$.
**If** $f(x_4) \leq f(x_3)$, recurse on $x_3, x_4, x_5$.
**Otherwise**, recurse on $x_2, x_3, x_4$.

We thus recurse on the subinterval that has an interior point with a smaller function value than its end points. [2]

The SSB algorithm generalizes this to non-convex functions in $n$ dimensions. It generalizes an interval to a simplex, rather than to a hyperbox, The latter has $2^n$ corners, and bisecting it requires computing the function value in $2^{n-1}$ new corners. The former has only $n+1$ corners, and bisecting it only requires calculating the function value in one new point.

**Core SSB Algorithm**

**Given** a set $\{T_k\}$ of non-overlapping simplexes that partition the original simplex $T_0$, each equipped with a positive score $s_k$.
**Select** the next simplex $T_k$ to bisect at random with probability $\frac{s_k}{\sum_{k'} s_{k'}}$.
**Select** a bisection point at random roughly in the middle of the longest edge of $T_k$.
**Replace** $T_k$ with its two offspring.

This algorithm is complete in the sense that no portion of the search space is ever discarded, and it avoids redundancy by using non-overlapping simplexes. These are two common pitfalls of stochastic optimization. The algorithm still reaps the benefits of stochastic search in exploring more promising regions earlier, in average, while granting also less promising regions a non-zero chance of being explored.

It is often desirable to start from a hyperbox. For example, constraints often take the form of bounds on the individual variables of each dimension. The tested SSB algorithm restarts the core SSB algorithm repeatedly from a hyperbox created in the previous iteration. It uses an outer loop over epochs that maintains the hyperbox, and an inner loop over rounds that implements the core SSB algorithm. Note that although partitioning a hyperbox into a set of simplexes is trivial in

[1] By strict convexity, one of the two end point values must be strictly larger, i.e., either $f(x_1) > f(x_3)$ or $f(x_3) < f(x_5)$, or both.

[2] If $f(x_2) = f(x_3)$, the algorithm could be clever and instead recurse on $x_2, x_{23}, x_3$, with $x_{23} \in ]x_2, x_3[$, where, by necessity $f(x_2) > f(x_{23}) < f(x_3)$, due to strict convexity. Similarly for $f(x_4) = f(x_3)$.

978-83-60810-66-8/$25.00©2015, IEEE

two dimensions, it is a challenging and time-consuming task in higher ones, see [7] and [8].

### A. Outer Loop: Maintaining a Hyperbox

The tested SSB algorithm consists of two nested loops. The outer loop over epochs maintains a hyperbox. Each *epoch* runs the inner loop over rounds, where each *round* consists of one simplex bisection, see Section II-B. The terms *best point*, *very best point*, and *epoch phases* will be defined shortly.

The hyperbox is modified after each epoch. If the elapsed epoch had enough best points, this is a hyperbox that contains all best points and the very best point as interior points. Otherwise, the previous hyperbox is increased in size and re-centered around the current very best point, which may have changed during the epoch. In the tested SSB algorithm, the padding is 100 percent of the interval length in each dimension, when there are enough best points, and the old interval length is quadrupled, when there aren't. It turns out that in the former case, the simple scheme of updating the lower and higher bounds of the hyperbox in each dimension, for each new best point, works well in practice.

A *best point* is any point found during the second phase of an epoch that is the best this far in that epoch. The best points thus start over each epoch. The *very best point*, on the other hand, is the globally best point found in any round of any epoch.

The *first phase* of each epoch consists of the first quarter of its rounds. The rest of its rounds constitute the *second phase.* Other choices than one quarter were tested, but found less effective, albeit one third only marginally so. Typical figures are 60 epochs of 500 rounds each, but this can be varied with the search conditions, cf. Section IV. Higher dimensions require more rounds; fewer function evaluations entail fewer epochs and much fewer rounds.

The outer loop may seem somewhat ad hoc. It captures the idea, that if there has been non-trivial local improvements, search should focus on these improvements, yet also consider the globally best point found. We note that any new best point must be a bisection point, or the midpoint of a simplex, with a lower function value than its corner points. In one dimension, these cases coincide. For convex functions, such an interval must contain the minimum, which our introductory algorithm exploits. For non-convex functions, or in several dimensions, the area surrounding such a point merits further investigation.

### B. Inner Loop: Bisecting Simplexes

The inner loop over rounds bisects simplexes. Each bisection replaces one simplex with two new ones. In the first phase, the simplexes are processed as a first-in-first-out (FIFO) queue to create an initial grid. In the second phase, the next simplex to bisect is selected randomly with probability

$$\frac{s_k}{\sum_{k'} s_{k'}}$$

where $s_k$ is the score of the $k$th simplex. Binary trees provide an efficient way of stochastic selection that allows adding and deleting scored elements. Indexing the $K$ simplexes in a binary tree yields $O(\log_2 K)$ time complexity for lookup, addition, and deletion, whereas naively using a list swells this to $O(K)$.

We define the simplex scores $s_k$ as follows. Let $\{T_k = \langle \mathbf{x}_k^{(1)}, \ldots, \mathbf{x}_k^{(n+1)} \rangle\}$ be a collection of $n$-dimensional simplexes with (dropping the index $k$ for clarity),

$$\bar{\mathbf{x}} = \frac{1}{n+1} \sum_{i=1}^{n+1} \mathbf{x}^{(i)} \quad ; \quad \bar{f} = \frac{f(\bar{\mathbf{x}}) + \sum_{i=1}^{n+1} f\left(\mathbf{x}^{(i)}\right)}{n+2}$$

where $\bar{\mathbf{x}}$ is the midpoint and $\bar{f}$ is the average function value over the corners and the midpoint.

$$\begin{aligned} f^- &= \min\left(f(\bar{\mathbf{x}}), \min_i f\left(\mathbf{x}^{(i)}\right)\right) \quad ; \quad \delta = \frac{\bar{f} - f^-}{4} \\ f^\star &= f^- - \delta \quad ; \quad f^\star \leftarrow \max\left(0, f^\star - f_{\mathrm{vb}}\right) \end{aligned}$$

$f^\star$ is a combined measure of the lowest function value $f^-$ and an estimate $\delta$ of how much it might potentially decrease, judging by the average value $\bar{f}$. We make $f^\star$ offset-invariant by subtracting the lowest function value $f_{\mathrm{vb}}$, in the very best point, then cap it to be at least zero.

$$\begin{aligned} s &= l \cdot \exp\left(-\lambda f^\star\right) \quad ; \quad l = \max_{ij} \left| \mathbf{x}^{(i)} - \mathbf{x}^{(j)} \right| \\ \lambda &= \lambda_0 \cdot \max\left(1, \frac{1}{f_{\mathrm{W}} - f_{\mathrm{vb}}}\right) \end{aligned}$$

The simplex score is $l \cdot \exp(-\lambda f^\star)$, where $l$ is the length of its longest edge. $\lambda$ is $\lambda_0$ times the reciprocal of the difference between the highest function value $f_{\mathrm{W}}$ of the corners of the bounding box and the lowest function value $f_{\mathrm{vb}}$. This renders the score scale-invariant. $\frac{\lambda}{\lambda_0}$ is capped to be at least one; $\lambda_0$ defaults to one. Thus, all simplexes must be rescored whenever a new very best point is found. As this happens rather seldom, it incurs very little overhead in practice.

Each round only creates two new simplexes: the longest edge of the selected simplex is bisected. All corners remain the same, save one of the two connected by this edge. Let these corners be $\mathbf{x}^{(i)}$ and $\mathbf{x}^{(j)}$. The edge bisection point $\bar{\mathbf{x}}'$—the new corner—is also randomized to counter-act any symmetries of the objective function $f(\mathbf{x})$ in its argument $\mathbf{x}$:

$$\bar{\mathbf{x}}' = (0.5 + \theta)\mathbf{x}^{(i)} + (0.5 - \theta)\mathbf{x}^{(j)} \quad \text{for} \quad \theta \sim \mathrm{U}(-\alpha, \alpha)$$

An empirically good choice is $\alpha = 0.05$ (max 10% randomness). $\bar{\mathbf{x}}'$ replaces $\mathbf{x}^{(i)}$ in one offspring simplex and $\mathbf{x}^{(j)}$ in the other one. Thus only three new function values need be calculated for each bisection: $f(\bar{\mathbf{x}}')$ and the function values of the midpoints of the two new simplexes.

### C. Related Work

The SSB algorithm uses a typical stochastic optimization scheme. It maintains a set of elements, each with a positive score; randomly selects some elements based on the scores; uses these elements to explore the search space, often creating new elements in the process; and updates the set of elements and their scores according to the findings. The scheme is however here applied to regions of the search space, not to points in it, as in, e.g., [9], [10], [11], [12], [13], and [14].

The simplex method [15], Chapter 9, doesn't actually use simplexes. To create new points, controlled random search [11] generates random simplexes. These may overlap and are not guaranteed to cover the search space. Nor are they subdivided. DIRECT [16] uses hyperboxes that partition the search space. It avoids the $2^n$ complexity by directional search from their midpoints, ignoring their corners. Each hyperbox potentially containing the global minimum is trisected, rather than bisected, along each dimension in turn. There is no randomized selection.

## III. The Opimizers of the SciPy.Optimize Module

The optimizers from the Python SciPy.Optimize module that we tested were code named "Nelder-Mead," "Powell," "CG," "BFGS," "L-BFGS-B," "TNC," and "SLSQP." We did not provide the gradient nor the Hessian of the objective functions. Whenever an optimizer used these, it had to estimate them itself numerically.

The SciPy module also contains the "Anneal," "COBYLA," "dogleg," and "trust-ncg" optimizers. Anneal proved too slow and performed too poorly to be included. COBYLA was not robust enough for large-scale testing. The dogleg and trust-ncg optimizers require explicit gradients, which were not provided.

Nelder-Mead uses the simplex method, see [17], [18]. Powell is a modification of Powell's algorithm, a conjugate direction method, that performs sequential one-dimensional minimizations, see [19], [20]. CG uses a nonlinear conjugate gradient method by Polak and Ribiere, a variant of the Fletcher-Reeves algorithm described in [21], pp. 120–122.

BFGS uses the quasi-Newton method of Broyden, Fletcher, Goldfarb, and Shanno, see [21], p 136, and L-BFGS-B uses the L-BFGS-B algorithm for bound constrained minimization, see [22], [23]. TNC uses a combined Newton and conjugate gradient method, aka a truncated Newton method, see [21], p 168, and [24]. SLSQP uses sequential least squares programming, see [25].

## IV. Experiments

A very reasonable baseline, seeing that the SSB algorithm essentially adds structure to randomized search, is to evaluate it against unstructured randomized search conducted by each ScyPy optimizer. In each trial, the ScyPy optimizer was repeatedly restarted in a new random point, until a limit on the total number of function evaluations had been exceeded.

### A. Experimental Setup

We tested all *two-dimensional* objective functions of Figure 2 (last page), most of which are from [26]. Function 0 comes from [5], Function 20 from [27], and Functions 21, 22, 24, and 25 are of our own design. All functions have unique global minima, except Function 0, due to symmetry in $x$ and $x + y$, and Functions 12, 14, and 17, which have four global minima, due to symmetry in $\pm x, \pm y$. Functions 16 and 17 were corrected using [28]. We did not provide the gradient nor the Hessian of these objective functions.

We investigated the frugal function evaluation scenario, where computing function values comes at a premium, and restricted the number of function evaluations to four thousand. The domain was $[-80, 120] \times [-80, 120]$, which is typically larger than that of the test set: often $[-10, 10] \times [-10, 10]$ or even $[-5, 5] \times [-5, 5]$. It was made asymmetric in $x$ and $y$, since many test functions have their global minimum in $\mathbf{x} = \mathbf{0}$. As in [5] and [28], success was defined as finding any argument with a function value within $10^{-6}$ of the known global minimal value. See Section IV-C for a discussion on this success criterion.

No attempt was made to optimize the optimizers. The SciPy optimizers were used with their default parameter settings, and the search parameters of the SSB algorithm were taken over from [5], Section 5.3: $\lambda_0$ was set ten; epoch phase one consisted of the first five of its 50 rounds in total; once the system had made 4000 function evaluations, the current epoch and the algorithm were terminated.

In each trial, the SciPy optimizer was repeatedly run starting from a randomized point and the best candidate point of the trial was updated if the new one was better. The trial continued until 4000 function evaluations had been exceeded. The best result in the trial determined success or failure.

### B. Experimental Results

Table I shows their respective success rates in 1000 trials. To analyze these results, we need to consider the nature of each test objective function. These can be classified into:

- unimodal quadratic forms, Fcns 2, 6, 8;
- oligo-modal [3] polynomials, Fcns 3, 4, 5, 10, 18;
- multimodal damped trigonometrics, Fcns 0, 1, 12–17, 25;
- mixed trigonometrics and quadratics, Fcns 9, 11, 20, 24;
- other (unimodal) functions, Fcns 7, 21, 22.

In exactly half of the cases (Functions 0, 1, 9, 11–17, and 22–25), the SSB algorithm stands head and shoulders above the competition, except for Powell's algorithm in two of these cases, namely Functions 1 and 9. *This includes all seriously multimodal functions.* Clearly, when faced with numerous local optima, the extra structure afforded by the SSB algorithm outweighs the benefit of highly accurate local search.

Conversely, it includes no unimodal or oligo-modal function, except Function 22. This stands to reason, as any adept local optimizer should succeed for these functions, even when starting from a randomized point some distance away. See Section IV-C for a discussion of Functions 2, 21, and 22.

Function 7 is very hard, and defeats all optimizers. It has a concave valley, kinks, and a very anisotropic variable coupling. The gradient is ill-defined and unbounded in the valley bottom, and especially ill-behaved in the optimum. *Memento mori.*

Viewing the results from another angle, we note that the SSB algorithm performs under 50% in only five cases of 22. In two of these, it still outperforms all other algorithms, and in a third case, all algorithms come up empty-handed. In one of the two remaining cases, Function 3, the SSB algorithm

TABLE I
SUCCESS RATE IN 1000 TRIALS OF THE SCIPY OPTIMIZERS AND THE SSB ALGORITHM.

is hampered by quadratic terms and a dominating variable coupling, and it lags behind the competition.

The other remaining case is Function 20. It has dominating quadratic terms and strong trigonometric confusion terms. The SSB algorithm outperforms half of the SciPy optimizers, but not the SLSQP, Simplex, and Powell optimizers, the latter two which excel. By contrast, all SciPy optimizers perform under 50% in more than half of the cases, except Powell's algorithm, which performs under 50% in exactly half of the 22 cases.

### C. A Digression on Success Regions

The success criterion $|f(\mathbf{s}) - f(\mathbf{x}^*)| < \epsilon$, where $\mathbf{x}^*$ is a known global optimum, is certainly reasonable for practitioners, who care mainly about finding a good enough solution $\mathbf{s}$. But when evaluating optimization algorithms, one must be careful not to draw incorrect conclusions from this criterion.

For example, when comparing performances on Functions 2, 21, and 22 in Table I, one might be tempted to conclude that the discontinuity in the gradient in the global optimum caused by the absolute value does some damage to gradient-based methods, and wreaks havoc with the simplex method, while the additional concavity of the square root foils all algorithms, save Powell's method and the SSB algorithm.

This analysis fails to take into account that the success region of Function 2 is a circle with diameter $2\sqrt{\epsilon}$, while that of Function 21 is a square with diagonal $2\epsilon$, and that of Function 22 is a concave diamond shape with diagonal $2\epsilon^2$. The alchemy-like Figure 1 illustrates this for the unrealistically large $\epsilon = 0.5$. The ratios of their surface areas are $\pi\epsilon : 2\epsilon^2 : \frac{2}{3}\epsilon^4$. This makes the latter two increasingly harder to hit, which is a potentially greater difficulty for the optimizers, given strict limitations on the number of function evaluations.

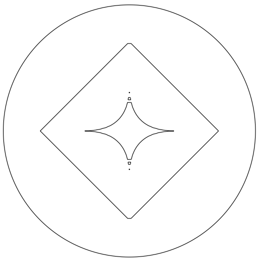

Fig. 1. $|f(x, y) - f(0, 0)| = 0.5$ for Fcns 2, 21, and 22.

## V. SUMMARY AND CONCLUSIONS

We evaluated the stochastic simplex bisection (SSB) algorithm against the optimizers of the Python SciPy.Optimize module on a prominent test set. The former employs a common stochastic optimization scheme, but unlike other stochastic approaches, it applies the scheme to search space regions, rather than to individual points. The latter are readily available, high-quality, local optimizers. This is the first evaluation of the SSB algorithm against other optimizers.

The experiments were conducted in two dimensions on a prominent test set. The domain was mostly larger, by an order of magnitude in each direction, than the domains indicated by the test set, and the number of function evaluations was limited to a few thousand. The SSB algorithm used the latter as a termination criterion and returned its very best point. Each ScyPy optimizer was repeatedly restarted in a random point, until it had exceeded the function evaluation limit, and the overall best result was returned. In both cases, if the returned solution was within $10^{-6}$ of the known global minimal value, it was deemed a successful trial. Each optimizer was tested 1000 times on each test function.

The SSB algorithm greatly outperformed all SciPy optimizers, save one, in exactly half the cases. It did slightly worse on polynomial functions, but excelled at trigonometric ones, highlighting its multimodal prowess. And unlike the SciPy optimizers, it sustained a high success rate.

We conclude that the SciPy optimizers would benefit from a more informed metaheuristic strategy and that the SSB algorithm would profit from quicker local convergence and better multidimensional capabilities. Conversely, the local convergence of the SciPy optimizers is impressive and the multimodal capabilities of the SSB algorithm in separable dimensions are uncanny.

## Objective Functions

Fcns 21, 22, 24, 25 are novel; Fcn 0 from [5]; Fcn 20 from [27]; remainder from [26]. Fcns 16 and 17 corrected using [28].

$$f(\mathbf{x}) = f(x_1,\ldots,x_n) = \prod_{k=1}^{n} f_0\left(\sum_{i=1}^{k} x_i\right) \quad \text{with} \tag{0}$$

$$f_0(x) = \sin(\sqrt{1+x^2}) \cdot \cos(2x(x+1)) \cdot \frac{\ln(1+x^2)}{\sqrt{1+x^2}}$$

$$f(\mathbf{x}) = 20\left(1-\exp\left(-0.2\sqrt{\frac{1}{n}\sum_{i=1}^{n} x_i^2}\right)\right) + e - \exp\left(\frac{1}{n}\sum_{i=1}^{n}\cos(2\pi x_i)\right) \tag{1}$$

$$f(\mathbf{x}) = f(x_1,\ldots,x_n) = \sum_{i=1}^{n} x_i^2 \tag{2}$$

$$f(\mathbf{x}) = f(x_1,\ldots,x_n) = \sum_{i=1}^{n-1}\left(100\cdot(x_{i+1}-x_i^2)^2 + (x_i-1)^2\right) \tag{3}$$

$$f(x,y) = (1.5-x+xy)^2 + (2.25-x+xy^2)^2 + (2.625-x+xy^3)^2 \tag{4}$$

$$\begin{aligned} f(x,y) = {} & \left(1+(x+y+1)^2(19-14x+3x^2-14y+6xy+3y^2)\right)\cdot \\ & \cdot\left(30+(2x-3y)^2(18-32x+12x^2+48y-36xy+27y^2)\right) \end{aligned} \tag{5}$$

$$f(x,y) = (x+2y-7)^2 + (2x+y-5)^2 \tag{6}$$

$$f(x,y) = 100\sqrt{|y-0.01x^2|} + 0.01|x+10| \tag{7}$$

$$f(x,y) = 0.26(x^2+y^2) - 0.48xy \tag{8}$$

$$f(x,y) = \sin^2(3\pi x) + (x-1)^2\left(1+\sin^2(3\pi y)\right) + (y-1)^2\left(1+\sin^2(2\pi x)\right) \tag{9}$$

$$f(x,y) = 2x^2 - 1.05x^4 + \frac{x^6}{6} + xy + y^2 \tag{10}$$

$$f(x,y) = -\cos(x)\cos(y)\exp\left(-(x-\pi)^2-(y-\pi)^2\right) \tag{11}$$

$$f(x,y) = -0.0001\left(|\sin(x)\sin(y)|\exp\left(\left|100-\frac{\sqrt{x^2+y^2}}{\pi}\right|\right)+1\right)^{0.1} \tag{12}$$

$$f(x,y) = -|\sin(x)\sin(y)|\exp\left(\left|1-\frac{\sqrt{x^2+y^2}}{\pi}\right|\right) \tag{14}$$

$$f(x,y) = 0.5 + \frac{\sin^2(x^2-y^2)-0.5}{1+0.001(x^2+y^2)^2} \tag{16}$$

$$f(x,y) = 0.5 + \frac{\cos^2(\sin(x^2-y^2))-0.5}{1+0.001(x^2+y^2)^2} \tag{17}$$

$$f(\mathbf{x}) = f(x_1,\ldots,x_n) = \frac{1}{2}\sum_{i=1}^{n}\left(x_i^4-16x_i^2+5x_i\right) \tag{18}$$

$$f(\mathbf{x}) = f(x_1,\ldots,x_n) = \sum_{i=1}^{n}\left(x_i^2+10\cdot(1-\cos(2\pi x_i))\right) \tag{20}$$

$$f(\mathbf{x}) = f(x_1,\ldots,x_n) = \sum_{i=1}^{n}|x_i| \tag{21}$$

$$f(\mathbf{x}) = f(x_1,\ldots,x_n) = \sum_{i=1}^{n}\sqrt{|x_i|} \tag{22}$$

$$f(\mathbf{x}) = f(x_1,\ldots,x_n) = \sum_{i=1}^{n}|x_i| + \left(10+x_i^2\right)\cdot(1-\cos(2\pi x_i)) \tag{24}$$

$$f(\mathbf{x}) = f(x_1,\ldots,x_n) = \sum_{i=1}^{n} 1-\text{sink}(x_i) \quad \text{with} \;\; \text{sink}(x) = \frac{\sin(x)}{x} \tag{25}$$

# Hybrid Metaheuristic for Portfolio Selection: Comparison with an exact solver and search space analysis

Giacomo di Tollo
Dipartimento di Economia, Universitá Ca' Foscari
Cannaregio 873, 30121-Venezia, Italia
Email: giacomo.ditollo@unive.it

***Abstract*—In this paper we use a metaheuristic approach to solve the Portfolio Selection problem, in a constrained formulation which is NP-hard and difficult to be solved by standard optimization methods. We are comparing the algorithm's performances with an exact solver and we are showing that different mathematical formulations lead to different algorithm's behaviour. Results show that our approach can be efficiently used to solve the problem at hand, and that a sound basin of attraction analysis may help developers and practitioners to design the experimental analysis.**

## I. Introduction

PORTFOLIO Selection main formulation dates back from the fifties and is concerned with selecting, out of a given set of assets, which assets to invest in and by how much, in order to minimise a risk measure for a given minimum required target return. Many measures can be used for assessing the risk, but the variance of portfolio's return was used in the seminal work by Markowitz [24] and is still the most used.

Portfolio Selection Problem (PSP) can be viewed as an optimisation problem to be described by three objects: variables, objective, and constraints. Every object have to be instantiated by a choice, and the combination of these choices leads to a specific formulation (model) of the problem, hence to different optimisation results. For instance, as stated by di Tollo and Roli[8], two main choices are possible for variables: continuous[15], [29], [31], [28] and integer[30], [21]. Choosing continuous variables is quite 'natural' and its representation is independent of the actual budget, while integer values (ranging between zero and the maximum available budget, or equal to the number of 'rounds') allow us to add constraints taking into account actual budget, minimum lots and to tackle other objective functions to better explain the problem at hand. As for the different results, the integer formulation is more suitable to explain the behaviour of rational operators such small investors, whose activity is strongly influenced by integer constraint[22].

Furthermore, the same representation can be modelled by means of different formulations, e.g., by adding auxiliary variables[20], symmetry breaking[27] or redundant[32] constraints. Although these extensions have no effect on the certified optimal solution found, they may affect the optimisation procedure. For example, it has been shown that symmetry breaking constraints have negative effect on local search performances[27].

In this work we will investigate how the use of different formulations for the very same problem can lead to different behaviours of the algorithm used. We will study this aspect by solving the Portfolio Selection Problem by metaheuristics[4], [8], which are general problem-solving strategies conceived as high level strategies that coordinate the behaviour of lower level heuristics, and provide the user with a solution which cannot be certified to be optimum, still it represents a good compromise when the optimal solution is impossible to be found. Through the use of meta-heuristic, and using the paradigm of separation between model and algorithm[17], we will show that different formulations affect the algorithm's performances and study the motivation of this phenomenon.

The paper will start recalling Portfolio Theory in Section II, before introducing the concept of meta-heuristics in Section III. Then we will introduce a meta-heuristic approach for the Portfolio Selection Problem in Section IV, while Section V will introduce the principles Search Space Analysis is based upon. Search Space Analysis will be applied to our instances on Section VI, before concluding with Section VII.

## II. Portfolio Selection Basis

We associate to each asset belonging to a set $A$ of $n$ *assets* ($A = \{a_1, \dots, a_n\}$) a real-valued *expected*

978-83-60810-66-8/$25.00©2015, IEEE

*return* $r_i$, and the corresponding return variance $\sigma_i$. We furthermore associate, to each pair of assets $\langle a_i, a_j \rangle$, a real-valued return *covariance* $\sigma_{ij}$. We are furthermore given a value $r_e$ representing the minimum required return.

In this context, a portfolio is defined as the $n$-sized real vector $X = \{x_1, \ldots, x_n\}$ in which $x_i$ represents the relative amount invested in asset $a_i$. For each portfolio we can define its variance as $\sum_{i=1}^{n} \sum_{j=1}^{n} \sigma_{ij} x_i x_j$ and its return as $\sum_{i=1}^{n} r_i x_i$. In the original formulation [25], PSP is formulated as the minimization of portfolio variance, imposing that the portfolio's return must be not smaller than $r_e$, leading to the following optimisation problem:

$$\min \quad \sum_{i=1}^{n} \sum_{j=1}^{n} \sigma_{ij} x_i x_j, \tag{1}$$

$$s.t. \quad \sum_{i=1}^{n} r_i x_i \geq r_e, \tag{2}$$

$$\sum_{i=1}^{n} x_i = 1, \tag{3}$$

$$x_i \geq 0 \qquad (i = 1, \ldots, n). \tag{4}$$

The aforecited return constrained is introduced in constraint (2); constraint (3) is referred to as *budget constraint*, meaning that all the capital must be invested; constraint (4) imposes that variables have to be non-negative (i.e., short sales are not allowed).

If we define a finite set of values for $r_e$ and solve the problem for all defined $r_e$ values, we obtain the *Unconstrained Efficient Frontier* (UEF), in which the minimum risk value is associated to each $r_e$.

This formulation may be improved to grasp financial market features, by introducing a binary variable $Z$ for each asset ($z_i = 1$ if asset $i$ is on the portfolio, $0$ otherwise). Additional constraints which can be added to the basic formulation are:

- **Cardinality constraint**, used either to impose an upper bound $k$ to the cardinality of assets in the portfolio

$$\sum_{i=1}^{n} z_i \leq k, \tag{5}$$

  or to force the resulting portfolio to contain exactly $k$ assets:

$$\sum_{i=1}^{n} z_i = k_{max}. \tag{6}$$

  This constraint is important for practitioners in order to reduce the portfolio management costs.
- **Floor and ceiling constraints**, used to set, for each asset, the minimum ($\varepsilon_i$) and maximum ($\delta_i$) quantity allowed to be held in the portfolio

$$\varepsilon_i z_i \leq x_i \leq \delta_i z_i. \tag{7}$$

  Those constraints are used to ensure diversification and to avoid tiny portions of assets in the portfolios, which would make their management difficult and lead to unnecessary transaction costs.
- **Preassignments.** This constraint is used to express subjective preferences: we want certain specific assets to be held in the portfolio, by determining a $n$-sized binary vector $P$ (i.e., $p_i = 1$ if $a_i$ has to be held in the portfolio) and imposing the following:

$$z_i \geq p_i \qquad (i = 1, \ldots, n). \tag{8}$$

## III. Meta-heuristics

As stated in the Introduction, in this work we are solving the PSP by using meta-heuristics[4], which can be defined as high-level strategies that coordinate the action of low-level algorithms (heuristics) in order to find near-optimal solutions for combinatorial optimization problem. They are used when it is impossible to find the certified optimum solution in a reasonable amount of time, and their features can be outlined as follows:

- They are used to explore the search space and to determine principles to guide the action of subordinated heuristics.
- Their level of complexity ranges from a simple escape-mechanism to complex populations procedures.
- They are stochastic, hence escape and restart procedures have to be devised in the experimental phase.
- The concepts they are built upon allow an abstract descriptions, that is useful to design hybrid procedures.
- They are not problem-specific, but additional components may be used to exploit the structure of the problem or knowledge acquired during the search process.
- They may make use of problem-specific knowledge in the form of heuristics that are controlled by the upper level strategy.

The main paradigm meta-heuristics are build upon is the *intensification-diversification* paradigm, meaning that they should incorporate a mechanism to balance the exploration of promising regions of the search landscape (intensification) and the identification of new areas in the search landscape (diversification). The way of implementing this balance is different depending on the specific meta-heuristic used. A completed description is out of the scope of this paper, and we forward the interested reader to Hoos and Stuetzle[18].

## IV. Our Approach for Portfolio Choice

We are using the solver introduced by di Tollo et al.[7], [9] to tackle a constrained PSP, in which the Markowitz' variance minimisation in a continuous formulation is enhanced by adding constraints (4), (6) and (7), leading to the following formulation:

$$\min \sum_{i=1}^{n} \sum_{j=1}^{n} \sigma_{ij} x_i x_j, \tag{9}$$

subject to

$$\sum_{i=1}^{n} r_i x_i \geq r_e, \tag{10}$$

$$\sum_{i=1}^{n} x_i = 1, \tag{11}$$

$$x_i \geq 0 \qquad i = 1 \ldots n, \tag{12}$$

$$k_{min} \leq \sum_{i=1}^{n} z_i \leq k_{max}, \tag{13}$$

$$\varepsilon_i z_i \leq x_i \leq \delta_i z_i, \tag{14}$$

$$x_i \leq z_i \quad i = 1 \ldots n. \tag{15}$$

Where $k_{min}$ and $k_{max}$ are respectively lower and upper bounds on cardinality. This problem formulation contains two classes of decision variables: integer (i.e., $Z$) and continuous (i.e., $X$). Hence, it is possible to devise an hybrid procedure in which each variable class is tackled by a different component. Starting from this principle, we have devised a master-slave decomposition, in which a meta-heuristic procedure is used in order to determine, for each search step, assets contained in the portfolio ($Z$). Once the assets contained in the portfolio are decided, the corresponding continuous $X$ values can be determined with proof of optimality. Hence at each step, after having selected which assets to be taken into account, we are resorting to a the Goldfarb-Idnani algorithm for quadratic programming (QP) [16] to determine their optimum value. The stopping criterion and escape mechanism depend on the metaheuristic used, which will be detailed in what follows.

As explained in section VI, this master-slave decomposition has a dramatic impact on the meta-heuristic performance due to the different structure determined by this formulation, in which the basin of attraction are greater than the ones determined by a monolithic approach based on the same meta-heuristic approaches. In what follows we are outlining the components of our meta-heuristic approach.

- **Search space** Since the *master* meta-heuristic component takes into account the $Z$ variables only, the search space $S$ is composed of the $2^n$ portfolios that are feasible w.r.t cardinality and pre-assignment constraints, while other constraints are directly ensured by the *slave* QP procedure. If the QP procedure does not succeed in finding a feasible portfolio, a greedy procedure is used to find the portfolio with maximum return and minimum constraint violations.
- **Cost function** In our approach the cost function corresponds to the objective function of the problem $\sigma^2$, and is computed, at each step of the search process, by the *slave* QP procedure.
- **Neighborhood relations** As in di Tollo et al.[9], we are using three neighborhood relations in which the neighbor portfolio are generated by *adding*, *deleting* or *replacing* one asset: the neighbor is created by defining the asset pair $\langle i, j \rangle (i \neq j)$, inserting asset $i$, and deleting asset $j$. Addition is implemented by setting $j = 0$; deletion is implemented by $i = 0$.
- **Initial solution** The initial solution must be generated to create a configuration of $Z$. Since the we aim to generate an approximation of the unconstrained efficient frontier, we are devising three different procedures for generating the starting portfolio, which are used w.r.t. different $r_e$ values: MaxReturn (in which the starting portfolio corresponds to the maximum return portfolio, without constraints on the risk); RandomCard (in which cardinality and assets are randomly generated); and WarmRestart (in which the starting portfolio corresponds to the optimal solution found for the previous $r_e$ value). MaxReturn is used when setting the highest $r_e$ value (i.e., first computed value); for all other $r_e$ values both RandomCard and WarmRestart have been used.

### A. Solution techniques

As specific meta-heuristics for the *master* procedure, we have used Steepest Descent (SD), First Descent (FD) and Tabu Search (TS). SD and FD are considered as the most simple meta-heuristic strategies, since they accept the candidate solution only when its cost function is better than the current one, otherwise the search stops. They differ to each other in the neighborhood exploration, since in SD all neighbors are generated and the best one is compared to the current solution, while in FD the first better solution found is selected as current one. TS enhances this schema by selecting, as the new current solution, the best one amongst the neighborhood, and using an additional memory (Tabu list) in which forbidden states (i.e., former solutions) are stored, so that they cannot be generated as neighbors. In our implementation, we have used a dynamic-sized tabu list, in which solutions are put in the Tabu list for a randomly generated period of time. The length range of the Tabu list has been determined by using F-Race [3], and has been set to $[3, 10]$.

The three meta-heuristics components have been coded in C++ by Luca Di Gaspero and Andrea Schaerf and are available upon request.

As for the *slave* Quadratic programming procedure, we have used the Goldfarb and Idnani dual set method [16] to determine the optimal $X$ values corresponding to $Z$ values computed by the *master* meta-heuristic component. This method has been coded in C++ by Luca Di Gaspero: it is available upon request, and has achieved good performances when matrices at hand are dense.

To sum up, the *master* meta-heuristic component determines the actual configuration of $Z$ variables (i.e., point of the search space), the *slave* QP procedure computes the cost of the determined configuration, which is accepted (or not) depending on the mechanism embedded in FD, SD or TS.

### B. Benchmark instances

We have used instances from the repository `ORlib` (http://people.brunel.ac.uk/~mastjjb/jeb/info.html) and instances used in Crama and Schyns[6], which have been kindly provided to us by the authors. The UEF for the `ORlib` instances is provided in the aforementioned website; the UEF for instances from Crama and Schyns[6] has been generated by us by using our *slave* QP procedure. In both cases, the resulting UEF consists of 100 portfolios corresponding to 100 equally distributed $r_e$ values. Benchmarks' main features are highlighted in Table I.

By measuring the distance of the obtained frontier (CEF) from the UEF we obtain the *average percentage loss*, which is an indicator of the solution quality and which is defined as:

$$\mathsf{apl} = \frac{100}{p} \sum_{l=1}^{p} (V(r_e) - V_U(r_e))/V_U(r_e) \qquad (16)$$

in which $r_e$ is the minimum required return, $p$ is the frontier cardinality, $V(r_e)$ and $V_U(r_e)$ are the values of the function $F$ returned by the solver and the risk on the UEF.

### C. Experimental analysis

Our experiments have been run on a computer equipped with a Pentium 4 (3.2 GHz), and in what follows we are showing results obtained on both instance classes. In order to assess the quality of our approach, in the following tables we also report results obtained by other works tackling the same instances. Table II reports results over `ORlib`instances, showing that our approach outperforms the meta-heuristic approach by Schaerf[29], and compares favourably with Moral-Escudero et al.[26]

Table III compares our results with the one by Crama and Schyns[6]: solutions found by our hybrid approach have better quality than the ones found by SA [6], but running times are higher, due to our QP procedure and to our complete neighbourhood exploration, which are not implemented by Crama and Schyns.

We have also compared our approach with Mixed Integer Non-linear Programming (MINLP) solvers, by encoding the problem in AMPL [14] and solving it using CPLEX 11.0.1 and MOSEK 5. We have run the MINLP solvers over ORLib instances, and compared their results with SD+QP (10 runs), obtaining the same solutions in the three approaches, hence showing that our approach is able to find the optimal solution in a low computational time. Computational times for SD+QP and for the MINLP solvers are reported in Table IV and in Figure 1. We can notice that for big-sized instances exact solvers require higher computation time to generate points in which cardinality constraints are binding (i.e., left part of the frontier). Our approach instead scales very well w.r.t. size and provides results which are comparable.

We can conclude this section by observing that SD+QP provides as satisfactory results as the more complex TS+QP. Since Tabu Search is conceived to better explore the search space, this can be considered rather surprising. The next sections will enlighten us about this phenomenon.

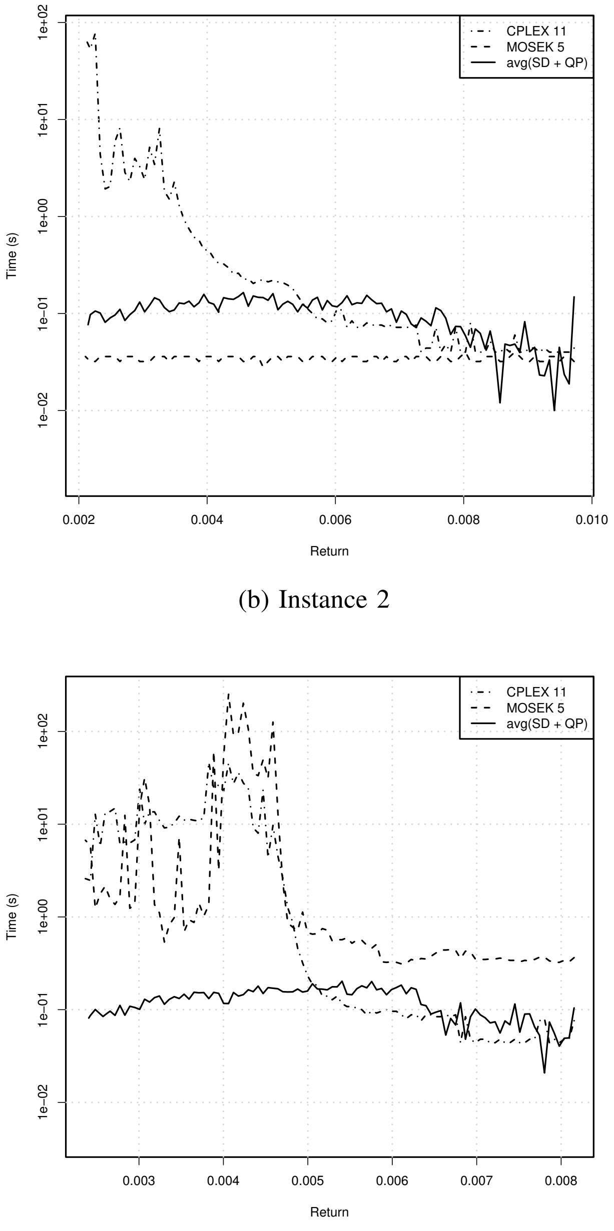
## V. SEARCH SPACE ANALYSIS

Search Space Analysis relies on the concept of *basin of attraction* (BOA), and is aimed to understand the features of the search space, when they are not deductible using exhaustive approaches.

In our meta-heuristic model, we are defining BOAs of search graph nodes. For this definition to be valid for any state of the search graph[2], we are relaxing the requirement that the goal state is an attractor. Therefore, the basin of attraction will also depend on the particular termination condition of the algorithm. In the following examples, we will suppose to end the execution as soon as a stagnation condition is detected, i.e., when no improvements are found after a maximum number of steps. In what follows we are following the definitions expressed by Roli[2], and we are applying our analysis to deterministic systems, before extending it to stochastic systems.

**Definition** Given a deterministic algorithm $\mathcal{A}$, the basin of attraction $\mathcal{B}(\mathcal{A}|s)$ of a point $s$, is defined as the set of states that, taken as initial states, give origin to trajectories that include point $s$.

Let $S^*$ be the set of global optima: for each $s \in S^*$ there exist a basin of attraction, and their union $I^* = \bigcup_{i \in S^*} \mathcal{B}(\mathcal{A}|i)$ contains the states that, taken as a starting solution, would have the search provide a certified global optimum. Hence, if we use a randomly chosen state as a starting solution,



(b) Instance 2

(c) Instance 3

Fig. 1. Computational time: comparison between SD+QP and MINLP approaches over ORLib Instances.

the ratio $|I^*|/|S|$ would measure the probability to find an optimal solution. As a generalization, we are defining a probabilistic basin of attraction as follows:

**Definition** Given a stochastic algorithm $\mathcal{A}$, the basin of attraction $\mathcal{B}(\mathcal{A}|s;p^*)$ of a point $s$, is defined as the set of states that, taken as initial states, give origin to trajectories that include point $s$ *with probability* $p \geq p^*$. Accordingly, the union of the BOA of global optima is defined as $I^*(p) = \bigcup_{i \in S^*} \mathcal{B}(\mathcal{A}|i;p)$. It is clear that that $\mathcal{B}(\mathcal{A}|s)$ is a special case for $\mathcal{B}(\mathcal{A}|s;p^*)$, hence in what follows we are using $\mathcal{B}(s;p^*)$ instead of $\mathcal{B}(\mathcal{A}|s;p^*)$, without loss of generalization. When $p^* = 1$ we want to find solutions belonging to trajectories that ends in $s$. Notice that $\mathcal{B}(s;p_1) \subseteq \mathcal{B}(s;p_2)$ when $p_1 > p_2$.

The effectiveness of a meta-heuristic $\mathcal{A}$ is dramatically influenced by the topology and structure of the search landscape, and since the aim is to reach an optimal solution, the need of an analysis of BOA features arises. Please notice that our definition of basins of attraction enables both a complete/analytical study —when probabilities can be deducted from the search strategy features— and a statistical/empirical analysis (e.g., by sampling).

## VI. Search space analysis for Portfolio Selection Problem

When solving an optimisation problem, a sound modelling and development phase should be based on the separation between the model and the algorithm: this stems from constraint programming, and several tools foster this approach (i.e., Comet[17]). In this way, it is possible to draw information about the structure of the optimisation problem, and this knowledge can be used, for instance, for the choice of the algorithm to be used. Up to the author's knowledge, literature about portfolio selection by meta-heuristics has hardly dealt with this aspect, though some attempts have been made to study the problem structure. For instance, Maringer and Winker [23] draw some conclusion about the objective function landscape by using a memetic algorithm which embeds, in turn, Simulated Annealing (SA)[19] and Threshold Acceptance (TA)[11]. They compare the use of SA and TA inside the memetic algorithm dealing with different objective functions: Value-at-Risk(*Var*) and Expected Shortfall (*ES*)[8]. Their results indicates that TA is suitable when using *VaR*, while SA performs best when using *ES*. An analysis of the search space is made to understand this phenomenon.

Other works compare different algorithms on the same instance to understand which algorithm perform best, and in what portion of the frontier. Amongst them, Crama and Schyns[6] introduce three different Simulated Annealing strategies, showing that there is no clear dominance among them. Armañanzas and Lozano [1] introduces Ant Colony Optimisation (ACO)[10], refining solutions with a greedy search, comparing results with Simulated Annealing and Iterative Improvement, and showing that ACO and SA performances greatly depends on the expected return (see Sec. II). A common way of tackling this analysis is to run the different algorithms, and then to pool the obtained solutions. After this phase, the dominated solutions are deleted and it is possible to understand which algorithm performs best w.r.t. a given part of the frontier [5], [13].

The main shortcoming of these approaches is that they identify which algorithm performs well in a given portion of the frontier, without explaining the motivation beneath this behaviour. Hence, an additional effort has to be made to understand the model and how it can affect the algorithm performance. In this section, we are aimed in comparing different formulations for the PSP and in understanding how the structure of the problem affects the algorithm's performances through Search Space Analysis.

When using a meta-heuristic, search space analysis represents an effective tool to assess the algorithm performances and the instance hardness. In what follows we are discussing results obtained over real instances and over hard-handmade instances in order to outline the connections between search space analysis and algorithm performances.

*Analysis for Real Instances:* We define five equally distributed $r_e$ values, referred to as $R_i$ $(i = 1 \ldots 5)$ and we analyse the search space corresponding to each $r_i$ over the five `ORlib` instances in order to assess the local minima distribution, that is an indicator of the search space ruggedness. This concept is important since it has been shown that there exists a negative correlation between ruggedness and meta-heuristic performances[18]. We have implemented and run a deterministic version of SD (referred to as $SD_{det}$) to estimate the number of minima of an instance of the problem discussed in Sec. IV, which combines continuous variables $x$ with integer variables $z$. As for the constraints, we have set both a minimum ($k_{min}$) or a maximum ($k_{max}$) bound on cardinality in order to understand the differences arising when using a maximum or strict cardinality constraint. As for determining the initial states, we have resorted either to complete enumeration (if the instance at hand is small) or to uniform sampling.

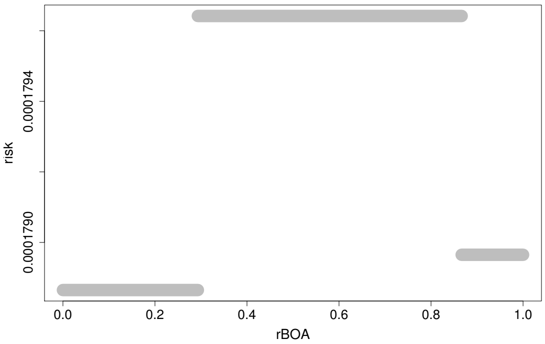


Fig. 2. Instance 4: BOA analysis. $k_{min} = 1$, $k_{max} = 10$, $R = 0.00375$.

Results are shown in table V, where we report the number of the different local minima found by 30 runs of $SD_{det}$. Dashed entries mean that no feasible solution exists.

Results indicate that instances at hand show a small number of local minima and only one global minimum. This clearly indicates a situation in which the search landscape is rather smooth, and explains why different strategies such TS and FD/SD lead to similar optimization results: since local optimum are few and far between, there is no need of using complex strategies or escape mechanisms, since the probability of meeting a trajectory leading to one of the optima are quite high. We recall that those values have been found by using a deterministic version of $SD$, and their inverse represents an upper bound on the probability to reach the certified optimum when using the stochastic SD and TS defined in section IV-A.

We conclude that when using our formulation, global minima have a quite large BOA. This can be seen in Fig. 2, in which segments length corresponds to *rBOA* (i.e., ratio between size of *BOA(s)* and search space size) and their y-value corresponds to the minimum found: global minima *rBOA* ranges from 30% to 60%.

In the next paragraph we will show that the same problem, modeled in a different way, leads to different basin of attractions.

*Monolithic Search Basin of Attraction:* In the previous paragraph we have shown that, when using our problem formulation, the BOAs of local optima are quite big, making the search landscape smooth and the problem easy to be tackled by our hybrid solver. BOAs depend on the search strategy used and on the problem

TABLE V

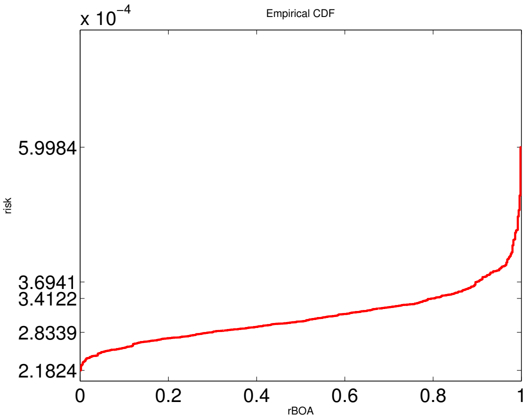
| 10,10 | – | 1 | 1 | 3 | 2 |

formulation, and this can be shown by running a different strategy, i.e., a monolithic one, on the same problem instances. We have used a SD based on a variant of Threshold Accepting [12], in which only a variable class is considered, i.e., $w$ variables corresponding to actual asset weights. The desired outcome of this problem is the same as the previously introduced one, but they are represented in a different way. In the following we explain the main features of this meta-heuristic approach:

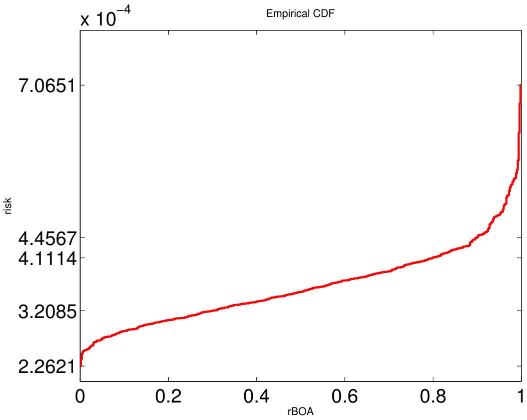
- **Search Space** The *master-slave* decomposition is not used anymore, and a state is represented by a sequence $W = w_1 \dots w_n$ such that $w_b$ corresponds to the relative amount invested in asset $b$. Furthermore, the portfolio has to be feasible w.r.t. cardinality, budget, floor and ceiling constraints.
- **Neighborhood relations** A given amount (*step*) is transferred from asset $a$ to another $b$, no matter if $b$ is already in the portfolio or not. If this leads one asset value to be smaller than $\epsilon_i$, its value is set to $\epsilon_i$. If the move consists in decreasing the value of an asset being set to $\epsilon_i$, its value is set to $0$.
- **Initial solution** The initial solution has to be feasible w.r.t. cardinality, budget, floor and ceiling constraints and is always created from scratch.
- **Cost Function** As for the cost function we are using a penalty approach, hence it is given by adding the degree of constraints violations to the portfolio risk.
- **Local Search Strategies** SD that explores the space of $w$ variables.

Results about BOAs analysis for this approach are shown in figure 3. Even from visual inspection only, it turns out that the number of local minima is dramatically higher than the one corresponding to the *master-slave* approach; furthermore basin of attraction are tiny, and the certified optimum has not been found.

*Analysis for artificial instances:* In the previous paragraph we have shown that, for the PSP we are solving, instances at hand are easy to solve, since our *master-slave* decomposition leads to search spaces with a small number of local optima with huge BOAs. Hence, there is no need for complex approaches and escape mechanisms, and this explains why simple meta-heuristics performances are comparable with more sophisticated one such TS. Furthermore, preliminary analysis have



(a) Instance 4: $k_{min} = 1$, $k_{max} = 10$, $R = 0.00375$



(b) Instance 4: $k_{min} = 1$, $k_{max} = 6$, $R = 0.00193$

Fig. 3. Two ORlib instances: Monolithic BOA analysis with different constraints.

$$\sigma = \left(\begin{array}{ccccccccccc}
1 & -1 & 0 & 0 & 0 & & & \cdots & & & 0\\
-1 & 1 & 0 & 0 & 0 & & & \cdots & & & 0\\
0 & 0 & 1 & -0.9 & 0 & 0 & 0 & \cdots & & & \vdots\\
0 & 0 & -0.9 & 1 & 0 & 0 & 0 & \cdots & & & \vdots\\
\vdots & & 0 & 0 & 1 & -0.9 & 0 & \cdots & & & \vdots\\
\vdots & & 0 & 0 & -0.9 & 1 & 0 & \cdots & & & \vdots\\
\vdots & & \ddots & & 0 & 0 & \ddots & & & & \vdots\\
\vdots & & & \ddots & \vdots & \vdots & & \ddots & & & \vdots\\
\vdots & & & & \cdots & & & & 1 & 0 & 0\\
\vdots & & & & \cdots & & & & 0 & 1 & -0.9\\
0 & & & & \cdots & & & & 0 & -0.9 & 1
\end{array}\right) \qquad (6)$$

suggested us that this is a common feature in financial market related instances: this could be considered as a good point for practitioners, but makes impossible to test the robustness of our approach, in which we have developed TS+QP in order to tackle more difficult instances. Hence, we have designed an artificial hand-made instance featuring a huge number of minima with tiny BOAs, containing an even number $n$ of assets $i$, in which $r_i = 1 \forall i$ and whose covariance matrix is depicted here above.

It is easy to see that for every $r_e$ the best portfolio contains the first two assets only, but also that portfolios consisting of assets $i$ (odd) and $i + 1$ only are local optima, since all their neighbors feature higher risk.

It can be shown show that it is necessary to visit a portfolio $s$ having $z_1 = 1$ or $z_2 = 1$ to reach the global optimum $s^*$. Furthermore, portfolios containing an odd asset $i$ ($i > 1$) whose $z_i = 1$ and $z_{i+1} = 1$ will never entry in a trajectory in which this couple would be removed. Hence, $\mathcal{B}(s^*)$ contains all portfolios featuring $z_1 = 1$ or $z_2 = 1$, and in which there is no $i$ odd and $> 1$ such that $z_i = 1$ and $z_{i+1} = 1$. In this case, *rBOA*$(s^*)$ is inversely proportional to $n$.

By running our master-slave approach over this instance ($\epsilon_i = 0.01$ and $\delta_i = 1$ for $i = 1 \dots n$) we have remarked that TS+QP easily find a solution comparable to that provided by CPLEX, while SD and FD performances are greatly affected by the starting solution (and anyhow much poorer than TS+QP).

It has to be noticed that such an instance could be hardly found over real markets, even its presence is not forbidden by structural properties, but when tackling it the need of larger neighborhoods arises. Anyhow, no matter the neighborhood size, it is always possible to devise artificial instances whose minima are composed by subsets that have to be moved jointly.

From the Search Space Analysis conducted in this section, we may conclude that different formulations (hybrid vs continuous only) lead to different Basin of Attraction analysis on the instances at hand. This turns into different algorithm behaviours. The formulation that leads to a smooth search landscape (hybrid) can be tackled by algorithms with weak diversification capabilities (i.e., SD in the proposed hybrid formulation), whilst these algorithms are to be replaced by more sophisticated ones when the search landscape becomes rugged (see the behaviour of SD in the monolithic version). The artificial instance places itself in the middle of these phenomena, as it provides room for the use of more complex strategies (i.e., TS) in the hybrid case, due to the neighbor moves used which make the search to get stuck in the first local optimum found, but when embedded in the continuous only formulation doesn't provide different performances from the real instances.

## VII. Conclusion

In this work we have used a meta-heuristic approach to study the impact of different formulations on the Portfolio Selection algorithm's behaviour, and we have devised a methodology to understand the root of the different behaviours (search space analysis through BOA analysis). To this aim we have compared an approach based on a master-slave decomposition with a monolithic approach. Results have shown that the search space defined by the monolithic approach is quite rugged and need an algorithm featuring an escape mechanism to be solved efficiently, whilst the hybrid approach leads to a smoother search landscape to be explored efficiently also by simpler algorithms such SD.

# Fast Solvers for Nonsmooth Optimization Problems in Phase Separation

Pawan Kumar
Department of Mathematics and Computer Science
Freie Universität Berlin
Arnimallee 6, 14195 Berlin

***Abstract*—The phase separation processes are typically modeled by well known Cahn-Hilliard equation with obstacle potential. Solving these equations correspond to a nonsmooth and nonlinear optimization problem. Recently a globally convergent Newton Schur method was proposed for the non-linear Schur complement corresponding to this $2 \times 2$ non-linear system. The proposed method is similar to an inexact active set method in the sense that the active sets are first identified by solving a quadratic obstacle problem corresponding to the $(1, 1)$ block of the $2 \times 2$ system, and later solving a reduced linear system by annihilating the rows and columns corresponding to identified active sets. For solving the quadratic obstacle problem, various optimal multigrid like methods have been proposed. However solving the reduced system remains a major bottleneck. In this paper, we explore an effective preconditioner for the reduced linear system that allows solving large scale optimization problem corresponding to Cahn-Hilliard and to possibly similar models.**

## I. Introduction

THE Cahn-Hilliard equation was first proposed in 1958 by Cahn and Hilliard [1] to study the phase separation process in a binary alloy. Here the term phase stands for the concentration of different components in the alloy. It has been empirically observed that the concentration changes from a possibly mixed state to a distinct spatially separated two phase state when the alloy under preparation is subjected to a rapid cooling at a certain critical temperature. This rapid reduction in the temperature the so-called *deep quench limit* has been found to be modeled efficiently by obstacle potential proposed by Oono and Puri [2] in 1987; also see Blowey and Elliot [3, p. 237, (1.14)]. The phase separation has been noted to be highly non-linear (point nonlinearity to be precise), and the obstacle potential emulates the nonlinearity and non-smoothness that is empirically observed. Dealing with the non-smoothness and designing robust iterative procedure has been the subject of much active research in last decades. Assuming semi-implicit time discretizations [4] to alleviate the time step restrictions, most of the proposed methods essentially differ in the way the nonlinearity and non-smoothness are handled. Two of the main approaches for such problems are: regularization around the non-smooth region [5] or an active set approach [6] i.e., identify the active sets and solve a reduced problem which is linear, [6] unlike [5] also ensures global convergence of the Newton method by using proper damping parameter. The nonlinear problem corresponding to Cahn-Hilliard problem with obstacle potential could be written as a non-linear system in block $2 \times 2$ matrix form as follows:

$$\begin{pmatrix} F & B^T \\ B & -C \end{pmatrix} \begin{pmatrix} u^* \\ w^* \end{pmatrix} \ni \begin{pmatrix} f \\ g \end{pmatrix}, \quad u^*, w^* \in \mathbb{R}^n \tag{1}$$

where $u^*, w^*$ are unknowns, $F = A + \partial I_{\mathcal{K}}$, where $I_{\mathcal{K}}$ denotes the indicator functional of the admissible set $\mathcal{K}$. The matrices $A, C$ are essentially Laplacian with $A$ augmented by a non-local term (a rank one term) reflecting mass conservation. By nonlinear Gaussian elimination of the $u^*$ variables, the system above could be reduced to a nonlinear Schur complement system in $w^*$ variables [6], where the nonlinear Schur complement is given by $-(C + BF^{-1}B^T)$. In [6], a globally convergent Newton method is proposed for this nonlinear Schur complement system which is later interpreted as a preconditioned Uzawa iteration. Note that $F(x)$ is a set valued mapping due to the presence of set-valued operator $\partial I_{\mathcal{K}}$; to solve the inclusion $F(x) \ni y$, or equivalently, $x \in F^{-1}y$ corresponding to the quadratic obstacle problem, many methods have been proposed: projected block Gauss-Seidel [7], monotone multigrid method [8], [9], [10], truncated monotone multigrid [11], and recently introduced truncated Newton multigrid [11]. See the excellent review article [11] that compares all these methods. Solving the quadratic obstacle problem corresponds to identifying the active sets. By annihilating the corresponding rows and columns that belong to the identified active sets, we obtain a reduced linear system as follows:

$$\begin{pmatrix} \hat{A} & \hat{B}^T \\ \hat{B} & -C \end{pmatrix} \begin{pmatrix} \hat{u} \\ \hat{w} \end{pmatrix} = \begin{pmatrix} \hat{f} \\ \hat{g} \end{pmatrix}, \quad \hat{u}, \hat{w} \in R^n \tag{2}$$

The overall nonlinear iteration is performed in the sense of inexact Uzawa, and the preconditioners are updated with next available active sets.

In this paper our goal is to design effective preconditioner for (2). In particular we consider the Schur complement preconditioner proposed in [5] and adapt it to our linear system. Our linear system differs from [5]; we have to deal with nontrivial kernels at (1,1) and (2,2) block. We study the effectiveness of the preconditioner for various active set configurations that allow solving large scale nonsmooth optimization problem corresponding to similar model problems when similar nonsmooth Newton Schur method is used.

The rest of this paper is organized as follows. In Section III, we describe the Cahn-Hilliard model with obstacle potential,

Funded by EC math and Matheon

we discuss the time and space discretizations and variational formulations. In Section IV, we discuss briefly the solver for Cahn-Hilliard with obstacle problem. In particular, we briefly discuss the recent Nonsmooth Newton Schur method, and the truncated monotone multigrid for the obstacle problem; we describe how the linear system appears. The preconditioners for the reduced linear systems are discussed in Section IV-E. Finally in Section V, we show numerical experiments with the proposed preconditioner.

## II. Notation

Let SPD and SPSD denote symmetric positive definite and symmetric positive semi-definite respectively. Let $|x|$ denote the absolute value of $x$, whereas, for a set $\mathcal{K}$, $|\mathcal{K}|$ denotes the number of elements in $\mathcal{K}$. Let $Id \in \mathbb{R}^{n\times n}$ denote the identity matrix. For a vector $u$ let $u(i)$ denote the $i^{th}$ entry of vector $u$. Similarly for a matrix we use the notation $K(i,j)$ to denote the $(i,j)^{th}$ entry of $K$. For any matrix $K$, $K^+$ shall denote a pseudoinverse of $K$.

## III. Cahn-Hilliard Problem with Obstacle Potential

### A. The Model

The Cahn-Hilliard equation in PDE form with inequality constraints reads:

$$\partial_t u = \Delta w, \tag{3}$$

$$w = -\epsilon\Delta u + \psi_0^{'}(u) + \mu, \tag{4}$$

$$\mu \in \partial\beta_{[-1,1]}(u), \tag{5}$$

$$|u| \le 1, \tag{6}$$

$$\frac{\partial u}{\partial n} = \frac{\partial w}{\partial n} = 0 \text{ on } \partial\Omega, \tag{7}$$

where $\partial\beta_{[-1,1]}(u)$ is the subdifferential of $\beta_{[-1,1]}(u) := \int_\Omega I_{[-1,1]}(u)$. The obstacle potential $\psi$ is given as follows:

$$\psi(u) = \psi_0(u) + I_{[-1,1]}(u), \text{ where } \psi_0(u) = \frac{1}{2}(1-u^2). \tag{8}$$

Here the indicator function $I_{[-1,1]}(u)$ is defined as follows:

$$I_{[-1,1]} = \begin{cases} 0, \text{ if } u(i) \in [-1,1], \\ \infty, \text{ otherwise.} \end{cases} \tag{9}$$

The subscript $[-1,1]$ correspond to the fact that $u$ is allowed to take values only between $-1$ and $+1$, which we sometimes refer to as upper and lower obstacles respectively.

In (3)-(7) the unknowns $u$ and $w$ are called order parameter and chemical potential respectively. For a given $\epsilon > 0$, final time $T > 0$ and initial condition $u_0 \in \mathcal{K}$ where

$$\mathcal{K} = \{v \in H^1(\Omega) \,:\, |v| \le 1\}, \tag{10}$$

the equivalent initial value problem for Cahn-Hilliard equation with obstacle potential interpreted as variational inequality reads:

$$\left\langle \frac{du}{dt}, v \right\rangle + (\nabla w, \nabla v) = 0, \; \forall v \in H^1(\Omega), \tag{11}$$

$$\epsilon(\nabla u, \nabla(v-u)) - (u, v-u) \ge (w, v-u), \; \forall v \in \mathcal{K}, \tag{12}$$

where we use the notation $\langle\cdot,\cdot\rangle$ to denote the duality pairing of $H^1(\Omega)$ and $H^1(\Omega)^{'}$. Note that we used the fact that $\psi_0^{'}(u) = -u$ in the second term on the left of inequality (12) above. The existence and uniqueness of the solution of (11), (12) above has been established in Blowey and Elliot [3]. We next consider an appropriate discretization in time and space for the model.

### B. Time and Space Discretizations

We consider a fixed non-adaptive grid in time $(0,T)$ and in space $\Omega = (0,1)\times(0,1)$. The time step $\tau = T/N$ is kept uniform, $N$ being the number of time steps. We consider the semi-implicit Euler discretization in time and finite element discretization as in Barrett et. al. [7] with triangulation $\mathcal{T}_h$ with the following spaces:

$$\mathcal{S}_h = \{v \in C(\overline{\Omega}) \,:\, v|_T \text{ is linear} \forall T \in T_h\}, \tag{13}$$

$$\mathcal{P}_h = \{v \in L^2(\Omega) \,:\, v_T \text{ is constant} \forall T \in \mathcal{T} \in \mathcal{T}_h\}, \tag{14}$$

$$\mathcal{K}_h = \{v \in \mathcal{P}_h \,:\, |v_T| \le 1 \forall T \in \mathcal{T}_h\} = \mathcal{K}\cap\mathcal{S}_h \subset \mathcal{K}, \tag{15}$$

which leads to the following discrete Cahn-Hilliard problem with obstacle potential:
Find $u_h^k \in \mathcal{K}_h, w_h^k \in \mathcal{S}_h$ such that

$$\langle u_h^k, v_h\rangle + \tau(\nabla w_h^k, \nabla v_h) = \langle u_h^{k-1}, v_h\rangle, \; \forall v_h \in \mathcal{S}_h, \tag{16}$$

$$\epsilon(\nabla u_h^k, \nabla(v_h - u_h^k)) - \langle w_h^k, v_h - u_h^k\rangle \ge \langle u_h^{k-1}, v_h - u_h^k\rangle, \tag{17}$$

$$\forall v_h \in \mathcal{K}_h.$$

holds for each $k = 1,\ldots,N$. The initial solution $u_h^0 \in \mathcal{K}_h$ is taken to be the discrete $L^2$ projection $\langle u_h^0, v_h\rangle = (u_0, v_h), \forall v_h \in \mathcal{S}_h$. Existence and uniqueness of the discrete Cahn-Hilliard equations has been established in [4]. The discrete Cahn-Hilliard equation is equivalent to the set valued saddle point block $2\times 2$ nonlinear system (1) with $F = A + \partial I_{\mathcal{K}_h}$ and

$$A = \epsilon(\langle\lambda_p, 1\rangle\langle\lambda_p, 1\rangle + (\nabla\lambda_p, \nabla\lambda_q))_{p,q\in\mathcal{N}_h}, \tag{18}$$

$$B = -(\langle\lambda_p, \lambda_q\rangle)_{p,q\in\mathcal{N}_h}, \; C = \tau((\nabla\lambda_p, \nabla\lambda_q))_{p,q\in\mathcal{N}_h}. \tag{19}$$

where $\mathcal{N}_h$ stands for the set of vertices in $\mathcal{T}_h$, and $\lambda_p, p \in \mathcal{N}_h$ denote the standard nodal basis. We write the above in more compact notation as follows

$$A = \epsilon(K + mm^T), \quad B = -M, \quad C = \tau K, \tag{20}$$

where $K$ and $M$ are stiffness and mass matrices respectively.

## IV. Iterative solver for Cahn-Hilliard with Obstacle Potential

In [6], a nonsmooth Newton Schur method is proposed which is also interpreted as a preconditioned Uzawa iteration. For a given time step $k$, the Uzawa iteration reads:

$$u^{i,k} = F^{-1}(f^k - B^T w^{i,k}), \tag{21}$$

$$w^{i+1,k} = w^{i,k} + \rho^{i,k}\hat{S}_{i,k}^{-1}(Bu^{i,k} - Cw^{i,k} - g^k) \tag{22}$$

for the saddle point problem (1). Here $i$ denotes the $i^{th}$ Uzawa step and $k$ denotes the $k^{th}$ time step. Here $f^k$ and $g^k$ are defined in (16) and (17). The time loop starts with an initial value for $w^{0,0}$ which is taken arbitrary, and with the initial value $u^{0,0}$. The Uzawa iteration requires three main computations that we describe below.

### A. Computing $u^{i,k}$

The first step (21) corresponds to a quadratic obstacle problem:

$$u^{i,k} = \arg \min_{v \in \mathcal{K}} \left( \frac{1}{2} \langle Av, v \rangle - \langle f^k - B^T w^{i,k}, v \rangle \right). \tag{23}$$

As mentioned in the introduction, this problem has been extensively studied during last decades [7], [8], [9], [11].

### B. Computing $\hat{S}_{i,k}^{-1}(Bu^{i,k} - Cw^{i,k} - g^k)$

The descent direction $d^{i,k+1} = \hat{S}_{i,k}^{-1}(Bu^{i,k} - Cw^{i,k} - g)$ in (22) is obtained as a solution of the following reduced linear block $2 \times 2$ system:

$$\begin{pmatrix} \hat{A} & \hat{B}^T \\ \hat{B} & -C \end{pmatrix} \begin{pmatrix} \tilde{u}^{i,k} \\ d^{i,k} \end{pmatrix} = \begin{pmatrix} 0 \\ g + Cw^{i,k} - Bu^{i,k} \end{pmatrix}, \tag{24}$$

where

$$\hat{A} = TAT + \hat{T}, \quad \hat{B} = TB. \tag{25}$$

Here $T$ and $\hat{T}$ are defined as follows:

$$T = \text{diag} \begin{pmatrix} 0, \text{if } u^{i,k}(j) \in \{-1, 1\} \\ 1, \text{otherwise} \end{pmatrix}, \ j = 1, \ldots, |\mathcal{N}_h|, \tag{26}$$

$$\hat{T} = Id - T, \quad Id \in \mathbb{R}^{|\mathcal{N}_h| \times |\mathcal{N}_h|}, \tag{27}$$

where $u^{i,k}(j)$ is the $j^{th}$ component of $u^{i,k}$. In other words, $\hat{A}$ is the matrix obtained from $A$ by replacing the $i^{th}$ row and the $i^{th}$ column by the unit vector $e_i$ corresponding to the active sets identified by diagonal entries of $T$. Similarly, $\hat{B}$ is the matrix obtained from $B$ by annihilating columns, and $\hat{B}^T$ is the matrix obtained from $B^T$ by annihilating rows.

### C. Computing Step Length $\rho^{i,k}$

The step length $\rho^{i,k}$ is computed using a bisection method. We refer the reader to [12, p. 88].

### D. Algebraic Monotone Multigrid for Obstacle Problem

To solve the quadratic obstacle problem (21), we use the truncated monotone multigrid method proposed in [8]. However, here we use algebraic coarsening [13] that we describe briefly.

*1) Aggregation Based Coarsening:* We first discuss the coarsening for two-grid, the multilevel interpolations are applied recursively. In classical two-grid, a set of coarse grid unknowns is selected and the matrix entries are used to build interpolation rules that define the prolongation matrix P, and the coarse grid matrix $A_c$ is computed from the following Galerkin formula

$$A_c = P^T A P. \tag{28}$$

In contrast to the classical two-grid approach, in aggregation based multigrid, first a set of aggregates $G_i$ is defined. Let $|\mathcal{N}_{h,c}|$ be the total number of such aggregates, then the interpolation matrix $P$ is defined as follows

$$P_{ij} = \begin{cases} 1, & \text{if } i \in G_j, \\ 0, & \text{otherwise}, \end{cases}$$

Here, $1 \le i \le |\mathcal{N}_h|$, $1 \le j \le |\mathcal{N}_{h,c}|$. Further, we assume that the aggregates $G_i$ are such that

$$G_i \bigcap G_j = \phi, \text{ for } i \neq j \text{ and } \bigcup_i G_i = \{i \in \mathbb{N} : 1 \le i \le |\mathcal{N}_h|\}. \tag{29}$$

The matrix $P$ defined above is a $|\mathcal{N}_h| \times |\mathcal{N}_{c,h}|$ matrix, but since it has only one non-zero entry (which are "one") per row, the matrix is compactly represented by a single array of length $\mathcal{N}_{h,c}$ storing the location of the non-zero entry on each row. The coarse grid matrix $A_c$ may be computed as follows

$$(A_c)(i, j) = \sum_{k \in G_i} \sum_{l \in G_j} A(k, l),$$

where $1 \le i, \ j \le |\mathcal{N}_{h,c}|$, and $A(k, l)$ is the $(k, l)^{th}$ entry of $A$.

Numerous aggregation schemes have been proposed in the literature, but in this paper we consider the standard aggregation based on strength of connection [14, Appendix A, p. 413] where one first defines a set of nodes $\mathcal{S}_i$ to which $i$ is strongly negatively coupled, using the Strong/Weak coupling threshold $\beta$:

$$\mathcal{S}_i = \{ \, j \neq i \mid A(i, j) < -\beta \ \text{max}|A(i, k)| \, \}.$$

Then an unmarked node $i$ is chosen such that priority is given to a node with minimal $M_i$, here $M_i$ being the number of unmarked nodes that are strongly negatively coupled to $i$. For a complete algorithm of aggregation, the reader is referred to Notay [13], [15].

### E. Preconditioner for Reduced Linear System

In Bosch et. al. [5], a preconditioner is proposed in the framework of semi-smooth Newton method combined with Moreau-Yosida regularization for the same problem. However, the preconditioner was constructed for a linear system which is different from the one we consider in (24). For convenience of notation, we rewrite the system matrix in (24) as follows

$$\mathcal{A} x = b, \tag{30}$$

where scripted $\mathcal{A}$ above is

$$\mathcal{A} = \begin{pmatrix} \hat{A} & \hat{B}^T \\ \hat{B} & -C \end{pmatrix}, \quad x = \begin{pmatrix} x_1 \\ x_2 \end{pmatrix}, \quad b = \begin{pmatrix} b_1 \\ b_2 \end{pmatrix}, \tag{31}$$

where

$$x_1 = \tilde{u}^{i,k}, \quad x_2 = d^{i,k}, \quad b_1 = 0, \quad b_2 = g + Cw^{i,k} - Bu^{i,k}. \tag{32}$$

The preconditioner proposed in [5] has the following block lower triangular form

$$\mathcal{B} = \begin{pmatrix} \hat{A} & 0 \\ \hat{B} & -S \end{pmatrix}, \tag{33}$$

where $S = C + \hat{B}\hat{A}^{-1}\hat{B}^T$ is the Schur complement. Note that such preconditioners are also called inexact or preconditioned Uzawa preconditioners for the *linear* saddle point problems. By block $2 \times 2$ inversion formula we have

$$\mathcal{B}^{-1} = \begin{pmatrix} \hat{A} & 0 \\ \hat{B} & -S \end{pmatrix}^{-1} = \begin{pmatrix} \hat{A}^{-1} & 0 \\ S^{-1}\hat{B}^T\hat{A}^{-1} & -S^{-1} \end{pmatrix}. \tag{34}$$

Let $\hat{S}$ be an approximation of Schur complement $S$ in $\mathcal{B}$, then the new preconditioner $\hat{\mathcal{B}}$ and the corresponding preconditioned operator $\hat{\mathcal{B}^{-1}}\mathcal{A}$ are given as follows

$$\hat{\mathcal{B}} = \begin{pmatrix} \hat{A} & 0 \\ \hat{B} & -\hat{S} \end{pmatrix}, \quad \hat{\mathcal{B}}^{-1}\mathcal{A} = \begin{pmatrix} I & \hat{A}^{-1}\hat{B}^T \\ 0 & \hat{S}^{-1}S \end{pmatrix}. \tag{35}$$

Using (35) above, we can note the following trivial result.

*Theorem 4.1:* Let $\mathcal{B}$ defined in (35) be a preconditioner for $\mathcal{A}$ defined in (31), then there are $|\mathcal{N}_h|$ eigenvalues of $\mathcal{B}^{-1}\mathcal{A}$ equal to one, and the rest are the eigenvalues of the preconditioned Schur complement $\hat{S}^{-1}S$.

*Remark 4.1:* When using GMRES [16], right preconditioning is preferred. Similar result as for the left preconditioner above Theorem 4.1 holds.

The preconditioned system $\mathcal{B}^{-1}\mathcal{A}x = \mathcal{B}^{-1}b$ is given as follows

$$\begin{pmatrix} I & \hat{A}^{-1}\hat{B}^T \\ 0 & \hat{S}^{-1}S \end{pmatrix} \begin{pmatrix} x_1 \\ x_2 \end{pmatrix} = \begin{pmatrix} \hat{A}^{-1} & 0 \\ S^{-1}\hat{B}^T\hat{A}^{-1} & -S^{-1} \end{pmatrix} \begin{pmatrix} b_1 \\ b_2 \end{pmatrix} \tag{36}$$

from which we obtain the following set of equations

$$x_1 + \hat{A}^{-1}\hat{B}^T x_2 = \hat{A}^{-1}b_1, \tag{37}$$

$$\hat{S}^{-1}Sx_2 = S^{-1}(\hat{B}^T\hat{A}^{-1}b_1 - b_2). \tag{38}$$

```
Algorithm 4.1: Objective: Solve $\mathcal{B}^{-1}\mathcal{A}x = \mathcal{B}^{-1}b$
1) Solve for $x_2 : \hat{S}^{-1}Sx_2 = \hat{S}^{-1}(\hat{B}^T\hat{A}^{-1}b_1 - b_2)$
2) Set $x_1 = \hat{A}^{-1}(b_1 - \hat{B}^T x_2)$
```

Here if Krylov subspace method is used to solve for $x_2$, then matrix vector product with $S$ and a solve with $\hat{S}$ is needed. However, when the problem size i.e. $|\mathcal{N}_h|$ is large, it won't be feasible to do exact solve with $\hat{A}$, and we need to solve it inexactly, for example, using algebraic multigrid methods. In the later case, the decoupling of $x_1$ and $x_2$ as in Algorithm 4.1 is not possible, and we shall need matrix vector product with $\mathcal{A}$ (31) and a solve (forward sweep) with $\hat{\mathcal{B}}$. We discuss at the end of this subsection on how to take advantage of the special structure of $\hat{A}$ in both cases of exact and inexact solves.

As a preconditioner $\tilde{S}$ of $S$, we choose the preconditioner first proposed in [5]. The preconditioner is given as follows:

$$\tilde{S} = S_1\hat{A}^{-1}S_2 = -(\hat{B} - \tau^{1/2}K)\hat{A}^{-1}(\hat{B}^T - \tau^{1/2}\hat{A}), \tag{39}$$

where $K$ is the stiffness matrix from (19). We observe that the preconditioned Schur complement $\tilde{S}^{-1}S$ is not symmetric, in particular, not symmetric w.r.t. $\langle\cdot,\cdot\rangle_S$ or w.r.t. $\langle\cdot,\cdot\rangle_{\tilde{S}}$ which is a sufficient condition for the convergence of preconditioned conjugate gradient method [16, p. 262]. Hence we shall use GMRES in Saad [16, p. 269] that allows nonsymmetric preconditioners.

*1) Exact and Inexact Solve with $\hat{A}$:* In step 1 of Algorithm 4.1, we need to solve with $\hat{A}$ when constructing right hand side, and also in step 2. Let $P$ be a permutation matrix, then solving a system of the form $\hat{A}h = g$ is equivalent to solving $P^T\hat{A}h = P^Tg$ as $P^T$ is nonsingular. With a change of variable $Py := h$, we then solve for $y$ in

$$P^T\hat{A}Py = Pg, \tag{40}$$

and we set $h = Py$ to obtain the desired solution. By choosing $P$ that renumbers the nodes corresponding to the coincidence set, we obtain

$$P^T\hat{A}P = \begin{pmatrix} I & \\ & R^TP^T\hat{A}PR \end{pmatrix}, \tag{41}$$

where $R$ is the restriction operator defined as follows

$$R^TP^T\hat{A}PR = \hat{A}\restriction_{\mathcal{N}_h \setminus \mathcal{N}_h^\bullet}, \tag{42}$$

where

$$\mathcal{N}_h^\bullet = \{i \, : \, T(i,i) = 0\} \tag{43}$$

is nothing but set of active nodes. Here $R$ is explicitly given as follows:

$$R = \begin{pmatrix} \begin{pmatrix} 0 & 0 & \dots & 0 \\ \vdots & \dots & \dots & 0 \\ 0 & 0 & \dots & 0 \end{pmatrix} \\ \begin{pmatrix} 1 & 0 & \dots & 0 \\ 0 & 1 & \dots & 0 \\ \vdots & \ddots & \dots & 0 \\ 0 & 0 & \dots & 1 \end{pmatrix} \end{pmatrix}, \; R \in \mathbb{R}^{|\mathcal{N}_h| \times |\mathcal{N}_h \setminus \mathcal{N}_h^\bullet|} \tag{44}$$

Let $\hat{K} = TKT$, we have

$$\begin{aligned} R^TP^TDPR &= R^TP^T\hat{A}PR \\ &= R^TP^T\epsilon(\hat{K} + \hat{m}\hat{m}^T)PR \\ &= \epsilon(R^TP^T\hat{K}PR + R^TP^T\hat{m}\hat{m}^TPR), \end{aligned}$$

where

$$R^TP^T\hat{K}PR = (P^TKP)|_{\mathcal{N}_h \setminus \mathcal{N}_h^\bullet}, \; \hat{K} = TKT, \; \hat{m} = Tm, \tag{45}$$

where $m$ is the rank-one term defined in (20). For convenience of notation, we write

$$R^TP^T\hat{A}PR = \epsilon(\widetilde{K} + \tilde{z}\tilde{z}^T), \tag{46}$$

where $\widetilde{K} = R^TP^T\hat{K}PR$ and $\tilde{z} = R^TP^T\hat{z}$. In the new notation, we have

$$P^T\hat{A}P = \begin{pmatrix} I & \\ & \epsilon(\widetilde{K} + \tilde{z}\tilde{z}^T) \end{pmatrix}. \tag{47}$$

Thus (40) now reads

$$\begin{pmatrix} I & \\ & \epsilon(\widetilde{K} + \tilde{z}\tilde{z}^T) \end{pmatrix} \begin{pmatrix} y_1 \\ y_2 \end{pmatrix} = Pg =: \begin{pmatrix} g_1 \\ g_2 \end{pmatrix}, \tag{48}$$

which reduces to two-set of equations

$$y_1 = g_1, \tag{49}$$

$$\epsilon(\widetilde{K} + \tilde{z}\tilde{z}^T)y_2 = g_2. \tag{50}$$

To solve the latter, we use the Sherman-Woodbury formula

$$(\widetilde{K} + \tilde{m}\tilde{m}^T)^+ = \widetilde{K}^+ - \frac{\widetilde{K}^+\tilde{m}\tilde{m}^T\widetilde{K}^+}{1 + \tilde{m}^T\widetilde{K}^+\tilde{m}}. \tag{51}$$

The AMG discussed before is used to pseudo-invert $\widetilde{K}$, and we thus avoid constructing the dense matrix which would be the case when rank one term is explicitely added.

## V. Numerical Experiments

All the experiments were performed in double precision arithmetic in MATLAB. The Krylov solver used was GMRES with subspace dimension of 200, and maximum number of iterations allowed was 300. The iteration was stopped as soon as the relative residual was below the tolerance of $10^{-7}$.

We consider two samples of active set configurations that occur when a square region evolves as shown in figures 1 and 2. The region between the two squares and the circles is the interface between two bulk phases taking values +1 and -1; initially we chose random values between -0.3 and 0.5 in the interface region. The width of the interface is kept to be 10 times the chosen mesh size. The time step $\tau$ is chosen to be equal to $\epsilon$. We compare various mesh sizes leading to number of grid points upto just above 1 million, and compare various values of epsilon for each mesh sizes. We observe that the number of iterations remain independent of the mesh size, however it depends on $\epsilon$. But we observe that for a fixed epsilon, with finer mesh, the number of iterations actually decrease significantly. For example the number of iterations for $h = 2^{-7}, \epsilon = 10^{-6}$ is 84 but the number of iterations for $h = 2^{-10}, \epsilon = 10^{-6}$ is 38, a reduction of 46 iterations! It seems that finer mesh size makes the preconditioner more efficient. We also observe that the time to solve is proportional to number of iterations; the inexact solve for the (1,1) block remains optimal because the (1,1) block is essentially Laplacian for which AMG remains very efficient.

## VI. Conclusion

For the solution of large scale optimization problem corresponding to Cahn-Hilliard problem with obstacle problem, we proposed an efficient preconditioning strategy that requires two elliptic solves. In our initial experiments upto over million unknowns, the preconditioner remains mesh independent. Although, for coarser mesh, there seems to be strong dependence on epsilon, but as the mesh becomes finer, we observe a significant reduction in iteration count, thus making the preconditioner effective and useful on finer meshes. It is likely that the iteration count continues to decrease on finer meshes.

# Computer Science & Systems

CSS is a FedCSIS conference area aiming at integrating and creating synergy between FedCSIS events that thematically subscribe to more technical aspects of computer science and related disciplines. The CSNS area spans themes ranging from hardware issues close to the discipline of computer engineering via software issues tackled by the theory and applications of computer science and to communications issues of interest to distributed and network systems. Events that constitute CSNS are:

- BCPC'15—1st International Workshop on Biological, Chemical and Physical Computations
- CANA'15—8th Computer Aspects of Numerical Algorithms
- IWCPS'15—2nd International Workshop on Cyber-Physical Systems
- MMAP'15—8th International Symposium on Multimedia Applications and Processing
- WAPL'15—5th Workshop on Advances on Programming Languages

# 1st International Workshop on Biological, Chemical and Physical Computations

THE First International Workshop on Biological, Chemical and Physical Computations (BCPC'15) is a unique interdisciplinary workshop which brings together computer scientists and engineers with biologists, chemists, and physicists to initiate development of novel paradigms, architectures and implementations of computing devices adopting principles of information processing in physical, chemical and biological systems. The workshop aims to bring together world-leading scientists whose research focuses on non-traditional theoretical machines, experimental prototypes and genuine implementations of non-classical computing devices, who try to revisit existing approaches in unconventional computing, provide scientists and engineers with blueprints of realizable computing devices, and take a critical glance at the design of novel and emergent computing systems to point out failures and shortcomings of both theoretical and experimental approaches.

## Topics

The topics of interest include, but are not limited to:

- Physics of computation,
- Slime mould computing,
- Social insects computing,
- Chemical computing,
- Bio-molecular computing,
- Cellular automata as models of massively parallel computing,
- Logics of unconventional computing,
- Reaction-diffusion computing,
- Molecular machines incorporating information processing,
- Memristors,
- Organic electronics,
- Noise-based computing,
- Novel hardware systems,
- Mechanical computing,
- Physical limits to mechanical computation.

***Abstract*—The main charter of this work is the organism *Physarum polycephalum*, in particular plasmodium, *Physarum*'s vegetative phase. During this latter form, the organism is more active and moves searching for food. Plasmodium behaves like a giant amoeba, and more interestingly, its way of foraging can be interpreted as a computation. By comparing the reaction of this organism with attractors and repellents, knowing its capability of solving computational problems with natural parallelism, we dedicated the present work to study the behavior of *Physarum polycephalum* slime mold under different conditions.**

## I. Introduction

*PHYSARUM polycephalum's* behavior [1] has been the object of different studies belonging to different research fields, from biology to unconventional computing and from experimental to theoretical science. Thus, considering the sentence just mentioned, the question coming out is "Why does *Physarum* attract so many different scientists?"

It belongs to one of the predominant groups in the world of eukaryotes: Amoebozoa [2] a family hundreds millions of years old. Although they are probably one of the first forms of life on Earth, few are data about them because of the evolutionary variation happened across the years to this group. In this field, most of the interest of scientists is focused on slime molds [3]. *Physarum polycephalum*, in particular, can be considered as a reaction-diffusion medium enwrapped in a growing membrane. Moreover, the plasmodium of *Physarum* is simple enough to be modeled and implemented in unconventional computing algorithms as a non-linear media. However, on the other hand, it is a robust organism, reach of challenging features allowing many different computational studies [4].

In [5] *Physarum* has been compared to a labelled transition system whose behavior has been modeled by a rough set models, implemented in a specific language and properly developed to describe *Physarum polycephalum's* response to spatial configuration of stimuli [6]. Additionally, its foraging behavior has been related to computation [4], in fact, attracting/repelling sources are able to induce in it excitation waves, affecting its motion. Thus, because of the parallel processing of inputs and outputs, it can be seen also as a massive-parallel amorphous computer, taking data from food sources in the space around and giving, as a result, the protoplasmic network created by its own body [7]. A recent example of *Physarum's* capability of designing optimized networks, allows the retracing of Canadian Highway Networks [8]. Additionally it has been developed an algorithm [9] able to find the shortest path, as slime mold naturally does. Among all these feature, its behavior can be resumed as: capability of optimizing shortest path [10], calculation of proximity and planar graphs [11], calculation of basic logical operation [12], motion control [13], self-adaptation [14], and self-reparation [15].

This paper shows experiments done to study the behavior of this organism under different conditions and stimuli. In particular, we analyzed not only spatial distribution of attractants/repellents, but also the effect of external elements inserted and transported by *Physarum polycephalum*. Therefore, considering the obtained results, we can say that it should be possible to program this transition system [5] to realize deterministic adaptive networks and spatial distribution of nanoscale and microscale materials. Choosing, among transported materials, those able to change electrical, optical and, magnetic properties of the system it should be possible to enable information sensing and processing. The work is organized as follows: the first section analyzes *Physarum*'s behavior in presence of rose and geranium, while the second one is dedicated to chemical compounds. Then, we distributed food around the experimental area in a particular way, like the hours of a clock, in order to see how would appear *Physarum*'s realized network. The fourth study is devoted to light, a strong repellent for the mold, able also to induce sclerotization, its dormient phase, assumed in case of not proper environment conditions [16]. The fifth section presents the reaction of *Physarum* to music and sounds of different frequencies. As was already presented in [17] there is a correlation between

This work has been financially supported by: European project FP7-ICT-2011-8 "PhyChip-Physarum Chip: Growing Computers from Slime Mould" Grant Agreement n.316366.

motion of plasmodium and the music or sound frequency. Last section describes the experiments performed using *Physarum* as a bio-robot, able to transport microparticles whithin its own body, as in [18]. In particular, we worked with polystyrene and $MnCO_3$ microparticles.

The results here reported can be useful for unconventional computing and bio-computing application devices. In such field, *Physarum polycephalum's* networks become the scaffolds of hybrid circuits at the micro and nano-scale. For the development of self-growing computational systems, we must consider and study the slime mold as a medium capable of integrating and redistributing foreign particles. Therefore, *Physarum polycephalum* acts as a programmable transport medium as showed in [19].

.

## II. Experiments

*Physarum polycephalum*'s colony has been grown starting from sclerotized samples. The organism was fed with oat-flakes and kept in a dark and humid chamber in 9 cm diameter Petri dishes with 1,5% Agar non nutrient gel. Moreover, in order to allow a proper grown and safety conditions for the colony itself, the organism was periodically replanted to fresh Agar Petri.

### A. Biological elements

In wild nature *Physarum polycephalum* can be found in the underwood, near leaves, where the sun light is partially shielded by the trees. Therefore, it is reasonable to think that the mold could meet, during its motion, elements like flowers, leaves, grass, etc.

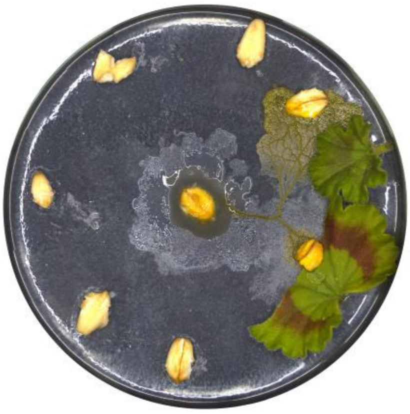

Fig. 1 Optical microscope photograph of a Petri dish with *Physarum polycephalum* growing networks firstly in the direction of the geranium.

In this section, we used as biological elements, geranium's leaves and rose-hip petals. Photographs in Fig.1 and Fig.2 show two similar experimental set-up. *Physarum polycephalum* was in the middle of a Petri dish, with Agar non nutrient gel, and starting from an oat-flake. Then, we distributed oat flakes along the perimeter, but near two of them, we added respectively: geranium's leaves in the first case and rose-hips petals in the second. The experiments have been developed keeping the set-up in the dark and humid chamber exploited for maintaining the colony and taken out of just for checking. After 10 hours, *Physarum* reached the oat-flakes near the leaves or petals, as shown respectively in Fig. 1 and Fig. 2. Repeating each case 10 times, we verified that mold's behavior was always the same. Therefore, we can conclude that both geranium and rose-hips work as attractors for *Physarum*.

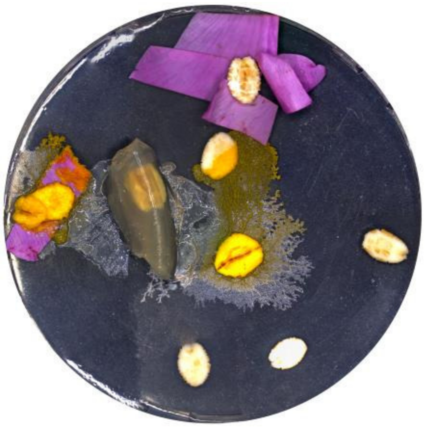

Fig. 2 Optical microscope photograph of a Petri dish with *Physarum polycephalum* growing networks firstly in the direction of rose-hip petals.

### B. Chemicals

In this experimental section, we studied slime mold's behavior in presence of two polysaccharides compounds, able to create a gel: pectin and chitosan. Firstly, we prepared the samples by dipping a circular glass, 10 mm in diameter, in the polysaccharide solution. The latter when drying forms a homogeneous gel layer on which we posed a small blob of *Physarum.* Then, the so created sample was positioned into a Petri dish with Agar non-nutrient gel, oat-flakes were spread around the glass to push *Physarum* growing its networks on the substrate and reaching them. As in the case of biological elements, the experimental Petri dishes were kept in the dark and humidity. We developed the same set-up for chitosan and for pectin; in both cases and for all the experiments, we got positive results, i.e. the mold survived creating networks towards the food. Fig. 3 shows one of the chitosan experiments performed, after one night. The mold reached the food surviving and forming protoplasmic tubes across the substrate, thus, proving the biocompatibility of chitosan for *Physarum*.

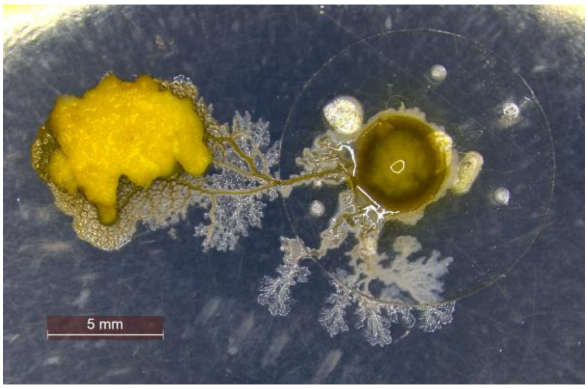

Fig. 3 Optical microscope photograph of a glass with chitosan from which the mould started its motion

Fig. 4 shows an experiment performed with pectin. The sample has been photographed after 14 hours; *Physarum* created networks and veins of protoplasmic tubes going out of the glass and reaching the oat-flakes. Therefore, also pectin can be considered a biocompatible element for slime mold.

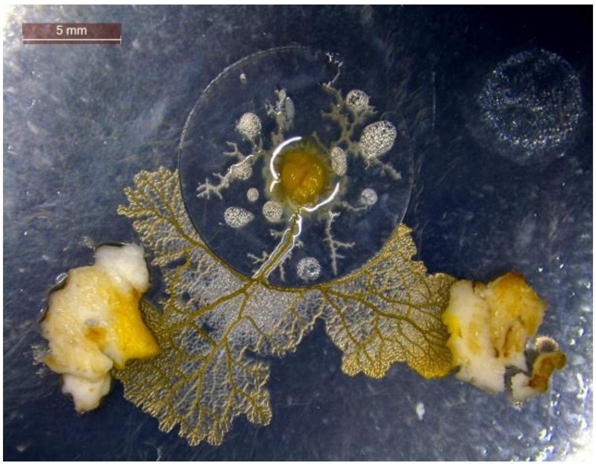

Fig. 4 Optical microscope photograph of a glass with pectin from which the mold started its motion

### *C. Clock*

We developed this series of experiment in order to understand if *Physarum* has a preferential direction, and how its networks will appear, considering a so particular food distribution.

These are three sequential optical microscope photographs, see Fig. 5, of the same sample defined as *clock*. Pictures refer to three times interval, after 24, 48 and 72 hours respectively.

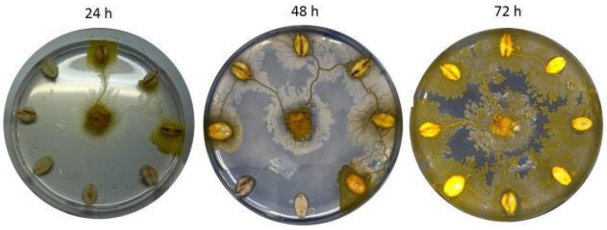

Fig. 5 Photograph of the same sample after 24h-48 and 72 hours of *Physarum* growing on agar non nutrient gel with oat-flakes distributed like hours in a clock

The mold started from the middle of the Petri, placed on an oat-flake; then, after disposing all other oats along the perimeter, like clock's hours. The sample was kept in a dark and humid environment for the whole time, and just photographed at the time-break abovementioned. As it is visible from the first Petri (i.e. after 24 hours), *Physarum polycephalum* created 2 protoplasmic tubes in the direction of two neighbors oats and, than it grew at the same time in the two opposite directions. Fig. 6 is another photograph of *clock* experiment after 12 and 24 h.

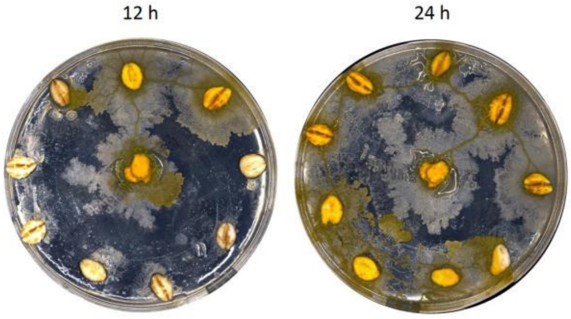

Fig. 6 Photograph of a sample in the clock series after 12 and 24 hours

Fig. 7 is another experiment of *clock*, but it is different from previous cases. Here oat-flakes have been placed closer to the starting point (in the middle of the Petri) and, as it is clearly visible, *Physarum* started on three oat flakes.

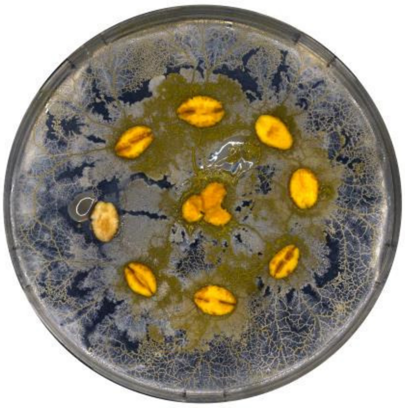

Fig. 7 Photograph of a sample in the *clock* series, in this case mold started from three oat-flakes in the middle of the Petri. Other flakes have been placed closer than in other cases.

What we got after all these experiments was that Physarum seems to have a preferential direction, on right, as many animals and insects [20]. However, there is still not statistical significance about these right decisions.

### *D. Light*

In Fig. 8 we worked with light and *Physarum*, studying the repellent effect that the first has to the latter. Starting from the generally used Petri with Agar gel inside, we masked with a black tape the outer part of the Petri dish, leaving transparent just an area with an *S* shape. Therefore, we placed a cold light source underneath the Petri and developed the experiment. What stands out from Fig. 8 is that *Physarum*, from its starting point moved in the food direction avoiding the illuminated area of the Petri.

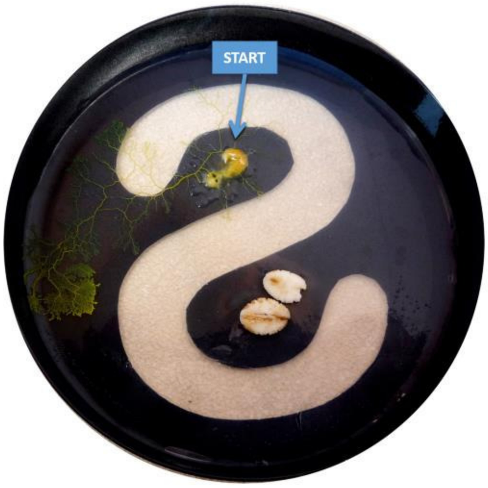

Fig. 8 Photograph of a sample in which has been tested the repellent effect of light on *Physarum polycephalum*

### *E. Music*

The Photograph of Fig. 9 presents a series of three Petri Dishes with the same set-up: agar non-nutrient gel, the same quantity of *Physarum* starting from the middle and 4 oats placed at 45 degree one with respect to the other.

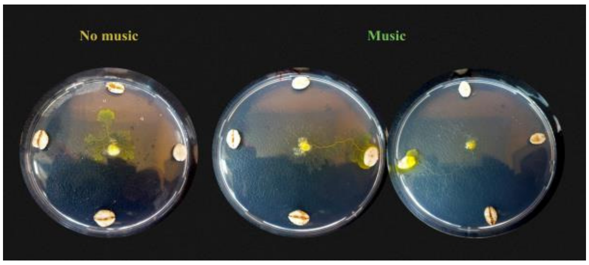

Fig. 9 Photograph of three sample in which the effect of Mozart's music on the mold's speed has been tested

Therefore, two of these samples were placed near a sound source, in particular Mozart symphony; the third one was in a silent place. What we observed, not only in these cases, but in all the so developed experiments, was that the frequencies of Mozart's music have a positive effect on *Physarum polycephalum* increasing its speed. Moreover, we performed other experiments changing kind of music, in particular hard rock songs (ACDC and Iron Maiden) and heavy metal (Carribean Corps and Marilyn Manson). It was interesting to verify that, in case of hard rock, there was not appreciable difference in the speed of *Physarum* samples under music with respect to those in a silence environment. However, when the mold was exposed to heavy metal, the sound resulted in the fact that the organism reduced substantially its speed, and in a 10% of cases, the whole motion was interrupted and it starts sclerotizing. For this study, we repeated each experiment ten times placing in parallel a sample under music and another under silence, thus keeping the same surrounding conditions.

### *F. Microparticles*

We loaded *Physarum polycephalum* slime mold with two kind of microparticles:

1_ Polystyrene microparticles (bought by Sigma-Aldrich), an aqueous dispersion (% 0.5 p/p) of particles 3 μm in diameter.

2_ $MnCO_3$ microparticles (bought by Plasma Chem., Berlin) with a diameter of 3 μm in aqueous dispersion (% 0.5 p/p).

3_ $BaFe_{12}O_{19}$ nanoparticles (obtained by a sol-gel method [14]) were solved in a homogeneous suspension in pure water with a final concentration equal to 2 mg/L. The solution was sonicated before its deal.

The performed experiments had, as an objective to verify the compatibility and the ability of the mold to transport micro and nan-objects, of different nature. Microparticles were chosen because of their nature, in particular organics, polystyrene, and non organics, $MnCO_3$. The latter, nanoparticles of Barium hexaferrite were selected because they are magnetic, a necessary feature to develope the experiments we were planning to carry out.

Additionally, we studied two kinds of transport: first case we loaded *Physarum* with particles, by directly mixing the two elements together; in the second one, we observed what happened if *Physarum* had to cross a strip of particles. The latter study, however, was performed only with polystyrene microparticles. Moreover, it has to be distinguished two main transport mechanisms: in a first case, particles are transported on *Physarum* veins, in a second one, they are taken inside the body of the mold. The first case is typical of those substances that *Physarum* almost ignore; they are not dangerous, nor interesting for it. Thus, they are transported just because, during its motion, they sticked to its body, but they are not incorporated. Therefore, it is possible to find them only on the surface of mold's body, and not inside it. In the second case, particles are mistaken as food, so they are engulfed inside *Physarum* that picks them up and tries to absorb.

We proceeded in parallel with both micro-particles (polystyrene and $MnCO_3$) solutions: 20–30 µL of particles were directly added to the plasmodium and mechanically mixed. The so obtained solution, of *Physarum*-particles, was placed on a silicon substrate. To induce the organism in moving and, to understand if it is able to transport these object, and in which way, we placed oat-flakes on a second silicon substrate, posed next to the one the mold was starting from. Then, we placed samples in a dark and humid environment and, after 12 hours, loaded *Physarum* not only survived, but, creating networks of protoplasmic tubes, reached also the food on the second substrate. The latter was used to perform scanning electron microscopy (SEM) analysis, after sclerotizing the network by light illumination. In this way, we are sure that the particles, we will found, have to be transported by *Physarum.*

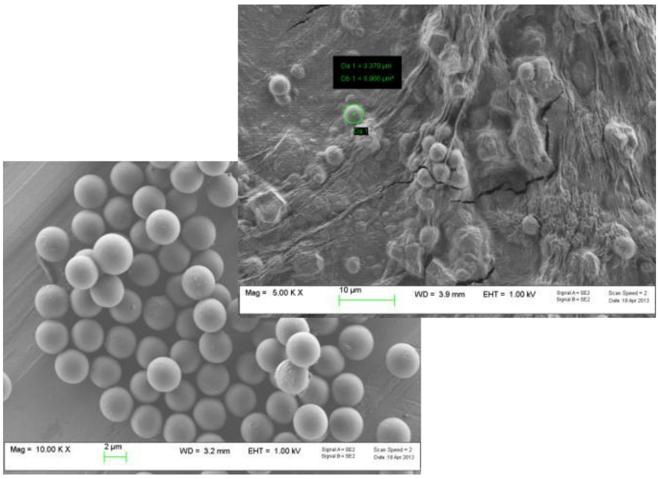

Fig. 10 Two SEM pictures: the one on left depicts polystyrene microparticles, while, on right, there is a sclerotic *Physarum* vein loaded with polystyrene microparticles by mechanically mixing method.

The right picture of Fig. 10 shows polystyrene particles within *Physarum*'s body. We found particles inside and on the surface of the mold, thus, *Physarum* incorporates and integrates polystyrene micro-objects. Moreover, we proved also that *Physarum* transports these materials, bringing them actively from the starting point, where they have been mixed, to the point the mold moved to in order to reach the food.

Figure 11 shows SEM measurements of a sclerotized vein of *Physarum* and $MnCO_3$ microparticles. The latter are clearly visible within the crack and near the veins of the mold.

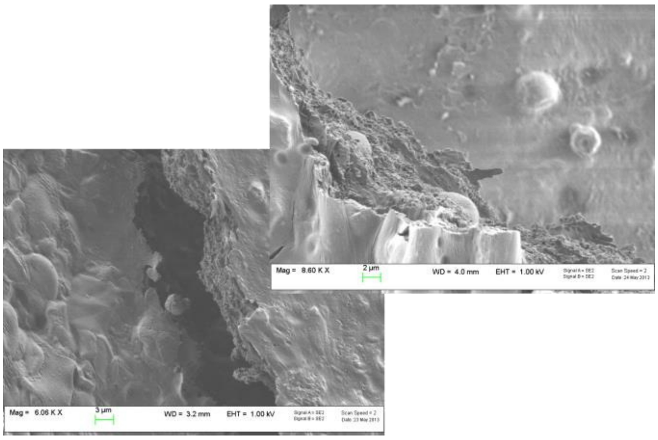

Fig. 11 SEM measurements performed on the sclerotized *Physarum* veins charged with MnCO3 particles. Also in this case the analyzed samples are those where *Physarum* moved to after loading. In both pictures particles are distinguishable within veins and cracks of the mold, in addition there are also two particles near the cut vein (right picture).

We performed a second type of study, just considering the polystyrene microparticles. Creating a strip of particles and an "ad hoc" experimental set-up, we forced *Physarum* in crossing particles' strip. Moreover, starting from a rounded glass, placed into a Petri dish with Agar non-nutrient gel, we designed a strip, one mm width, with the help of kapton, in a way that finally the strip divided the glass in two half. At this point, we placed a 2 µl of *Physarum* blob on one-half of the glass. However, in order to force *Physarum* in crossing the strip and not reaching the food, beyond the particles, by alternative paths, we created a semicircle with repellent agar, all around the mold. Therefore, the only possible way for *Physarum* to reach the food was through the particles strip. Fig. 12 shows that *Physarum polycephalum,* from the starting point, created protoplasmic tubes in the direction of food and, during its motion, crossed the strip made by particles. As in the previous cases, the mold transported particles that were found inside its slime after its crossing.

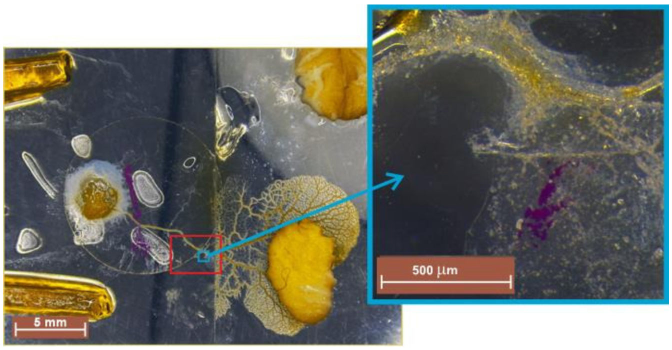

Fig. 12 Optical microscopy photograph of one of the developed experiment with slime mold and red polystyrene microparticles.

Last series of experiments have been performed with magnetic nanoparticles. In order to be able to recognize them once inside the mold we analyzed firstly the nanoparticles solution deposited on silicon substrate as in Fig.13

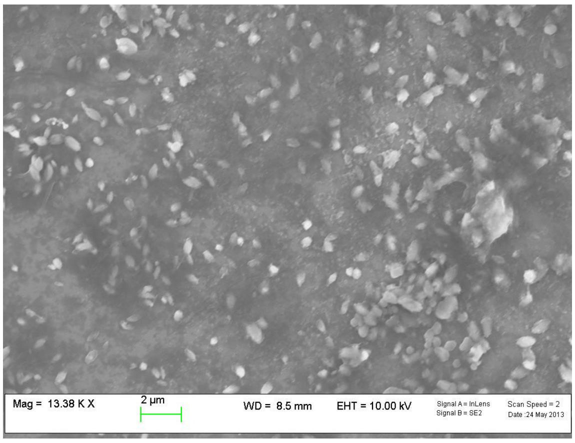

Fig. 13 SEM image of $BaFe_{12}O_{19}$ nanoparticles on silicon substrate

Slime mold was loaded with barium hexaferrite nanoparticles by mixing 100-200 µL of *Physarum* with 20-30 µL of the magnetic particles suspension.

Magnetic nanoparticles typically form big aggregates, due to the magnetic interactions, being ferromagnetic at that size. As in case of microparticles, we studied the efficiency of the slime mold loaded with magnetic nanoparticles. Firstly, we verified that the mixing procedure of the slime mold, with these particles, did not result in the organism death. As we saw, the slime mold kept its activity for more than a month, we focused the experiment on *Physarum*'s capability of transporting nanoparticles during its growth, proceeding exactly as in the case of polystyrene and $MnCO_3$ microparticles. However, even if *Physarum* moved to the second substrate, as we expected, a direct SEM imaging (Fig. 14) did not allow visualizing the presence of particles, due to their dimension that can be mistaken with nuclei of *Physarum*. For this reason, we fixed particles on the substrate surface and removed the slime mold

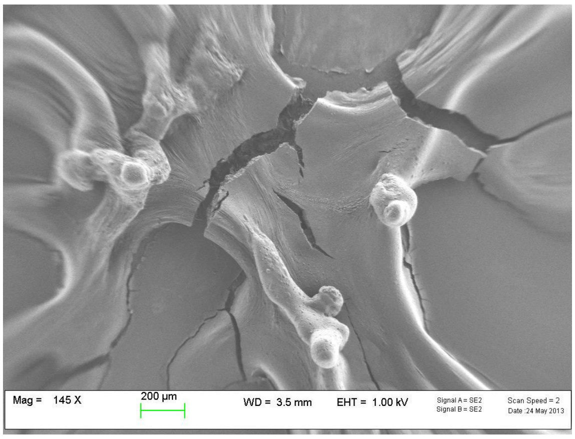

Fig. 14 SEM measurement of a sclerotized vein of Physarum polycephalum loaded with magnetic nanoparticles $BaFe_{12}O_{19}$. What stands out from this picture, as in the other done with such kind of particles inside the mold, are particular and curious 3D structures. The latter have been observed only in the samples when *Physarum* was loaded with magnetic nanoparticles of $BaFe_{12}O_{19}$

Considering that particles are magnetic, we decided to fix them by means of an external magnet placed under the sample where *Physarum* moved to by networks formation. Therefore, particles would be attracted by the magnet downwards and kept attached to the sample surface during the removal of the slime mold, by washing. Finally, the sample, always keeping the magnet attached, was dried and analyzed by SEM measurements. In order to show that the elements are really connected to the particles, element mapping was performed. The appropriate SEM image is shown in Fig. 15.

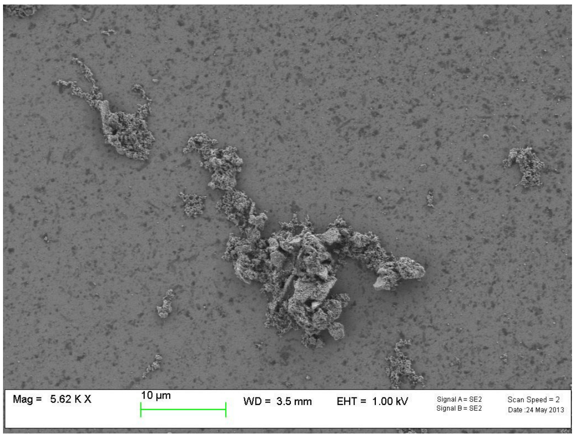

Fig. 15 SEM image of tubes formed by *Physarum* during its growth towards the food and subsequently washed, as described in the text.

## III. Conclusions

In this work we studied the behavior of *Physarum polycephalum* as an organism able to realize natural transition systems [4], *Physarum* is an interesting starting point for sensing, computing, novel biological substrate formation and circuit design. The possibility of targeting the growth with external disposition of attractants and repellents provides new capabilities for the realization of bio-inspired computational or robotic systems, based on *Physarum polycephalum*. In fact, such action can accelerate and/or suppress the propagation in certain directions. In order to illustrate this statement, let us consider a slime mold growth on the support, supplied with position sensors (in the simplest case – just electrodes, varying the capacity when the slime mold arrives to them). Moreover, analyzing *Physarum's* position, it will be possible to dispose attractants and/or repellent in such a way that the sequence of the food sources, where the slime mold will arrive, can be predetermined. By complementing with colored food [19], it will be possible to make any desirable mixture of colors. Of course, instead of the color, the food can include substances that, transported in special zones, evolve in some desired reactions. The final product will depend on the sequence of the reagents mixing. Thus, the *Physarum* will act as a bio-robotic system to delivery and control chemical reactions. The attractive and repellent parameters, such as the presence of food, light, humidity, chemistry of the surfaces, can be considered as inputs of this biocomputing/actuating system. The final distribution of the grown tubular pattern shows the system's output. The increase of the number of the control stimuli can improve the computational capabilities [11] of slime mold, especially if there will be a possibility of targeting the growing active zones of slime mold with robust external stimuli. The possibility, of targeting the growth with external actions, provided by author [21] serving *Physarum* also as a bio-living-robot, opens new capabilities for the realization of bio-inspired computational or robotic systems based on the slime mold. Future works involve the feeding of *Physarum* slime mold with nanoparticles that would be adsorbed in different way, depending on the biocompatibility; another field, that could be considered related to the previous one, concern nanoengineered polymeric capsules with shell made by mold-attractants, but filled with some solutions not so appealing for the bio-robot. These ideas open a huge amount of experiments, studies and analysis.

***Abstract*—In the paper, we describe selected functionality of the current version of a new software tool, called *PhysarumSoft*, developed for programming *Physarum* machines and simulating *Physarum* games. The tool was designed for the Java platform. A *Physarum* machine is a biological computing device implemented in the plasmodium of *Physarum polycephalum* or *Badhamia utricularis* that are one-cell organisms able to build programmable complex networks. The plasmodial stage of such organisms is a natural transition system that can be used as a medium for solving different computational tasks as well as creating bio-inspired strategy games.**

## I. Introduction

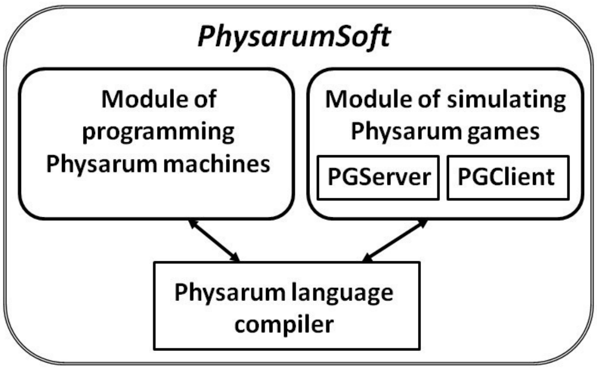
A *Physarum* machine is a programmable amorphous biological computing device, experimentally implemented in the plasmodium of *Physarum polycephalum*, also called true slime mould [1]. *Physarum polycephalum* is a single cell organism belonging to the species of order *Physarales*. In the considered case, the term of *Physarum* machine covers, in general, a hybrid device implemented in two plasmodia (cf. [2]), namely the plasmodium of *Physarum polycephalum* as well as the plasmodium of *Badhamia utricularis*. *Badhamia utricularis* is also the species of order *Physarales*. The plasmodium of *Physarum polycephalum* or *Badhamia utricularis*, spread by networks, can be programmable. In propagating and foraging behavior of the plasmodium, we can perform useful computational tasks. This ability was firstly discerned by T. Nakagaki et al. [3]. The *Physarum* machine comprises an amorphous yellowish mass with networks of protoplasmic veins, programmed by spatial configurations of attracting and repelling stimuli. When several attractants are scattered in the plasmodium range, the plasmodium looks for attractants, propagates protoplasmic veins towards them, feeds on them and goes on. Repellents play the role of elements blocking propagation of protoplasmic veins.

Solving computational tasks by means of *Physarum* machines is one of the main goals of the *Physarum* Chip Project: Growing Computers from Slime Mould [4] funded by the Seventh Framework Programme (FP7). In this project, we are going to construct an unconventional computer on programmable behaviour of *Physarum polycephalum*.

To program computational tasks for *Physarum* machines, we are developing a new object-oriented programming language [5], [6], [7], called a *Physarum* language. The *Physarum* language is a prototype-based language [8] consisting of inbuilt sets of prototypes corresponding to both the high-level models used for describing behaviour of *Physarum polycephalum* (e.g., ladder diagrams, transition systems, timed transition systems, Petri nets) and the low-level model (distribution of stimuli). More information is given in Section II.

Another task that can be performed in *Physarum* machine environments concerns bio-inspired strategy games. Fundamental topics of the research area related to bio-inspired games on *Physarum* machines were earlier considered, for example in [2] and [9]. Simulating *Physarum* games is considered in Section III.

To support reserach on programming *Physarum* machines and simulating *Physarum* games, we are developing a specialized software tool, called the *Physarum* software system, shortly *PhysarumSoft*. The tool was designed for the Java platform. In the paper, we describe selected functionality of the current version of *PhysarumSoft*. A general structure of this system is shown in Figure 1. We can distinguish three main parts of *PhysarumSoft*:



PhysarumSoft
Module of programming Physarum machines
Module of simulating Physarum games
PGServer
PGClient
Physarum language compiler

Fig. 1. A general structure of *PhysarumSoft*

- *Physarum* language compiler. The *Physarum* language is an object-oriented high-level programming language.

978-83-60810-66-8/$25.00©2015, IEEE

For generating the compiler of the language, the Java Compiler Compiler (JavaCC) tool [10] was used. JavaCC is the most popular parser generator for use with Java applications. For the programming purpose, a compiler embodied in our tool translates the high-level code describing a model of the *Physarum* machine into the spatial distribution (configuration) of stimuli (attractants, repellents) controlling propagation of protoplasmic veins of the plasmodium. A grammar of our language was described in [6].

- Module of programming *Physarum* machines described in Section II.
- Module of simulating *Physarum* games described in Section III.

The main features of *PhysarumSoft* are the following:

- Portability. Thanks to the Java technology, the created tool can be run on various software and hardware platforms. In the future, the tool will be adapted for platforms available in mobile devices and as a service in the cloud.
- User-friendly interface (see some screenshots shown in Sections II and III).
- Modularity. The project of *PhysarumSoft* and its implementation covers modularity. It makes the tool extend in the future easily.

## II. Programming Physarum Machines

To program *Physarum* machines (i.e., to set the spatial distribution (configuration) of stimuli (attractants, repellents) controlling propagation of protoplasmic veins of the plasmodium), we are developing a new object-oriented programming language [5], [6], [7], called the *Physarum* language. Our language is based on the prototype-based approach (cf. [8]) that is less common than the class-based one, although, it has a great deal to offer. This approach is also called classless or instance-based programming because prototype-based languages are based upon the idea that objects, representing individuals, can be created without reference to class-defining. In this approach, the objects, that are manipulated at runtime, are prototypes. In our language, there are inbuilt sets of prototypes corresponding to both the high-level models used for describing behaviour of *Physarum polycephalum* (e.g., ladder diagrams, transition systems, timed transition systems, Petri nets) and the low-level model (distribution of stimuli). According to the prototype-based approach, objects are created by means of a copy operation, called cloning, which is applied to a given prototype. Objects can be instantiated (cloned) via the keyword *new* using defined constructors. Different methods are used to manipulate features of the objects and create relationships between objects.

In our approach, the starting point, in programming the behaviour of the *Physarum* machine, is a high-level model describing propagation of protoplasmic veins of *Physarum*. We have proposed several high-level models used in programming *Physarum* machines, i.e.:

- ladder diagrams (see [11]),
- transition systems ([5]) and timed transition systems (see [12]),
- Petri nets (see [13]).

In the remaining part of this section, we recall basic definitions concerning transition systems, timed transition systems and Petri nets. They are general purpose tools that can be used to model dynamic systems with distinguished states and transitions between states. Application of ladder diagrams is restricted to modelling digital circuits. The recalled definitions are illustrated with some examples.

Transition systems are a simple and powerful tool for explaining the operational behaviour of models of concurrency. Formally, a transition system is a quadruple $TS = (S, E, T, I)$, cf. [14], where:

- $S$ is the non-empty set of states,
- $E$ is the set of events,
- $T \subseteq S \times E \times S$ is the transition relation,
- $I$ is the set of initial states.

Usually transition systems are based on actions which may be viewed as labelled events. If $(s, e, s') \in T$, then the idea is that $TS$ can go from $s$ to $s'$ as a result of the event $e$ occurring at $s$. Any transition system $TS = (S, E, T, I)$ can be presented in the form of a labelled graph with nodes corresponding to states from $S$, edges representing the transition relation $T$, and labels of edges corresponding to events from $E$.

The behaviour of *Physarum* machines is often dynamically changed in time. It is assumed, in the transition systems mentioned earlier, that all events happen instantaneously. Therefore, in [12], we proposed to use another high-level model, based on timed transition systems [15]. In the timed transition systems, timing constraints restrict the times at which events may occur. The timing constraints are classified into two categories: lower-bound and upper-bound requirements.

Let $N$ be a set of nonnegative integers. Formally, a timed transition system $TTS = (S, E, T, I, l, u)$ consists of:

- an underlying transition system $TS = (S, E, T, I)$,
- a minimal delay function (a lower bound) $l : E \rightarrow N$ assigning a nonnegative integer to each event,
- a maximal delay function (an upper bound) $u : E \rightarrow N \cup \infty$ assigning a nonnegative integer or infinity to each event.

In *Physarum* machines, timing constraints can be implemented through activation and deactivation of stimuli (attractants and/or repellents). Each state corresponds to either an original point of the plasmodium or an attractant. Especially, initial states of transition systems can be presented by original points, where protoplasmic veins originate from. Edges represent plasmodium transitions between attractants as well as the original points of the plasmodium.

In case of transition system and timed transition system models, the main prototypes defined in the *Physarum* language and their selected methods are collected in Table I.

Let us consider an exemplary timed transition system shown in Figure 2. Formally, we have $TTS = (S, E, T, I, l, u)$, where:

- $S = \{s_1, s_2, s_3, s_4\}$,

TABLE I
MAIN PROTOTYPES, CORRESPONDING TO TRANSITION SYSTEM AND TIMED TRANSITION SYSTEM MODELS, DEFINED IN THE PHYSARUM LANGUAGE, AND THEIR SELECTED METHODS

| Prototype | Selected methods |
|---|---|
| TS.State | *setDescription*, *setAsInitial* |
| TS.Event | *setDescription*, *setTimingConstraints* |
| TS.Transition | |

- $E = \{e_1, e_2, e_3\}$,
- $T = \{(s_1, e_1, s_2), (s_2, e_2, s_3), (s_3, e_3, s_4)\}$,
- $I = \{s_1, s_2\}$,
- $l(e_1) = l(e_2) = l(e_3) = 0$,
- and $u(e_1) = u(e_2) = \infty$, $u(e_3) = 3$.

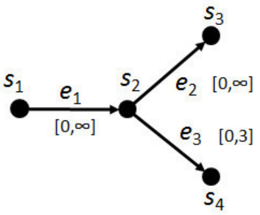


Fig. 2. An exemplary timed transition system $TTS$

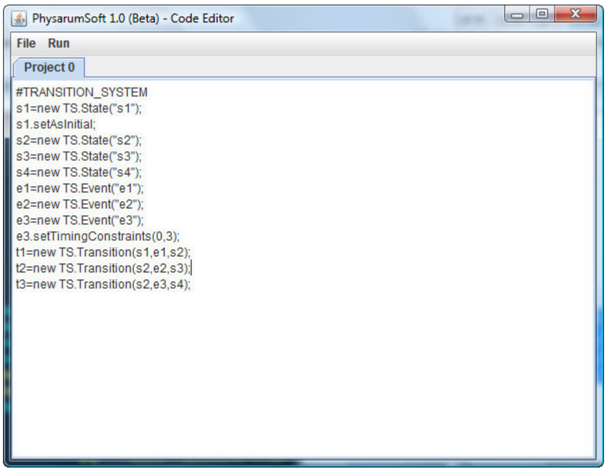

```
#TRANSITION_SYSTEM

s4=new TS.State("s4");
e1=new TS.Event("e1");
e2=new TS.Event("e2");
e3=new TS.Event("e3");
e3.setTimingConstraints(0,3);
t1=new TS.Transition(s1,e1,s2);
t2=new TS.Transition(s2,e2,s3);
t3=new TS.Transition(s2,e3,s4);
```

Fig. 3. The code for the model in the form of $TTS$

The code, for the model in the form of $TTS$, in the *Physarum* language written in the editor of the module of programming *Physarum* machines, is shown in Figure 3. The result of compilation, i.e., the spatial distribution of stimuli (attractants, repellents) controlling propagation of protoplasmic veins of the plasmodium, is shown in Figure 4.

One can see that:

- *Physarum* $Ph\_1$ represents initial state $s_1$, attractants $A\_1$, $A\_2$, $A\_3$ represent states $s_2$, $s_4$, $s_3$, respectively.
- Splitting the plasmodium at $A\_1$ is supported by repellent $R\_1$.
- Repellent $R\_2$ is placed next to attractant $A\_2$ because timing constraints are set for event $e_3$.
- For $t > 3$, $R\_2$ must be activated to annihilate the vein of the plasmodium between $A\_1$ and $A\_2$.

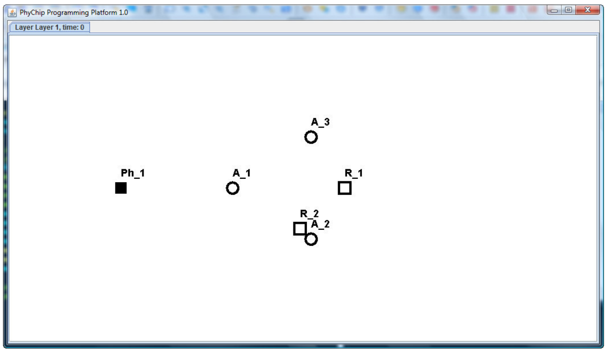

Fig. 4. The result of compilation

Petri nets introduced by C.A. Petri [16] are a formal tool used to model discrete event systems. In [13], we proposed to use Petri nets with inhibitor arcs (cf. [17]) to model behaviour of *Physarum polycephalum*. The inhibitor arcs test the absence of tokens in a place and they can be used to disable transitions. This fact can model repellents in *Physarum* machines. A transition can only fire if all its places connected through inhibitor arcs are empty (cf. [18]).

Formally, a marked Petri net with inhibitor arcs is a five-tuple

$$MPN = (Pl, Tr, Ar, w, m),$$

where:

- $Pl$ is the finite set of places (marked graphically with circles),
- $Tr$ is the finite set of transitions (marked graphically with rectangles),
- $Ar = Ar_O \cup Ar_I$ such that $Ar_O \subseteq (Pl \times Tr) \cup (Tr \times Pl)$ is the set of ordinary arcs (marked graphically with arrows) from places to transitions and from transitions to places whereas $Ar_I \subseteq Pl \times Tr$ is the set of inhibitor arcs (marked graphically with lines ended with small circles) from places to transitions,
- $w : Ar \to \{1, 2, 3, \dots\}$ is the weight function on the arcs,
- $m : Pl \to \{0, 1, 2, \dots\}$ is the initial marking function on the places.

In describing the Petri net behaviour, it is convenient to use for any $t \in Tr$:

- $I_O(t) = \{p \in Pl : (p, t) \in Ar_O\}$ - a set of input places connected through ordinary arcs to the transition $t$,
- $I_I(t) = \{p \in Pl : (p, t) \in Ar_I\}$ - a set of input places connected through inhibitor arcs to the transition $t$,
- $O(t) = \{p \in Pl : (t, p) \in Ar_O\}$ - a set of output places connected through ordinary arcs from the transition $t$.

In the proposed approach, we have additionally assumed the following limits for the Petri net:

TABLE II
THE MEANING OF TOKENS IN PLACES REPRESENTING CONTROL STIMULI

| Token | Meaning |
|---|---|
| Present | Stimulus activated |
| Absent | Stimulus deactivated |

TABLE III
THE MEANING OF TOKENS IN PLACES REPRESENTING OUTPUT STIMULI

| Token | Meaning |
|---|---|
| Present | Stimulus occupied by plasmodium of *Physarum polycephalum* |
| Absent | Stimulus not occupied by plasmodium of *Physarum polycephalum* |

TABLE IV
MAIN PROTOTYPES, CORRESPONDING TO PETRI NET MODELS, DEFINED IN THE *Physarum* LANGUAGE, AND THEIR SELECTED METHODS

| Prototype | Selected methods |
|---|---|
| PN.Place | *setDescription*, *setRole* |
| PN.Transition | *setDescription* |
| PN.Arc | *setAsInhibitor*, *setAsBidirectional* |

- $w(a) = 1$ for each $a \in Ar$,
- $m(p) \leq 1$ for each $p \in Pl$ (the capacity limit).

If $m(p) = 1$, then a token (i.e., a black dot) is drawn in the graphical representation of the place $p$. Assuming limits as the ones above, a transition $t \in Tr$ is said to be enabled if and only if $m(p) = 1$ for all $p \in I_O(t)$, i.e., the token is present in all input places $p$ connected with the transition $t$ through the ordinary arcs, and $m(p) = 0$ for all $p \in I_I(t)$, i.e., the token is absent in all input places $p$ connected with the transition $t$ through the inhibitor arcs, and $m(p) = 0$ for all $p \in O(t)$, i.e., the token is absent in all output places $p$ of the transition $t$. If the transition $t$ is enabled, we say that it can fire. A new marking function $m' : Pl \to \{0, 1, 2, \dots\}$ defines the next state of the Petri net after firing the transition $t$:

$$m'(p) = \begin{cases} m(p) - 1 & \text{if } p \in I_O(t) \text{ and } p \notin O(t), \\ m(p) + 1 & \text{if } p \in O(t) \text{ and } p \notin I_O(t), \\ m(p) & \text{otherwise.} \end{cases}$$

It is worth noting that in all figures including Petri net models, to simplify them, we have used bidirectional arcs between input places and transitions instead of arcs from input places to transitions and from transitions to input places. A bidirectional arc causes that the token is not consumed (removed) from the input place after firing a transition. This fact has a natural justification, i.e., firing a transition does not cause deactivation of the attractants and disappearance of the plasmodium from the original point. The plasmodium grows to build a dendritic network of veins.

In the proposed Petri net models of *Physarum* machines, we can distinguish three kinds of places:

- Places representing *Physarum polycephalum*.
- Places representing control stimuli (repellents).
- Places representing output stimuli (attractants).

In the *Physarum* language, the kind of a place is determined by the role played by it.

For each kind of places, we adopt different meaning (interpretation) of tokens. The meaning of tokens in places representing *Physarum polycephalum* is natural, i.e., the token in a given place corresponds to the presence of the plasmodium of *Physarum polycephalum* in an original point, where it starts to grow. The meaning of tokens in places representing control stimuli is shown in Table II, whereas the meaning of tokens in places representing output stimuli is shown in Table III. In case of control stimuli, we are interested in whether a given stimulus is activated or not. In case of output stimuli (attractants), we are interested in whether a given attractant is occupied by the plasmodium of *Physarum polycephalum*. Transitions in Petri net models represent the flow (propagation) of the plasmodium from the original points to attractants as well as between attractants.

In case of Petri net models, the main prototypes defined in the *Physarum* language and their selected methods are collected in Table IV.

Let us consider an exemplary Petri net shown in Figure 5. Formally, we have $MPN = (Pl, Tr, Ar, w, m)$, where:

- $Pl = \{P_1, P_2, P_3, P_4\}$,
- $Tr = \{T_1, T_2\}$,
- $Ar = Ar_O \cup Ar_I$, such that
  - $Ar_O = \{(P_1, T_1), (T_1, P_2), (P_2, T_2), (T_2, P_3), (T_2, P_4)\}$,
  - and $Ar_I = \emptyset$,
- $w(a) = 1$ for all $a \in Ar$,
- and $m(p) = 0$ for each $p \in Pl$,

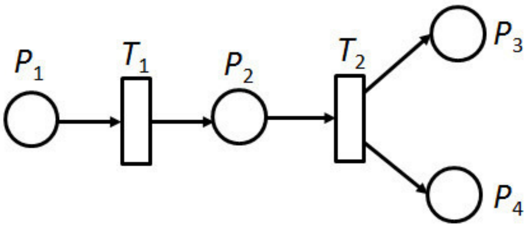

Fig. 5. An exemplary Petri net $MPN$

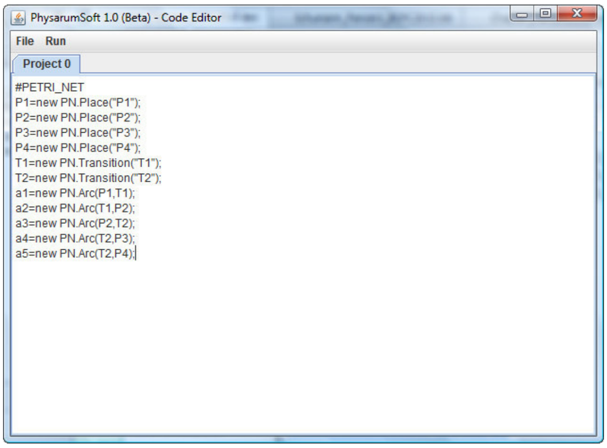
The code, for the model in the form of $MPN$, in the *Physarum* language written in the editor of the module of programming *Physarum* machines, is shown in Figure 6.

The result of compilation is shown in Figure 7. One can see that *Physarum* $Ph\_1$ represents place $P_1$, attractants $A\_1$, $A\_2$, $A\_3$ represent places $P_2$, $P_4$, $P_3$, respectively. Splitting the plasmodium at $A\_2$ is supported by repellent $R\_1$.

In [6], we showed how to use high-level models (transition systems and Petri nets) to describe four basic forms of *Physarum* motions:



```
#PETRI_NET
P1=new PN.Place("P1");
P2=new PN.Place("P2");
P3=new PN.Place("P3");
P4=new PN.Place("P4");
T1=new PN.Transition("T1");
T2=new PN.Transition("T2");
a1=new PN.Arc(P1,T1);
a2=new PN.Arc(T1,P2);
a3=new PN.Arc(P2,T2);
a4=new PN.Arc(T2,P3);
a5=new PN.Arc(T2,P4);
```

Fig. 6. The code for the model in the form of $MPN$

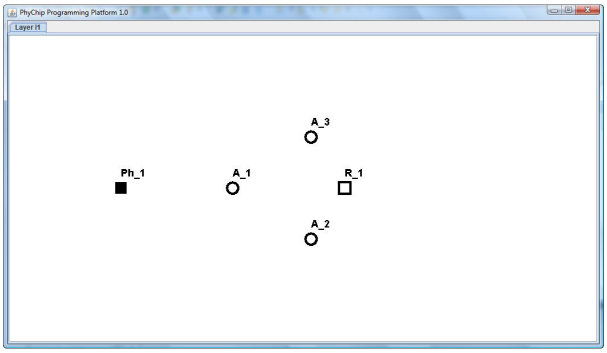


Fig. 7. The code for the model in the form of $MPN$

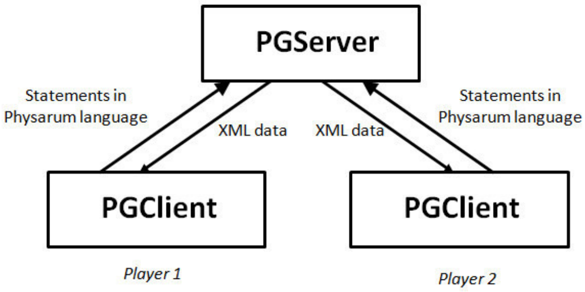
- *direct* - direction, i.e., a movement from one point, where the plasmodium is located, towards another point, where there is a neighbouring attractant,
- *fuse* - fusion of two plasmodia at the point, where they meet the same attractant,
- *split* - splitting the plasmodium from one active point into two active points, where two neighbouring attractants with a similar power of intensity are located,
- *repel* - repelling of the plasmodium or inaction.

It is worth noting that four basic forms are fundamental components used to build or describe more complex systems.

## III. Simulating Physarum Games

In [2], we showed that the slime mould (*Physarum polycephalum*) is a natural transition system which can be considered a biological model for strategic games. General assumptions for such games were presented both in [2] and [9]. They are based on the experiments performed by A. Adamatsky and M. Grube. If there are only two agents of the plasmodium game, where the first agent is presented by a usual *Physarum polycephalum* plasmodium and the second agent by its modification, a *Badhamia utricularis* plasmodium, then both start to compete with each other.

To simulate games on *Physarum* machines, we are developing a special module of *PhysarumSoft* called the *Physarum* game simulator. This module works under the client-server paradigm. A general structure of the *Physarum* game simulator is shown in Figure 8.



PGServer

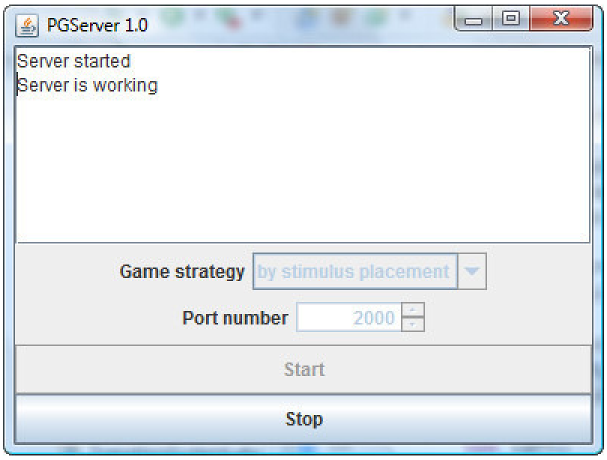
XML data
XML data
Statements in Physarum language
PGClient
PGClient
Player 1
Player 2

Fig. 8. A general structure of the *Physarum* game simulator

The server-side application of the *Physarum* game simulator is called *PGServer*. The main window of *PGServer* is shown in Figure 9. In this window, the user can:

- select the port number on which the server listens for connections,
- start and stop the server,
- set the game strategy:
  - strategy by stimulus placement,
  - strategy by stimulus activation,
- shadow information about actions undertaken.



```
Server started
Server is working
```

Game strategy: by stimulus placement
Port number: 2000

Fig. 9. The main window of *PGServer*

The client-side application of the *Physarum* game simulator is called *PGClient*. The main window of *PGClient* is shown in Figures 10 and 12. In this window, the user can:

- set the server IP address and its port number,
- start the participation in the game,
- manipulate stimuli (place or activate them) during the game,
- monitor the current result.

In the *Physarum* game simulator, we have two players:

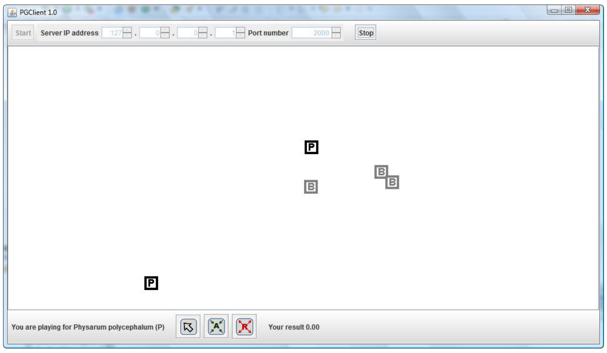
- the first one plays for the *Physarum polycephalum* plasmodia,

- the second one plays for the *Badhamia utricularis* plasmodia.

Locations of the original points of both plasmodia are randomly generated. The players can control motions of plasmodia via attracting or repelling stimuli. There are two strategies which can be defined for the game:

1) Locations of attractants and repellents are *a priori* generated in a random way. During the game, each player can activate one stimulus (attractant or repellent) at each step.
2) Locations of attractants and repellents are determined by the players during the game. At each step, each player can put one stimulus (attractant or repellent) at any location and this stimulus becomes automatically activated.

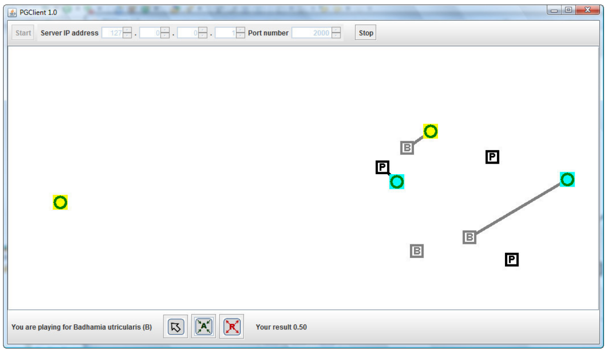
The client-side main window for the first strategy (locations of attractants and repellents are *a priori* generated in a random way) is shown in Figure 10. At the beginning, the original points of *Physarum polycephalum* and *Badhamia utricularis*, as well as stimuli, are scattered randomly on the plane. The window after several player's movements is shown in Figure 11. A box labelled by $P$ represents an original point of *Physarum polycephalum*. A box labelled by $B$ represents an original point of *Badhamia utricularis*. A single circle denotes an attractant whereas a double circle - repellent. Different background colors of stimuli differentiate between players.



You are playing for Physarum polycephalum (P)

Your result 0.00

Fig. 10. The main window of *PGClient* for the first strategy

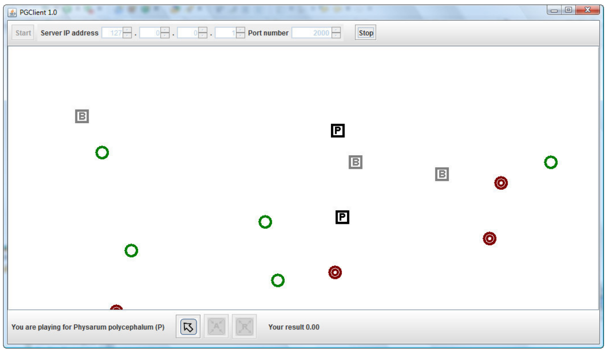


You are playing for Badhamia utricularis (B)

Your result 0.50

Fig. 11. The main window of *PGClient* for the first strategy after several player's movements

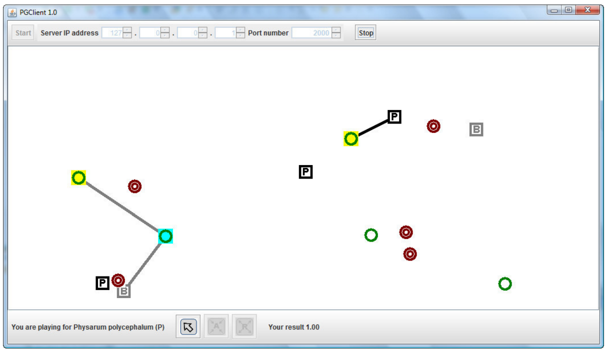
The client-side main window for the second strategy (locations of attractants and repellents are determined by the players during the game) is shown in Figure 12. At the beginning, the original points of *Physarum polycephalum* and *Badhamia utricularis* are scattered randomly on the plane. During the game, players can place stimuli. New veins of plasmodia are created. The window after several player's movements is shown in Figure 13.



You are playing for Physarum polycephalum (P)

Your result 0.00

Fig. 12. The main window of *PGClient* for the second strategy



You are playing for Physarum polycephalum (P)

Your result 1.00

Fig. 13. The main window of *PGClient* for the second strategy after several player's movements

Communication between clients and the server is realized through text messages containing statements of the *Physarum* language. The exemplary code responsible for creation of stimuli has the form:

```
p1_a1=new Attractant(195,224,1);
p1_a2=new Attractant(541,310,1);
p1_a1=new Attractant(580,92,2);
p2_r1=new Repellent(452,130,2);
p2_r1=new Repellent(659,327,1);
```

The first two parameters of stimulus constructors determine the location whereas the last parameter is the player's ID.

The server sends to clients information about the current configuration of the *Physarum* machine (localization of the original points of *Physarum polycephalum* and *Badhamia utricularis*, localization of stimuli, as well as a list of edges, corresponding to veins of plasmodia, between active points) through the XML file. The exemplary XML file has the form:

```
<?xml version="1.0" encoding="UTF-8" standalone="no"?>
<network>
<elements>
```

```
<element id="0" player="0" type="0" x="96" y="310"/>
<element id="1" player="0" type="0" x="766" y="178"/>
<element id="2" player="0" type="0" x="566" y="248"/>
<element id="3" player="0" type="3" x="550" y="53"/>
<element id="4" player="0" type="3" x="374" y="534"/>
<element id="5" player="0" type="3" x="746" y="217"/>
<element id="6" player="1" type="1" x="195" y="224"/>
<element id="7" player="1" type="1" x="541" y="310"/>
<element id="8" player="2" type="1" x="580" y="92"/>
<element id="9" player="2" type="2" x="452" y="130"/>
<element id="10" player="1" type="2" x="659" y="327"/>
</elements>
<veins>
<vein createdBy="0" firstNodeID="2" secondNodeID="7"/>
<vein createdBy="3" firstNodeID="3" secondNodeID="8"/>
</veins>
</network>
```

The attribute "player" equal to 0 means that elements are created by the system, in this case, the original points of plasmodia (*Physarum polycephalum* or *Badhamia utricularis*).

As payoffs for the created bio-inspired games on *Physarum* machines, we may define a variety of tasks, including simple ones like achieving as many attractants as possible, occupied by plasmodia of organisms for which we play or constructing the longest path consisting of attractants occupied by plasmodia. Determining different payoffs for *Physarum* games appears to be an interesting field of research due to a huge number of different methodologies and paradigms which can be applied.

The activated attractant $A^*$ causes that the plasmodia propagate protoplasmic veins towards it and feed on it. It means that new transitions are created between the current active points of plasmodia and a new one on the attractant $A^*$. Propagating protoplasmic veins is possible if the current active points are located in the region of influence (ROI) of $A^*$. It means that a proper neighborhood of $A^*$ is taken into consideration. From that moment, the activated attractant $A^*$ is occupied by plasmodia. It is worth noting that, as the experiments showed, the attractant occupied by the plasmodium of *Physarum polycephalum* cannot be simultaneously occupied by the plasmodium of *Badhamia utricularis* and vice versa. Moreover, the *Physarum polycephalum* plasmodium grows faster and could grow into branches of *Badhamia utricularis*, while the *Badhamia utricularis* plasmodium could grow over *Physarum polycephalum* veins.

The activated repellent $R^*$ can change the direction of plasmodium motions or can avoid propagating plasmodium protoplasmic veins towards activated attractants. Such influences are possible if plasmodia are in the region of influence (ROI) of $R^*$.

The control capabilities presented above enable the players to choose, at each step, one of the possible tactics:

1) The attractant or repellent activated by the player can help propagation of his/her plasmodia (of either *Physarum polycephalum* or *Badhamia utricularis*).
2) The attractant or repellent activated by the player can disturb propagation of the second player's plasmodia.

The second possibility is worth considering if we adopt the payoff approximations based on the rough set model described in [19]. It will be the main direction of further investigations. During the game, the players can switch between two possible tactics according to the current game configuration. At the end of the game, we determine who wins.

## IV. Conclusions and Further Work

In the paper, we have described selected functionality of the current version of a new software tool called *PhysarumSoft*. This tool is intended for programming *Physarum* machines and simulating *Physarum* games. For over the last two years, we have designed a new object-oriented programming language, called the *Physarum* language, that constitutes the basis for modelling behaviour of *Physarum* maachines. This language is used in *PhysarumSoft*. In the nearest future, we plan to extend *PhysarumSoft* to other high-level models, e.g., $\pi$-calculus and cellular automata. Moreover, we are developing a new model, based on rough sets [20], to approximate payoffs of strategy games created on *Physarum* machines.

## Acknowledgment

This research is being fulfilled by the support of FP7-ICT-2011-8.

*Abstract*—**We simulate the motions of *Physarum polycephalum* plasmodium by the game of Go, the board game originated in ancient China more than 2,500 years ago. Then we concentrate just on Go games, where locations of black and white stones simulate syllogistic reasoning, in particular reasoning of Aristotelian syllogistic and reasoning of performative syllogistic. For the first kind of reasoning we need a special form of coalition games. For the second kind of reasoning we appeal to usual antagonistic games.**

## I. Introduction

IN the *Physarum Chip Project: Growing Computers From Slime Mould* [1] we are working on designing a biological computer, where logic circuits are represented by programmable behaviors of *Physarum polycephalum* plasmodium, the one-cell organism that behaves according to different chemical stimuli called attractants and repellents and propagates networks connecting all reachable food attractants [2], [12]. The behavior of plasmodia is very sensitive and intelligent [4], [5], [6], [7], [8], [15], [17], [18], [19]. This behavior can be represented as a bio-inspired game theory on plasmodia [14], i.e. an experimental game theory, where, on the one hand, all basic definitions are verified in the experiments with *Physarum polycephalum* and *Badhamia utricularis* and, on the other hand, all basic algorithms are implemented in the object-oriented language for simulations of plasmodia [13].

We show that the slime mold can be a model for concurrent games and context-based games defined in [11]. In context-based games, players can move concurrently as well as in concurrent games, but the set of actions is ever infinite. In our experiments, we follow the following interpretations of basic entities: (1) attractants as payoffs; (2) attractants occupied by the plasmodium as states of the game; (3) active zones of plasmodium as players; (4) logic gates for behaviors as moves (available actions) for the players; (5) propagation of the plasmodium as the transition table which associates, with a given set of states and a given move of the players, the set of states resulting from that move.

In this game theory we can demonstrate creativity of primitive biological substrates of plasmodia. The point is that plasmodia do not strictly follow spatial algorithms like Kolmogorov-Uspensky machines, but perform many additional actions. So, the plasmodium behavior can be formalized within strong extensions of spatial algorithms, e.g. within concurrent games or context-based games [11].

In this paper we show how we can represent the plasmodium behavior as a *Go game*. It is board game with two players (called Black and White) who alternately place black and white stones, accordingly, on the vacant intersections (called points) of a board with a 19x19 grid of lines. Black moves first. Stones are placed until they reach a point where stones of another color are located. There are the following two basic rules of the game: (1) each stone must have at least one open point (called liberty) directly next to it (up, down, left, or right), or must be part of a connected group that has at least one such open point; stones which lose their last liberty are removed from the board; (2) the stones must never repeat a previous position of stones. The aim of the game is in surrounding more empty points by player’s stones. At the end of game, the number of empty points player's stones surround are counted, together with the number of stones the player captured. This number determines who the winner is. The Go game originated in ancient China more than 2,500 years ago and it is very popular till now.

We can consider the game of Go as a model of plasmodium motions. In this view the black stones are considered attractants occupied by the plasmodium and the white stones are regarded as repellents. By this interpretation, we have two players, also: Black (this player places attractants) and White (this player places repellents). The winner is determined by the number of empty points player's stones surround.

Notice that the number of possible Go games is too large, $10^{761}$. Therefore it is better to focus just on games, where locations of black and white stones simulate spatial reasoning. In this paper we propose two logics in the universe of possible Go games: (1) Aristotelian syllogistic [3]; (2) performative syllogistic [9], [10].

## II. Classical Game of Go on Plasmodia of *Physarum Polycephalum*

The plasmodium of *Physarum polycephalum* moves to attractants to connect them and in the meanwhile it avoids places, where repellents are located. The radius, where chemical signals from attractants (repellents) can be detected by the plasmodium to attract (repel) the latter, determines the structure of natural *Voronoi cells*, where each Voronoi cell is a place, where a chemical signal holds (see Fig. 1).

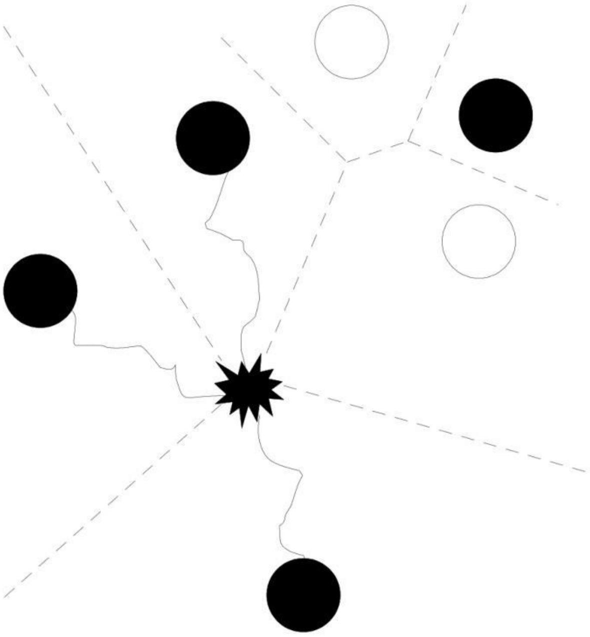

Fig. 1 The six Voronoi cells in accordance with the four attractants denoted by the black stones and with the two repellents denoted by the white stones. The plasmodium located in the center of the picture connects the three attractants by the three protoplasmic tubes. It cannot see the fourth attractant because of the two repellents

For the plasodium of Fig. 1 we have just the four neighbor cells. Notably that in Go games at each point we have only four neighbors everywhere. So, we can design the space for plasmodia in the way to have just four neighbors at each point. So, the cells of a Go game board are considered Voronoi cells with the same radius of intensity and power of attractants and repellents located in these cells. We associate black stones with attractants occupied by plasmodia and white stones with repellents. For the sake of convenience and more analogy with Voronoi cells, let us consider cells (not intersections of lines) as points for stone locations (see Fig. 2). Then we can use all rules of Go games to simulate plasmodium motions.

Thus, our Go game is represented in the universe of 18x18 Voronoi cells (see Fig. 2).

## III. Aristotelian Go Game on Plasmodia

Let us assume that the game of Go is a coalitional game with two players who choose only strategies to place black and white stones so that their locations can be interpreted as a spatial Aristotelian syllogistic reasoning.

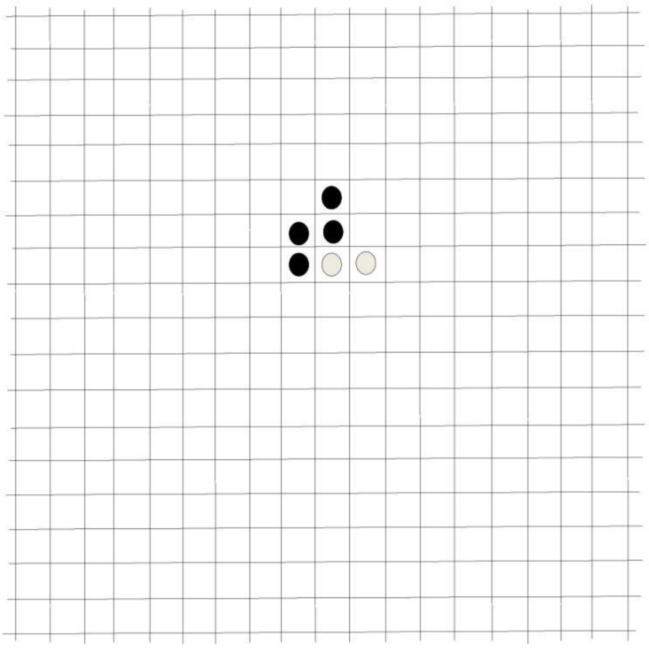

Fig. 2 The Go game board with two white stones designating repellents and four black stones designating attractants

Let us recall that the axiomatization of the Aristotelian syllogistic was laid first by Łukasiewicz [3]. In his axiomatization, the alphabet consists of the syllogistic letters *S*, *P*, *M*, …, the syllogistic connectives *a*, *e*, *i*, *o*, and the propositional connectives $\neg$, $\vee$, $\wedge$, $\Rightarrow$. Atomic propositions are defined as follows: *SxP*, where $x \in \{a, e, i, o\}$. All other propositions are defined in the following way: (i) each atomic proposition is a proposition, (ii) if *X*, *Y* are propositions, then ¬*X*, ¬*Y*, *X* å *Y*, where $å \in \{\vee, \wedge, \Rightarrow\}$, are propositions, also. The axioms proposed by Łukasiewicz are as follows:

$$SaP := (\exists A(AisS) \wedge \forall A(AisS \Rightarrow AisP)); \tag{1}$$

$$SiP := \exists A(AisS \wedge AisP); \tag{2}$$

$$SeP := \neg(SiP); \tag{3}$$

$$SoP := \neg(SaP); \tag{4}$$

$$SaS; \tag{5}$$

$$SiS; \tag{6}$$

$$(MaP \wedge SaM) \Rightarrow SaP; \tag{7}$$

$$(MaP \wedge MiS) \Rightarrow SiP. \tag{8}$$

In the Go implementation of Aristotelian syllogistic, the syllogistic letters *S*, *P*, *M*, … are interpreted as single cells of the board with the 18x18 Voronoi cells. The letter *S* is understood as empty if and only if the white stone is located on an appropriate cell denoted by *S*. Let us recall that in our plasmodium interpretation of Go games white stones mean ever repellents so that their location in a Voronoi cell means that this cell cannot be occupied by plasmodia. This letter *S* is treated as non-empty if and only if the black stone is located on an appropriate cell denoted by *S*. Recall that black stones mean ever attractants so that their location in a Voronoi cell means that this cell is occupied by plasmodia. If a cell does not contain any stone, this means that this cell is out of the game.

Hence, in the *Physarum* interpretation of this Go game, the non-empty syllogistic letters *S*, *P*, *M*, …, i.e. the cells denoted by *S*, *P*, *M*, … containing black stones are considered attractants and the empty syllogistic letters *S*, *P*, *M*, …, i.e. the cells denoted by *S*, *P*, *M*, … containing white stones are considered repellents. So, a data point *S* is regarded as non-empty if and only if an appropriate attractant located in *S* is occupied by plasmodium. This data point *S* is regarded as empty if and only if an appropriate repellent located in *S* repell plasmodium.

Thus, in the Aristotelian version of the Go game we have syllogistic strings of the form *SP* with the following interpretation: '*S* is *P*', and with the following meaning: *SP* is true if and only if *S* and *P* are neighbors and both *S* and *P* are not empty, otherwise *SP* is false. We can extend this meaning as follows: *SP* is true if and only if *S* and *P* are not empty and there is a line of non-empty cells between points *S* and *P*, otherwise *SP* is false. By the definition of true syllogistic strings, we can define atomic syllogistic propositions as follows:

*In the formal syllogistic*: there exists *A* such that *A* is *S* and for any *A*, if *A* is *S*, then *A* is *P*. *In the Go game model*: there is a cell *A* containing the black stone and for any *A*, if *AS* is true, then *AP* is true. *In the Physarum model*: there is a plasmodium in the cell *A* and for any *A*, if *AS* is true, then *AP* is true.

*In the formal syllogistic*: there exists *A* such that both *AS* is true and *AP* is true. *In the Go game model*: there exists a cell *A* containing the black stone such that *AS* is true and *AP* is true. *In the Physarum model*: there exists a plasmodium in the cell *A* such that *AS* is true and *AP* is true.

*In the formal syllogistic*: for all *A*, *AS* is false or *AP* is false. *In the Go game model*: for all cells *A* containing the black stones, *AS* is false or *AP* is false. *In the Physarum model*: for all plasmodia *A*, *AS* is false or *AP* is false.

*In the formal syllogistic*: for any *A*, *AS* is false or there exists *A* such that *AS* is true and *AP* is false. *In the Go game model*: for all cells *A* containing the black stones, *AS* is false or there exists *A* such that *AS* is true and *AP* is false. *In the Physarum model*: for any plasmodia *A*, *AS* is false or there exists *A* such that *AS* is true and *AP* is false.

Formally, this semantics is defined as follows. Let *M* be a set of attractants. Take a subset $|X| \subseteq M$ of cells containing the black stones (i.e. of cells containing attractants and occupied by the plasmodium) as a meaning for each syllogistic variable *X*. Next, define an ordering relation $\subseteq$ on subsets $|S|, |P| \subseteq M$ as: $|S| \subseteq |P|$ iff all attractants from $|P|$ are reachable for the plasmodium located at the attractants from $|S|$, i.e. iff for all cells of $|S|$ with black stones there are lines of black stones connecting them to cells of $|P|$ also containing black stones. Hence, $|S| \cap |P| \neq \varnothing$ means that some attractants from $|P|$ are reachable for the plasmodium located at the attractants from $|S|$ and $|S| \cap |P| = \varnothing$ means that no attractants from $|P|$ are reachable for the plasmodium located at the attractants from $|S|$. In the Go game model $|S| \cap |P| \neq \varnothing$ means that some cells from $|P|$ occupied by the black stones are connected by the lines of black stones with the cells from $|S|$ occupied by the black stones and $|S| \cap |P| = \varnothing$ means that there are no lines of black stones from the cells of $|P|$ to the cells of $|S|$.

This gives rise to models $\mathsf{M} = \langle M, |\cdot| \rangle$ such that

$$\mathsf{M} \models SaP \text{ iff } |S| \subseteq |P|;$$

$$\mathsf{M} \models SiP \text{ iff } |S| \cap |P| \neq \varnothing;$$

$$\mathsf{M} \models SeP \text{ iff } |S| \cap |P| = \varnothing;$$

$$\mathsf{M} \models p \wedge q \text{ iff } \mathsf{M} \models p \text{ and } \mathsf{M} \models q;$$

$$\mathsf{M} \models \quad p \vee q \text{ iff } \mathsf{M} \models p \text{ or } \mathsf{M} \models q;$$

$$\mathsf{M} \models \neg p \text{ iff it is false that } \mathsf{M} \models p.$$

*Proposition 1:* The Aristotelian syllogistic is sound and complete relatively to $\mathsf{M}$ if we understand $\subseteq$ as an inclusion relation (it is a well-known result [16]).

However, relatively to all possible Go games (plasmodium behaviors) the Aristotelian syllogistic is not complete. Indeed, the relation $\subseteq$ can have the following verification on the *Aristotelian Go game model on plasmodia* according to our definitions: $|S| \subseteq |P|$ and $|S| \subseteq |P'|$, where $|P| \cap |P'| = \varnothing$, i.e. all attractants from $|P|$ are reachable for the plasmodium located at the attractants from $|S|$ and all attractants from $|P'|$ are reachable for the plasmodium located at the attractants from $|S|$, but between $|P|$ and $|P'|$ there are no paths. In this case $\subseteq$ is not an inclusion relation and proposition 1 does not hold. Hence, we need repellents to make $\subseteq$ the inclusion relations in all cases. Therefore, to obtain the Aristotelian Go game model on plasmodia we shall deal with the coalitional game, where two players will cooperate to build spatial reasoning satisfying the rules of Aristotelian syllogistic. The first player places black stones to designate places of growing plasmodia. The second player places white stones to designate places of repelling plasmodia. So, both players follow coalitional strategies to simulate Aristotelian syllogistic reasoning.

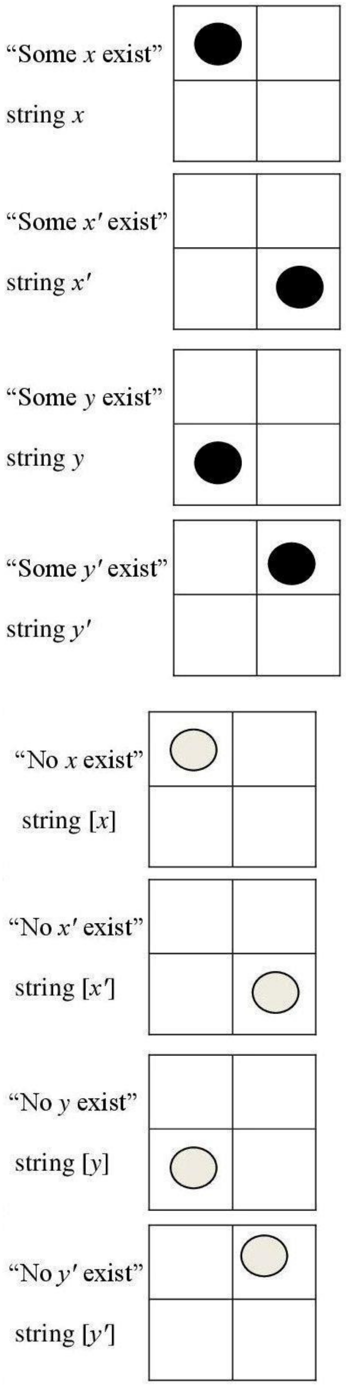

Fig. 3 The Aristotelian Go game diagrams for the basic existence strings

### A. *Coalition Go Game for Verifying Aristotelian Reasoning*

In the Aristotelian Go game model for verifying all the basic syllogistic propositions, we will use the following four cells: $x$, $y$, $x'$, $y'$ of the game board with the 19x19 grid of lines, where $x'$ means all cells which differ from $x$, but they are neighbors for $y$, and $y'$ means all cells which differ from $y$ and are neighbors for $x$. These cells express appropriate meanings of syllogistic letters. The corresponding universe of discourse will be denoted by means of the following diagram:

| | |
|---|---|
| $x$ | $y'$ |
| $y$ | $x'$ |

Assume that a black stone denotes an attractant and if it is placed within a cell $x$, this means that "this Voronoi cell contains an attractant $N_x$ activated and occupied by the plasmodium". It is a verification of the syllogistic letter $S_x$ at cell $x$ of the board. A white stone denotes a repellent and if it is placed within a cell $x$, this means that "this Voronoi cell contains a repellent $R_x$ activated and there is no plasmodium in it". It is a verification of a new syllogistic letter $[S_x]$. For the sake of convenience, we will denote $S_x$ by $x$ and $[S_x]$ by $[x]$. Using these stones, we can verify all the basic existence syllogistic propositions (see Fig. 3).

Aristotelian Go game strings of the form $xy$, $yx$ are interpreted as particular affirmative propositions "Some $x$ are $y$" and "Some $y$ are $x$" respectively, strings of the form $[xy]$, $[yx]$, $x[y]$, $y[x]$ are interpreted as universal negative propositions "No $x$ are $y$" and "No $y$ are $x$". A universal affirmative proposition "All $x$ are $y$" are presented by a complex string $xy \,\&\, x[y']$. The sign & means that we have strings $xy$ and $x[y']$ simultaneously and they are considered the one complex string. All these strings are verified on the basis of the diagrams of Fig. 4. So, we use only black stones for building particular propositions, only white stones for building universal negative propositions, and we combine black and white stones for building universal affirmative propositions. Consequently, we need a cooperation of two players to implement a spatial version of Aristotelian syllogistic within coalition Go games.

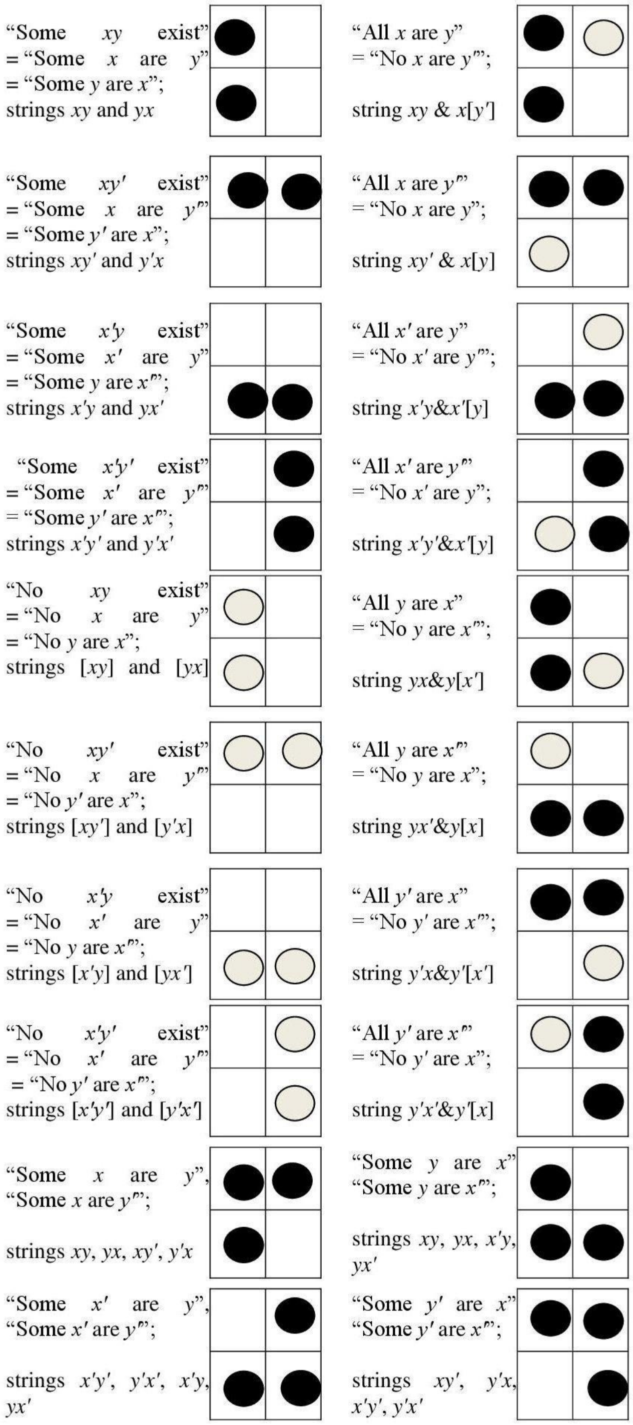
For verifying syllogisms we will use the following diagrams symbolizing some neighbor cells:

| | | | |
|---|---|---|---|
| | $m$ | $m'$ | |
| $m'$ | $x$ | $y'$ | $m$ |
| $m$ | $y$ | $x'$ | $m'$ |
| | $m'$ | $m$ | |

The motion of plasmodium starts from one of the central cells ($x$, $y$, $x'$, $y'$) and goes towards one of the four directions (northwest, southwest, northeast, southeast). The syllogism shows a connection between two not-neighbor cells on the basis of its joint neighbor and says if there was either multiplication or fusion of plasmodia (i.e. either splitting or fusion of the lines of black stones). As a syllogistic conclusion, we obtain another diagram:

| | |
|---|---|
| $x$ | $m'$ |
| $m$ | $x'$ |

Different syllogistic conclusions derived show directions of plasmodium's propagation. Some examples are provided in Fig. 5 – 7.



“Some $xy$ exist” = “Some $x$ are $y$” = “Some $y$ are $x$”; strings $xy$ and $yx$

“All $x$ are $y$” = “No $x$ are $y'$”; string $xy$ & $x[y']$

“Some $xy'$ exist” = “Some $x$ are $y'$” = “Some $y'$ are $x$”; strings $xy'$ and $y'x$

“All $x$ are $y'$” = “No $x$ are $y$”; string $xy'$ & $x[y]$

“Some $x'y$ exist” = “Some $x'$ are $y$” = “Some $y$ are $x'$”; strings $x'y$ and $yx'$

“All $x'$ are $y$” = “No $x'$ are $y'$”; string $x'y$&$x'[y]$

“Some $x'y'$ exist” = “Some $x'$ are $y'$” = “Some $y'$ are $x'$”; strings $x'y'$ and $y'x'$

“All $x'$ are $y'$” = “No $x'$ are $y$”; string $x'y'$&$x'[y]$

“No $xy$ exist” = “No $x$ are $y$” = “No $y$ are $x$”; strings $[xy]$ and $[yx]$

“All $y$ are $x$” = “No $y$ are $x'$”; string $yx$&$y[x']$

“No $xy'$ exist” = “No $x$ are $y'$” = “No $y'$ are $x$”; strings $[xy']$ and $[y'x]$

“All $y$ are $x'$” = “No $y$ are $x$”; string $yx'$&$y[x]$

“No $x'y$ exist” = “No $x'$ are $y$” = “No $y$ are $x'$”; strings $[x'y]$ and $[yx']$

“All $y'$ are $x$” = “No $y'$ are $x'$”; string $y'x$&$y'[x']$

“No $x'y'$ exist” = “No $x'$ are $y'$” = “No $y'$ are $x'$”; strings $[x'y']$ and $[y'x']$

“All $y'$ are $x'$” = “No $y'$ are $x$”; string $y'x'$&$y'[x]$

“Some $x$ are $y$”, “Some $x$ are $y'$”; strings $xy$, $yx$, $xy'$, $y'x$

“Some $y$ are $x$” “Some $y$ are $x'$”; strings $xy$, $yx$, $x'y$, $yx'$

“Some $x'$ are $y$”, “Some $x'$ are $y'$”; strings $x'y'$, $y'x'$, $x'y$, $yx'$

“Some $y'$ are $x$” “Some $y'$ are $x'$”; strings $xy'$, $y'x$, $x'y'$, $y'x'$

No $m'$ are $y$.

Some $m$ are $x$.

15. No $x$ are $y$;
Some $m$ are $y$.

Some $m$ are $x'$.

16. Some $y$ are $x$;
All $y$ are $m'$.

Some $x$ are $m'$.

17. All $y$ are $x$;
All $y'$ are $m'$.

No $x'$ are $m$.

18. Some $x$ are $y$;
All $y$ are $m$.

Some $x$ are $m$.

Fig. 7 The Aristotelian Go game diagrams for syllogisms (part 3)

Continuing in the same way, we can construct a syllogistic system, where conclusions are derived from three premises. The Aristotelian Go game (i.e. the suitable motion of plasmodium) starts from one of the central cells ($x$, $y$, $x'$, $y'$) and goes towards one of the four directions (northwest, southwest, northeast, southeast), then towards one of the eight directions (north-northwest, west-northwest, south-southwest, west-southwest, north-northeast, east-northeast, south-southeast, east-southeast), etc.

Hence, a Go game or spatial expansion of plasmodium is interpreted as a set of syllogistic propositions. The universal affirmative proposition $xy$ & $x[y']$ means that the plasmodium at the place $x$ goes only to $y$ and all other directions are excluded. The universal negative proposition $x[y]$ or $[xy]$ means that the plasmodium at the place $x$ cannot go to $y$ and we know nothing about other directions. The particular affirmative proposition $xy$ means that the plasmodium at the place $x$ goes to $y$ and we know nothing about other directions. Syllogistic conclusions allow us to mentally reduce the number of syllogistic propositions showing plasmodium's propagation.

For the implementation of Aristotelian syllogistic we appeal to repellents to delete some possibilities in the plasmodium propagation. So, model $\mathsf{M}$ defined above should be understood as follows:

$\mathsf{M} \models$ *All x are y* iff $xy$ & $x[y']$, i.e. the plasmodium is located at $x$ and can move only to $y$ and cannot move towards all other directions (the black stone is placed at $x$ and we can build the line of black stones only to $y$);

$\mathsf{M} \models$ *Some x are y* iff $xy$, i.e. the plasmodium is located at $x$ and can move to $y$ (the black stone is placed at $x$ and we can build the line of black stones to $y$);

$\mathsf{M} \models$ *No x are y* iff $x[y]$ or $[xy]$, i.e. the plasmodium cannot move to $y$ in any case (there is no line of black stones to $y$).

It is evident in this formulation that the Aristotelian syllogistic is so unnatural for plasmodia. Without repellents (the coalition game of two players), this syllogistic system cannot be verified in the medium of plasmodium propagations (Go game). In other words, we can prove the next proposition:

*Proposition 2:* The Aristotelian syllogistic is not sound and complete on the plasmodium without repellents. In other words, the Aristotelian syllogistic is not sound and complete in the Go game without a coalition of two players.

In other words, the Aristotelian syllogistic reasoning can be implemented as a Go game if and only if two players agree to play cooperatively to place black and white stones in accordance with spatial implementation of syllogisms.

### B. Examples of Aristotelian Go Game

Let us consider a game of Go at time step 10, i.e. when White and Black players have placed the 10 white stones and the 10 black stones respectively. Let this game be pictured in Figure 8. Each Voronoi cell is denoted from $S_{1,1}$ to $S_{18,18}$. So, in Figure 8 syllogistic letters $S_{6,4}$, $S_{7,5}$, $S_{7,6}$, $S_{8,7}$, $S_{8,8}$, $S_{7,9}$, $S_{8,10}$, $S_{6,11}$, $S_{4,9}$, $S_{4,10}$ are understood as non-empty and syllogistic letters $S_{4,6}$, $S_{5,6}$, $S_{6,8}$, $S_{6,9}$, $S_{6,10}$, $S_{4,11}$, $S_{7,10}$, $S_{7,12}$, $S_{11,8}$, $S_{12,8}$ as empty. As a result, we can build some true syllogistic propositions in this universe like that: 'Some $S_{7,5}$ are $S_{7,6}$', 'Some $S_{8,7}$ are $S_{8,8}$', 'Some $S_{4,9}$ are $S_{4,10}$', 'No $S_{4,6}$ are $S_{5,6}$', 'No $S_{6,8}$ are $S_{6,9}$', 'No $S_{6,9}$ are $S_{6,10}$', 'No $S_{6,10}$ are $S_{7,10}$', 'No $S_{11,8}$ are $S_{12,8}$', etc.

Let us notice that in the universe of Fig. 8 we do not have universal affirmative propositions. But we can draw some syllogistic conclusions such as 'If $S_{4,10}[S_{4,11}]$ and $S_{4,9}$ $S_{4,10}$, then $S_{4,9}[S_{4,11}]$' (i.e. 'If no $S_{4,10}$ are $S_{4,11}$ and some $S_{4,9}$ are $S_{4,10}$, then no $S_{4,9}$ are $S_{4,11}$').

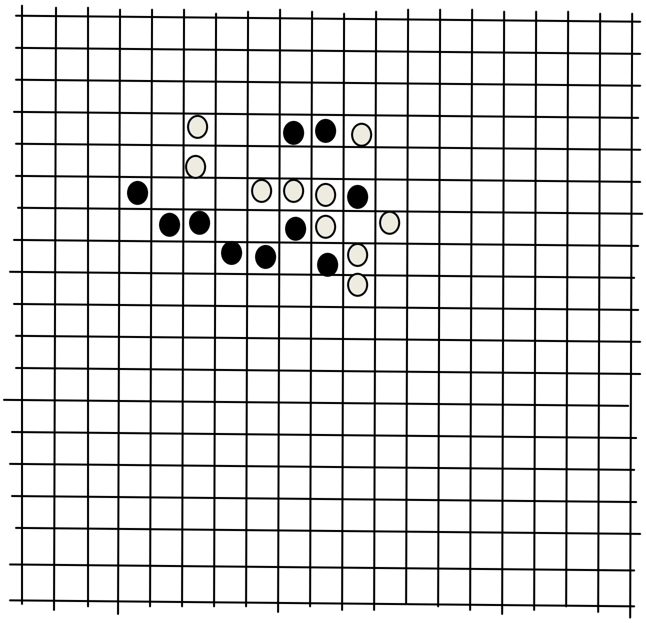

Fig. 8 The Aristotelian Go game 1 at time step 10

On the contrary, in the universe pictured in the Go game of Fig. 9 we have universal affirmative propositions such as 'All $S_{8,10}$ are $S_{8,11}$' and 'All $S_{4,9}$ are $S_{3,9}$'. Some possible conclusions: 'If no $S_{8,11}$ are $S_{8,12}$ and all $S_{8,10}$ are $S_{8,11}$, then no $S_{8,10}$ are $S_{8,12}$' and 'If no $S_{3,9}$ are $S_{3,10}$ and all $S_{4,9}$ are $S_{3,9}$, then no $S_{4,9}$ are $S_{3,10}$'.

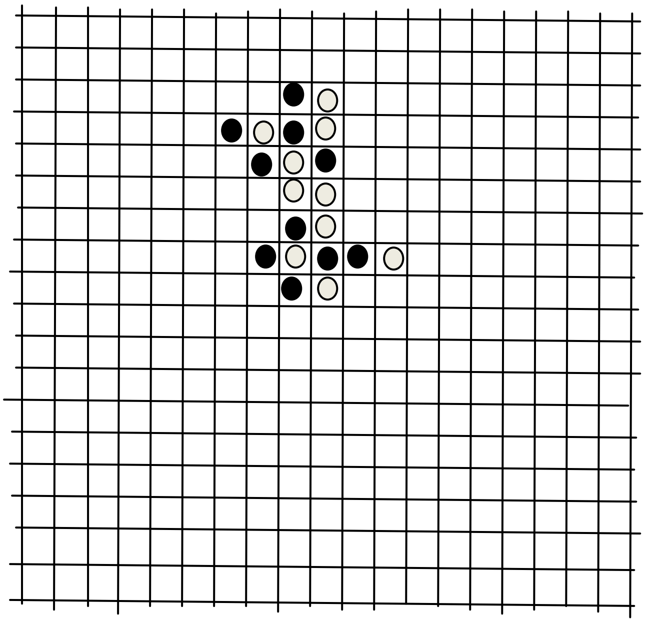

Fig. 9 The Aristotelian Go game 2 at time step 10

## IV. Non-Aristotelian Syllogistic Go Game on Plasmodia

While in Aristotelian syllogisms we are concentrating on one direction of many *Physarum* motions, and dealing with acyclic directed graphs with fusions of many protoplasmic tubes toward one data point, in most cases of *Physarum* behavior, not limited by repellents, we observe a spatial expansion of *Physarum* protoplasm in all directions with many cycles. Under these circumstances it is more natural to define all the basic syllogistic propositions $SaP$, $SiP$, $SeP$, $SoP$ in a way they satisfies the inverse relationship when all converses are valid: $SaP \Rightarrow PaS$, $SiP \Rightarrow PiS$, $SeP \Rightarrow PeS$, $SoP \Rightarrow PoS$. In other words, we can draw more natural conclusions for protoplasmic tubes which are decentralized and have some cycles. The formal syllogistic system over propositions with such properties is constructed in [9], [10]. This system is called the *performative syllogistic*. The alphabet of this system contains as descriptive signs the syllogistic letters $S$, $P$, $M$, …, as logical-semantic signs the syllogistic connectives $a$, $e$, $i$, $o$, and the propositional connectives $\neg$, $\vee$, $\wedge$, $\Rightarrow$. Atomic propositions are defined as follows: $SxP$, where $x \in \{a, e, i, o\}$. All other propositions are defined thus: (i) each atomic proposition is a proposition, (ii) if $X$, $Y$ are propositions, then $\neg X$, $\neg Y$, $X$å $Y$, where å $\in \{\vee, \wedge, \Rightarrow\}$, are propositions, too.

Let us consider Go games with the two different kinds of plasmodia: (i) plasmodia of *Physarum polycephalum* and (ii) plasmodia of *Badhamia utricularis* [14]. They try to occupy free attractants antagonistically. So, if an attractant is occupied by the plasmodium of *Physarum polycephalum*, it cannot be occupied by the plasmodium of *Badhamia utricularis* and if it is occupied by the plasmodium of *Badhamia utricularis*, it cannot be occupied by the plasmodium of *Physarum polycephalum*. In this way we observe a competition between two plasmodia.

In order to implement the performative syllogistic in the Go games with *Physarum polycephalum* and *Badhamia utricularis* plasmodia, we will interpret data points denoted by appropriate syllogistic letters as black stones (attractants) if we assume that appropriate cells are occupied by the plasmodium of *Physarum polycephalum* and we will interpret data points denoted by appropriate syllogistic letters as white stones (attractants) if we assume that appropriate cells are occupied by the plasmodium of *Badhamia utricularis*. A data point $S$ is considered empty for the Black player if and only if an appropriate attractant denoted by $S$ is occupied by the white stone (plasmodium of *Badhamia utricularis*). A data point $S$ is considered empty for the White player if and only if an appropriate attractant denoted by $S$ is occupied by the black stone (plasmodium of *Physarum polycephalum*). Let us define syllogistic strings of the form $SP$ with the following interpretation: (i) '$S$ is $P$': $SP$ is true for the Black player if and only if $S$ and $P$ are reachable for each other by the plasmodium of *Physarum polycephalum* and both $S$ and $P$ are not empty for the Black player, otherwise $SP$ is false; (ii) '$S$ is $P$': $SP$ is true for the White player if and only if $S$ and $P$ are reachable for each other by the plasmodium of *Badhamia utricularis* and both $S$ and $P$ are not empty for the White player, otherwise $SP$ is false. In other words, $SP$ is true for the Black player (respectively, for the White player) if and only if $S$ and $P$ are not empty for the Black player (respectively, for the White player) and there is a line of non-empty cells for the Black player (respectively, for the White player) between points $S$ and $P$, otherwise $SP$ is false. Using this definition of syllogistic strings, we can define atomic syllogistic propositions as follows:

*In the formal performative syllogistic*: there exists $A$ such that $A$ is $S$ and for any $A$, $AS$ is true and $AP$ is true. *In the Go game model:* there is a black (white) stone in $A$ connected by black (white) stones to $S$ and connected by black (white) stones to $P$. *In the Physarum model*: a plasmodium of *Physarum polycephalum* (a plasmodium of *Badhamia utricularis*) in $A$ occupies $S$ and for any plasmodia $A$ of *Physarum polycephalum* (for any plasmodia $A$ of *Badhamia utricularis*) which is a neighbor for $S$ and $P$, there are strings $AS$ and $AP$. This means that we have a massive-parallel occupation of the region by plasmodia of *Physarum polycephalum* (plasmodia of *Badhamia utricularis*) where the cells $S$ and $P$ are located.

*In the formal performative syllogistic*: for any $A$, both $AS$ is false and $AP$ is false. *In the Go game model*: for any cell $A$ there are no lines of black (white) stones connecting $A$ to $S$ and $A$ to $P$. *In the Physarum model*: for any plasmodium of *Physarum polycephalum* (of *Badhamia utricularis*) $A$ which is a neighbor for $S$ and $P$, there are no strings $AS$ and $AP$. This means that the plasmodium of *Physarum polycephalum* (of *Badhamia utricularis*) cannot reach $S$ from $P$ or $P$ from $S$ immediately.

*In the formal performative syllogistic*: there exists $A$ such that if $AS$ is false, then $AP$ is true. *In the Go game model*: there exists a cell $A$ with the black (white) stone which is a neighbor for cells $S$ and $P$ such that there is a string $AS$ or there is a string $AP$. *In the Physarum model*: there exists the plasmodium of *Physarum polycephalum* (of *Badhamia utricularis*) $A$ which is a neighbor for $S$ and $P$ such that there is a string $AS$ or there is a string $AP$. This means that the plasmodium of *Physarum polycephalum* (of *Badhamia utricularis*) occupies $S$ or $P$, but not the whole region where the cells $S$ and $P$ are located.

*In the formal performative syllogistic*: for any $A$, $AS$ is false or there exists $A$ such that $AS$ is false or $AP$ is false. *In the Go game model*: for any cell $A$ with the black (white) stone which is a neighbor for $S$ and $P$ there is no string $AS$ or there exists a black (white) stone in $A$ which is a neighbor for $S$ and $P$ such that there is no string $AS$ or there is no string $AP$. *In the Physarum model*: for any plasmodium of *Physarum polycephalum* (of *Badhamia utricularis*) $A$ which is a neighbor for $S$ and $P$ there is no string $AS$ or there exists $A$ which is a neighbor for $S$ and $P$ such that there is no string $AS$ or there is no string $AP$. This means that the plasmodium of *Physarum polycephalum* (of *Badhamia utricularis*) does not occupy $S$ or there is a neighboring cell which is not connected to $S$ or $P$ by a protoplasmic tube.

Notice that there are the following semantic correlations between propositions in the sense of the Black player and propositions in the sense of the White player:

- *SaP* is true for the Black player iff *SiP* is true for the White player with the same cells $S$ and $P$;
- *SoP* is true for the Black player iff *SeP* is true for the White player with the same cells $S$ and $P$;
- *SaP* is false for the Black player iff *SiP* is false for the White player with the same cells $S$ and $P$;
- *SoP* is false for the Black player iff *SeP* is false for the White player with the same cells $S$ and $P$.

Composite propositions are defined in the standard way.

In the performative syllogistic we have the following axioms:

$$SaP := (\exists A(A is S) \wedge (\forall A(A is S \wedge A is P))); \tag{9}$$

$$SiP := \forall A(\neg(A is S) \wedge \neg(A is P)); \tag{10}$$

$$\begin{aligned} &SoP := \neg(\exists A(A is S) \vee (\forall A(A is P \wedge A is S))), i.e. \\ &(\forall A \neg(A is S) \wedge \exists A(\neg(A is P) \vee \neg(A is S))); \end{aligned} \tag{11}$$

$$\begin{aligned} &SeP := \neg \forall A(\neg(A is S) \wedge \neg(A is P)), i.e. \\ &\exists A(A is S \vee A is P). \end{aligned} \tag{12}$$

$$SaP \Rightarrow SeP; \tag{13}$$

$$SaP \Rightarrow PaS; \tag{14}$$

$$SiP \Rightarrow PiS; \tag{15}$$

$$SaM \Rightarrow SeP; \tag{16}$$

$$MaP \Rightarrow SeP; \tag{17}$$

$$(MaP \wedge SaM) \Rightarrow SaP; \tag{18}$$

$$(MiP \wedge SiM) \Rightarrow SiP. \tag{19}$$

The formal properties of this axiomatic system are considered in [9], [10]. In the performative syllogistic we can analyze the collective dimension of behavior. Within this system we can study how the plasmodium of *Physarum polycephalum* and the plasmodium of *Badhamia utricularis* occupy all possible attractants in any direction if they can see them. So, this system shows logical properties of a massive-parallel behavior (i.e. the collective dimension of behavior). One of the most significant notions involved in this implementation of the performative syllogistic in plasmodia topology is a *neighborhood*. We can define a distance for the neighborhood differently, i.e. we can make it broader or narrower. So, from different neighborhoods it will follow that we deal with different 'universes of discourse'.

### A. Antagonistic Go Game for Verifying Performative Syllogistic Reasoning

In the Go game diagrams for the performative syllogistic, the 'universe of discourse' cover cells $x$, $y$, non-$x$ (which be denoted by $x'$), non-$y$ (which be denoted by $y'$):

| | |
|---|---|
| $x$ | $y'$ |
| $y$ | $x'$ |

where $x$, $y$, $x'$, $y'$ are neighbor cells containing black stones (interpreted as attractants for *Physarum polycephalum*) and white stones (interpreted as attractants for *Badhamia utricularis*), $x'$ are all neighbors for $y$ which differ from $x$, and $y'$ are all neighbors for $x$ which differ from $y$. Let us consider the Go game from the point of view just of the Black player. Suppose that we have black, white, and grey stones and (i) if a black stone is placed within a cell, this means that "this cell is occupied by the plasmodium of *Physarum polycephalum*" (i.e. "there is at least one thing in it for the Black player"), (ii) if a white stone is placed within a cell, this means that "this cell is not occupied the plasmodium of *Physarum polycephalum*" (i.e. "there is not thing in it for the Black player"), (ii) if a grey stone is placed within a cell, this means that "it is not known if this cell is occupied by the plasmodium of *Physarum polycephalum*" or "it is not known what color of stone placed within a cell is from the point of view of the Black player". All possible combinations of Go game diagrams for atomic propositions within our universe of discourse are pictured in Fig. 10.

The universe of discourse for simulating performative syllogisms by means of *Physarum* behaviors covers cells $x$, $y$, $m$, $x'$, $y'$, $m'$ in the following manner:

| | | | |
|---|---|---|---|
| $y'$ | $m$ | $m'$ | $x'$ |
| $m'$ | $x$ | $y'$ | $m$ |
| $m$ | $y$ | $x'$ | $m'$ |
| $x$ | $m'$ | $m$ | $y$ |

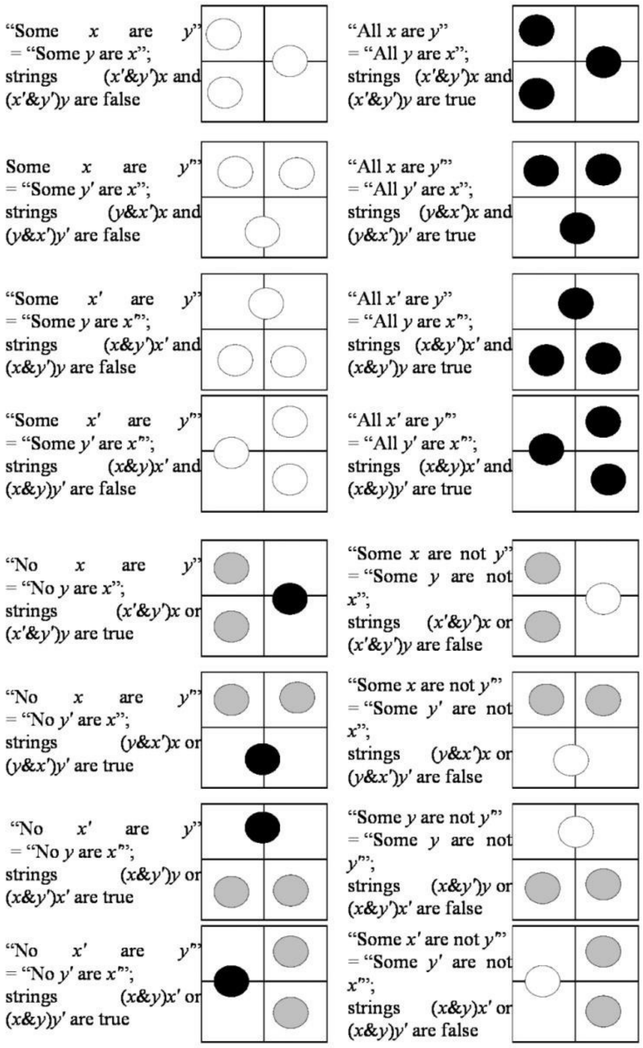
The motion of plasmodium starts from one of the central cells ($x$, $y$, $x'$, $y'$) and goes towards one of the four directions (northwest, southwest, northeast, southeast). The Go game diagram for syllogistic conclusions is as follows:

| | |
|---|---|
| $x$ | $m'$ |
| $m$ | $x'$ |

Some examples of performative syllogistic conclusions are regarded in Fig. 11.

Thus, the performative syllogistic allows us to study different zones containing attractants for *Physarum* *polycephalum* and *Badhamia utricularis* if they are connected by protoplasmic tubes homogenously.

A model $\mathsf{M}' = \langle M', |\cdot|_x \rangle$ for the performative syllogistic, where $M'$ is the set of attractants and $|X|_x \subseteq M'$ is a meaning of syllogistic letter $X$ which is understood as all attractants reachable for the plasmodium of *Physarum polycephalum* from the point $x$, is defined as follows:



“Some $x$ are $y$” = “Some $y$ are $x$”; strings $(x'\&y')x$ and $(x'\&y')y$ are false

“All $x$ are $y$” = “All $y$ are $x$”; strings $(x'\&y')x$ and $(x'\&y')y$ are true

Some $x$ are $y'$” = “Some $y'$ are $x$”; strings $(y\&x')x$ and $(y\&x')y'$ are false

“All $x$ are $y'$” = “All $y'$ are $x$”; strings $(y\&x')x$ and $(y\&x')y'$ are true

“Some $x'$ are $y$” = “Some $y$ are $x'$”; strings $(x\&y')x'$ and $(x\&y')y$ are false

“All $x'$ are $y$” = “All $y$ are $x'$”; strings $(x\&y')x'$ and $(x\&y')y$ are true

“Some $x'$ are $y'$” = “Some $y'$ are $x'$”; strings $(x\&y)x'$ and $(x\&y)y'$ are false

“All $x'$ are $y'$” = “All $y'$ are $x'$”; strings $(x\&y)x'$ and $(x\&y)y'$ are true

“No $x$ are $y$” = “No $y$ are $x$”; strings $(x'\&y')x$ or $(x'\&y')y$ are true

“Some $x$ are not $y$” = “Some $y$ are not $x$”; strings $(x'\&y')x$ or $(x'\&y')y$ are false

“No $x$ are $y'$” = “No $y'$ are $x$”; strings $(y\&x')x$ or $(y\&x')y'$ are true

“Some $x$ are not $y'$” = “Some $y'$ are not $x$”; strings $(y\&x')x$ or $(y\&x')y'$ are false

“No $x'$ are $y$” = “No $y$ are $x'$”; strings $(x\&y')y$ or $(x\&y')x'$ are true

“Some $y$ are not $y'$” = “Some $y$ are not $y'$”; strings $(x\&y')y$ or $(x\&y')x'$ are false

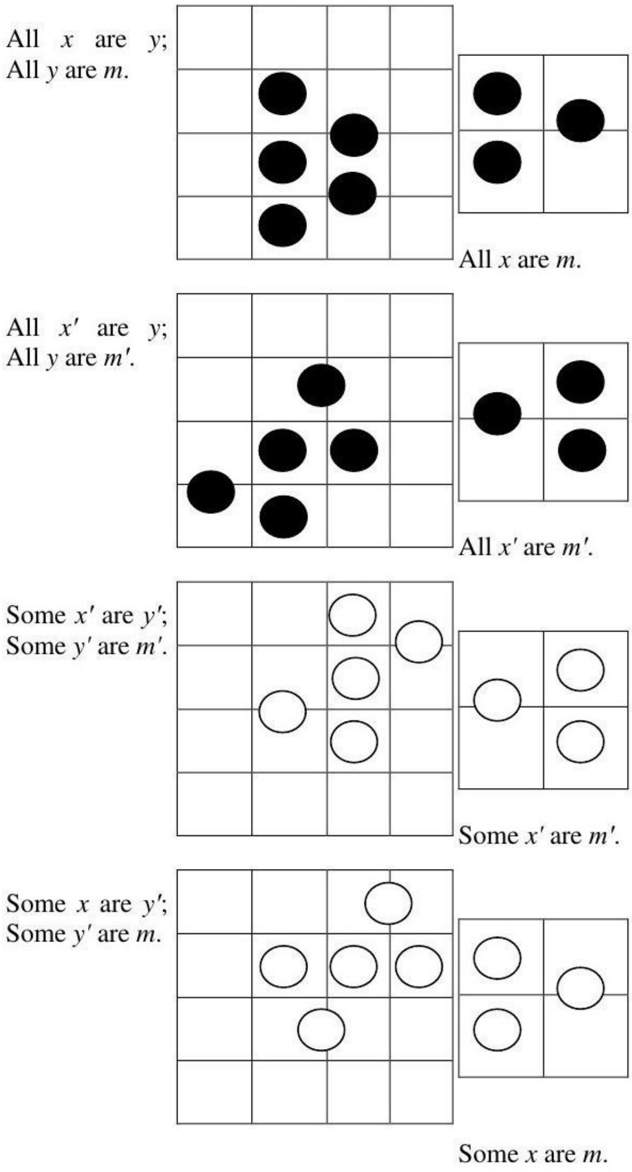
“No $x'$ are $y'$” = “No $y'$ are $x'$”; strings $(x\&y)x'$ or $(x\&y)y'$ are true

“Some $x'$ are not $y'$” = “Some $y'$ are not $x'$”; strings $(x\&y)x'$ or $(x\&y)y'$ are false

Fig. 10 The Go game diagrams for premises of performative syllogisms. Strings of the form $(x' \& y')x$ mean that in cells $x'$ and $y'$ there are neighbors $A$ for $x$ such that $Ax$, i.e. $(x' \& y')$ is a metavariable in $(x' \& y')x$ that is used to denote all attractants of $x'$ and $y'$ which are neighbors for the attractant of $x$

$\mathsf{M}' \models$ *All x are y* iff $|X|_x \neq \varnothing$, $|X|_y \neq \varnothing$, and $|X|_x \cap |X|_y \neq \varnothing$, more precisely both $(x' \& y')x$ and $(x' \& y')y$ hold in $\mathsf{M}'$, i.e. the plasmodium of *Physarum polycephalum* can move from neighbors of $y$ to $x$ and it can move from neighbors of $x$ to $y$ (we can place black stones in the line from neighbors of $y$ to $x$ and from neighbors of $x$ to $y$);

$\mathsf{M}' \models$ *Some x are y* iff $y \notin |X|_x$ and $x \notin |X|_y$, more precisely neither $(x' \& y')x$ nor $(x' \& y')y$ hold in $\mathsf{M}'$, i.e. the plasmodium of *Physarum polycephalum* cannot move from neighbors of $y$ to $x$ and it cannot move from neighbors of $x$ to $y$ (we can place white stones in the line from neighbors of $y$ to $x$ and from neighbors of $x$ to $y$);



All $x$ are $y$;
All $y$ are $m$.

All $x$ are $m$.

All $x'$ are $y$;
All $y$ are $m'$.

All $x'$ are $m'$.

Some $x'$ are $y'$;
Some $y'$ are $m'$.

Some $x'$ are $m'$.

Some $x$ are $y'$;
Some $y'$ are $m$.

Some $x$ are $m$.

Fig. 11 The Go game diagrams for performative syllogisms with true conclusions from the point of view of the Black player

$\mathsf{M}' \models$ *No x are y* iff $y \in |X|_x$ or $x \in |X|_y$, more precisely $(x' \& y')x$ or $(x' \& y')y$ hold in $\mathsf{M}'$, i.e. the plasmodium of *Physarum polycephalum* can move from neighbors of $y$ to $x$ or it can move from neighbors of $x$ to $y$ (we can place black stones in the line from neighbors of $y$ to $x$ or from neighbors of $x$ to $y$);

$$\mathrm{M}' \models \textit{Some } x \textit{ are not } y \text{ iff } y \notin |X|_x \text{ or } x \notin |X|_y,$$

more precisely ($x'$ & $y'$)$x$ or ($x'$ & $y'$) do not hold in $\mathrm{M}'$, i.e. the plasmodium of *Physarum polycephalum* cannot move from neighbors of $y$ to $x$ or it cannot move from neighbors of $x$ to $y$ (we can place white stones in the line from neighbors of $y$ to $x$ or from neighbors of $x$ to $y$);

$$\mathrm{M}' \models p \wedge q \text{ iff } \mathrm{M}' \models p \text{ and } \mathrm{M}' \models q;$$

$$\mathrm{M}' \models p \vee q \text{ iff } \mathrm{M}' \models p \text{ or } \mathrm{M}' \models q;$$

$$\mathrm{M}' \models \neg p \text{ iff it is false that } \mathrm{M}' \models p.$$

*Proposition 3:* The performative syllogistic is sound and complete in $\mathrm{M}'$.

For more details on formal properties of performative syllogistic, please see [9], [10]. This syllogistic describes the logic of plasmodium propagation in all possible directions. For the implementation of this syllogistic we do not need repellents. It is a natural system. The performative syllogistic as a Go game is an antagonistic game, where two players draw own conclusions without any coalition (see Fig. 10).

### B. Examples of Performative-Syllogistic Go Game

Let us also examine a game of Go at time step 10 to provide an example for performative syllogistic. Let this game be shown in Figure 12. As usual, each Voronoi cell is denoted from $S_{1,1}$ to $S_{18,18}$. In the universe of Fig. 12 there are no universal affirmative propositions and particular affirmative propositions. We face only universal negative propositions and particular negative propositions such as 'No $S'_{4,9}$ are $S'_{4,10}$', where $S'_{4,9}$ are neighbors for $S_{4,10}$ differing from $S_{4,9}$ and $S'_{4,10}$ are neighbors for $S_{4,9}$ differing from $S_{4,10}$, and 'Some $S'_{4,11}$ are not $S'_{5,11}$', where $S'_{4,11}$ are neighbors for $S_{5,11}$ differing from $S_{4,11}$ and $S'_{5,11}$ are neighbors for $S_{4,11}$ differing from $S_{5,11}$.

In the universe of Figure 13 there is a universal affirmative proposition: 'All $S_{6,5}$ are $S_{6,6}$', and a particular affirmative proposition: 'Some $S_{5,8}$ are $S_{5,9}$'.

## V. Conclusion

We have just shown that we can simulate the plasmodium motion as a Go game, where black stones are interpreted as attractants and white stones as repellents. We can consider configurations of stones as spatial reasoning. If we implement the Aristotelian syllogistic, we need a coalition of two players. If we implement the performative syllogistic [9], [10], we deal with an antagonistic game. In the latter case black stones are interpreted as attractants for *Physarum polycephalum* and white stones as attractants for *Badhamia utricularis.*

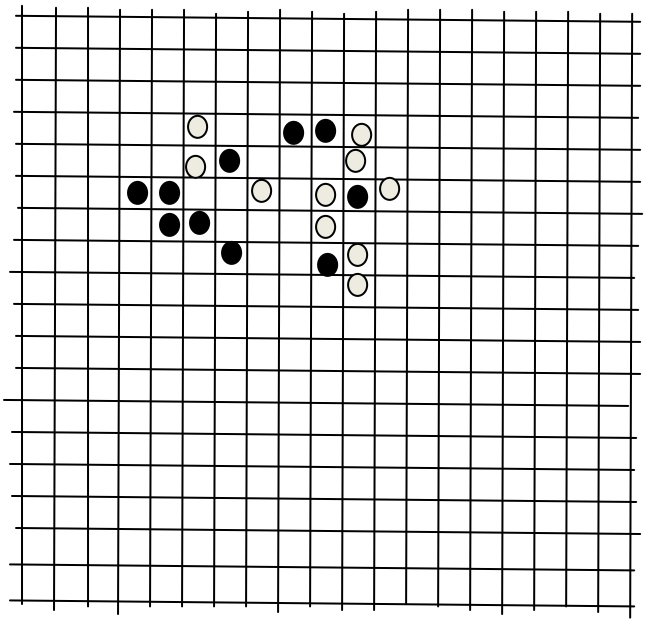


Fig. 12 The performative syllogistic Go game 1 at time step 10. The black stones are attractants occupied by the plasmodium of *Physarum polycephalum* and the white stones are attractants occupied by the plasmodium of *Badhamia utricularis*. So, we construct syllogisms from the point of view of the Black player

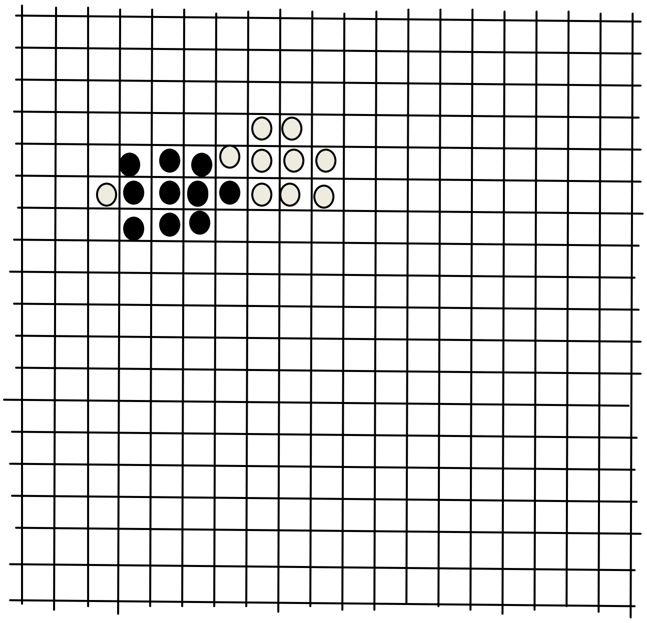

Fig. 13 The performative syllogistic Go game 2 at time step 10. The black stones are attractants occupied by the plasmodium of *Physarum polycephalum* and the white stones are attractants occupied by the plasmodium of *Badhamia utricularis*. We build syllogisms from the point of view of the Black player

# 8th Workshop on Computer Aspects of Numerical Algorithms

NUMERICAL algorithms are widely used by scientists engaged in various areas. There is a special need of highly efficient and easy-to-use scalable tools for solving large scale problems. The workshop is devoted to numerical algorithms with the particular attention to the latest scientific trends in this area and to problems related to implementation of libraries of efficient numerical algorithms. The goal of the workshop is meeting of researchers from various institutes and exchanging of their experience, and integrations of scientific centers.

## Topics

- Parallel numerical algorithms
- Novel data formats for dense and sparse matrices
- Libraries for numerical computations
- Numerical algorithms testing and benchmarking
- Analysis of rounding errors of numerical algorithms
- Languages, tools and environments for programming numerical algorithms
- Numerical algorithms on GPUs
- Paradigms of programming numerical algorithms
- Contemporary computer architectures
- Heterogeneous numerical algorithms
- Applications of numerical algorithms in science and technology

***Abstract*—In the WZ factorization the outermost parallel loop decreases the number of iterations executed at each step and this changes the amount of parallelism in each step. The aim of the paper is to present four strategies of parallelizing nested loops on multicore architectures on the example of the WZ factorization.**

**For random dense square matrices with the dominant diagonal we report the execution time, the performance, the speedup of the WZ factorization for these four strategies of parallelizing nested loops and we investigate the accuracy of such solutions.**

**It is possible to shorten the runtime when utlilizing the appropriate strategies with the use of good scheduling.**

**Keywords: linear system, WZ factorization, matrix factorization, matrix computations, multicore architecture, parallel nested loops, OpenMP**

## I. Introduction

MULTICORE computers with shared memory are used to solve the computational science problems. One of more important computational problems is solution of linear systems, the form of which is the following:

$$\mathbf{A}\mathbf{x} = \mathbf{b}, \qquad \text{where} \quad \mathbf{A} \in \mathbb{R}^{n\times n}, \quad \mathbf{b} \in \mathbb{R}^{n}. \tag{1}$$

One of the direct methods of solving a dense linear system (1) is to factorize the matrix $\mathbf{A}$ into some simpler matrices — that is its decomposition into factor matrices of a simpler structure — and then solving simpler linear systems.

Such factorization is hard to compute and that is why it is worth applying different optimization techniques and simultaneously using parellelism of contemporary computers.

The implementation of the factorization contains nested loops. The reasearch of the parallelization of nested loops have been undertaken by different scientistcs.

In the work [6], the authors study five different models for nested parallel loops execution on shared-memory multiprocessors and show a simulation based performance comparison of different techniques using real application. The possibility to take advantage of the parallelism in nested parallel loops with the use of good scheduling and synchronization algorithms is described.

An automatic mechanism to dynamically detect the best way to exploit the parallelism when having nested parallel loops is presented in the study [3]. This mechanism is based on a number of threads, size of the problem, number of iterations in a loop and its was implemented inside IBM XL runtime library. This paper examined (among other) an LU kerner, which decomposes the matrix $\mathbf{A}$ into the matrices: $\mathbf{L}$ (lower triangular matrix) and $\mathbf{U}$ (upper triangular matrix).

An algorithm for finding good distributions of threads to tasks is provided and the implementation of nested parallelism in OpenMP is discussed in the paper [1].

The main focus of [5] was to investigate the possibility of dynamically choosing, at runtime, the loop which best utilises the available threads.

To implement parallel programs on multicore systems with shared-memory, programmers usually use the OpenMP standard [8]. The programming model provides a set of directives to explicitly define parallel regions in applications. The compliator translates these directives. One of its most interesting features in the language is the support for nested parallelism.

This work investigate the issue of the parallelizing nested loops in OpenMP. The OpenMP standard supports loop paralelism. For OpenMP standard, it is done by the utilization of the directive `#pragma omp parallel for`, which provides a shourtcut for specifying a parallel region that contains a single `#pragma omp parallel`.

Parallelism of the nested loops in the WZ factorization is the aim of the work. In the WZ kerner the outermost parallel loop decreases the amount of iterations executed at each step and this changes the number of parallelism in each step. In this paper we investigate the time, the scalability, the speedup and the acuraccy for four different nested loops parallelism strategies for the WZ factorization.

The paper deals with the following issues. In Section II the idea of the WZ factorization [2], [7] and the way the matrix $\mathbf{A}$ is factorized to a product of matrices $\mathbf{W}$ and $\mathbf{Z}$ are described. Such a factorization exists for every nonsingular matrix (with pivoting) which was shown in [2].

Section III provides information about some strategies of parallelizing nested loops and their application to the orginal the WZ factorization. Section IV presents the results of our

978-83-60810-66-8/$25.00©2015, IEEE

experiments. The time, the speedup, the performance of WZ factorization for different strategies on the two platforms are analysed. The influence of the size of the matrix on the achieved numerical accuracy is studied as well. Section V is a summary of our experiments.

## II. WZ Factorization (WZ)

The chapter presents the WZ factorization usage to solve (1). The WZ factorization is described in [2], [4].

Let us assume that the $\mathbf{A}$ is a square nonsingular matrix of an even size (it is somewhat easier to obtain formulas for even sizes than for odd ones). We are to find matrices $\mathbf{W}$ and $\mathbf{Z}$ that fulfill $\mathbf{WZ} = \mathbf{A}$ and the matrices $\mathbf{W}$ and $\mathbf{Z}$ consist of the following rows $\mathbf{w}_i^T$ and $\mathbf{z}_i^T$ respectively:

$$\begin{aligned}
\mathbf{w}_1^T &= (1, \underbrace{0, \ldots, 0}_{n-1}) \\
\mathbf{w}_i^T &= (w_{i1}, \ldots, w_{i,i-1}, 1, \underbrace{0, \ldots, 0}_{n-2i+1}, w_{i,n-i+2}, \ldots, w_{in}) \\
&\quad \text{for} \quad i = 2, \ldots, \tfrac{n}{2}, \\
\mathbf{w}_i^T &= (w_{i1}, \ldots, w_{i,n-i}, \underbrace{0, \ldots, 0}_{2i-n-1}, 1, w_{i,i+1}, \ldots, w_{in}) \\
&\quad \text{for} \quad i = \tfrac{n}{2} + 1, \ldots, n-1, \\
\mathbf{w}_n^T &= (\underbrace{0, \ldots, 0}_{n-1}, 1) \\
\mathbf{z}_i^T &= (\underbrace{0, \ldots, 0}_{i-1}, z_{ii}, \ldots, z_{i,n-i+1}, 0, \ldots, 0) \\
&\quad \text{for} \quad i = 1, \ldots, \tfrac{n}{2}, \\
\mathbf{z}_i^T &= (\underbrace{0, \ldots, 0}_{n-i}, z_{i,n-i+1}, \ldots, z_{ii}, 0, \ldots, 0) \\
&\quad \text{for} \quad i = \tfrac{n}{2} + 1, \ldots, n.
\end{aligned} \tag{2}$$

After the factorization we can solve two linear systems:

$$\left\{ \begin{array}{lcl} \mathbf{Wy} & = & \mathbf{b} \\ \\ \mathbf{Zx} & = & \mathbf{y} \end{array} \right. \tag{3}$$

(where $\mathbf{y}$ is an auxiliary intermediate vector) instead of one (1).

In this paper we are interested only in obtaining the matrices $\mathbf{Z}$ and $\mathbf{W}$. The first part of the algorithm consists of setting succesive parts of columns of the matrix $\mathbf{A}$ to zeros. In the first step we do that with the elements in the 1st and $n$th columns — from the 2nd row to the $(n-1)$st row. Next we update the matrix $\mathbf{A}$.

More formally we can describe the first step of the algorithm the following way.

1) For every $i = 2, \ldots, n-1$ we compute $w_{i1}$ and $w_{in}$ from the system:

$$\left\{ \begin{array}{lclcl} a_{11} w_{i1} & + & a_{n1} w_{in} & = & -a_{i1} \\ a_{1n} w_{i1} & + & a_{nn} w_{in} & = & -a_{in} \end{array} \right.$$

and we put them in the matrix of the form:

$$\mathbf{W}^{(1)} = \begin{bmatrix} 1 & 0 & \cdots & 0 & 0 \\ w_{21} & 1 & \ddots & \vdots & w_{2n} \\ \vdots & 0 & \ddots & 0 & \vdots \\ w_{n-1,1} & \vdots & \ddots & 1 & w_{n-1,n} \\ 0 & 0 & \cdots & 0 & 1 \end{bmatrix}.$$

2) We compute:

$$\mathbf{A}^{(1)} = \mathbf{W}^{(1)} \mathbf{A}.$$

After the first step we get a matrix of the form:

$$\mathbf{A}^{(1)} = \begin{bmatrix} a_{11} & a_{12} & \cdots & a_{1,n-1} & a_{1n} \\ 0 & a_{22}^{(1)} & \cdots & a_{2,n-1}^{(1)} & 0 \\ \vdots & \vdots & & \vdots & \vdots \\ 0 & a_{n-1,2}^{(1)} & \cdots & a_{n-1,n-1}^{(1)} & 0 \\ a_{n1} & a_{n2} & \cdots & a_{n,n-1} & a_{nn} \end{bmatrix}, \tag{4}$$

where (for $i, j = 2, \ldots, n-1$):

$$a_{ij}^{(1)} = a_{ij} + w_{i1} a_{1j} + w_{in} a_{nj}. \tag{5}$$

Then, we proceed analogously — but for the inner square matrices — $\mathbf{A}^{(1)}$ of size $(n-2)$ and so on.

So, the whole algorithm is the following.

For $k = 1, 2, \ldots, \frac{n}{2} - 1$:

1) For every $i = k+1, \ldots, n-k$ we compute $w_{ik}$ and $w_{i,n-k+1}$ from the system:

$$\left\{ \begin{array}{lcl} a_{kk}^{(k-1)} w_{ik} & + & a_{n-k+1,k}^{(k-1)} w_{i,n-k+1} \\ & = & -a_{ik}^{(k-1)} \\ \\ a_{k,n-k+1}^{(k-1)} w_{ik} & + & a_{n-k+1,n-k+1}^{(k-1)} w_{i,n-k+1} \\ & = & -a_{i,n-k+1}^{(k-1)} \end{array} \right.$$

and we put them in a matrix of the form shown in Figure 1.

2) We compute:

$$\mathbf{A}^{(k)} = \mathbf{W}^{(k)} \mathbf{A}^{(k-1)}.$$

After $(\frac{n}{2} - 1)$ such steps we get the matrix

$$\mathbf{Z} = \mathbf{A}^{(\frac{n}{2} - 1)}.$$

Moreover, we know that:

$$\mathbf{W}^{(\frac{n}{2}) - 1} \cdot \ldots \cdot \mathbf{W}^{(1)} \cdot \mathbf{A} = \mathbf{Z},$$

so we get

$$\mathbf{A} = \{\mathbf{W}^{(1)}\}^{-1} \cdot \ldots \cdot \{\mathbf{W}^{(\frac{n}{2}) - 1}\}^{-1} \cdot \mathbf{Z} = \mathbf{WZ}.$$

Algorithm 1 shows the WZ algorithm.

The complexity of Algorithm 1 can be expressed by the formule

$$\sum_{k=1}^{\frac{n}{2}-1} \left( 3 + \sum_{i=k+1}^{n-k} \left( 8 + \sum_{j=k+1}^{n-k} 4 \right) \right) = \frac{4n^3 - 7n - 18}{6}. \tag{6}$$

So, this algorithm requires $O(n^3)$ arthmetic operations.

$$\mathbf{W}^{(k)} = \begin{bmatrix} 1 & & & & & & & \\ & \ddots & & & & & & \\ & & 1 & & & & & \\ & & w_{k+1,k} & \ddots & & w_{k+1,n-k+1} & & \\ & & \vdots & & \ddots & \vdots & & \\ & & w_{n-k,k} & & \ddots & w_{n-k,n-k+1} & & \\ & & & & & 1 & & \\ & & & & & & \ddots & \\ & & & & & & & 1 \end{bmatrix}$$

Ensure: W, Z
for $k = 1$ to $n/2 - 1$ do
    $k2 \leftarrow n - k + 1$
    $det \leftarrow a_{kk} * a_{k2k2} - a_{k2k} * a_{kk2}$
    for $i = k + 1$ to $k2 - 1$ do
        $w_{ik} \leftarrow (a_{k2k2} * a_{ik} - a_{k2k} * a_{ik2})/det$
        $w_{ik2} \leftarrow (a_{kk} * a_{ik2} - a_{kk2} * a_{ik})/det$
        for $j = k + 1$ to $k2 - 1$ do
            $a_{ij} \leftarrow a_{ij} - w_{ik} * a_{kj} - w_{ik2} * a_{k2j}$
        end for
    end for
end for
$Z \leftarrow A$
```

## III. Nested loops parallelism strategies

An application with nested loops can be performed parallely in different ways depending on compilators, hardware and run-time system support available. Nested loops require from of a programmer taking a decision concerning details of parallelism.

In this work we deal with the following parallelization strategies for nested loops:

1) *outer*
2) *inner*
3) *nested*
4) *split*

While all variables used in a parallel region are by default `shared`, in each strategy we declare explicitly all variables as `private` or `shared` for all directives respectively. Using the `private` clause, we specify that each thread has its own copy of variables.

To ensure load balancing for all threads we use the schedule clause, which specifies how the iterations of the loop are assigned to the threads. In the clause `schedule` of the directive `#pragma omp parallel for` we set the value `static`, because the computational cost of the tasks is known.

### A. Outer

*Outer* — the simplest parallelization strategy of nested loops is parallel execution of the most outer loop. All inner loops are executed in a sequence. This approach gives good results if the number of iterations in a loop is big and the iteration's granularity is coarse enough, which happens exactly in case of the WZ factorization. Algorithm 2 presents outer strategy for WZ factorization. The outermost $k$-loop cannot be parallelized, however, we can parallelize the $i$-loop. In this simple parallelization strategy the loop is divided equally between threads, so every thread performs the same amount of work, which ansure regular distribution of work beetwen threads.

### B. Inner

Another strategy of paralelizing nested loops involves executing the inner loops in parallel on all processors, but the outer loop is executed in a sequence. Clearly, in case of WZ factorization blocking barrier is used at the end of each parallel

**Algorithm 2** Outline of the WZ factorization algorithm (WZ) — outer strategy

```
Require: A
Ensure: W, Z
for $k = 1$ to $n/2 - 1$ do
    $k2 \leftarrow n - k + 1$
    $det \leftarrow a_{kk} * a_{k2k2} - a_{k2k} * a_{kk2}$
    #pragma omp parallel for private(i) shared(k, k2, w, a, det,j)
    for $i = k + 1$ to $k2 - 1$ do
        $w_{ik} \leftarrow (a_{k2k2} * a_{ik} - a_{k2k} * a_{ik2})/det$
        $w_{ik2} \leftarrow (a_{kk} * a_{ik2} - a_{kk2} * a_{ik})/det$
        for $j = k + 1$ to $k2 - 1$ do
            $a_{ij} \leftarrow a_{ij} - w_{ik} * a_{kj} - w_{ik2} * a_{k2j}$
        end for
    end for
end for
$Z \leftarrow A$
```

loop, which prevents incorect results. Parallelizing the inner loop will potentially provide smaller pieces of work so they can be distributed evenly between the available threads but it has more overhead due to work distribution and synchronization beetwen threads. This overhead may be high if the loop granularity is too fine. Algorithm 3 presents inner strategy for WZ factorization, in which the $j$-loop are parallelized.

### C. Nested

The third strategy of execution of nested loops paralelization is exploiting the paralelism on each level — nested parallelism. Standard OpenMP (from 2.5 version) makes it possible to nest parallel loops, however, it must be switched on by means of the environment variable `OMP_NESTED` or the function `omp_set_nested`. Each task needs at least one thread to its own disposal. Algorithm 4 presents the nested strategy.

This algorithm shows how a 2-level parallelism can be implemented in OpenMP based on the directives. Nesting parallel loops is a way to use more threads in a computation. This can easily create a large number of threads as their number is the product of the number of threads forked at each level of nested loops.

### D. Split

The final strategy concernes division of $i$-loops into two separate loops. Such a split facilites presentation of $k$th step in the form of a dag (directed acyclic graph), which shows the order of the task execution. The dag represents computational solutions in which the nodes represent tasks to be executed and edges represent precedence among the tasks. In the figure 2 a dag for $k$th step and shows, which part of the matrix is processed in a particular task is presented. By Task 1 we understand determining of valiables $k2$ and $det$ (lines 2 and 3 in Algorithm 1. Task 2 is the computation of $k$th and $k2$nd column of the matrix $\mathbf{W}$ (lines 4, 5 and 6 in Algorithm 1). Task 3 is the computation of values in the matrix $\mathbf{A}$ (lines 4, 7 and 8 in Algorithm 1).

Algorithm 5 shows the *split* strategy for WZ factorization. The first loop is parallelized. The second loop is nested loop and we use outer version to parallelize this loop.

## IV. Numerical Experiments

In this section we tested the time, the performance, the speedup and the absolute accuracy of the WZ factorization. Our intention was to investigate diffrent nested loops parallelization strategies for the WZ factorization on multicore architecuters. We examined five versions algorithms of the WZ factorization:

- *sequential* (Algorithm 1),
- *outer* (Algorithm 2),
- *inner* (Algorithm 3),
- *nested* (Algorithm 4),
- *split* (Algorithm 5).

Here we used experiments, based on information collected at runtime, to decide whether a loop should execute clause `static` or `dynamic` and we chose `static`.

The input matrices are generated (by the authors). They are random, dense, square matrices with a dominant diagonal of even sizes (1000, 2000,. . . , 9000)

We used two hardware platforms for testing: E5-2660 and X5650. Their details specifications are presented in Table I.

The algorithms *sequential*, *outer*, *inner*, *nested* and *split* were implemented with the use of the C language with the use of the double precision. Our codes were compiled by INTEL C Compiler (icc) with optimization flag `-O3`. Additionally, all algorithms were linked with the OpenMP library.

### A. The Time

All the processing times are reported in seconds. The time is measured with an OpenMP function `open_get_wtime()`. They were tested in the double precision.

In Figures 3 and 4 we have compared the average running time of the four parallel WZ decomposition algorithms and the sequential version on two platforms.

    for $j = k + 1$ to $k2 - 1$ do
      $a_{ij} \leftarrow a_{ij} - w_{ik} * a_{kj} - w_{ik2} * a_{k2j}$
    end for
  end for
end for
$Z \leftarrow A$
```

TABLE I
SOFTWARE AND HARDWARE PROPERTIES OF E5-2660 AND X5650 SYSTEMS

| | E5-2660 System | X5650 System |
|---|---|---|
| CPU | 2x Intel Xeon E5-2660 (20M Cache, 2.20 GHz, 8 cores with HT) | 2x Intel Xeon X5650 (12M Cache, 2.66 GHz, 6 cores with HT) |
| CPU memory | 48GB DDR3 | 48GB DDR3 |
| Operating system | CentOS 5.5 (Linux 2.6.18-164.el5) | Debian (GNU/Linux 7.0) |
| Libraries | OpenMP, Intel Composer XE 2013 | OpenMP, Intel Composer XE 2013 |
| Compilers | Intel | Intel |

Figure 3 shows the dependence of the time on the number of threads for the matrix of the size 9000 on two platforms (X5650 on the right side, E5-2660 on the left side).

Figure 4 shows the dependence of the time on the matrix size for 12 threads for X5650 system (the right side) and 16 threads for E5-2660 system (the left side).

Using obtained results we conclude that:

- For a growing number of threads E5-2660 architecture outperforms X5650, due to the fact that the latter one is its older. We were expecting this result.
- The time is the shortest for 12 threads on the X5650 system and for 16 threads on the E5-2660 system. For bigger number of threads the time is the same as for 12 threads on the X5650 system nad for 16 threads on E5-2660, which proves weakness of the hyperthrading technology.
- If the size matrix is increased, then the runtime is increased too and it becomes more profitable to use a big number of the threads.
- *split* and *outer* algorithms achieve very similar execution time, which is the shortest compared with other algorithms.
- The worse execution time was achieved by the *nested* algorithm and for E5-2660 it is even worse than sequential algorithm.

### B. The Performance

Figures 5 and 6 compare the performance (in Gflops) results obtained for those five algorithms (*sequential*, *outer*, *inner*, *nested*, *split*) — in the double precision on two platforms. The performance is based on the number of floating-point operations in the WZ factorization (6).

Figure 5 shows dependence of the performance on the number of threads (maximum number of the threads is 24) for the matrix of the size 9000 for two platforms (X5650 — the right, E5-2660 — the left).

Figure 6 shows dependence of the performance on matrix size for 12 threads for X5650 system (the right side) and 16 threads for E5-2660 (the left side).

We can see the best performance (about 5.5 Gflop/s) achieved by *split* algorithm for the matrix of the size 9000 for 16 threads on E5-2660 system, and worst (less than 1 Gflop/s) is for *nested* version and *sequential* algorithm for all matrix sizes. On X5650 system we obtain worse performance for all tested algorithms than on E5-2660 System. The performance is very low for all algorithms on X5650 system and almost the same for inner, outer and *split* algorithms on X5650 system.

### C. The Speedup

Figures 7 and 8 present the speedup results obtained for four algorithms implementations — in the double precision on two platforms. Figure 7 shows dependence of the speedup on the number of threads (maximum number of the threads is

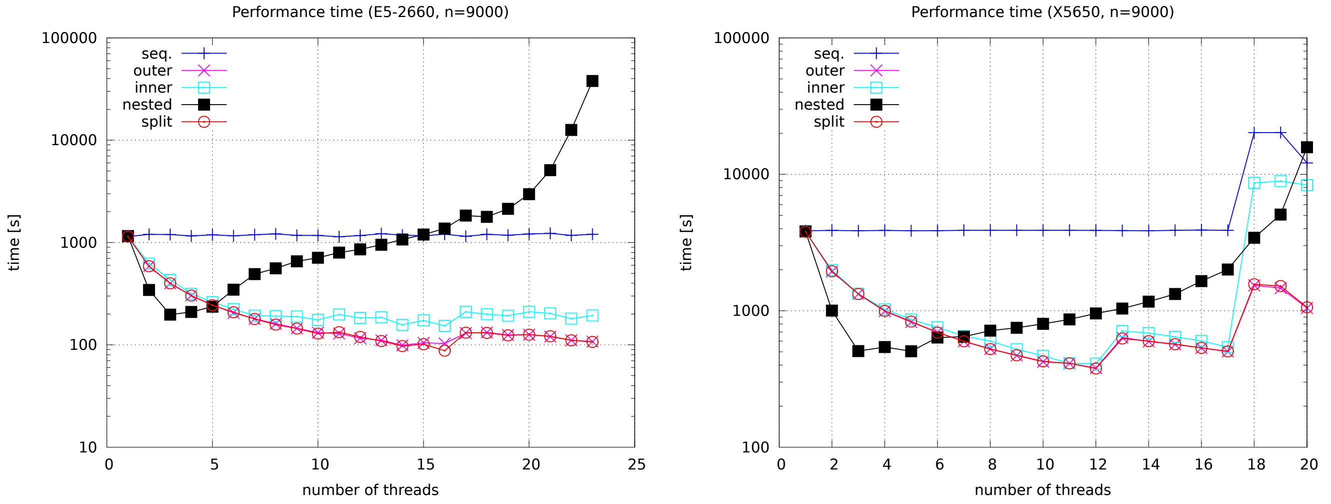

Fig. 3. The average running time of the WZ matrix decomposition as a function of the number of threads — for the five algorithms using the double precision on two platforms (E5-2660 on the left side and X5650 on the right side) for the matrix of the size 9000 (logarithmic $y$-axis).

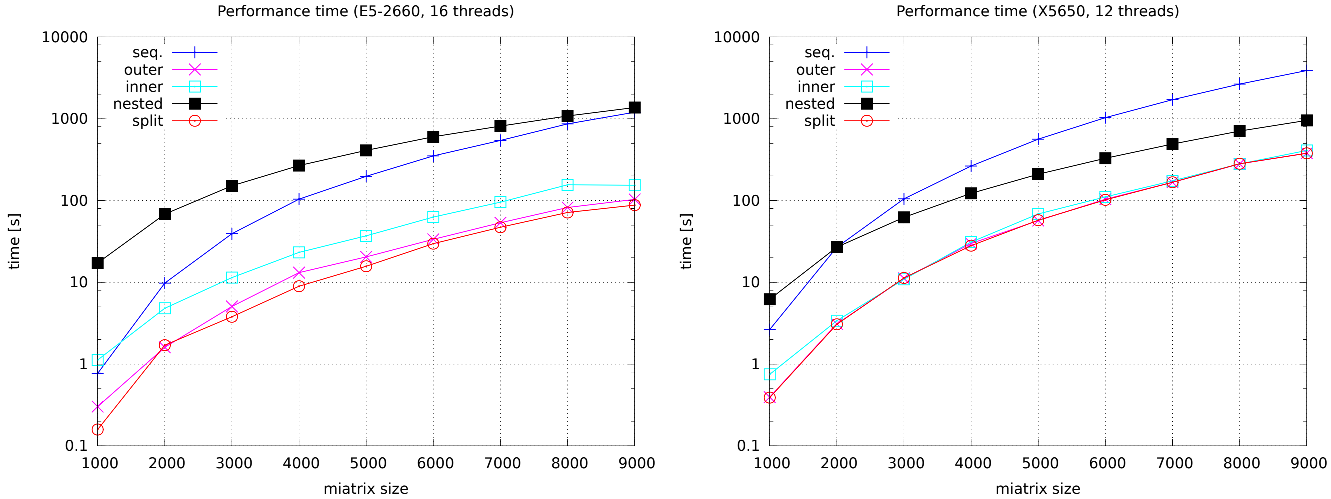

Fig. 4. The average running time of the WZ matrix decomposition as a function of the matrix size — for 16 threads on E5-2660 system (the left side) and for 12 threads on X5650 system (the right side) (logarithmic $y$-axis ).

23) for the matrix of the size 9000 for two platforms (X5650 — the right, E5-2660 — the left).

Figure 8 shows dependence of the performance on the matrix size for 12 threads for X5650 system (the right side) and 16 threads for E5-2660 (the left side).

Note that:

- All algorithms scale well with the size of a matrix; moreover,the bigger the matrix, the better the speedup.
- The speedup increases steadily until 12 threads on E5-2660 System and 16 threads on X5650 system, before it starts to level off.
- *Split* algorithm has the better speedup, even value up to 14 for 16 threads on E5-2660 system.
- On the X5650 system *split* and outer algorithm have similary seedup, but on E5-2660 System *split* algorithm has higher speedup than *split* algorithm.

### D. Numerical Accuracy

The purpose of this section is not to accomplish a full study of the numerical stability and accuracy of the WZ factorization, but justify experimentally that our implementation of the WZ algorithm can be used in practice.

As a measure of accuracy we took the following expression (where $||\mathbf{M}||$ is the Frobenius norm of the matrix $\mathbf{M}$) based on the absolute error:

$$||\mathbf{A} - \mathbf{WZ}||.$$

Table II illustrates the accuracy (given as the norms $||\mathbf{A} - \mathbf{WZ}||$) of the WZ factorization. The norms on both platforms (E5-2660 and X5650) are the same for appropriate matrix

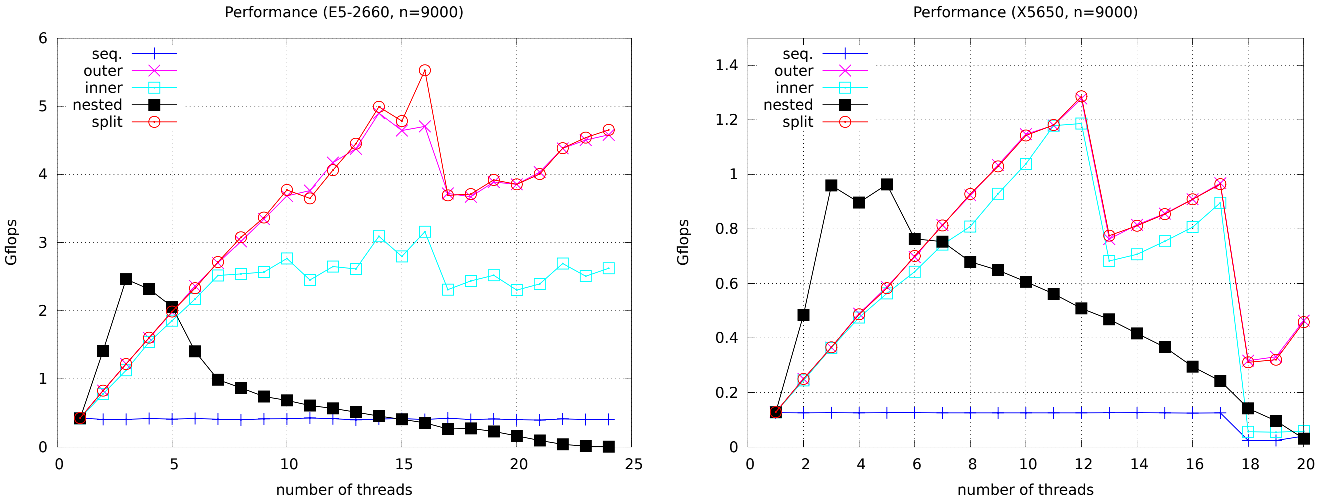

Fig. 5. The performance results for the WZ factorization — using the double precision on two platforms (E5-2660 — the left side; X5650 — the right side) for the five algorithms as the function of number of threads.

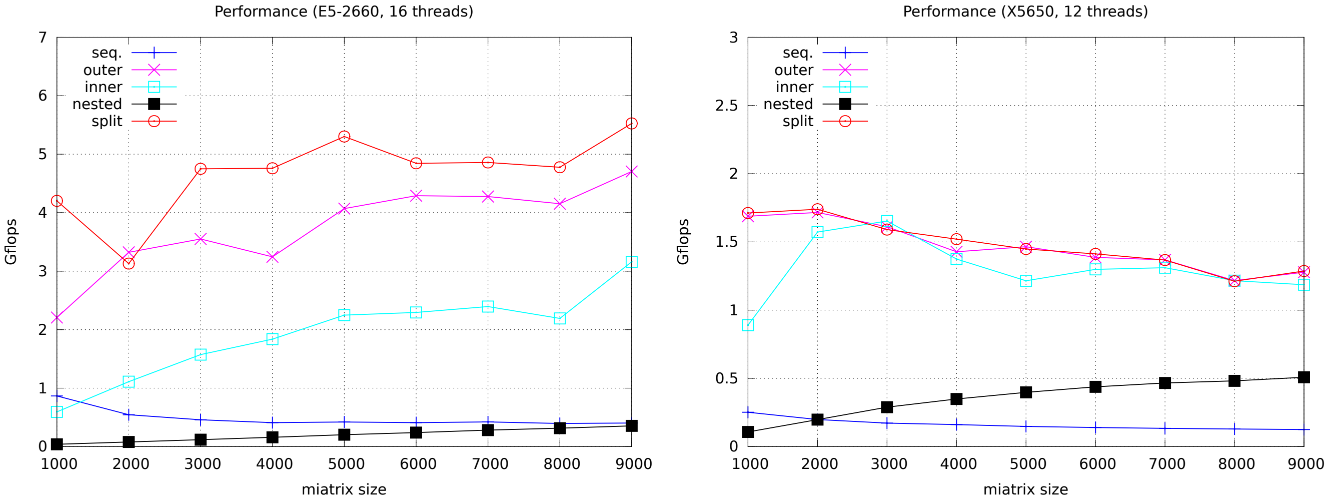

Fig. 6. The performance results for the WZ factorization — using the double precision for 16 threads on E5-2660 system (the left side) and for 12 threads on X5650 system (the right side) for the five algorithms as a function of the matrix size.

sizes. Values of the norm do not depend on the number of the threads and do not depend on a choice of algorithms (for all algorithms the norm depends only on the matrix size).

## V. Conclusion

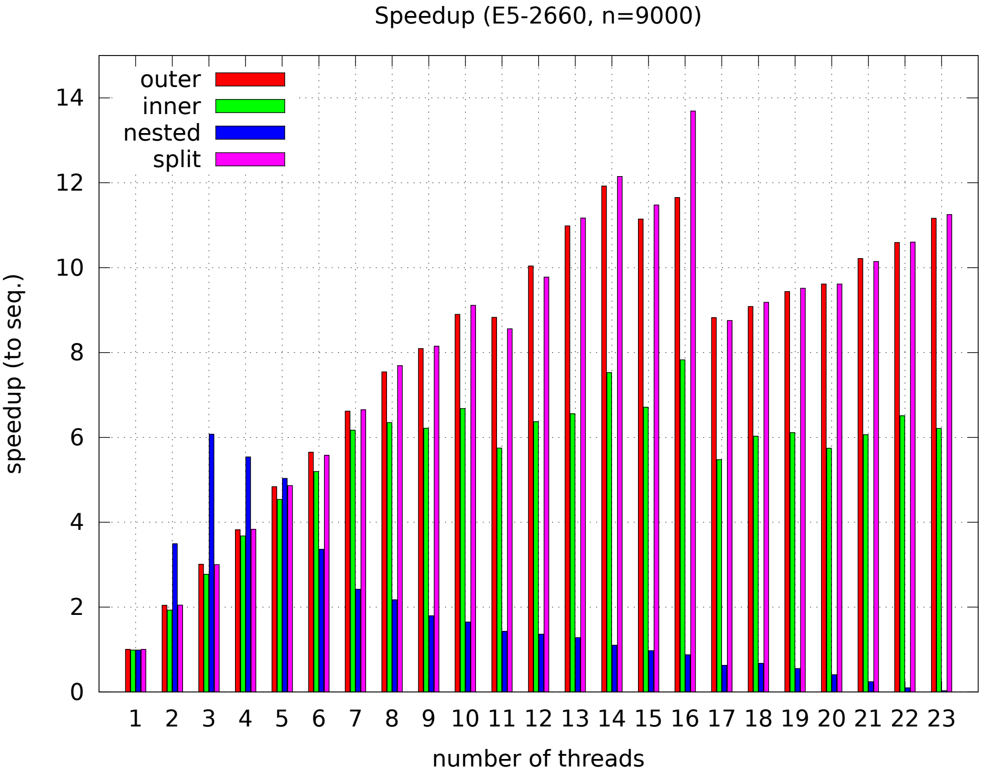
In this paper we examined several practical aspect of nested parallel loop execution. We used four different strategies for executing nested parallel loops on the examples of the WZ factorization. All proposed approaches usually accelerate sequential computations, except the *nested* algorithm.

*Nested* algorithm for a small number of threads proved to be the fastest, but for a big numer of threads its execution took longer time even than for a *sequential* algorithm. We may explain that creating any parallel region will cause the overhead. Overhead from nesting of parallel regions may cause overheads greater than necessary if, for example, an outer region could simply employ more threads in a computation. The appliaction lost the time on scheduling threads. OpenMP allows the specification of nested parallel loops, but for WZ factorization does not acquire satisfactory results. OpenMP uses nesting poorly.

The available number of threads exploited both outer and *split* algorithms best. *Split* approach achievs the best speedup. The speedup of 14 was achived for 16 threads on the E5-2660 system. We find this result very satisfactory.

The implementation had no impact on the accuracy of the factorization — the accuracy depended only on the size of the matrix what is quite self-evident.

The implementation of the *split* algorithm presented in this paper achieves high performance results, which has a direct



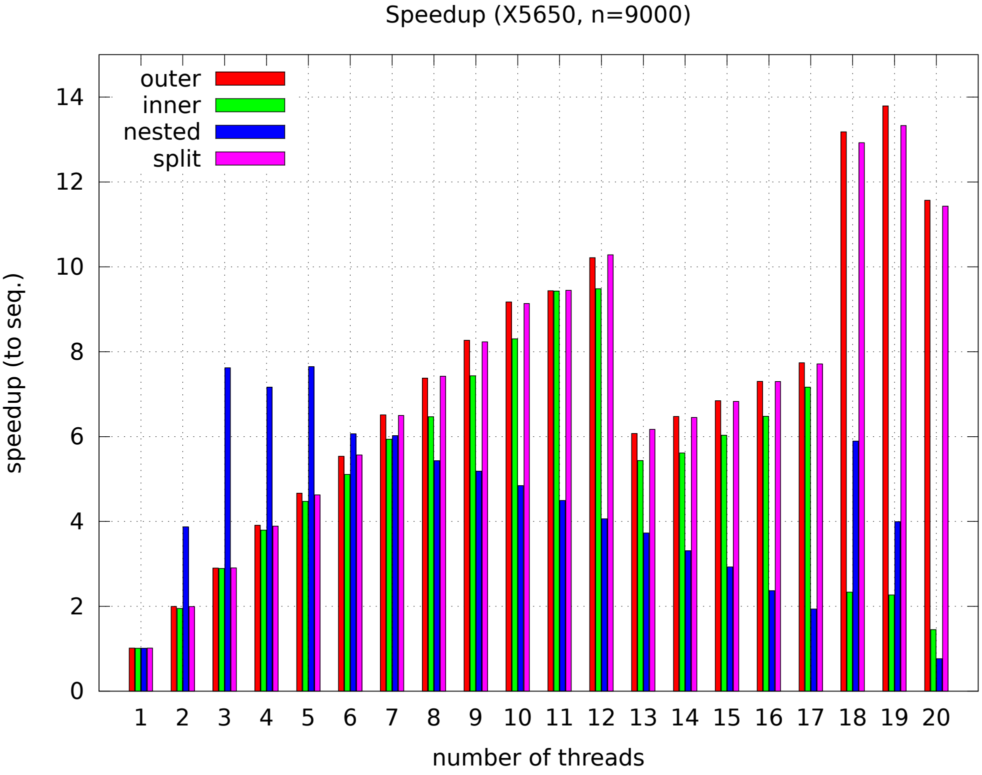


Fig. 7. The speedup results for the WZ factorization — using the double precision on two platforms (E5-2660 — top; X5650 — bottom) for the four algorithms as the function of number of threads.

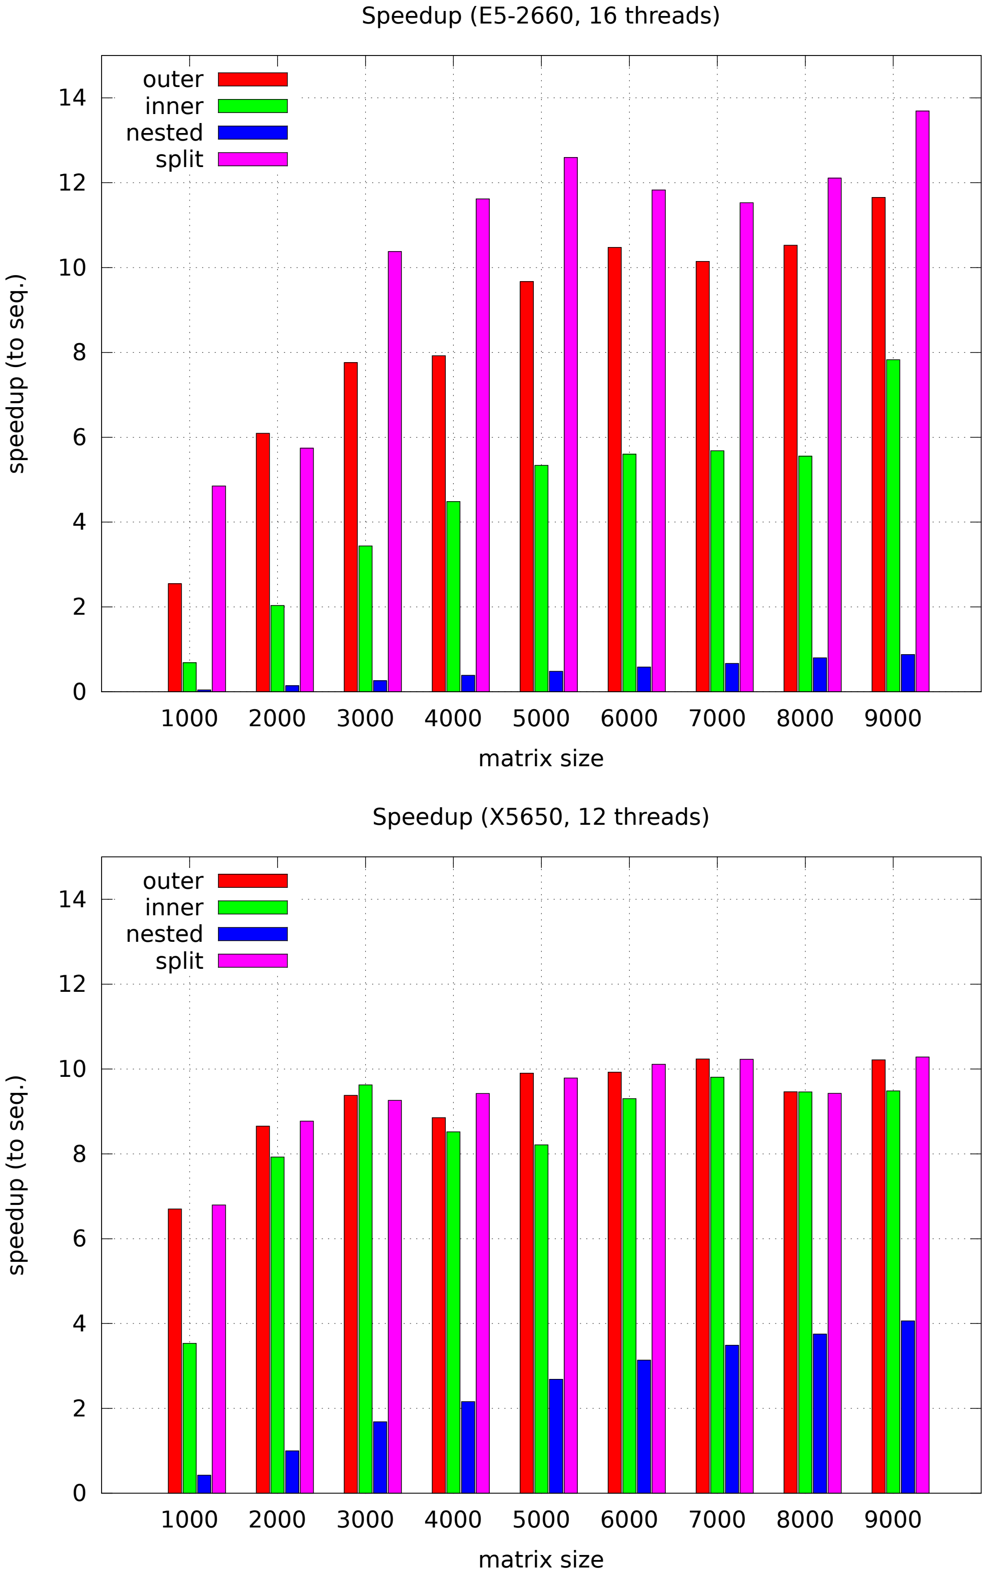

Fig. 8. The speedup results for the WZ factorization — using the double precision for 16 threads on E5-2660 System (top) and 12 threads on X5650 System (bottom) for the four algorithms as a function of the matrix size.

TABLE II
THE NORMS FOR THE WZ FACTORIZATIONS IN DOUBLE PRECISION ON E5-2660 SYSTEM AND X5650 SYSTEM FOR ALL THE ALGORITHMS IN DOUBLE PRECISION

| matrix size | $\|\|\mathbf{A}-\mathbf{WZ}\|\|$ |
|---|---|
| 1000 | $2.89 \cdot 10^{-22}$ |
| 2000 | $1.18 \cdot 10^{-21}$ |
| 3000 | $2.97 \cdot 10^{-21}$ |
| 4000 | $5.59 \cdot 10^{-21}$ |
| 5000 | $9.32 \cdot 10^{-21}$ |
| 6000 | $1.40 \cdot 10^{-20}$ |
| 7000 | $2.06 \cdot 10^{-20}$ |
| 8000 | $2.83 \cdot 10^{-20}$ |
| 9000 | $3.78 \cdot 10^{-20}$ |

impact on the solution of linear systems.

This paper is another example of the succesful use of OpenMP for solving scientific appliactions.

***Abstract*—Recursive Filters (RFs) are a well known way to approximate the Gaussian convolution and are intensively used in several research fields. When applied to signals with support in a finite domain, RFs can generate distortions and artifacts, mostly localized at the boundaries of the computed solution. To deal with this issue, heuristic and theoretical end conditions have been proposed in literature. However, these end conditions strategies do not consider the case in which a Gaussian RF is applied more than once, as often happens in several realistic applications. In this paper, we suggest a way to use the end conditions for such a $K$-iterated Gaussian RF and propose an algorithm that implements the described approach. Tests and numerical experiments show the benefit of the proposed scheme.**

## I. Introduction

Recursive filters (RFs) have achieved a central role in several research fields, as in data assimilation for operational three-dimensional variational analysis schemes (3Dvar) [4], [10], and in Electrocardiogram (ECG) denoising [1], [2]. Among RFs, the Gaussian RFs are particularly suitable for digital image processing [13] and applications of the scale-space theory [8], [15]. Gaussian RFs are an efficient computational tool for approximating Gaussian-based convolutions [3], [14], [10], [11], [12]. Gaussian RFs are mainly derived in three different ways: the Deriche strategy uses an approximation of the Gaussian function in the space domain [5]; the approximation procedure of Jin et al. is carried out in the $z$-domain, i.e. it is based on an approximation of the $z$-transform of the Gaussian function by means of rational polynomial functions [9]; and the approach followed by Vliet et al. [12], [16] approximates the Gaussian function in the Fourier domain. The latter approach is particularly attractive since the Fourier transform of a Gaussian function is a Gaussian.

From a mathematical point of view, a Gaussian RF consists of two infinite sequences of equations (forward and backward equations) that involve the entries of both the input and output signals. However, algorithms that implement RFs need to consider only a finite number of these equations, i.e. they take into account a finite number of input and output signal samples. Without additional assumptions, such a reduction (from the infinite to the finite) introduces distortions and artifacts on the computed finite output signals. In particular, these solutions present an error that affects the entries near to the boundaries. This phenomenon has been recognized as an edge effect in [3] and some authors, such as Purser et al. [10] and Triggs et al. [14], suggest how to avoid this by simulating the effect of the continuation of the neglected equations. This results in inserting the so-called boundary conditions, or end conditions, i.e. in modifying some of the filter equations so that the backward equations can be primed. These strategies are based on some heuristic assumptions on the input signal and seem to fix the edge effect problem.

In some real applications [3], [6], [7], Gaussian RFs are used iteratively. This relies on a more general definition of RFs, named $K$-iterated RFs, which have been formally introduced in [3]. So far, a comprehensive study of the conditions for the $K$-iterated RFs is still lacking. Moreover, as noticed in [3], and recalled in this work (see Section 3), edge effects reappear when the number $K$ of filter iterations increases, even though the classic RF end conditions are used. In this context, the purpose of this work is to provide an algorithm which combines classic end conditions with a suitable oversizing and reduction of both the input and the output signals, so that the edge effects are strongly mitigated. The paper is organized as follows. In Section 2, we recall the definitions of the discrete Gaussian convolution and Gaussian recursive filters, then we derive classic end conditions in a general way and show their specific features for the first-order Gaussian RF used in [3], [6], [7]. The benefit of the end conditions is shown through some numerical examples. In Section 3, we give the definition of the $K$-iterated RFs and point out how the filter coefficients of a $K$-iterated first-order RF have to be taken. Finally, we propose a numerical scheme that implements a $K$-iterated first-order RF with end

978-83-60810-66-8/$25.00©2015, IEEE

conditions and a strategy for preventing the occurrence of edge effects. In Section 4, we report some experiments to confirm the reliability of the proposed algorithm and give suggestions on how to set the parameters of the proposed $K$-iterated scheme. Finally, Section 5 contains some concluding remarks.

## II. Mathematical Background

Let

$$g(x) = \frac{1}{\sigma\sqrt{2\pi}} \exp\left(-\frac{x^2}{2\sigma^2}\right)$$

be the Gaussian function and

$$s^{(0)} = \{s_j^{(0)}\}_{j=-\infty}^{+\infty} = \left(\dots, s_{-2}^{(0)}, s_{-1}^{(0)}, s_0^{(0)}, s_1^{(0)}, s_2^{(0)}, \dots\right)$$

a signal (i.e. a complex function defined on the set of integers **Z**). The discrete Gaussian convolution of $s^{(0)}$ gives rise to an output signal $s^{(g)}$ whose entries are defined by:

$$s_j^{(g)} \overset{\text{def}}{=} \left(g * s^{(0)}\right)_j = \sum_{t=-\infty}^{+\infty} g(j-t) s_t^{(0)}. \qquad (1)$$

The entries $s_j^{(g)}$ of $s^{(g)}$ in (1) can be approximated by means of Gaussian recursive filters. The $n$-order Gaussian RF filter gives an output signal $s$, which is an approximation of $s^{(g)}$, whose entries solve the infinite sequences of equations:

$$p_j = \beta_j s_j^{(0)} + \sum_{t=1}^{n} \alpha_{j,t} p_{j-t}, \qquad j = -\infty, \dots, +\infty, \qquad (2)$$

$$s_j = \beta_j p_j + \sum_{t=1}^{n} \alpha_{j,t} s_{j+t}, \qquad j = -\infty, \dots, +\infty. \qquad (3)$$

The equations in (2) and (3) are conveniently referred to as the advancing and backing filters, respectively, since in the former the index $j$ must be treated as in increasing order while, in the latter, it must be treated in decreasing order [10]. The values $\alpha_{j,t}$ and $\beta_j$ are called *smoothing coefficients* and satisfy:

$$\beta_j = 1 - \sum_{t=1}^{n} \alpha_{j,t}.$$

The smoothing coefficients depend on $\sigma$, $n$ and, in a more general setting, even on the index $j$. Hereafter, we only consider the homogeneous case, i.e. we set:

$$\beta_j \equiv \beta, \qquad \alpha_{j,t} \equiv \alpha_t, \qquad (4)$$

where the advancing and backing filters take the form:

$$p_j = \beta s_j^{(0)} + \sum_{t=1}^{n} \alpha_t p_{j-t}, \qquad j = -\infty, \dots, +\infty, \qquad (5)$$

$$s_j = \beta p_j + \sum_{t=1}^{n} \alpha_t s_{j+t}, \qquad j = -\infty, \dots, +\infty. \qquad (6)$$

If we assume that the support of the input signal $s^{(0)}$ is in the grid $\{1, 2, \dots, N\}$, then equations (5) and (6) can be implemented in an algorithm in which the index $j$ increases from 1 to $N$, for the advancing filter, and decreases from $N$ to 1, for the backing filter. This scheme needs to prime the advancing filter, by setting the values $p_j$, for $j \in \{0, -1, \dots, 1-n\}$, and the backing filter, by setting the values $s_j$ for $j \in \{N+1, N+2, \dots, N+n\}$. For example, a common choice is to set at zero the required $p_j$ and $s_j$ values, i.e.:

$$\begin{aligned} p_{-n+1} = p_{-n+2} = \dots = p_0 = 0; \\ s_{N+1} = s_{N+2} = \dots = s_{N+n} = 0. \end{aligned} \qquad (7)$$

However, this assumption gives rise to a well-known edge effect, already noticed in [14], and discussed in detail in [3]. An outline of such a scheme, implementing (5), (6) and (7), is provided in **Algorithm 1**.

**Algorithm 1** Scheme of an $n$-order Recursive Filter with zero end constraints

```
Input: $s^{(0)}$, $\sigma$    Output: $s$
set $\beta, \alpha_1, \dots, \alpha_n$        % smoothing coefficient precomputation
for $j = 1, 2, \dots, n$        % left zero end conditions
    $p_{j-n} := 0$
endfor
for $j = 1, 2, \dots, N$        % advancing filter
    $p_j := \beta s_j^{(0)}$
    for $t = 1, 2, \dots, n$
        $p_j := p_j + \alpha_t p_{j-t}$
    endfor
endfor
for $j = 1, 2, \dots, n$        % right zero end conditions
    $s_{N+j} := 0$
endfor
for $j = N, \dots, 1$        % backing filter
    $s_j := \beta p_j$
    for $t = 1, 2, \dots, n$
        $s_j := s_j + \alpha_t s_{j+t}$
    endfor
endfor
```

**Example 1.** Now we provide some insights into the edge effect through the following example. Let $s^{(0)}$ be the input signal with entries:

$$s_j^{(0)} = \begin{cases} 0 & \text{for } j \leq 0; \\ 1 & \text{for } 1 \leq j \leq N = 30; \\ 0 & \text{for } j \geq N+1 = 31; \end{cases} \qquad (8)$$

In Figure 1, we report the results obtained by applying the first-order RF and third-order RF to the signal $s^{(0)}$. In particular, the red line represents the signal $s^{(g)}$, i.e. the discrete Gaussian convolution of $s^{(0)}$ with $\sigma = 4$. Conversely, the white squares and gray diamonds are the values of the output signals computed by means of the first-order RF and third-order RF, respectively. Notice that both computed solutions differ from $s^{(g)}$ mostly on the boundary entries. In particular, the third-order filter seems to not well approximate the entries of $s^{(g)}$ close to the right boundary. This phenomenon can be better

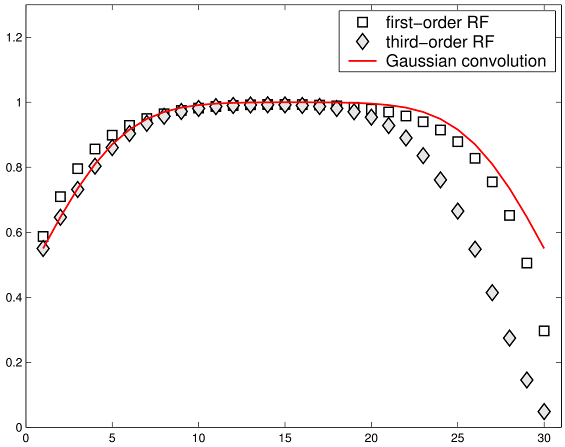

Fig. 1. Red line: discrete Gaussian. White squares: first-order RF solution. Gray diamonds: third-order RF solution.

understood by looking at the relative errors

$$e_j = \frac{|s_j - s_j^{(g)}|}{|s_j^{(g)}|}. \tag{9}$$

The value of the errors $e_j$, for the first-order RF and third-order RF, are shown in Figure 2. Observing the order of magnitude of the values $e_j$, we can conclude that, in general, the output signals present a larger error at the boundaries.

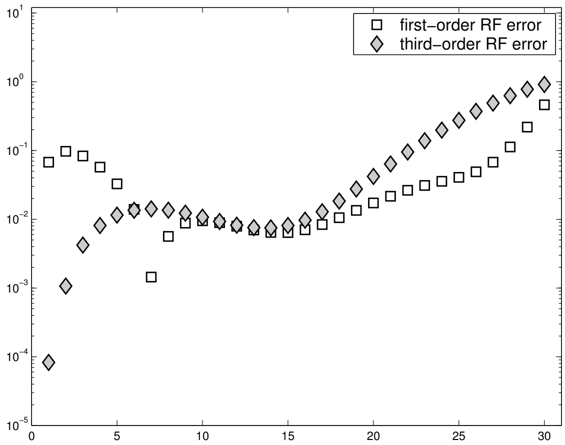

Fig. 2. White squares: first-order RF relative errors. Gray diamonds: third-order RF relative errors.

### A. *Introducing end conditions*

The edge effect, shown in the previous example, can be partly explained by observing that, in the transition from the infinite sequences of equations to the finite algorithm, the computed solution $s$ has been constrained to assume the value zero on the right off-grid points $N+1, N+2, \ldots, N+n$, while this property is not true for $s^{(g)}$. Hence, assumption (7) introduces a sort of perturbation error on the output signal $s$ of the RF. This drawback can be avoided by simulating, in the finite setting, the effect of the continuation of the neglected equations (for $j > N$). To achieve this aim, we adapt to our setting and notations the derivation of the end conditions (e.c.) described in [14].

We consider an $n$-order recursive filter with smoothing coefficients $\alpha_1, \ldots, \alpha_n$ and $\beta_j$. Let $C$ and $A$ be the following $n \times n$ matrices:

$$\mathbf{A} = \begin{pmatrix} \alpha_1 & \ldots & \alpha_{n-1} & \alpha_n \\ 1 & \ldots & 0 & 0 \\ \vdots & \ddots & \vdots & \vdots \\ 0 & \ldots & 1 & 0 \end{pmatrix} \tag{10}$$

$$\mathbf{C} = \begin{pmatrix} \beta & 0 & \ldots & 0 & 0 \\ 0 & 0 & \ldots & 0 & 0 \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & \ldots & 0 & 0 \end{pmatrix} \tag{11}$$

Now, by setting:

$$\begin{aligned} \vec{p}_t &= \left(p_t, p_{t-1}, \ldots, p_{t-n+1}\right)^T, \\ \vec{s}_t &= \left(s_t, s_{t+1}, \ldots, s_{t+n-1}\right)^T, \\ \vec{s}_t^{(0)} &= \left(s_t^{(0)}, s_{t+1}^{(0)}, \ldots, s_{t+n-1}^{(0)}\right)^T, \end{aligned}$$

the forward and backward filters in (5) and (6), take the form:

$$\vec{p}_{t+1} = C\vec{s}_{t+1}^{(0)} + A\vec{p}_t, \tag{12}$$

$$\vec{s}_t = C\vec{p}_t + A\vec{s}_{t+1}. \tag{13}$$

Then, applying recursively (12) and (13), we obtain:

$$\vec{p}_{t+k} = \sum_{l=0}^{k-1} A^l C \vec{s}_{t+k-l}^{(0)} + A^k \vec{p}_t, \tag{14}$$

$$\vec{s}_t = \sum_{l=0}^{k-1} A^l C \vec{p}_{t+l} + A^k \vec{s}_{t+k}. \tag{15}$$

Assuming that the support of the input signal $s^{(0)}$ is in $\{1, 2, \ldots, N\}$, the equation (14), for $k > 0$ and $t \geq N$, becomes:

$$\vec{p}_{t+k} = A^k \vec{p}_t. \tag{16}$$

Now, using (16) in (15), and taking the limit for $l \to \infty$, provided that $s$ is bounded, we obtain:

$$\vec{s}_t = M\vec{p}_t, \qquad \text{with} \qquad M \overset{\text{def}}{=} \sum_{l=0}^{\infty} A^l C A^l. \tag{17}$$

For $t = N$, equation (17) provides a way of priming the backing filter. In other words, (17) behaves as a sort of *turning* condition that accounts for the infinite sequence of neglected equations and allows us to skip from the advancing filter to the backing filter. Indeed, the values $s_N, s_{N+1}, \ldots, s_{N+n-1}$ are linear functions of the values $p_N, p_{N-1}, \ldots, p_{N-n+1}$ which are computed by the advancing filter. In this approach, we need to precompute the matrix $M$. This can be done in several ways: in [14], it is observed that the recursive definition of $M$ implies that it solves the equation:

$$M = C + AMA;$$

otherwise, one could compute an approximation of $M$ as the partial sum $M_k = \sum_{l=0}^{k} A^l C A^l$, provided that $A^{k+1} C A^{k+1}$ is negligible. Observe that, for the first-order RF with smoothing coefficients $\alpha \equiv \alpha_1$ and $\beta = 1 - \alpha$, we simply have:

$$A = \alpha, \quad C = \beta, \quad M = \sum_{l=0}^{\infty} \beta \cdot \alpha^{2l} = \frac{\beta}{1-\alpha^2} = \frac{1}{1+\alpha}$$

and for $t = N$ in (17),

$$s_N = \frac{1}{1+\alpha} p_N.$$

An exact expression of the matrix $M$, in terms of the coefficients $\alpha_1$, $\alpha_2$, $\alpha_3$ and $\beta$, can be derived for the third-order RF [14] and will be used in the example below. In order to take into account the end conditions, steps 11. 12. and 13. of **Algorithm 1** must be replaced with the computation of $M$ and the computation of $\vec{s}_N$. Moreover, the last loop (steps 14.-19.) must start from $N - 1$.

**Example 2.** To see the effect of the e.c. on the RFs, we consider the input signal $s^{(0)}$ in (8). The results obtained by applying the first-order and the third-order RFs, with and without e.c., are plotted in Figure 3 and Figure 4, respectively.

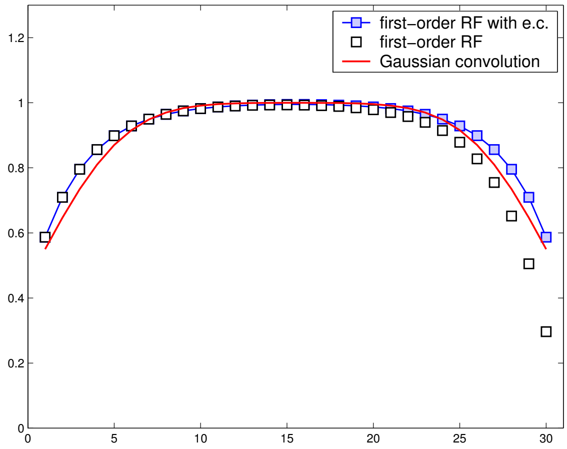

Fig. 3. Red line: discrete Gaussian. White squares: first-order RF without end conditions. Blue squares: first-order RF with end conditions.

In Figure 3 the solutions of the first-order RFs with and without e.c. are compared; analogously, Figure 4 deals with the third-order RFs. In both cases, one can notice the improvement of the computed solutions, especially on their right boundary entries, when the e.c. are considered. In particular, the output signal of the third-order RF with e.c. is very close to the Gaussian convolution output $s^{(g)}$.

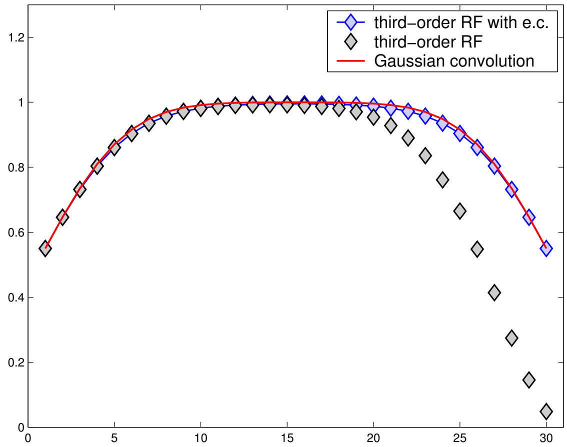

Fig. 4. Red line: discrete Gaussian. Gray diamonds: third-order RF without end conditions. Blue diamonds: third-order RF with end conditions.

## III. $K$-ITERATED GAUSSIAN RECURSIVE FILTERS

The latter example highlights that the third-order filter mimics very well the effect of the discrete Gaussian convolution. Conversely, the output signal of the first-order RF, even with e.c., is still a poor approximation of $s^{(g)}$. Purser et al. [10] suggest that applying several times the same RF can improve the accuracy of the approximation. This fact could be seen as a consequence of the central limit theorem applied to the Gaussian convolution. This idea has been discussed and implemented in [3], [6] and [7] where the authors iteratively used the first-order RF (without e.c.) to solve a three-dimensional variational data assimilation problem. Here, we are interested in formalizing such an iterative approach.

A $K$-iterated $n$-order Gaussian RF filter computes the output signal $s^{(K)}$, i.e. the $K$-iterated approximation of $s^{(g)}$, as follows:

$$p_j^{(k)} = \beta s_j^{(k-1)} + \sum_{t=1}^{n} \alpha_t p_{j-t}^{(k)}, \qquad j = -\infty, \ldots, +\infty, \quad (18)$$

$$s_j^{(k)} = \beta p_j^{(k)} + \sum_{t=1}^{n} \alpha_t s_{j+t}^{(k)}, \qquad j = -\infty, \ldots, +\infty. \quad (19)$$

The filter iteration counter $k$ goes from 1 to $K$, where $K$ is the total number of filter iterations. For $K > 1$, the problem of triggering the advancing filter at iteration $k = 2, \ldots, K$ can be faced with the same strategy used to generate the (right) end conditions for a classic RF ($K = 1$). Assuming indeed that, at the iteration $k$:

$$\begin{aligned} p_{-n+1}^{(k)} &= p_{-n+2}^{(k)} = \ldots = p_0^{(k)} = 0, \\ s_{N+1}^{(k)} &= s_{N+2}^{(k)} = \ldots = s_{N+n}^{(k)} = 0, \end{aligned} \quad (20)$$

and rearranging the equations (12) and (13), it results:

$$\vec{p}_1^{(k)} = M \vec{s}_1^{(k-1)}, \quad (21)$$

with $M$ as in (17). Similarly, the backing filter, for iterations $k = 2, \ldots, K$, can be triggered by setting

$$\vec{s}_N^{(k)} = M \vec{p}_N^{(k)}. \quad (22)$$

The smoothing coefficients depend on $\sigma$, $n$ and even on $K$. The correct setting of the smoothing coefficients is crucial for the convergence. We remark that, in the Fourier domain, the Gaussian convolution in (1) becomes

$$S^{(g)}(\omega) = G(\omega, \sigma) \cdot S^{(0)}(\omega), \tag{23}$$

where

$$S^{(g)}(\omega) = \Big(\mathcal{F}\big(s^{(g)}\big)\Big)(\omega), \qquad S^{(0)}(\omega) = \Big(\mathcal{F}\big(s^{(0)}\big)\Big)(\omega)$$

and

$$G(\omega, \sigma) = \Big(\mathcal{F}(g)\Big)(\omega) = \exp\left(-\frac{\omega^2\sigma^2}{2}\right)$$

are the Fourier Transforms of the signals $s^{(g)}$, $s^{(0)}$ and $g$, respectively. Rewriting (23) as:

$$S^{(g)}(\omega) = \left(G\left(\omega, \frac{\sigma}{\sqrt{K}}\right)\right)^K \cdot S^{(0)}(\omega), \tag{24}$$

we obtain, in the signal domain, that $s^{(g)}$ can be seen as the result of $K$ successive Gaussian convolutions with an identical Gaussian function with a standard deviation:

$$\sigma_K = \frac{\sigma}{\sqrt{K}}.$$

This argument suggests that $\sigma_K$ must replace $\sigma$ in the expression of the smoothing coefficients of a $K$-iterated RF. For example, the smoothing coefficients $\alpha$ and $\beta$ of the (one-iterated) first-order Gaussian RF, in the homogeneous case, are set as:

$$\alpha = 1 + E_\sigma - \sqrt{E_\sigma(E_\sigma + 2)}, \qquad \beta = \sqrt{E_\sigma(E_\sigma + 2)} - E_\sigma. \tag{25}$$

with

$$E_\sigma = \frac{1}{\sigma^2}.$$

Then, for the $K$-iterated first-order Gaussian RF, the value of $E_\sigma$ must be replaced by:

$$E_{\sigma_K} = \frac{1}{\sigma_K^2} = \frac{K}{\sigma^2}.$$

**Example 3.** To see the behaviour of such a $K$-iterated filter, we apply it to a random input signal with support in $\{1, 2, \dots, 30\}$. In Figure 5, the RF output signals for three different values of the number iterations ($K = 12, 25, 50$) are reported. The results show that, despite the fact that the accuracy on the central entries does not seem to change, the edge effects reappear when the number of filter iterations increases. In particular (see Figure 6), the relative errors $e_j$, defined as in (9), increase both in the left and right boundary entries as $K$ increases. Conversely, the convergence to the Gaussian convolution output signal may be observed by looking at the central entries of the errors in Figure 6. We highlight that, in the previous test, the end conditions (21) and (22) have been used. The fact that the e.c. do not work as expected, mostly at the edges, can be simply explained as a consequence of the wrong assumptions in (20).

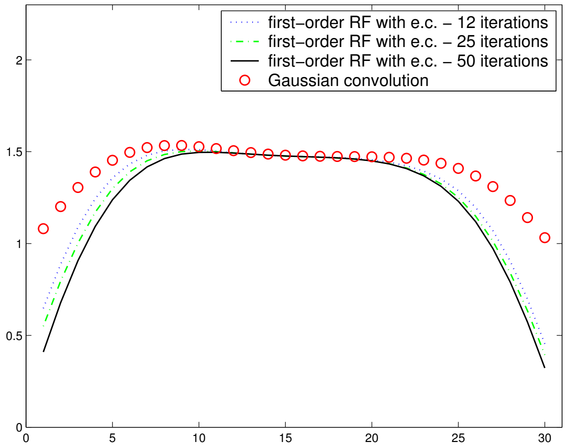

Fig. 5. Discrete Gaussian (red circles) versus first-order RF solutions with 12 iterations (dotted blue line), 25 iterations (dashdot green line) and 50 iterations (solid black line).

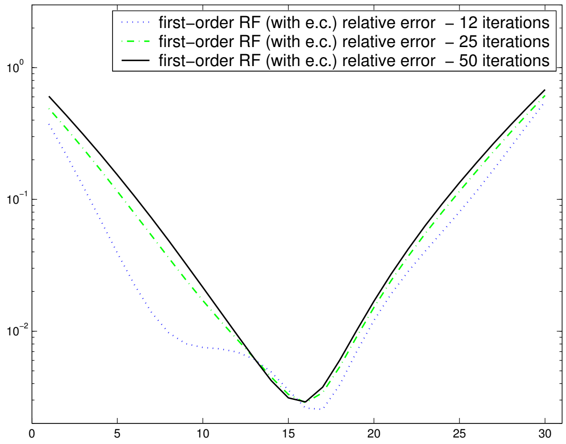

Fig. 6. First-order RF relative errors for 12 iterations (dotted blue line), 25 iterations (dashdot green line) and 50 iterations (solid black line).

Here, we suggest a scheme that allows the use of the $K$-iterated first-order Gaussian RF and prevents the edge effect. Our idea consists in three steps:

(i) *extending* the given input signal $s^{(0)}$, with support in $\{1, 2, \dots, N\}$, by adding artificial zero entries at the left and right boundaries. More specifically, we introduce the extended signal:

$$s^{(0),m} = \big(0, \dots, 0, s_1^{(0)}, \dots, s_N^{(0)}, 0, \dots, 0\big), \tag{26}$$

which is obtained by placing $m$ zeros before $s_1^{(0)}$ and $m$ zeros after $s_N^{(0)}$;

(ii) applying the $K$-iterated first-order Gaussian RF to $s^{(0),m}$;

(iii) reducing the output signal $s^{(K),m}$, by removing its first and last $m$ entries.

The underlying idea of that scheme is to shift the edge effects on the artificially added entries. Steps (i)-(iii) are summarized in the following algorithm. For the sake of simplicity, we consider the case of the first-order RF. Nevertheless, the same algorithm could be easily modified for any $K$-iterated $n$-order RF.

**Algorithm 2** Scheme of the $K$-iterated first-order recursive filter with end conditions

```
Input: $s^{(0)}, \sigma, m, K$      Output: $s^{(K)}$
extend $s^{(0)}$ to $s^{(0),m}$
set $s^{(0)} := s^{(0),m}$; $\beta, \alpha$ as in (25); $M := 1/(1+\alpha)$
for $k = 1, 2, \dots, K$                          % filter loop
    compute $p_1^{(k)} := M s_1^{(k-1)}$          % left end conditions
    if $k = 1$ then
        $p_1^{(k)} := \beta s_1^{(k-1)}$
    end
    for $j = 2, \dots, N$                         % advancing filter
        $p_j^{(k)} := \beta s_j^{(k-1)} + \alpha p_{j-1}^{(k)}$
    endfor
    compute $s_N^{(k)} := M p_N^{(k)}$            % right end conditions
    for $j = N-1, \dots, 1$                       % backing filter
        $s_j^{(k)} := \beta p_j^{(k)} + \alpha s_{j+1}^{(k)}$
    endfor
endfor
reduce $s^{(K)}$ as described in step (iii)
```

In the next section, through some numerical examples, it will be pointed out how the parameter $m$ has to be set, in order to obtain a satisfactory accuracy on the computed RF output signals, even at their boundary entries.

## IV. Numerical experiments

In this section, we present two experiments. The aim of the first test is to prove the effectiveness of **Algorithm 2** in removing the edge effects. In the second test, we show that a suitable value of $m$ can guarantee a negligible edge error, regardless of the filter number iterations $K$ and the size $N$ of the input signal.

### A. *Convergence at the edges*

We consider the random input signal of **Example 3.**. We use **Algorithm 2** varying both the number of iterations and the size of $s^{(0),m}$. More precisely, in Figure 7, we report the output signals obtained with $K = 12$ iterations and by extending the input signal $s^{(0)}$ with $m = 1, 3, 6$ zeros at each boundary. Figure 8 shows the results obtained with the same values of $m$ and increasing the number of iteration to $K = 25$.

Looking at Figure 7 and Figure 8, we observe that the edge effects seem to disappear as $m$ increases. Notice that, comparing the behaviour of the blue curves ($m = 1$), the results worsen as $K$ increases. This drawback can be avoided by suitably increasing the value of $m$. Figure 9 shows pictorially that, taking $m = 3\sigma = 12$, the accuracy is preserved also at the boundaries. Moreover, Figure 10 indicates that the component-wise convergence holds as $K$ increases.

### B. *Suitable choice of* $m$

In this test we measure the error $\|s^{(g)} - s^{(K)}\|_2$, where $s^{(K)}$ is the output signal obtained by applying the **Algorithm 2** to the random input signal $s^{(0)}$ of **Example 3.** varying the values of $m$ and $K$. The results summarized in Table I, for $\sigma = 4$, show that the convergence is reached, as $K$ increases, provided that $m \geq 2\sigma$. For $m \leq \sigma$ the convergence is not achieved due to the edge effects. We also note that increasing $m$ beyond $3\sigma$ does not improve significantly the accuracy.

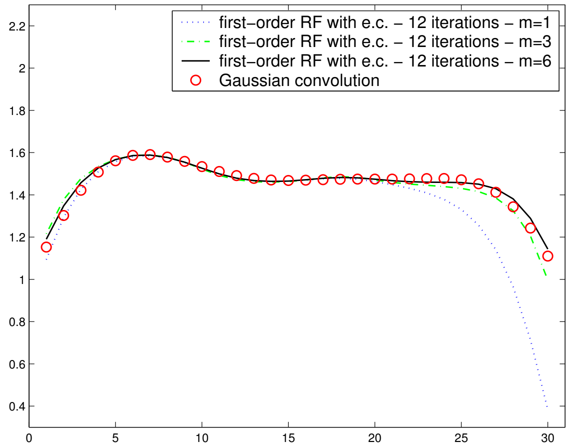

Fig. 7. Discrete Gaussian (red circles) versus first-order RF solutions with 12 iterations and $m = 1$ (dotted blue line), $m = 3$ (dashdot green line) and $m = 6$ (solid black line).

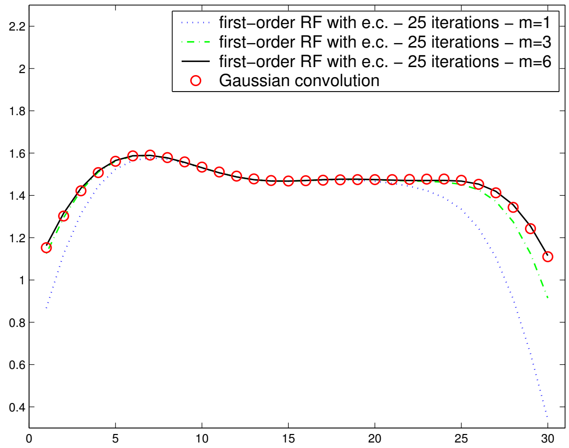

Fig. 8. Discrete Gaussian (red circles) versus first-order RF solutions with 25 iterations and $m = 1$ (dotted blue line), $m = 3$ (dashdot green line) and $m = 6$ (solid black line).

TABLE I
NORMS $\|s^{(g)} - s^{(K)}\|_2$ FOR SEVERAL VALUES OF $K$ AND $m$.
$\sigma = 4, N = 30$.

| $K \backslash m$ | $0.25\sigma$ | $0.5\sigma$ | $\sigma$ | $2\sigma$ | $3\sigma$ | $6\sigma$ |
|---|---|---|---|---|---|---|
| 5 | 9.85e-01 | 4.70e-01 | 1.00e-01 | 1.23e-01 | 1.42e-01 | 1.16e-01 |
| 15 | 1.14e+00 | 5.66e-01 | 7.75e-02 | 4.96e-02 | 6.00e-02 | 5.73e-02 |
| 30 | 1.19e+00 | 6.07e-01 | 8.14e-02 | 3.41e-02 | 3.48e-02 | 3.00e-02 |
| 50 | 1.23e+00 | 6.18e-01 | 8.61e-02 | 2.48e-02 | 2.49e-02 | 2.54e-02 |
| 100 | 1.26e+00 | 6.40e-01 | 9.09e-02 | 1.71e-02 | 1.70e-02 | 1.70e-02 |

Table II shows that the above results about convergence and accuracy hold true also for different values of $\sigma$. We remark

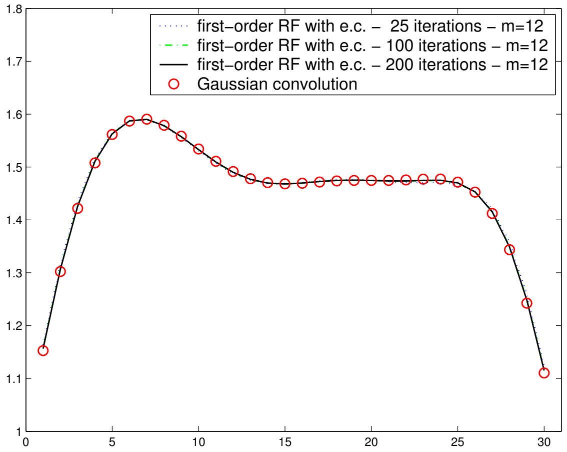

Fig. 9. Discrete Gaussian (red circles) versus first-order RF solutions with 25 iterations (dotted blue line), 100 iterations (dashdot green line) and 200 iterations (solid black line). $m$ is set to 12 and the computed solutions can not be distinguished.

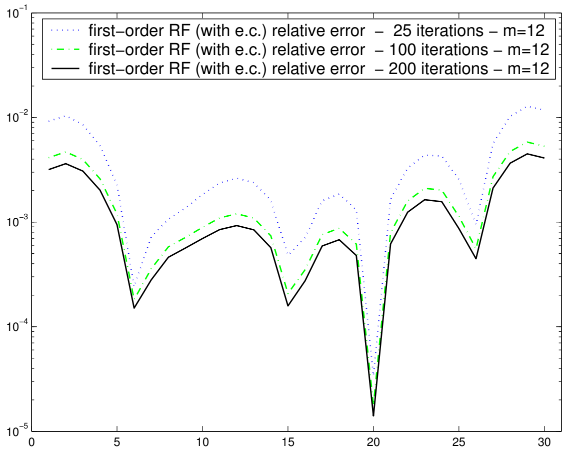

Fig. 10. First-order RF relative errors for 25 iterations (dotted blue line), 100 iterations (dashdot green line) and 200 iterations (solid black line).

that, for any fixed value of $K$, the value $m = 3\sigma$ represents a good trade-off between accuracy and efficiency.

TABLE II
NORMS $\|s^{(g)} - s^{(K)}\|_2$ FOR SEVERAL VALUES OF $K$ AND $m$.
$\sigma = 6, N = 30$.

| $K\backslash m$ | $0.25\sigma$ | $0.5\sigma$ | $\sigma$ | $2\sigma$ | $3\sigma$ | $6\sigma$ |
|---|---|---|---|---|---|---|
| 5 | 1.02e+00 | 4.88e-01 | 1.01e-01 | 1.13e-001 | 1.61e-001 | 1.18e-01 |
| 15 | 1.13e+00 | 5.63e-01 | 7.71e-02 | 4.57e-002 | 4.98e-002 | 5.43e-02 |
| 30 | 1.20e+00 | 6.02e-01 | 8.31e-02 | 3.24e-002 | 3.65e-002 | 3.48e-02 |
| 50 | 1.23e+00 | 6.21e-01 | 8.62e-02 | 2.31e-002 | 2.41e-002 | 2.30e-02 |
| 100 | 1.26e+00 | 6.42e-01 | 9.08e-02 | 1.64e-002 | 1.74e-002 | 1.65e-02 |

The results in Table III prove that the above conclusions do not depend on the size of the input signal.

## V. CONCLUSIONS

In this paper, we have discussed a way to overcome the edge effect in $K$-iterated Gaussian RFs, by a suitable choice of the end conditions. We have introduced an algorithm that implements the described approach. We have shown by means of several numerical experiments the effectiveness of the proposed $K$-iterated scheme. Finally, we have discussed in detail several issues related to the suitable choice of the parameter of our method.

***Abstract*—We propose to use a randomization technique based on Random Butterfly Transformations (RBT) in the Algebraic Recursive Multilevel Solver (ARMS) to improve the preconditioning phase in the iterative solution of sparse linear systems. We integrated the RBT technique into the parallel version of ARMS (pARMS). The preliminary experimental results on some matrices from the Davis' collection show an improvement of the convergence and accuracy of the results when compared with existing implementations of the pARMS preconditioner.**

## I. Introduction

With the evolution of recent computer architectures, the growing gap between communication and computation efficiency makes communication very expensive (at a cost of one communication we can generally perform thousands of arithmetical operations). This requires the rethinking of most of numerical libraries in order to take advantage of current parallel architectures which are commonly based on multicore processors [1], possibly with accelerators [2], such as Graphics Processing Units (GPU) or Intel Xeon Phi.

In this work we are concerned with the solution of linear systems $Ax = b$ where $A$ is an $n \times n$ real matrix (dense or sparse), $b$ is a real n-vector and $x$ is the n-vector of unknowns. This operation is at the heart of many applications in high-performance computing (HPC) and is usually solved using either direct or iterative methods.

Direct methods [3] usually solve a linear system of equations $Ax = b$ using factorization techniques depending on the properties of the original matrix $A$. For a general system, we compute an $LU$ factorization of $A$ that decomposes the input matrix $A$ into the product $L \times U$, where $L$ is a lower triangular matrix and $U$ is an upper triangular matrix. When $A$ is positive definite, then we decompose the matrix $A$ into the product $A = L \times L^T$ (Cholesky decomposition, which requires half the number of flops of the $LU$ factorization). In both cases ($LU$ or Cholesky), the solution is then obtained by solving successively 2 triangular systems.

Another possibility to solve $Ax = b$ is to use an iterative method to compute an approximate solution. These methods involve passing from one iteration to the next one by modifying one or a few components of an approximate vector solution at a time. Classical examples of iterative methods are the Jacobi, Gauss-Seidel, Successive Over-Relaxation (SOR), or Krylov subspace methods [4].

The Algebraic Recursive Multilevel Solver (ARMS) is one of the solvers which applies the iterative Krylov subspace methods in sparse linear systems, it relies on multilevel partial elimination. The preconditioning separates the entries into two parts, the first part called fine set which is composed of block independent set, and the second part called coarse set which contains the rest of the entries. The coarse set can be used to built the Schur complement, which allows us to perform a block $LU$ factorization. The inter-level $LU$ factorization can be built from the upper level $LU$ factorization and the fine set, up to the first level.

Parallel ARMS (pARMS) is a distributed-memory implementation of ARMS, which relies on distributed group independent sets. It provides a set of standard preconditioners such as Additive Schwartz, Schur complement and Block Jacobi, which allow to run performance tests.

When solving square linear systems $Ax = b$ using Gaussian elimination (e.g., in $LU$ factorization), we commonly use partial pivoting to avoid having zero or too-small numbers on the diagonal. This technique is implemented in current linear algebra libraries and ensures stability [5]. However, partial pivoting requires communication (search for pivots, swapping of rows). For example, on a hybrid CPU/GPU system, the $LU$ algorithm in the MAGMA library [2] spends more than 20% of the factorization time in pivoting even for a large random matrix of size 10, 000 × 10,000 [6].

As an alternative to pivoting, an approach based on randomization called Random Butterfly Transformation (RBT) [7] was recently revisited. Following the RBT method, $A$ is transformed into a matrix that would be sufficiently random to avoid pivoting (with a probability close to 1). RBT is a random transformation of $A$ which can avoid pivoting and then can reduce the amount of communication. We can obtain

satisfying accuracy with an additional computational cost, which is negligible compared to the cost of factorization. This method has been successfully applied to dense linear systems for either general [6] or symmetric indefinite [8] systems, in the context of direct methods based on matrix factorization.

In this work we want to study the possibility of using RBT in iterative linear system solvers based on Krylov Subspace methods, which are widely used in physical and industrial applications.

This paper is organized as follows. Section II presents the preconditioned Krylov subspace method (PKSM) and the parallel Algebraic Recursive Multilevel Solver (pARMS) for solving sparse linear systems. Section III explains how randomization through Random Butterfly Transformation can be integrated into pARMS. For the obtained solver, Section IV proposes performance and accuracy results. Conclusions are presented in Section V.

## II. Preconditioned Krylov Methods and the pARMS Solver

### A. Preconditioned Krylov Methods

A preconditioned Krylov subspace method (PKSM) is used to solve the linear system $Ax = b$, where $A$ is square non-symmetric matrix, in general. If $M$ is a preconditioning matrix, then the right-preconditioned system is may be expressed as:

$$AM^{-1}y = b, \text{ where } y = Mx \ , \tag{1}$$

which is solved instead of the original system $Ax = b$. To solve this system by using iterative methods, first, we compute the residual $r_0 = b - Ax_0$ [9] after initializing $x_0$, then we may use a right-preconditioned Krylov subspace method to find an approximate solution from the affine subspace [10]:

$$x_m = x_0 + \text{span}\{r_0,\ AM^{-1}r_0, \ldots, (AM^{-1})^{m-1}r_0\} \ , \tag{2}$$

which satisfies certain conditions. For instance, the GMRES algorithm [4] requires that the residual $r_m = b - Ax_m$ has a minimal 2-norm. The flexible GMRES is abbreviated as FGMRES [4]. Its implementation differs from that of GMRES mainly in storing the preconditioned vectors $z_j = M_j^{-1}v_j$ because the relation $AZ_m = V_{m+1}\bar{H}_m$ is used instead of a simpler one $(AM^{-1})V_m = V_{m+1}\bar{H}_m$ from GMRES.

One way to obtain the preconditioning matrix $M$ is to use an incomplete $LU$ (ILU) factorization. ILU is constructed by performing an approximate Gaussian Elimination (GE) [11] on a sparse matrix $A$ and dropping certain nonzero entries of the factorization according to different dropping strategies. A dropping strategy that relies on levels of the matrix fill-in results in a factorization called $ILU(K)$.

The preconditioner $ILU(0)$ is obtained by performing the $LU$ factorization of $A$ and dropping all fill-in elements generated during the process. Conversely, if the nonzeros are dropped according to their numerical value magnitudes, then the resulting factorization is called $ILU$ with the threshold or—if combined with the dropping strategy based on the number of remaining nonzero—with dual threshold ($ILUT$) and is performed as follows. In the algorithm $ILUT(k, \tau)$, there are two important rules. (1) If an element is less than relative tolerance $\tau_i$ ($\tau$ × the norm of the $i$th row), it is dropped. (2) Keep only the $k$ largest elements in the $L$ and $U$ parts of the row along with the diagonal element.

In this work, we use a preconditioner called Algebraic Recursive Multilevel Solver (ARMS) [12], which is based on a block incomplete $LU$ factorization with different dropping strategies. This block factorization consists of an approximate GE process separating the unknowns into two sets; and an idea of independent or "group independent" set is exploited to define the separation. Hence, the original linear system $Ax = b$ is permuted into the form:

$$\begin{pmatrix} B & F \\ E & C \end{pmatrix} \times \begin{pmatrix} u \\ y \end{pmatrix} = \begin{pmatrix} f \\ g \end{pmatrix} , \tag{3}$$

where the submatrix $B$ corresponds to group-independent set reorderings, thereby generating a block-diagonal matrix $B$ [13]. Thus, it is convenient to eliminate the $u$ variable to obtain a system with only $y$ variable. The coefficient matrix for the resulting "reduced system" is the Schur complement $S = C - EB^{-1}F$ [14]. A recursion can now be exploited, such that dropping is applied to $S$ to limit the fill-ins followed by the reordering of the resulting reduced system into the form (3) by using the group-independent set reordering again. This process is repeated for several levels of recursion until the Schur-complement system is small enough or until a maximum number of recursion levels is reached. Then, the last Schur complement may be solved by a direct or an iterative solver. Note that the sparsification of the Schur complement may be undertaken at each level of recursion, to keep down the preconditioning costs.

In this paper, we are interested in parallelizing the iterative methods rather than direct methods. There are two reasons can explicate our choices. First, the direct methods are scale poorly with problem size, when the problem size augment rapidly, the iterative methods are the only choice, which can compute the approximate solution of linear system $Ax = b$. Second, it is hard to parallelize the direct methods which need more space and time to compute, while iterative methods involve passing from one iteration to the next one by modifying one or a few components of an approximate vector solution at a time and it is easy to parallelize.

### B. Parallel Implementation of ARMS

Figure 1 outlines distributed linear system solution using pARMS [15]. First, the initial matrix $A$ is distributed among the processors, using a graph partitioning method. In Figure 1, each column of blocks depicts one processor, hence there are five processors shown. Second, each processor solves its part of the system in parallel to construct its portion of the global preconditioner. Then FGMRES solves the preconditioned system with a given accuracy.

When considering the parallel implementation, it is important to specify how the matrix is distributed and handled in parallel. In particular, our pARMS implementation partitions

the whole matrix on a single processor using a distributed site expansion (DSE) technique, which is rather simple yet effective in constructing well-balanced subdomains with small interfaces [16]. Although partitioning the entire matrix by a single processor lacks scalability, we note here that this is done by the driver routine, which may be adapted to an application matrix size and format at hand. Given a distributed matrix, Figure 2 shows the per-subdomain division of variables into internal, interdomain interface, and external (residing on the neighboring processors) sets.

We outline now three global preconditioners types available in pARMS: Block-Jacobi preconditioner (BJ), Schur complement preconditioner (SCHUR), and Schur-complement based Restrictive Additive Schwartz preconditioner (SchurRAS). BJ is the simplest global preconditioner because it does not take into account the interface information between neighboring subdomains [17]. SCHUR relates equations associated with the local and interdomain interface points [18]. SchurRAS is constructed from the local ARMS preconditioners in each subdomain using an overlap similar to a standard RAS preconditioner [19] and acting on the Schur complement system as shown in [20]. Specifically, for each of the three preconditioner types, the following algorithms may be implemented in each subdomain.

**BJ preconditioner**:
1. Update local residual: $r_i = (b - Ax)_i$,
2. Solve: $A_i \delta_i = r_i$,
3. Update local solution: $x_i = x_i + \delta_i$.

**SCHUR preconditioner**:
1. From (3) compute: $g_i' = g_i - E_i B_i^{-1} f_i$,
2. Solve: $S_i y_i + \sum_{j \in N_i} E_{ij} y_j = g_i'$, where $S_i = C_i - E_i B_i^{-1} F$ and $N_i$ is a set of neighboring subdomains,
3. Back substitute: $u_i$ with $B_i u_i = f_i - E_i y_i$.

**SchurRAS preconditioner**:
1. Compute local right-hand side $g_i'$.
2. Solve local Schur-complement system extended with rows for all external variables $y_{i,ext}$.
3. Back substitute: $u_i$ with $B_i u_i = f_i - E_i y_i$.

Note that the local solves in step 2 of BJ, SCHUR, and SchurRAS may be accomplished using incomplete $LU$ or ARMS procedures, mentioned in section II-A. In this work, we apply ARMS enhanced with Recursive Butterfly Transformations (RBT) in step 2 of SCHUR to alleviate the extra work associated with pivoting that may be required in the Schur-complement matrix $S_i$ due to its poor conditioning.

## III. Overview of Random Butterfly Transformations and Implementation

In this section we recall the main definitions related to RBT and how it can be applied to pARMS.

### A. Randomization

Random Butterfly Transformation (RBT) is a randomization technique initially described by Parker [7] and recently revisited in [6] for general dense systems and [8] for symmetric indefinite systems. It has also been applied recently to a sparse direct solver in a preliminary paper [21]. The procedure to solve $Ax = b$, where $A$ is a general matrix, using a random transformation and the $LU$ factorization is summarized in Algorithm 1. The random matrices $U$ and $V$ are chosen among a particular class of matrices called *recursive butterfly matrices*. A *butterfly matrix* is a *random* $n \times n$ matrix of the form

$$B^{<n>} = \frac{1}{\sqrt{2}} \begin{bmatrix} R_0 & R_1 \\ R_0 & -R_1 \end{bmatrix},$$

where $R_0$ and $R_1$ are random diagonal $\frac{n}{2} \times \frac{n}{2}$ matrices. A *recursive butterfly matrix* of size $n$ and depth $d$ is defined recursively as

$$W^{<n,d>} = \begin{bmatrix} B_1^{<n/2^{d-1}>} & & \\ & \ddots & \\ & & B_{2^{d-1}}^{<n/2^{d-1}>} \end{bmatrix} \cdot W^{<n,d-1>}$$

with $W^{<n,1>} = B^{<n>}$ where the $B_i^{<n/2^{d-1}>}$ are butterflies of size $n/2^{d-1}$, and $B^{<n>}$ is a butterfly of size $n$.

In the original work by Parker, $d = \log_2 n$; it is proved that, given two recursive butterfly matrices $U$ and $V$, the matrix $U^T AV$ can be factored into $LU$ without pivoting with probability 1 in exact arithmetic, or with probability $1 - O(2^{-t})$ using $t$-bit floating point numbers. RBT was extensively studied for dense matrices and it was shown in [6] that in practice, $d = 1$ or 2 is enough to obtain a satisfactory accuracy (in most cases a few steps of iterative refinement can recover the digits that have been lost). It has been showed that random butterfly matrices are cheap to store and to apply ($O(nd)$ and $O(dn^2)$ respectively) and they proposed implementations using the dense linear algebra PLASMA and MAGMA. As was demonstrated in the related papers, the preprocessing by RBT can be easily parallelized and provides good scalability.

**Algorithm 1** Random Butterfly Transformation Algorithm

```
  Generate recursive butterfly matrices $U$ and $V$
  Perform randomization to update the matrix $A$ and obtain
  the randomized matrix $A_r = U^T AV$
  Factorize the randomized matrix with no pivoting [22]
  Compute $U^T b$ and solve $A_r y = U^T b$, then $x = Vy$
```

### B. Integration of RBT into pARMS

We describe in this section how Random Butterfly Transformations can be integrated into pARMS. Our goal is to find the last level of preconditioning and then replace the original $ILUT$ factorization by the RBT pre-processing. Note that RBT usually concerns dense linear systems, while ARMS addresses sparse linear systems. So we have to convert the last Schur complement which is a sparse matrix into a dense format, and after that we can use RBT. Then after randomizing the last Schur complement $A$ with recursive butterfly matrices $U$ and $V$, the dense matrix is factorized using a Lapack-like [23] routine that performs Gaussian elimination without pivoting, followed by two triangular solves. Note that RBT requires the size of the matrix to be a power of 2, which can be obtained by "augmenting" the matrix $A$ with additional 1's on the diagonal.

The pARMS solver manages the parallel part by using global preconditioning with MPI instructions, while the local part of the code, more precisely the local preconditioning phase does not use MPI instructions. Then the parallelism is entirely managed by pARMS. The local preconditioning can be based on $ilu0$, $iluk$, $ilut$ or $arms$. The essential part resides in the last Schur complement, where we implemented RBT and the preconditioned matrix is then used in FGMRES in order to solve the linear system.

## IV. Numerical Experiments

This section describes preliminary results obtained by integrating RBT into the pARMS solver. The experiments have been carried out using one node (2 twelve-core AMD MagnyCours Opteron 6172 processors running at 2.10GHz) of the Hopper machine located at NERSC[1]. In these experiments, we used matrices from the Davis' collection [24] to test the performance of different preconditioners. The first matrix (`Sherman5`) is a real non-symmetric matrix of size $3,312$ ($nnz$ = 20,793). `Sherman5` arises from a three dimensional simulation model on a $n_x \times n_y \times n_z$ grid using a seven-point finite-difference approximation with $n_c$ equations and unknowns per grid block, where $n_x$ is 16, $n_y$ is 23, $n_z$ is 3, $n_c$ is 3. The second matrix (`Raefsky3`) is a real non-symmetric matrix of size $21,200$ ($nnz$ =1,488,768), which arises from a fluid structure interaction turbulence problem. The third matrix (`Cant`) is a real symmetric matrix that comes from a 2D/3D FEM problem, of size 62,451 ($nnz$ = 2,034,917). For the three matrices, we study the results obtained when using a global Schur complement-based preconditioner with the following local preconditioners: $ilu0$, $iluk$, $ilut$, $arms$, or $arms\_rbt$. The pARMS parameters are chosen for these matrices following the guidance for the local ARMS preconditioner, as explained in [12], for example. Certain parameters influence considerably the size and density of the last Schur Complement, which, in turn, affects greatly the performance of RBT. Since the RBT for dense matrices is used in this work, it is desirable that the last Schur Complement remains dense while being

[1] http://www.nersc.gov

relatively small. Hence, parameter values for the number of ARMS levels and the ARMS independent block size were chosen such that a small Schur Complement is obtained. In particular, the former parameter was small (equals two) while the latter was large (allowing to form the blocks up to the entire local matrix size). At the same time, the drop tolerance for the last Schur Complement was kept quite low (0.001) as well as all the other intermediate-level drop tolerances, so that there is close to none sparsification of the Schur Complement.

The experiments are performed using 4 to 12 cores, and we use one MPI process per core and no multi-threading. In Figure 3, we compare the number of iterations required for convergence. We observe that, for matrices `Sherman5` (fig. 3(a)), `Raefsky3` (fig. 3(b)), $arms\_rbt$ performs better than the other local preconditioners. For `Cant`, $arms\_rbt$ converges in fewer iterations than the other preconditioners do so when using up to eight cores. This observation suggests that $arms\_rbt$ may be a more versatile preconditioner to use for obtaining superior convergence. Note that, for different numbers of subdomains (one per MPI process) in a given matrix, the obtained parallel preconditioning varies leading to the differences in the number of iterations to converge. Note that for these preliminary tests, $arms\_rbt$ requires more time to solve the system since, in our preliminary implementation, a dense-matrix solver was used to solve the last Schur complement system in pARMS. In the future, we plan to develop a sparse RBT solver based on a sparse direct solver, such as SuperLU [25]. Figure 4 represents the residual obtained with the five local preconditioners. We observe that these preconditioners provide us with a similar accuracy, $arms\_rbt$ being more accurate for the matrix `Raefsky3`.

## V. Conclusion and Future Work

We have investigated the feasibility of using RBT randomization in the pARMS solver and how RBT may enhance the iterative convergence. Most of our experiments showed an improvement in the number of iterations and accuracy of results. However, our integration of RBT in pARMS necessitates an implementation that may adjust the sparsity of the last Schur complement matrix based on the available memory and on the performance characteristics of its (direct) solver at hand. As a future work, we will integrate a sparse RBT direct solver based on SuperLU, which will also enable us to solve large-scale sparse linear systems.

***Abstract*—The block preconditioned conjugate gradient method for extraction of eigenfrequencies and eigenmodes is presented for finite element software in structural analysis. The proposed approach is focused on multi-core desktops and laptops and allows us to effectively analyze large design models, when classical methods based on the factoring of stiffness matrix, significantly reduce performance by intensive use of disk memory. The main attention is paid to proper construction of preconditioning, application of shift technique and creation of the block algorithm allowing the improvement of computing stability and multithreaded parallelization.**

## I. Introduction

CURRENTLY, the vast majority of methods for determining the frequency and modes of natural oscillations in finite element software, usually based on factorization of stiffness matrix **K** or matrix $\mathbf{K}_\sigma = \mathbf{K} - \sigma\mathbf{M}$, where **M** is a mass matrix and σ is a shift.

However, if the dimension of the problem becomes large, the factored matrix does not fit in memory and is written to disk. Thus on each iteration in Lanczos method or in subspace iteration method it is necessary to read the factored matrix from a disk twice when performing forward and back substitutions. The performance of the specified methods considerably degrades because the task is carried out at an intensive use of a disk. Especially sharply this problem becomes when desktops and laptops with usually small amount of core memory are used.

It would seem the alternative approach consists in application of conjugate gradient method or steepest descent method for solution of the generalized algebraic eigenvalue problem to which the natural vibration problem is reduced when using the finite element method. The [13] presents survey of some other approaches using preconditioning technique. However, application of such methods to problems of structural mechanics usually results in to the slow convergence of the iterative process. Often there is a locking of convergence of numerical solution owing to a wide scattering of stiffness in design model, existence of a large number of close natural vibration frequencies etc. This is confirmed by the fact that the widely used commercial FEA software offer a wide selection of iterative solvers for static analysis, which leads to solving systems of linear algebraic equations. However for the solution of the generalized algebraic eigenvalue problem as a rule are used the methods based on factorization of a stiffness matrix. The exception is ANSYS in which the preconditioned conjugate gradient method is applied for generation of Lanczos vectors. The survey of existing software packages devoted to solution of algebraic eigenvalue problems in technical and scientific applications is in [10].

In this article, we confine ourselves to consideration of the methods applying to a class of problems, difficult for numerical realization, – to the large problems of structural mechanics arising when the finite element method is used to modeling of tall buildings and constructions. We present the preconditioned conjugate gradient (PCG) method for solution of partial generalized algebraic eigenvalue problem – extraction of natural vibration frequencies and modes

$$\mathbf{K}\mathbf{v}_i - \lambda_i \mathbf{M}\mathbf{v}_i = 0 \tag{1}$$

where **K** is a symmetrical positive definite stiffness matrix, **M** is a mass matrix, $\lambda_i$ and $\mathbf{v}_i$ is an eigenpair, $i \in [1, n]$, $n << N$, $N$ is dimension of problem.

For ensuring sustainable convergence of method, we paid the main attention to designing of an effective preconditioning, use of shift technique and creation of a block algorithm of PCG method. In addition, we used the multithreaded parallelization to accelerate computations.

## II. Block Preconditioned Conjugate Gradient Solver

### A. Sparse incomplete Cholesky conjugate gradient preconditioning

The problems of structural mechanics often demonstrate the slow convergence due to using of different types of finite elements, thin-walled finite elements of floors, roofs and walls, considerable scattering of stiffness etc. [15]. Therefore, it is crucial to construct the effective preconditioning for accelerating of convergence of the PCG method.

We use an incomplete Cholesky factoring "by value" approach, based on sparse matrix technique [6], allowing to keep a small value of drop parameter ψ ($\psi \in [10^{-9}, 10^{-20}]$). The small entries $\mathbf{H}_{ij} < \psi \cdot \mathbf{H}_{ii} \cdot \mathbf{H}_{jj}$ erasing on each step of

978-83-60810-66-8/$25.00©2015, IEEE

triangular solution procedure practically does not depend on number of threads. The duration of triangular solution for considered class of problem of structural mechanics, requiring a preconditioner of high ability to improve of convergence, is essentially larger than duration of **Kv** and other remaining procedures. Therefore, namely this procedure should be accelerated firstly. However, it is a large problem on SMP multicore computers [6].

Table IX depicts results obtained by non-block sequential PCG eigenvalue solver presented in [3], [4].

TABLE IX
PROBLEM 1. NAÏVE SEQUENTIAL APPROACH. COMPUTER A (AMD OPTERON 6276, 64 GB RAM)

| np | Time of K*v | Time of B*z = r → z | Time of iterations, s | Nos of iterations |
|---|---|---|---|---|
| PCG with shift correction over each 100 iterations ($k_{max}$ = 100) | | | | |
| 1 | 326 | 6107 | 7601 | 1144 |

This method uses naïve algorithms of matrix vector product and triangular solution, taking into account only symmetry of sparse matrices. Besides, the loop unrolling is used in triangular solution procedure.

Comparison between Tables VIII and IX show that the application of the matrix vector product procedure in the Intel MKL runs up to 3 times faster. However, the procedure of a triangular solution of Intel MKL is slower than naïve. This leads to the fact that the naïve sequential PCG method solves the problems of this class faster.

The problem with acceleration of triangular solution procedure does inefficient the approach based on internal parallelization of leading procedures of PCG method.

## III. CONCLUSION

The block conjugate gradient method with shifts in sparse incomplete Cholesky factorization preconditioning is proposed for extraction of lower eigenpairs applying to natural vibration problems arising due to application of finite element method to problems of structural mechanics.

On examples of typical problems of structural mechanics, it is shown that on achievement of high computing stability of a method the specific construction of a preconditioning, introduction of shifts to a preconditioning, and iterations in the block have a crucial importance.

The comparison with shifted block Lanczos method based on parallel sparse direct solver PARFES shows that proposed SBPCG method may be very efficient on computers with restricted amount of core memory, when factorized stiffness matrix block-by-block is stored on disk. In such a situation, the proposed SBPCG method in contrast to Lanczos method runs in core memory.

Department of Physics and Applied Informatics,
Faculty of High-Energy Astrophysics,
90-236 Łódź, Pomorska 149, Poland
Email: dariusz.glas@uni.lodz.pl

***Abstract*—The Linear Predictor (LP) is a finite impulse response adaptive filter using linear prediction to suppress radio frequency interferences (RFI) in the Auger Engineering Radio Array (AERA). AERA focus on the electromagnetic part of the Extensive Air Showers. The electromagnetic part of the shower produces radio signals in geomagnetic radiation and charge excess processes. Due to the reflection of the atmosphere AERA radio stations can observe these signals in the frequency band 30 - 80 MHz. This frequency range is contaminated by narrow-band and other human-made RFI. To suppress these contaminations AERA uses two kind of filters: the Median filter and the infinite impulse response - notch filter, however both of them have disadvantages. LP is a new approach in real-time signal filtering. Laboratory and pampas tests show fast adaptation, acceptable power consumption and very good efficiency of the LP filter.**

## I. Introduction

THE radio emission detection of extensive air showers is widely used in many experiments all over the world [1] [2]. The experiment, which focus on this task within the Pierre Auger Observatory (PAO) [3] is the Auger Engineering Radio Array (AERA) [4].

When ultra-high energy cosmic ray (UHECR) reaches the Earth's atmosphere it produces avalanches of secondary particles, called air showers. The study of the air shower allows understanding the mass of primary particle, its energy and incoming direction. These data help to understand emission mechanisms and help to find sources of the UHECR.

The Earth's magnetic field can deflect the trajectory of electrons and positrons generated in the air shower. This process generates a synchrotron radiation, which can be detected by radio stations [5] [6] [7]. Charged particles are concentrated in a thin disk in front of the shower. The coherent emission from this disk is up to 100 MHz. The frequency band from 30 to 80 MHz was chosen due to the reflection of the atmosphere. The noise in this frequency range consists of galactic noise, human made continuous contamiantions and machine generated transients.

Radio detectors, installed in AERA radio stations have high angular resolution and their duty cycle is nearly 100%. Moreover, they are sensitive to the evolution of longitudal air-showers and the total cost of their instalation and work is relatively low. Data taken by radio stations are next digitized by 12bit 200 MHz analog-to-digital converter and processed in real time by FPGA chip. The triggering depends on a signal shape, so it requires good-quality data. The filtering of the signal is crucial.

## II. Mathematical background

The Linear Predictor (LP) is an adaptive finite impulse response (FIR) filter based on the linear prediction. If the periodic signal is hidden in data, we can use several data samples (stages of the filter) to predict how it would look like in the future [8]. Next, we can subtract the predicted periodic signal from the original one, to get the clean data. The graphical presentation of this process is shown on fig. 1.

If the $s(i)$ represents the continuous stream of data samples, the $a_n$ are the filter coefficients and $e(i)$ is cleaned signal, we can describe the LP filter as:

$$e(i) = s(i) - \sum_{n=1}^{p} a_n s(i - D - n), \tag{1}$$

where $p$ is the number of used data samples and simultaneously number of the coefficients of the LP filter, $D$ is the delay between data we used for prediction and data we want to predict. This delay is necessary to minimize the distortion of the transient signals. It would be discussed later. The predicted signal $\hat{s}(i)$ can be described as:

$$\hat{s}(i) = \sum_{n=1}^{p} a_n s(i - D - n). \tag{2}$$

We can find the optimal solution of the coefficients by

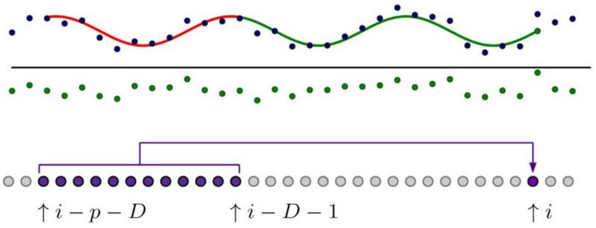

Fig. 1. Graphical illustration of algorithm of the LP filter. Several stages of data are used to predict how the periodic signal hidden in data will look like in the future (above the line). Filtered signal (below the line) is received after subtraction predicted signal form the original one.

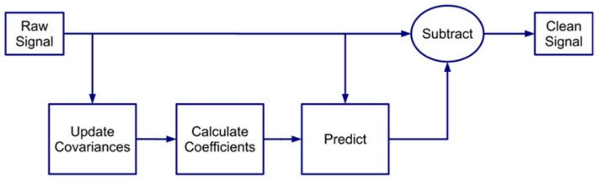

Fig. 2. Schematics showing the LP filter data flow in FPGA. After updating covariance matrix, coefficients can be found by solving a system of linear equations. Prediction step is just summing the products of the coefficients and delayed data. This predicted signal is used for subtraction from original data samples, to get filtered signal.

assuming the Gaussianity and calculating the estimated mean square error:

$$E = \frac{1}{N}\sum_{i=0}^{N-1} e^2(i) = \frac{1}{N}\sum_{i=0}^{N-1}(s(i)-\hat{s}(i))^2, \qquad (3)$$

where $N$ is number of data samples used for calculation of the covariance matrix. In our tests we used $N = 1024$. The next step in finding the best values of coefficients is the minimization of the mean square error, by derivating it with respect to every coefficient and comparing the result to zero:

$$\frac{\partial}{\partial a_i}E = 0. \qquad (4)$$

As a result we get the system of $p$ equations:

$$\sum_{i=0}^{N-1} s(i-D-n)s(i) = \sum_{i=0}^{N-1}\sum_{m=1}^{p} a_m s(i-n)s(i-m). \qquad (5)$$

We can rewrite this equation in vectorial form:

$$\overrightarrow{r^*} = \boldsymbol{R}\vec{a}, \qquad (6)$$

where $\vec{a}$ is vector of the coefficients and $\overrightarrow{r^*}$ is defined as follows:

$$r^*(n) = \sum_{i=0}^{N-1} s(i-D-n)s(i). \qquad (7)$$

**R** is the covariance matrix described as:

$$R(m,n) \equiv \sum_{i=0}^{N-1} s(i-n)s(i-m). \qquad (8)$$

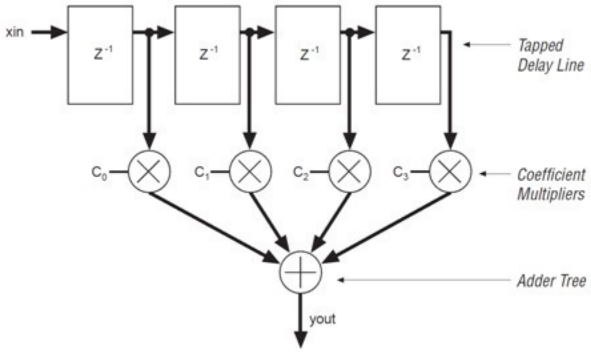

Fig. 3. Schematics of prediction step. Delayed data are multiplied by proper coefficients. Products are summed by several steps of accumulation.

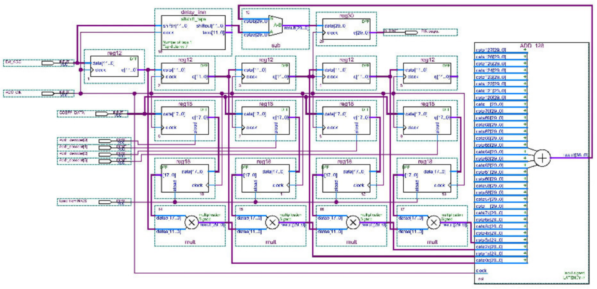

Fig. 4. Fragment of fast logic block connections required for the prediction step.

This matrix is symmetric and diagonal-constant (Toeplitz matrix). The system of linear equations consisting on the Toeplitz matrix can be solved using Levinson procedure instead of Gauss-Jordan elimination. The Levinson procedure algorithm runs in $o(n^2)$ time, which is significant improvement in comparison to Gaussian algorithm, which runs in $o(n^3)$.

## III. FPGA IMPLEMENTATION

Fig. 2 shows the FPGA data flow of the LP filter. The 1024 ADC samples are used to build the covariance matrix. This step can be done either in the virtual processor NIOS® or in fast logic blocks. The creation of the matrix and the $(\overrightarrow{r^*})$ vector in fast logic requires the delay line to get $s(i-D-n)$, the multiplier to get the partial terms and the accumulator. The covariance matrix can be created in fast logic blocks in time of 5 $\mu$s, when in the NIOS® it can be done in several tens of ms. The main reason of this is relatively slow data transfer to the NIOS®. When virtual processor NIOS® receives the data, it sends the signal, that it is ready to receive the next data and the address of this data in DPRAM. This process is very time consuming. Moreover, the NIOS® processor can work with maximal frequency only 100 MHz (80 MHz for tests). The fast logic works with 200MHz clock and can be used in situations, when time is an important factor.

The calculation of the LP coefficients is the most time consuming step in the refreshing of the LP filter. It cannot be done in the fast logic due to a complexity of the task,

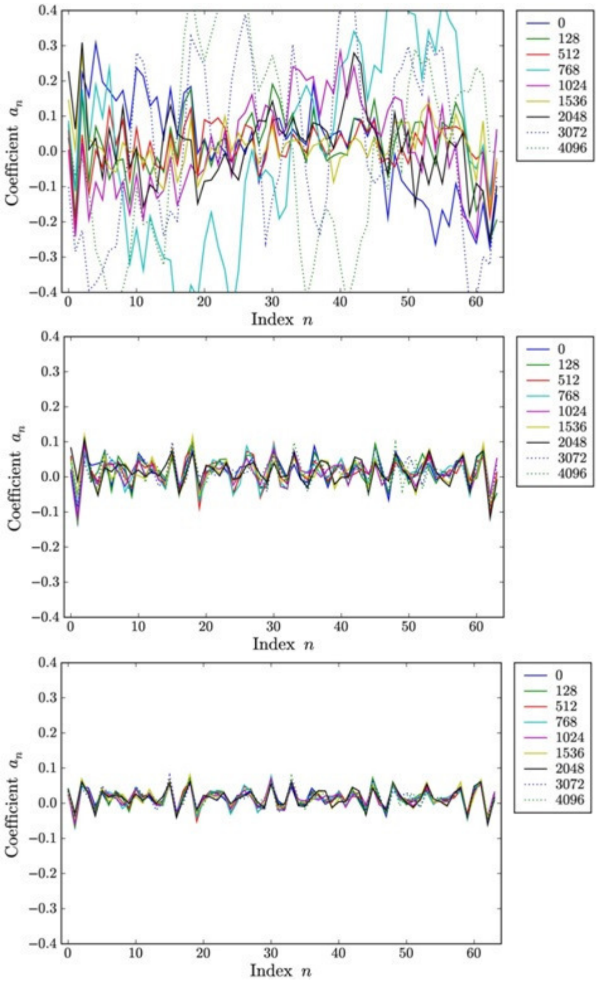

Fig. 5. Stability of the calculated coefficients. Upper plot shows the situation when the determinant of the covariance matrix is close to zero. After introducing the fudge factor $f$ coefficients are stabilized slightly (middle graph $f$=0.1). For $f$=1 (bottom plot) the stabilization is the best.

but it can be done in the virtual processor NIOS®. This step consists in solving the vectorial equation (eq. 6) and highly depends on the number of coefficients and the method used for solving. The Levinson method needs 191 ms for solving the 64x64 covariance matrix, when the Gauss elimination for the same task requires almost 2 seconds. For solving the 128x128 covariance matrix Levinson procedure needs 760 ms and Gauss elimination almost 15 seconds.

Results of both methods are the same. After the calculation, coefficients are transferred from the NIOS® to fast logic temporary registers one by one, which requires at least $p$ clock cycles, where $p$ is the number of the coefficients. When all coefficients are transferred to temporary registers, they are reloaded in one clock cycle to destination registers. This step is required to avoid the situation, when some of coefficients are ”old” and some are ”new”.

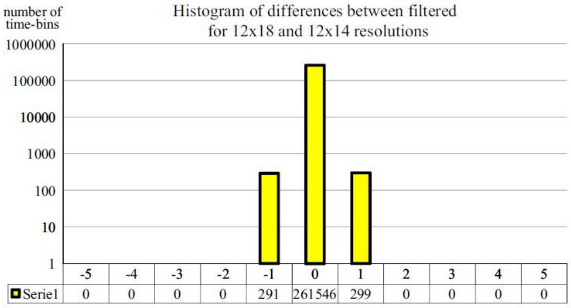

Fig. 6. Histogram of differences between 12x14 and 12x18 resolutions. Differences shows only on the LSB and are on the level of 0.01%.

The prediction step consists in summing multiplications of coefficients and delayed data (eq. 2). This step is done in FPGA fast logic. Data are delayed to get $s(i-D-n)$ and next they are multiplied by an appropriate coefficient. This product is next added in several steps to get the predicted, periodical signal, hidden in the original data. Fig. 3 shows the schema of this process and fig. 4 shows fast logic blocks connections required for calculations. The prediction step can work continuously, because it does not require the gap to update the coefficients. After the prediction we just have to subtract the predicted, periodic signal from the original one to get the clean data.

## IV. Optimization of the LP filter

The stability of the coefficients in time is shown on the fig. 5. The instability of the coefficients seen in the first plot is caused by the specific situation, when determinant of the covariance matrix is close to zero. To avoid this situations we introduce the fudge factor ($f$) and change the covariance matrix:

$$\tilde{R}_{nn} = (1+f)\cdot R_{nn}$$

$$\tilde{R}_{mn} = R_{mn} \text{ for } m \neq n$$

Middle and bottom graphs show the stabilization of the coefficients for $f$=0.1 and $f$=1 respectively. The stabilization is the best for The next specific parameter is the width of coefficients data. The algorithm of the LP filter requires multiplications of coefficients and data from the ADC. The dedicated multiplier requires the different number of DSP blocks, depending on data width. Single DSP block can be used if ADC data width and coefficients width are maximally 9 bits, however data received from the ADC is 12 bits. This implicates the multiplier must use at least 2 DSP blocks. Using 2 DSP blocks allow to multiply 12 bit data with maximally 18 bit coefficient. The 18 bit accuracy of coefficients is not necessary, so it can be reduced to 14 bits without special loses in the efficiency. Differences between those two cases for the filtered signal are only on the LSB and appear to be on the level of 0.01% (fig. 6). Moreover, the reduction from 18 to 14 bits reduces by ~30mW the power consumption. The further reduction of the coefficients width (to 12 bits) increases differences to the level of 1%. The reduction of the power consumption is only

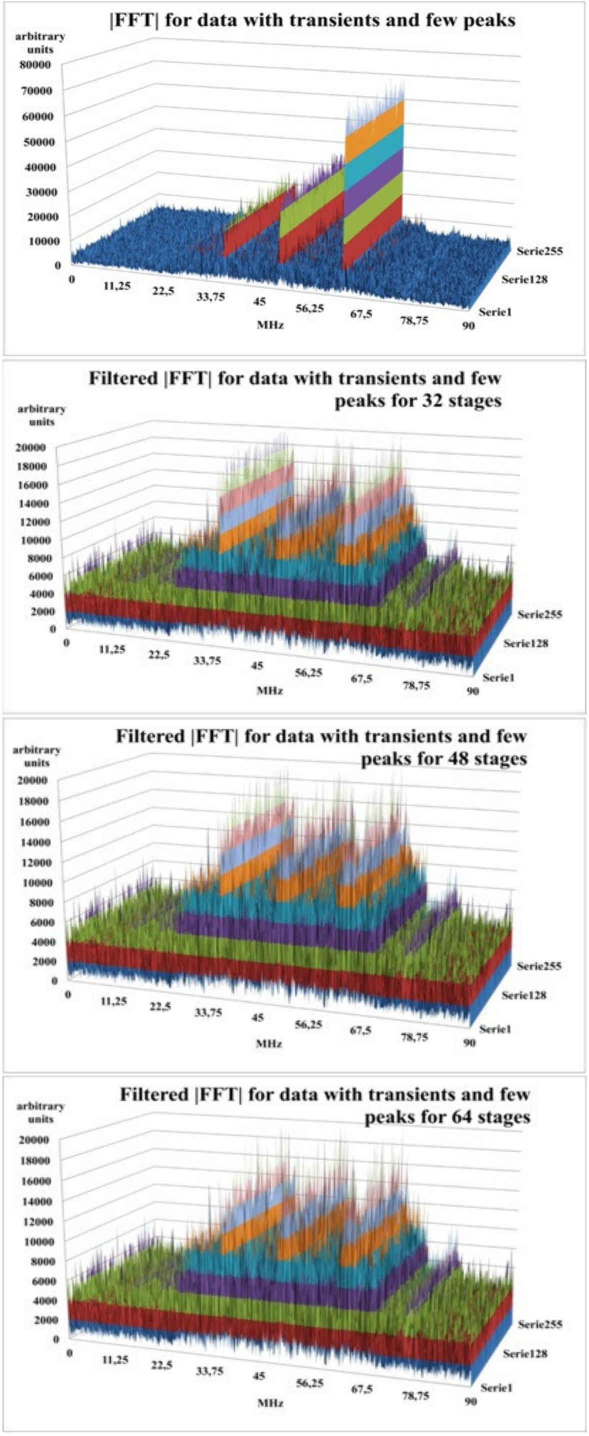

Fig. 7. Original and filtered data with transients and few peaks. LP filter variants with 32, 48 and 64 stages give almost the same result. Slightly contaminated data can be filtered using LP filter with 32 stages

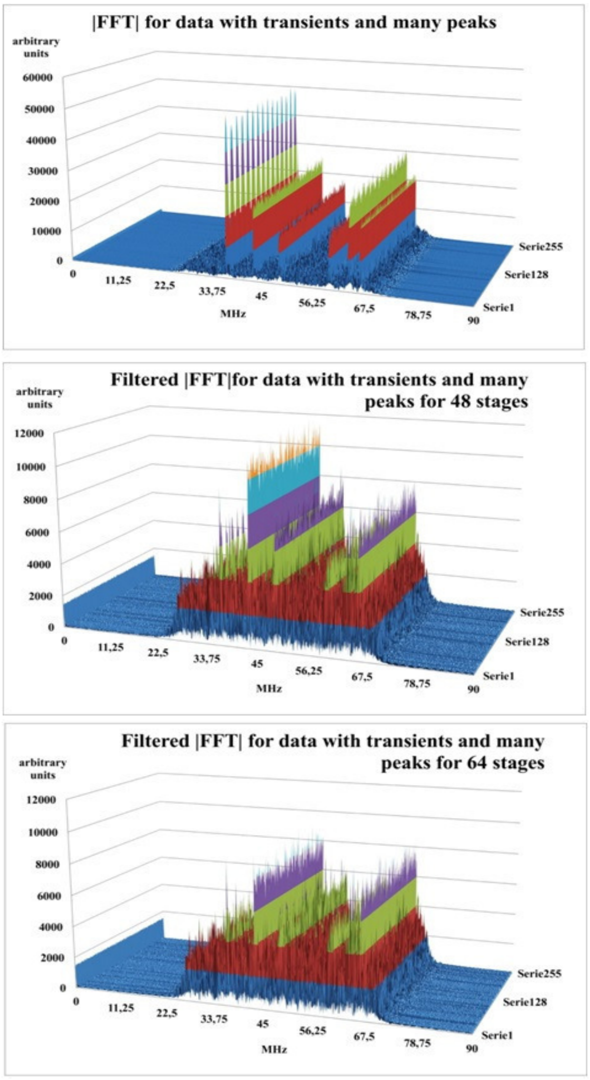

Fig. 8. Original and filtered data with transients and many peaks. In this case the suppression factor is much better in 64-stages variant of the LP filter, however variant with 48 stages also significantly suppresses the contamination. It is recommended to use 64 stages for strongly contaminated data.

~10mW, which is negligible. It was decided that width of the coefficients would be 14 bits.

The length of the filter is an important parameter, which has significant influence on the efficiency of the LP filter. The length of the filter is the number of data used for the prediction and it is the same as the number of coefficients of the filter.

Various lengths of the filter: 64, 48 and 32 have been tested. The filter with length 128 was decided not to be tested, because of the long time of the refreshment (almost 0.8 s). Results of tests are shown on fig. 7 and fig. 8. Fig. 7 shows the data contaminated only by few narrow RFI. The results of the filtering for this case are almost the same for 64, 48 and even for 32 stages of the filter. However, when data are contaminated by many RFI (fig. 8) the filtering using 64 coefficients is more efficient than using 48 stages of the

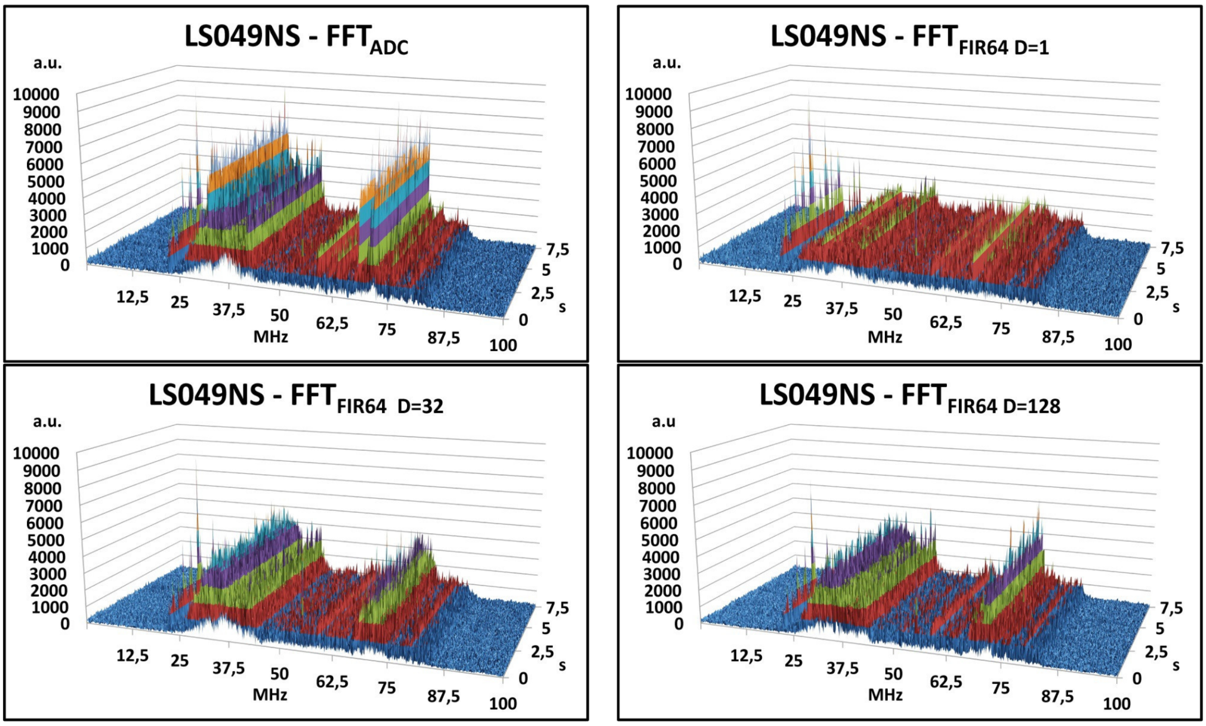

Fig. 9. |FFT| of original and filtered data from station LS049, polarization NS for several variants of delay line $D$. Filtering is the best, when the delay line $D = 1$. In rest of cases filtering is on the same, acceptable level.

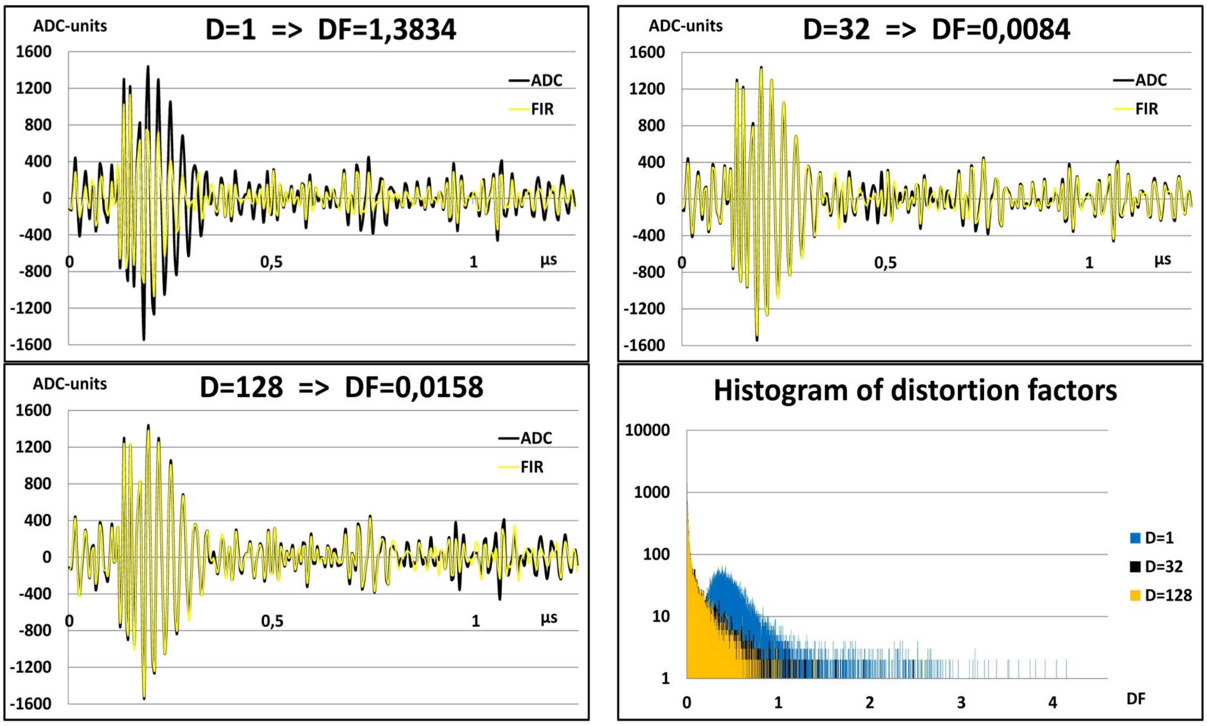

Fig. 10. Original and filtered data in time domain. Although suppression of the variant of the LP filter with delay-line $D = 1$ is the best, it distorts signal too much and has to be rejected. Both variants, with 32 and 128 length of the delay-line move the distortion made by signal appropriately 32 or 128 data samples away from the signal. In these cases signal remains almost unaffected.

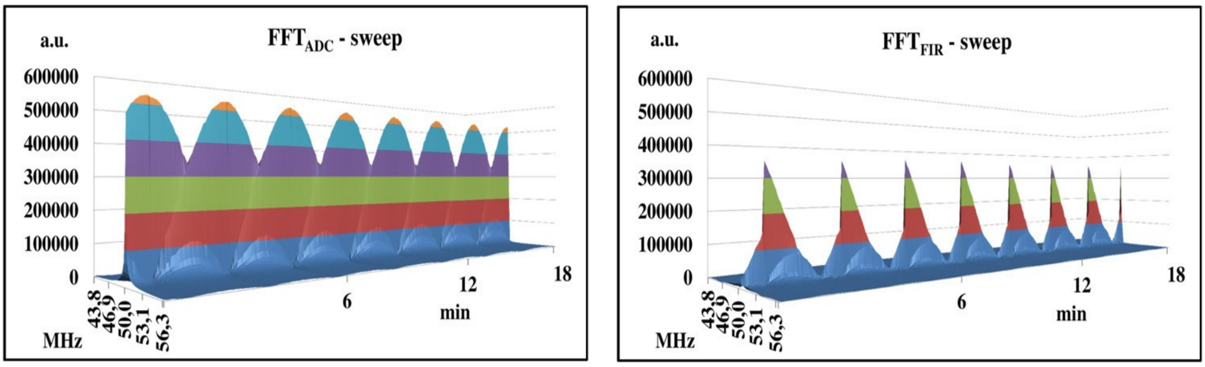

Fig. 11. |FFT| of original and filtered mono-carrier with 2 minutes drift in frequency from 50.0 MHz to 50.2 MHz. When frequency of the contamination is the same as in time of calculation coefficients for the LP filter, suppression level is very high. This result is repeated every 2 minutes.

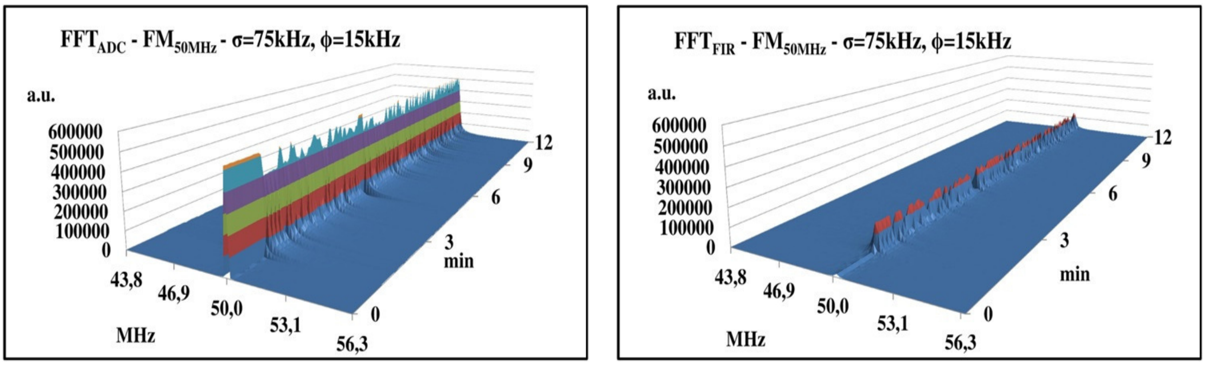

Fig. 12. |FFT| of original and filtered mono-carrier with restrictive FM modulation. The efficiency of the filtering is still very high.

filter. Shorter filters require less FPGA resources, use less power and can be calculated much faster ( ~2 times faster for 48 stages and ~4 times faster for 32 stages of the filter). Simulations show, the LP filter can be used with 32 stages in situations, where the contamination is not sophisticated. For very contaminated data we can use the LP filters with 48 or 64 stages.

The delay line $D$ between the data we used for prediction and data we want to predict was introduced to avoid the distortion of the signal. We can define the distortion factor ($DF$) to calculate how the filter affects data and the registered signal:

$$DF = \sum_{k=-16}^{16} \left( \frac{(x_{FIR})_k \; - \; (x_{ADC})_k}{(x_{ADC})_k} \right)^2 \qquad (9)$$

Fig. 9 shows filtered data for three variants of parameter $D$. For all values of the $D$ factor the LP filter shows good efficiency, but filtering is the best when data we want to predict is located just after data we used for prediction ($D$=1). However, this case introduce significant distortion of the signal (fig. 10 upper left plot) and has to be rejected. Histogram of distortion factors (fig. 10 bottom right plot) shows explicitly, that delay-line $D$=128 distorts signal minimally. $D$=128 moves the distortion made by signal 128 data samples away from the signal region. To keep this safety margin, it was decided to use delay-line $D$=128 for all tests.

## V. Laboratory Tests

All laboratory tests were made using Altera DK-DEV-5CEA7N development kit with Cyclone V FPGA. The generated signals were transferred from generators to Texas Instr. ADS4249EVM Evaluation Module with 2-channel 14-bits 250 MSps ADC. Connection between both modules was provided using the LVDS data transmission by Altera HSMC-ADC-BRIDGE (fig. 22).

The long-term stability of the filter was tested by using a single mono-carrier, which frequency drifted from 50.0 MHz to 50.2 MHz in 2 minutes. Coefficients of the LP filter had been calculated and had been loaded to the registers before this test. These coefficients were not changed during this test. Fig. 11 shows results of the test in time of several minutes. We can observe very good suppression when the frequency goes back to the frequency, which was used for calculation of LP filter coefficients. If data are contaminated by RFI which frequency slowly changes in time, coefficients of the LP filter do not have to be refreshed frequently.

Next test consists on checking the Hi-Fi FM configuration. The signal was contaminated by 50 MHz carrier with 75 kHz deviation, with acoustic modulation 15 kHz. This conditions

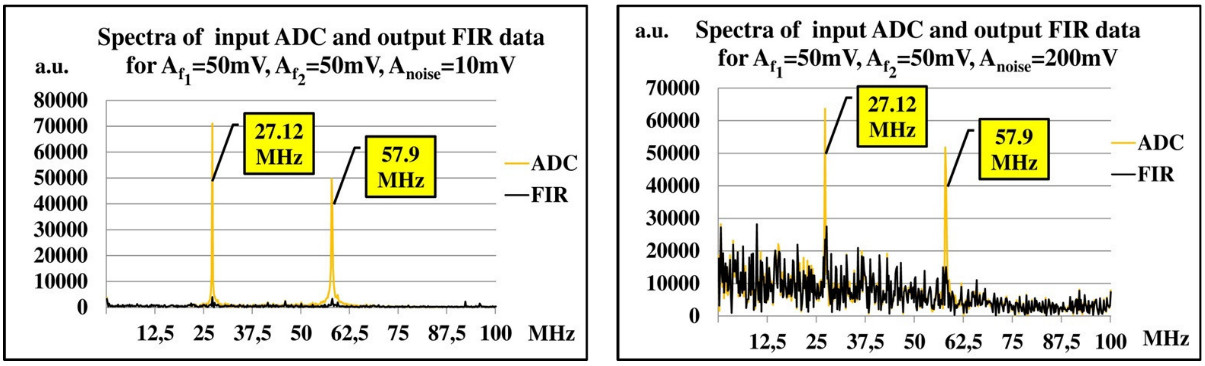

Fig. 13. |FFT| of original (ADC) and filtered (FIR) data of two mono-carriers with 2 variants of noise level. Suppression of carriers is on very good level, even if the amplitude of the noise is greater than the amplitude of carriers.

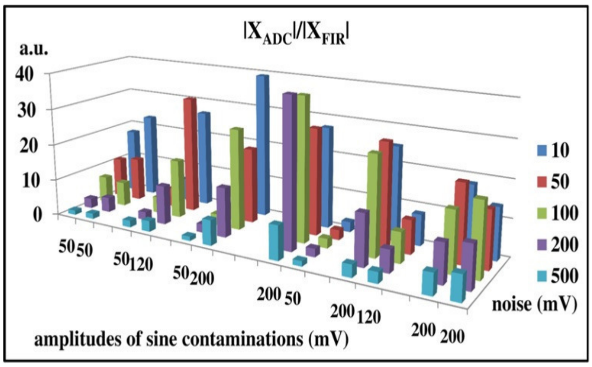

Fig. 14. Suppression levels of two sine contamination in dependancy of noise level and several variants of sine amplitudes. Noise level can greatly change the suppression factor. Contamination with higher amplitude is much more suppressed than the second one. This effect is not dependant on noise level.

are very restrictive and they should not appear in real conditions in detectors on pampas. Frequency band for Hi-Fi FM transmissions is 88 - 108 MHz and it is cut-off by already installed analog filters. The suppression of these restrictive contamination is very good (fig. 12).

The LP filter was also tested to check the suppression efficiency. The generated signal was two carriers (27.12 and 57.9 MHz) with noise. Suppression was almost total, when signals were much stronger than noise, but there was also a significant suppression when signals and noise were on the same level (fig. 13).

Several variants of the carriers and noise amplitudes had been tested. Fig. 14 shows the dependency of the suppression level on amplitudes of contamination. Higher noise level reduces efficiency of filtering. We can also observe, that if the amplitude of one carrier is much higher than the amplitude of the second carrier, the suppression level of the second carrier is much lower than the suppression level of the first carrier.

## VI. Comparison to the currently used filters

### A. Median filter

AERA uses two kinds of filters to improve the signal to noise ratio. The first kind is the Median filter. It is based on the Fast Fourier Transform (FFT) technique. Radio signals are transferred from the time domain to the frequency domain by FFT. In the next step, the Median filter suppresses narrow peaks, which correspond to stationary mono-frequent contaminations. This filtering does not affect the radio pulses from cosmic showers. After this step, the cleaned signal is transformed to the time domain again by using the inversed FFT. The whole process is shown on fig. 15. The Median filter has also several disadvantages. Theoretically, the chain of the FFT and inversed FFT should give same data. However, due to finite representation of data in the FPGA, this chain of transformations introduces approximation errors. There are two possible architectures of the FFT: streaming and variable streaming. The streaming architecture uses less resources and is faster than the variable streaming, but the approximation error is much bigger. In the variable streaming architecture the error is reduced to the last significant bit. Another problem is aliasing. When the pulses are located near the converted data blocks, the reconstructed signal may change. Aliasing elimination can be done using overlapping neighboring data blocks, which require over-clocking of the signal processing. This approach is much more energy and resource consuming. The Median filter also distorts the signal in the region near the peak, which is responsible for the trigger. Fig. 16 shows the distortion factors of the Median filter and the LP filter for comparison. We can see, that the LP filter distorts the signal less than the Median filter. Another issue is the power consumption, which can be on the level of 1W per channel. The power consumption is an important factor for experiment powered by solar panels.

### B. Notch filter

Notch filter is infinite impulse response (IIR) filter, which is currently used by AERA. Its power consumption is much lower than the power consumption of the Median filter, which is important for the experiment powered by solar panels. Notch filter is not adaptive and can reject only four arbitrary chosen frequencies from the signal. After programming in the FPGA, these frequencies cannot be changed dynamically, because of potential instability of the filter. These selected frequencies

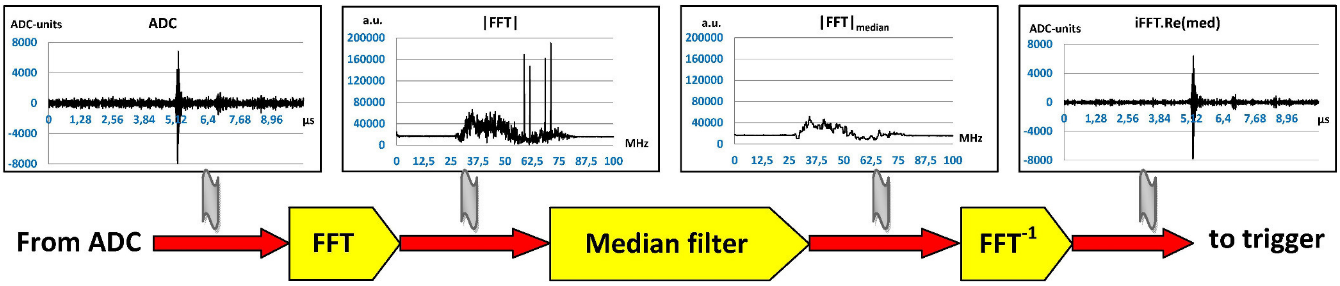

Fig. 15. Diagram showing the data flow in Median filter. Input signals are transfered to frequency domain by FFT and after the filtering by Median filter, cleaned signals are transfered to time domain again using inversed FFT.

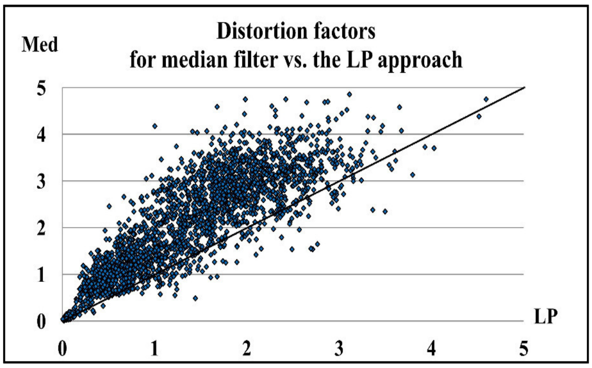

Fig. 16. Comparison of distortion factors for Median and LP filters. In most cases the LP filter distorts the signal less than the Median one.

were found by averaging data from entire array. Fig. 17 shows the comparison of the Notch and LP filters. The efficiency of the Notch filter is very high only near rejected frequencies. Suppression outside the rejected band is much lower. The current consumption of the IIR and the several variants of the LP filter is shown on the fig. 18. The variant with 32 stages has the power consumption compared to the IIR filter. Despites of their limitations, Median and Notch filters were implemented and have successfully worked in the AERA radio stations for several years.

## VII. HPS IMPROVEMENTS

The laboratory tests shows high efficiency of the LP filter, however noise on pampas is much more sophisticated. Besides of narrow-band mono-carriers tests show additional, non-stationary RFI. This type of contamination is weakly affected by the LP filter and strongly decreases filters efficiency. Currently used Notch filter also cannot suppress this kind of contamination, because it can only reject fixed frequency RFI. The main reason of weak suppression by LP filter is probably too long refreshment time of filter coefficients. In laboratory tests, coefficients were calculated by virtual processor NIOS®. This processor can work with maximal frequency 100 MHz, but for tests this frequency was lowered to 80 MHz (to have safety margin). Refreshment time of the filter coefficients in these conditions is 190 ms. The LP filter can suppress RFI, which are longer than the time of its refreshment (fig. 19

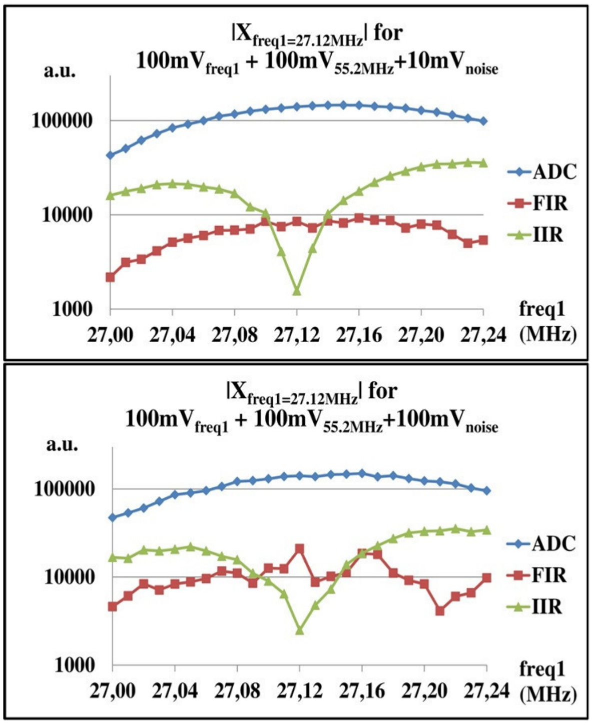

Fig. 17. Comparison of efficiency of LP FIR filter and IIR Notch filter for two variants of noise level. Suppression factor of the Notch filter is more efficient than LP filter only in narrow frequency band near the rejected frequency. Higher noise slightly decreases efficiency of the FIR filter.

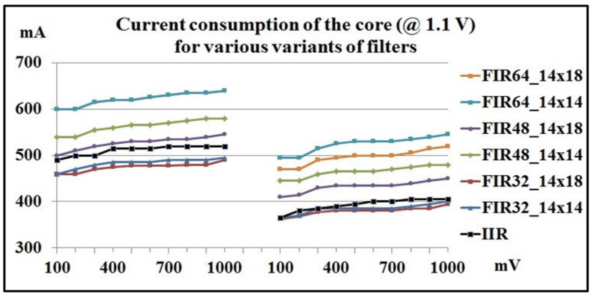

Fig. 18. The current consumption calculated for several variants of the LP filter and for currently used IIR Notch filter. Power consumption for LP filter with 32 stages is on the same level as for IIR filter.

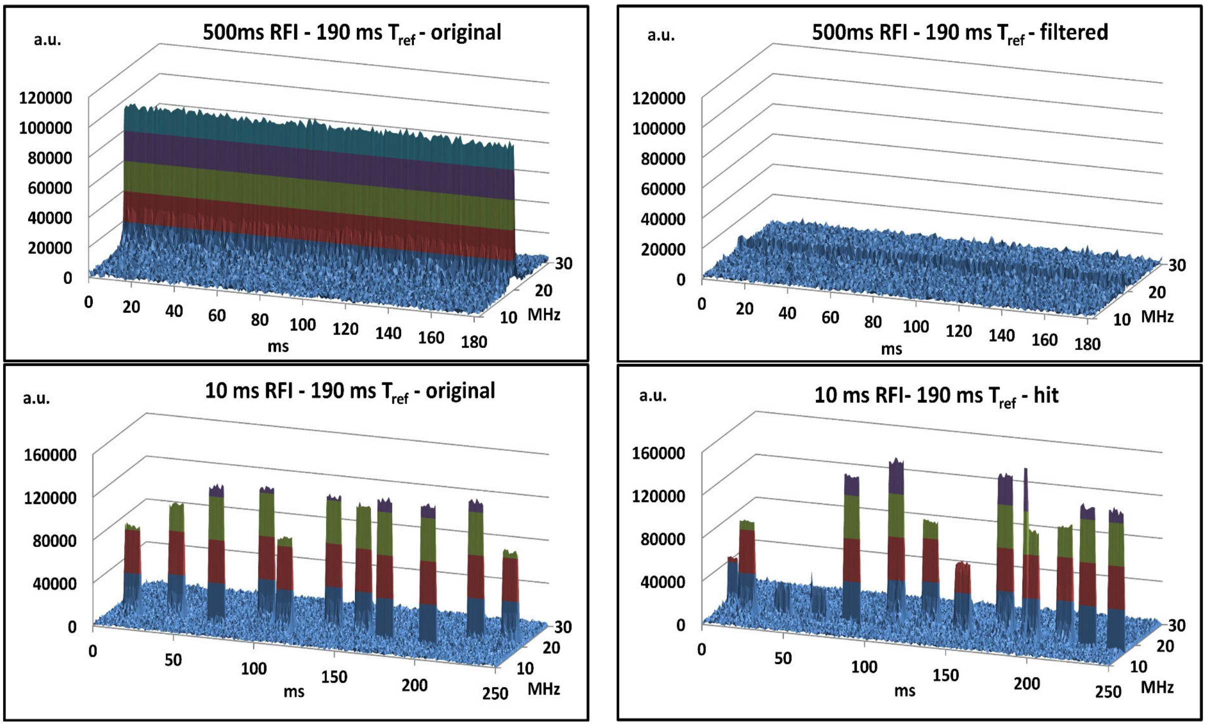

Fig. 19. Suppression achieved by LP filter with coefficients calculated in 190 ms by NIOS® for signals much longer (upper plots) and much shorter (bottom plots) than the refreshment time of the filter. In first case, the suppression is almost total. In second case suppression depends on similarity of data used for calculation and currently filtered data.

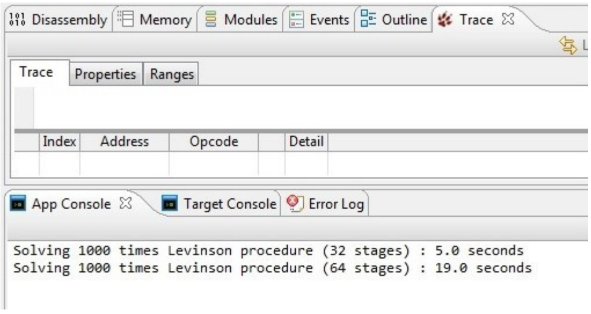
upper graphs). If the RFIs length is shorter than refreshment time of LP coefficients, the suppression factor depends on the similarity the signal on which the coefficients were calculated to signal, which is currently filtered (fig. 19 bottom graphs). We can define the suppression factor:

$$SF = \frac{\sum FFT_{original} - \sum FFT_{filtered}}{\sum FFT_{original}}. \tag{10}$$

To reduce the non-stationary RFI, coefficients of the LP filter have to be calculated more frequently. To achieve this we can use Cyclone V SoC HPS, which contains embedded ARM processor. This processor can work with maximal frequency 925 MHz. To have the safety margin, all laboratory tests were made using 800 MHz. Fig. 20 shows the calculation time of the coefficients for two variants of the LP filter. Refreshment time can be reduced from 190 ms to several milliseconds. Fig. 21 shows the simulated results of the filtering by this filter for three different lengths of RFI. The efficiency of the filter is very high for all tests. Suppression factors for case with 100 ms length RFI is SF=72% and for 50 ms RFI SF=59%. If the coefficients were calculated during the gap between the signals, the filter does not suppress the signal. It is seen on all graphs containing filtered data. In 50 ms and 20 ms RFI one of peaks is increased. The probable reason is a short gap between two peaks, so old coefficients were calculated using the data from the previous peak. Every peak is independent, so filter may not work properly in this case. If the refreshment time of LP coefficients is slightly lower than the length of the RFI (fig. 21 bottom graphs), suppression is highly dependent on the moment of starting the calculation of new coefficients. The best scenario is when the calculation starts just after new RFI shows. New set of coefficients starts working near the middle of the peak and can significantly suppress rest of the peak. If the calculation use data just before the new RFI, next calculation would be done in the middle of the RFI occur and starts working at the end or just after the RFI. The suppression factor for this case is much lower than in longer RFI cases, but it is still on acceptable level SF=24%.



```
Solving 1000 times Levinson procedure (32 stages) : 5.0 seconds
Solving 1000 times Levinson procedure (64 stages) : 19.0 seconds
```

Fig. 20. Calculation time for solving by ARM processor system of 32 and 64 linear equations for two variants of LP filter using Levinson algorithm. Calculation time can be shorten from 190 ms to several ms.

The communication between the FPGA and ARM processor is much faster than between the NIOS® and FPGA. The 128 bit bridge between the ARM and FPGA allows sending up

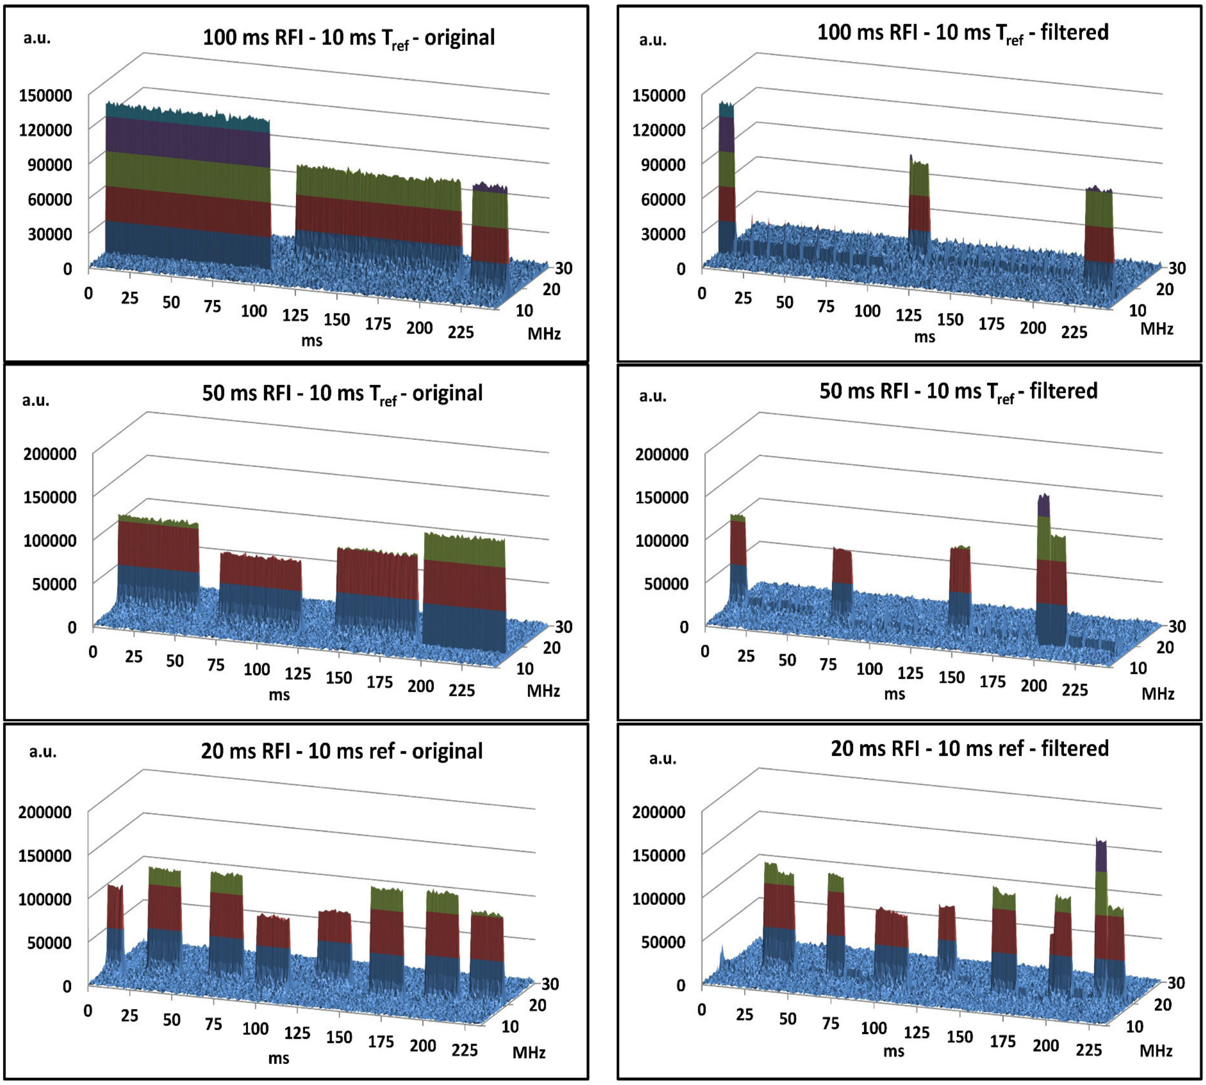


Fig. 21. Suppression achieved by LP filter with coefficients calculated in 10 ms by ARM processor for signals much longer (upper plots) and slightly longer (middle and bottom plots) than the refreshment time of the filter. In upper and middle graphs suppression is very high. The filter does not work only when its coefficients were calculated during the gap between peaks. In bottom graphs suppression strongly depends on the moment of coefficients calculation.

to 10 coefficients in one clock cycle. This means that 64 coefficients can be send in 7 clock cycles and 32 coefficients in 4 clock cycles. Virtual processor NIOS® allows to send only one coefficient per clock cycle.

## VIII. Conclusions

The Linear Predictor is a new kind of filter, which can be used in AERA radio stations. Fast adaptation to new environment conditions, high efficiency in suppression contaminations and reasonable power consumption show it can succesfully replace currently used Notch and Median filters. Additionally, the LP filter leaves almost unaffected signal used for triggering. Using the ARM processor allows to suppress very short non-stationary RFI, which are not suppressed by currently used filters. Moreover, the LP filter is very flexible. The shorter versions of the filter can be implemented in radio stations, where RFI is relativelly weak. Longer versions can be used in radio stations, where filtering is crucial.

***Abstract*—Differences in simulation results may be observed from one architecture to another or even inside the same architecture. Such reproducibility failures are often due to different rounding errors generated by different orders in the sequence of arithmetic operations. Reproducibility problems are particularly noticeable on new computing architectures such as multicore processors or GPUs (Graphics Processing Units). DSA (Discrete Stochastic Arithmetic) enables one to estimate rounding error propagation in simulation programs. In this paper, it is shown that DSA can be used to estimate which digits in simulation results may be different from one environment to another because of rounding errors. A particular implementation of DSA, which enables numerical validation in hybrid CPU-GPU environments, is described. The estimation of numerical reproducibility using DSA is illustrated by a wave propagation code which can be affected by reproducibility problems when executed on different architectures.**

## I. Introduction

RESULTS of numerical simulations may be different from one architecture to another, or even inside the same architecture if they are computed using different compilers for instance. In sequential or parallel environments, different orders in the sequence of floating-point operations may lead to differences in rounding error propagation and therefore to reproducibility failures. It must be pointed out that the cause of differences in results may be difficult to identify: rounding errors or bug? Such differences are particularly noticeable with new computing architectures such as multicore processors, GPUs (Graphics Processing Units) and APUs (Accelerated Processing Units). In high performance numerical simulations, reproducibility problems have been identified in various domains: energy science [1], climate science [2], atomic or molecular dynamics [3], [4], fluid dynamics [5]. Various studies have been carried out on numerical reproducibility on different architectures. On the one hand, strategies have been proposed [2], [3], [4], [5] to improve numerical accuracy, using for instance accurate summations. Other works aim at forcing the reproducibility of results, either affected by the same rounding errors [6], [7] or correctly rounded [8], [9], [10], [11].

DSA (Discrete Stochastic Arithmetic) [12], [13] enables one to estimate rounding error propagation in simulation programs. This paper shows that DSA can be used, not to force a code to be reproducible, but to estimate the number of digits in the results which may be different from one execution to another because of rounding errors. The CADNA[1] library [14], [15], [16], which implements DSA, enables the numerical quality estimation of sequential programs in C or Fortran and of parallel programs using MPI for communication [17]. This paper describes a version of CADNA, briefly introduced in [18], that can be used in hybrid CPU-GPU environments to estimate rounding errors in CUDA programs. This paper is organized as follows. In Section 2, differences in results provided by a wave propagation code executed on several architectures - CPU, GPU and APU - are pointed out. Section 3 presents the principles of DSA. Section 3 also describes the CADNA library and presents the particularities of a CADNA version for CPU-GPU codes. Section 4 shows that the reproducibility problems observed in wave propagation results can be explained by rounding error propagation thanks to the CADNA library. Finally, concluding remarks are presented in Section 5.

## II. Reproducibility failures in a wave propagation code

We consider the three-dimensional acoustic wave equation

$$\frac{1}{c^2}\frac{\partial^2 u}{\partial t^2} - \sum_{b\in\{x,y,z\}} \frac{\partial^2}{\partial b^2} u = 0,$$

where $u$ is the particle velocity, $c$ is the wave velocity, and $t$ is the time. This equation, used for instance in oil exploration [19], is solved with an explicit finite difference scheme of order 2 in time and $p$ in space (in our case $p = 8$). We denote by $u^n_{i,j,k}$ (respectively $f^n_{i,j,k}$) the wave (respectively source) field in $(i, j, k)$ coordinates and $n$th time step, $a_l$ $(l = -p/2, \ldots, p/2)$ the finite difference coefficients, $\Delta t$ the time step and $\Delta h$ the spatial step size. Two mathematically equivalent implementations of the finite difference scheme are proposed:

$$u^{n+1}_{i,j,k} = 2u^n_{i,j,k} - u^{n-1}_{i,j,k} + \frac{c^2\Delta t^2}{\Delta h^2} S^n_{i,j,k} + c^2\Delta t^2 f^n_{i,j,k}$$

[1] URL address: http://www.lip6.fr/cadna

978-83-60810-66-8/$25.00©2015, IEEE

where

$$S^n_{i,j,k} = \sum_{l=-p/2}^{p/2} a_l \left(u^n_{i+l,j,k} + u^n_{i,j+l,k} + u^n_{i,j,k+l}\right) \quad (1)$$

or

$$S^n_{i,j,k} = \sum_{l=-p/2}^{p/2} a_l u^n_{i+l,j,k} + \sum_{l=-p/2}^{p/2} a_l u^n_{i,j+l,k} + \sum_{l=-p/2}^{p/2} a_l u^n_{i,j,k+l}. \quad (2)$$

In order to satisfy the CFL (Courant-Friedrichs-Lewy) necessary stability condition [20], the time step is computed by taking into account the wave velocity $c$, the spatial step size $\Delta h$ and the spatial order $p$. Because these two implementations require the same number of arithmetic operations, they should lead to similar performance. However it would be interesting to determine whether they differ in the numerical quality of their results.

The code is executed for $64 \times 64 \times 64$ space steps and 1000 time iterations in IEEE-754 binary32 arithmetic with rounding to the nearest [21] and the following environments:

- AMD Opteron 6168 CPU with gcc 4.7.2 compiler;
- NVIDIA C2050 GPU (Graphics Processing Unit) with CUDA (Compute Unified Device Architecture) platform;
- NVIDIA K20c GPU with OpenCL (Open Computing Language);
- AMD Radeon HD 7970 GPU with OpenCL;
- AMD Trinity APU (Accelerated Processing Unit) with OpenCL.

Different kinds of reproducibility problems are observed. The results numerically vary

1) from one execution to another inside a GPU or an APU; these repeatability problems are due to differences in the execution order of the threads;
2) from one implementation of the finite difference scheme to another; the maximal relative difference between results is of the order of $10^{-1}$ to 1 depending on the architecture, and the mean value of the relative difference between results is of the order of $10^{-5}$ whatever the architecture;
3) from one architecture to another; again, the maximal relative difference between results is of the order of $10^{-1}$ to 1 and its mean value is $10^{-5}$.

Indeed if two sets of results computed in binary32 are compared, the results at the same space coordinates can have from 0 to 7 significant digits in common, and the average number of common significant digits is about 4. We recall that results computed using binary32 arithmetic precision can have at most 7 correct significant digits. To illustrate these reproducibility problems, Table I presents at three space coordinates $(i, j, k)$, $0 \leq i, j, k \leq 63$, the results obtained after 1000 times iterations using the processing units and languages previously mentioned. These results have different orders of magnitude. Both implementations of the finite difference scheme are considered. Considering the example points presented in Table I, any two results computed at the same point in the space domain have 3 to 6 common significant digits.

TABLE I

## III. ESTIMATING ROUNDING ERRORS WITH DISCRETE STOCHASTIC ARITHMETIC (DSA)

### *A. Principles of DSA*

Based on a probabilistic approach, the CESTAC method [12] allows the estimation of rounding error propagation which occurs with floating-point arithmetic. When no overflow occurs, the exact result of any non exact floating-point arithmetic operation is bounded by two consecutive floating-point values $R^-$ and $R^+$. The basic idea of the method is to perform each arithmetic operation $N$ times, randomly rounding each time, with a probability of 0.5, to $R^-$ or $R^+$. The computer's deterministic arithmetic, therefore, is replaced by a stochastic arithmetic where each arithmetic operation is performed $N$ times before the next one is executed, thereby propagating the rounding error differently each time. The CESTAC method furnishes us with $N$ samples $R_1, \ldots, R_N$ of the computed result $R$. The value of the computed result, $\overline{R}$, is the mean value of $\{R_i\}_{1 \leqslant i \leqslant N}$ and the number of exact significant digits in $\overline{R}$, $C_{\overline{R}}$, is estimated as

$$C_{\overline{R}} = \log_{10}\left(\frac{\sqrt{N}\left|\overline{R}\right|}{\sigma \tau_\beta}\right)$$

$$\text{with } \overline{\mathrm{R}} = \frac{1}{\mathrm{N}}\sum_{\mathrm{i}=1}^{\mathrm{N}} \mathrm{R_i} \text{ and } \sigma^2 = \frac{1}{\mathrm{N}-1}\sum_{\mathrm{i}=1}^{\mathrm{N}} \left(\mathrm{R_i} - \overline{\mathrm{R}}\right)^2.$$

$\tau_\beta$ is the value of Student's distribution for $N - 1$ degrees of freedom and a probability level $1 - \beta$. In practice $N = 3$ and $\beta = 0.05$. Indeed, it has been shown [22], [23] that $N = 3$ is in some reasonable sense the optimal value. The estimation with $N = 3$ is more reliable than with $N = 2$ and increasing the size of the sample does not improve the quality of the estimation. The probability of overestimating the number of exact significant digits of at least 1 is 0.054% and the probability of underestimating the number of exact significant digits of at least 1 is 29%. By choosing $\beta = 0.05$, we prefer to guarantee a minimal number of exact significant digits with a high probability (99.946%), even if we are often pessimistic by 1 digit. The complete theory can be found in [12], [23].

The validity of $C_{\overline{R}}$ is compromised if the two operands in a multiplication or the divisor in a division are not significant [23]. It is essential, therefore, that these results with no significance are detected and reported, since their subsequent use may invalidate the method. The need for this dynamic control of multiplications and divisions has led to the concept of the computational zero. A computed result is a computational zero, denoted by @.0, if $\forall i, R_i = 0$ or $C_{\overline{R}} \leq 0$. This means that a computational zero is either a mathematical zero or a number without any significance, *i.e.* numerical noise.

To establish consistency between the arithmetic operators and the relational operators, discrete stochastic relations are defined as follows. Let $X = (X_1, ..., X_N)$ and $Y = (Y_1, ..., Y_N)$ be two results computed using the CESTAC method, we have from [24]

$$X = Y \text{ if and only if } X - Y = @.0;$$
$$X > Y \text{ if and only if } \overline{X} > \overline{Y} \text{ and X} - \text{Y} \neq @.0;$$
$$X \geq Y \text{ if and only if } \overline{X} \geq \overline{Y} \text{ or X} - \text{Y} = @.0.$$

Discrete Stochastic Arithmetic (DSA) [12], [13] is the combination of the CESTAC method, the concept of the computational zero, and the discrete stochastic relationships.

### *B. Numerical validation of sequential codes using DSA*

The CADNA software [14], [15], [16] is a library which implements DSA in any code written in C++ or in Fortran and allows to use new numerical types: the stochastic types. In practice, classic floating-point variables are replaced by the corresponding stochastic variables, which are composed of three floating-point values and an integer to store the accuracy. The library contains the definition of all arithmetic operations and order relations for the stochastic types. For instance, let us consider an arithmetic operation $\circ \in \{+, -, *, /\}$ between two stochastic variables A and B. This arithmetic operation is performed three times on the associated floating-point values $A_i \circ B_i$, the rounding mode being randomly set to rounding towards $+\infty$ or $-\infty$. The control of accuracy is performed only on variables of stochastic type. Only exact significant digits of a stochastic variable are printed or "@.0" for a computational zero. Because all operators are redefined for stochastic variables, the use of CADNA in a program requires only a few modifications: essentially changes in the declarations of variables and in input/output statements. The CADNA software has been successfully used for the numerical validation of real-life applications [17], [25], [26], [27], [28].

Attention has been paid to rounding mode setting in terms of performance, because the rounding mode must be frequently changed. On CPU the rounding mode is determined by two bits in the Control Word, a 16-bit register in the FPU (Floating-Point Unit). At the beginning of a program using CADNA, the rounding mode is arbitrarily set to $-\infty$. Then the rounding mode is randomly changed using the CADNA *rnd_switch* function that switches the rounding mode from $+\infty$ to $-\infty$, or from $-\infty$ to $+\infty$. To reduce the cost of rounding mode changes, the *rnd_switch* function is written in assembly language and is specific to the processor and the compiler chosen. The *rnd_switch* function changes in the FPU Control Word the two bits associated with the rounding mode. For performance reasons, a random number generator is not called at each arithmetic operation. A long random sequence is generated at the beginning of the program and stored in an array. Then successive array elements are used cyclically when random numbers are required.

CADNA can detect numerical instabilities which occur during the execution of the code. When a numerical instability is detected, dedicated CADNA counters are incremented. At the end of the run, the value of these counters together with appropriate warning messages are printed on standard output. These warnings are of two types.

1) Warnings related to the self-validation of CADNA. These include: unstable multiplication where the two operands are computational zeroes and unstable division where the divisor is a computational zero. These warnings indicate that the validity of $C_{\overline{R}}$ has been compromised and the CADNA results cannot be relied on.
2) Warnings concerning other numerical instabilities. These instabilities can occur in overloaded mathematical functions or in branching statements involving a computational zero. A numerical instability is also reported in the case of a cancellation, *i.e.* the subtraction of two very close values which generates a sudden loss of accuracy.

At the end of the run, each type of anomaly together with their occurrences are printed. If no anomaly has been detected the computed results are reliable and the accuracy of each has been correctly estimated up to a certain probability. Otherwise the messages need to be analysed, the source of the anomaly identified and, if necessary, the code changed. The user can specify the instabilities to be detected. One may choose, for instance, to activate only self-validation, to detect all types of instabilities or to deactivate the detection of instabilities.

### *C. Numerical validation of hybrid CPU-GPU codes using DSA*

An asynchronous implementation of the CESTAC method for the estimation of rounding errors in GPU codes written in CUDA is proposed in [29]. Unfortunately with such an implementation of the CESTAC method, the whole code is executed several times with the random rounding mode and no instability in arithmetic operations can be detected. We present here a version of CADNA which implements DSA for the numerical validation of hybrid CPU-GPU codes written in

CUDA. This version differs from the sequential version in two main respects: rounding mode change and instability detection.

On GPU an arithmetic operation can be performed with a specified rounding mode. For instance a multiplication with rounding towards $+\infty$ can be executed using the *fmul_ru* function and a multiplication with rounding towards $-\infty$ using the *fmul_rd* function. Therefore a stochastic operation on GPU implies three floating-point operations randomly rounded towards $+\infty$ or $-\infty$ using the appropriate arithmetic function. Unlike on CPU, random numbers are not stored in a global array on GPU, because it is incompatible with GPU programming paradigms. Each GPU thread being independent, it generates random numbers using its own seed and taking into account its own thread index. On GPU, random numbers are generated when they are required, *i.e.* during the stochastic operations. As a remark, because of the robustness of accuracy estimation by DSA [22], the quality of the random number generator is not a critical issue: only boolean values are required.

On CPU, numerical instabilities that occur during the execution are counted. Such a count is not performed on GPU because it would consume shared memory and require many atomic operations. On GPU an unsigned char is associated with each result to store the numerical instabilities that have affected it. Each bit of this char is associated with a type of instability. For instance, its last bit is set to 1 if the result has been affected by at least one unstable multiplication. Therefore in the CPU-GPU version of CADNA a stochastic variable is composed of three floating-point variables and four unsigned char: one for the accuracy, one for the instabilities and two for padding to respect memory alignment. Instability detection increases the execution time with CADNA. Cancellation detection is particularly costful because it requires to compare for all additions and subtractions the operands accuracy with the result accuracy. For performance reasons, the main instabilities can be detected with the GPU version of CADNA: the instabilities related to the self-validation of CADNA (unstable multiplications and unstable divisions) and the unstable branching statements.

## IV. Estimation of reproducibility in wave propagation results by means of DSA

The acoustic wave propagation code has been executed with the CADNA library on CPU and on GPU. Results presented in this section have been computed in the following environments:

- an AMD Opteron 6168 CPU with gcc 4.7.2 compiler;
- an NVIDIA C2050 GPU with CUDA 5.0 platform.

With implementations (1) and (2) of the finite difference scheme, the number of exact significant digits in the results computed with CADNA varies from 0 to 7. On CPU its mean value is 4.06 with both schemes; on GPU it is 3.43 with scheme (1) and 3.49 with scheme (2). These remarks are consistent with the observations described in Section II. Numerical instabilities occur during the execution: 272,394 losses of accuracy due to cancellations with scheme (1) and 285,186 with scheme (2). This kind of instability is detected by the CPU version of CADNA if the subtraction of two close floating-point numbers leads to a loss of accuracy of at least 4 digits.

Table II presents results obtained on CPU and on GPU at the same points in the space domain as in Table I. These results have been computed, on the one hand, using CADNA and, on the other hand, using IEEE floating-point arithmetic with rounding to the nearest. With CADNA, only the exact significant digits, *i.e.* the digits not affected by rounding errors, are printed. Results in the first four rows in Table II have been computed using binary32 arithmetic precision. Results in the last row have been obtained in binary64 on CPU with CADNA. Although CADNA prints 11 to 14 exact significant digits in these three results, only their first 10 digits are reported in Table II. The number of exact significant digits estimated by CADNA depends on the point considered in the space domain. As already mentioned in Section III, accuracy estimation by DSA is rather pessimistic than optimistic. Because of the probabilistic aspect of DSA, the number of exact significant digits estimated by CADNA may slightly differ on CPU and on GPU. In Table II one can notice that the digits provided by CADNA in binary32 are in common with those computed in binary64. Results reported in Table II have been computed using implementation (1) of the finite difference scheme. The same digits are provided by CADNA with the other implementation, except one less digit is given on GPU for point $p_1$.

TABLE II
Results computed at three different points in the space domain with and without CADNA using implementation (1) of the finite difference scheme

| | Point in the space domain | | |
|---|---|---|---|
| | $p_1$: (0, 19, 62) | $p_2$: (50, 12, 2) | $p_3$: (20, 1, 46) |
| IEEE CPU | -1.110479 | 54.54238 | 614.1038 |
| IEEE GPU | -1.110204 | 54.54224 | 614.1046 |
| CADNA CPU | -1.1 | 54.54 | 614.104 |
| CADNA GPU | -1.11 | 54.5 | 614.10 |
| Reference | -1.108603879 | 54.54034021 | 614.1041156 |

Figures 1 and 2 present, respectively on CPU and on GPU, the number of exact significant digits estimated by CADNA in the results computed with scheme (1) with respect to their absolute values. Similar results are observed with the other scheme. The highest results (in absolute value) are affected by low rounding errors and the highest rounding errors impact negligible results. Although the same trend can be observed on CPU and on GPU, there are differences between the two distributions due to the probabilistic aspect of DSA. Depending on the point in the space domain, the number of exact significant digits may be higher on CPU or on GPU. The average difference between results accuracy on CPU and on GPU is 0.6 digit. Furthermore because of differences in the execution order of the threads, the accuracy distribution may be slightly different from one execution to another on GPU.

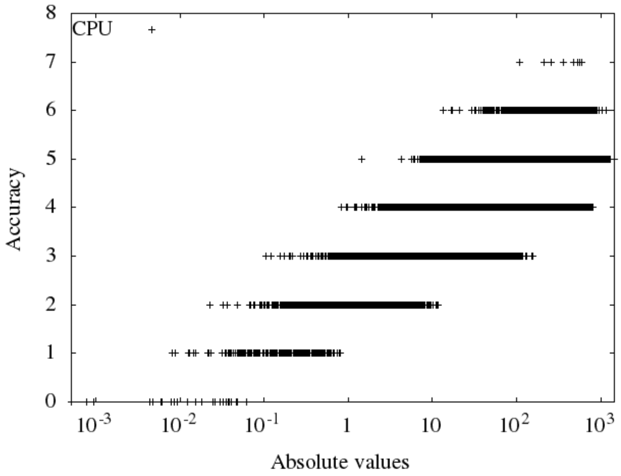

Fig. 1. Number of exact significant digits in the results computed on CPU with respect to their absolute values.

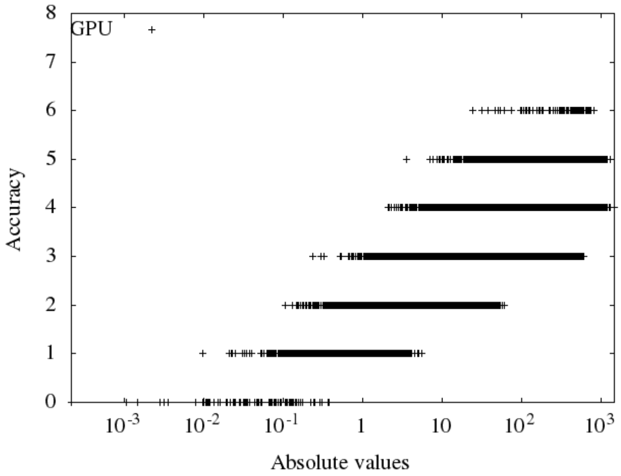

Fig. 2. Number of exact significant digits in the results computed on GPU with respect to their absolute values.

Table III presents execution times of the acoustic wave propagation code in the environments mentioned at the beginning of this section. Because the execution times measured with implementations (1) and (2) of the finite difference scheme are similar, only the performance of implementation (1) is reported in Table III. The code has been run in binary32 both on CPU and on GPU. CADNA has been used on CPU with several kinds of instability detection:

- the detection of all kinds of instabilities;
- no detection of instabilities. With this mode, which is not recommended, the execution time can be considered the minimum that can be obtained whatever instability detection chosen;
- the detection of unstable multiplications, unstable divisions and unstable branching statements. This mode, which enables the self-validation of CADNA, is also available on GPU.

One can notice that the cost of CADNA with instability detection in multiplications, divisions and branching statements is very close to its cost with no instability detection. Actually this code cannot generate such instabilities: in all multiplications at least one operand is a constant, all divisors are constants and it has no branching statement. The cost of CADNA with the detection of any kind of instability is 2.6 times higher. This is essentially due to the cancellation detection which is particularly expensive in terms of execution time. The cost of CADNA on GPU is about twice lower than on CPU with the same level of instability detection. This may be explained by the pipeline flush at each change of rounding mode on CPU which affects instruction level parallelism.

TABLE III
EXECUTION TIMES WITH AND WITHOUT CADNA ON CPU AND GPU

| CPU | | | |
|---|---|---|---|
| execution | instability detection | execution time (s) | ratio |
| IEEE | - | 110.8 | 1 |
| CADNA | all instabilities | 4349 | 39.3 |
| | no instability | 1655 | 14.9 |
| | mul., div., branching | 1663 | 15.0 |

| GPU | | | |
|---|---|---|---|
| execution | instability detection | execution time (s) | ratio |
| IEEE | - | 0.80 | 1 |
| CADNA | mul., div., branching | 5.73 | 7.2 |

## V. Conclusion

In this paper, we have shown that DSA can provide an estimation of the reproducibility of numerical programs. By estimating which digits are affected by rounding errors, DSA may explain why differences are observed in the results of a program executed in different environments. Therefore when the deployment of a code on a parallel architecture generates differences in the computed results, the presence of a bug can possibly be discarded. Based on a probabilistic approach, DSA can provide a trend of the distribution or the evolution of results accuracy. If results differences are due to different orders in the sequence of floating-point operations, a similar trend should be provided by DSA whatever the environment chosen. But a sequential implementation of DSA is not sufficient and efficient methods must be proposed for the numerical validation of large scale simulation programs. This paper has shown the feasibility of numerical validation with DSA for CPU-GPU programs. Furthermore DSA can be used for accuracy estimation in distributed memory environments [17]. It has recently been shown how to take advantage of SIMD units such as AVX (Advanced Vector eXtensions) in programs using DSA [30]. However, work must still be carried out to extend efficiently DSA to emerging computing architectures that are prone to numerical reproducibility failures.

# TRACO: An Automatic Loop Nest Parallelizer for Numerical Applications

Marek Palkowski, Tomasz Klimek, Wlodzimierz Bielecki
West Pomeranian University of Technology in Szczecin
ul. Zolnierska 49, 71-210 Szczecin, Poland
Email: mpalkowski@wi.zut.edu.pl, tklimek@wi.zut.edu.pl, wbielecki@wi.zut.edu.pl

***Abstract*—We present the source-to-source TRACO compiler allowing for increasing program locality and parallelizing arbitrarily nested loop sequences in numerical applications. Algorithms for generation of tiled code and extracting synchronization-free slices composed of tiles are presented. Parallelism of arbitrary nested loops is obtained by creating a kernel of computations represented in the OpenMP standard to be executed independently on many CPUs. We consider benchmarks, typical from compute-intensive sequences of algebra operations or numerical computation from industry and engineering. The speed-up of programs generated by TRACO are discussed. Related compilers and techniques are considered. Future work is outlined.**

## I. Introduction

EFFICIENT parallel numerical algorithms for commonly occurring problems in scientific computing are more difficult to write than sequential ones. Developers must analyze their performance, granularity and scalability. Optimizing and parallelizing compiler research with empirical evaluation is significant for an efficient usage of widely available multi-core systems.

Because for many numerical kernels and solvers most computations are contained in program loop nests, automatic extraction of parallelism available in loop nests is extremely important for multi-core processing. However, there is a lack of automated and completed tools permitting for exposing parallelism in serial programs. The most advanced approach to improve program locality and parallelization is based on the Affine Transformation Framework (ATF). Unfortunately, this approach can fail to parallelize loop nests exposing storage-related dependences, and as consequence potential parallelism is left unexploited in some cases [1]. This paper presents an alternative approach to increasing program locality and parallelization which is implemented in the open source tool, TRACO [2], based on calculating the **TRA**nsitive **C**l**O**sure of dependence graphs. It currently parallelizes loop nests being written in the C language.

The purpose of this source-to-source compiler is to automatically convert existing serial numerical applications to parallel ones to be run on multicore systems and high performance computers. It produces parallel target code that is semantically identical with original source code.

## II. Background

The source-to-source TRACO compiler implements Iteration Space Slicing (ISS) techniques together with the free-scheduling, variable privatization and parallel reduction techniques. Output code, produced by TRACO, is compilable and contains OpenMP directives [3]. TRACO is available at the website http://traco.sourceforge.net.

ISS was introduced by Pugh and Rosser [4]. It takes dependence information as input to find all statement instances that must be executed to produce the correct values for the specified array elements. Dependences available in a loop nest are described by dependence relations with constraints presented by means of the Presburger arithmetic that is the first-order theory of the integers in the language $L$ having 0, 1 as constants, +,- as binary operations, and equality =, order $<$ and congruences $\equiv_n$ modulo all integers $n$ $\geq$1 as binary relations.

Coarse-grained code is presented with synchronization-free slices. TRACO uses the dependence analysis [5] proposed by Pugh and Wonnacott where dependences are represented by dependence relations. This analysis is implemented in Petit [6].

Standard operations on relations and sets are used, such as intersection ($\cap$), union ($\cup$), difference (-), domain (dom $R$), range (ran $R$), relation application ($S'$= $R(S)$: $e'\in S'$iff exists $e$ s.t. $e\to e'\in R,e\in S$), positive transitive closure of relation $R$, $R$+ = $\{[e]\to[e']$ : $e\to e'\in$ $R$ $\vee$ $\exists$ $e$ $''$, $e\to$e$''\in$ $R$ $\wedge$ $e''\to e'\in$ $R$+$\}$, transitive closure $R$* = $R$+ $\cup$ $I$. In detail, the description of these operations is presented in papers [5], [7].

The positive transitive closure for a given relation $R$, $R^+$, is defined as follows [7]
$R^+ = \{e \to e' :\ e \to e' \in R \vee \exists e'' s.t.\ e \to e'' \in R \wedge e'' \to e' \in R^+\}$.
It describes which vertices $e'$ in a dependence graph (represented by relation $R$) are connected directly or transitively with vertex $e$.

Transitive closure, $R^*$, is defined as follows [8]: $R^* = R^+ \cup I$, where $I$ the identity relation. It describes the same connections in a dependence graph (represented by $R$) that $R^+$ does plus connections of each vertex with itself.

To perform operations on sets and relations as well as calculating transitive closure, TRACO uses the ISL library [9].

## III. Iteration Space Slicing for Parallelism Extraction

ISS algorithms, presented in paper [1], allow us to generate parallel code representing synchronization-free slices. An (iteration-space) slice is defined as follows.

**Definition 1**. Given a dependence graph defined by a set of dependence relations, a slice *S* is a weakly connected component of this graph, i.e., a maximal sub-graph such that for each pair of vertices in the sub-graph there exists a forward or backward path.

**Definition 2**. An ultimate dependence source is a source that is not the destination of another dependence. Given a dependence relation *R,* describing all the dependences in a loop, set, $S_{UDS}$, including all ultimate dependence sources can be calculated as domain(*R*) - range(*R*).

**Definition 3**. The representative of a slice is its lexicographically minimal ultimate source.

An approach to extract synchronization-free slices takes two steps [1]. First, for each slice, a representative statement instance is defined (it is the lexicographically minimal statement instance from all the sources of a slice). Next, slices are reconstructed from their representatives and code scanning these slices is generated.

Given a dependence relation *R,* describing all the dependences in a loop, we calculate set of all ultimate dependence sources of slices , $S_{UDS}$, as follows

$$S_{UDS} = domain(R) - range(R). \tag{1}$$

In order to find elements of $S_{UDS}$ that are representatives of slices, we build a relation, $R_{USC}$, that describes all pairs of the ultimate dependence sources being transitively connected in a slice, as follows:

$$R_{USC} = \{[e] \to [e'] : e, e' \in S_{UDS}, e \prec e', (R^*(e) \cap R^*(e'))\}. \tag{2}$$

The condition ($e \prec e'$) in the constraints of relation $R_{USC}$ above means that *e* is lexicographically smaller than *e*′. Such a condition guarantees that the lexicographically smallest element from *e* and *e*′ will always appear in the input tuple of $R_{USC}$ (its representative source), i.e., it can never appear in the output tuple. The intersection (*R**(*e*)∩*R**(*e*′)) in the constraints of $R_{USC}$ guarantees that vertices *e* and *e*′ are transitively connected, i.e., they are the sources of the same slice.

Next, set, $S_{repr}$, containing representatives of each slice is found as $S_{repr}$ = $S_{UDS}$ - range($R_{USC}$). Each element *e* of set $S_{repr}$ is the lexicographically minimal statement instance of a synchronization-free slice. If *e* is the representative of a slice with multiple sources, then the remaining sources of this slice can be found applying relation ($R_{USC}$)* to *e*, i.e., ($R_{USC}$)*(*e*). If a slice has the only source, then ($R_{USC}$)*(*e*)=*e*. The elements of a slice represented with *e* can be found applying relation *R** to the set of sources of this slice:

$$S_{slice} = R^*((R_{USC})^*(e)). \tag{3}$$

To generate code, we insert in the first positions of the tuple of set $S_{slice}$ the elements of the tuple of set $S_{repr}$ (together with corresponding constraints) and apply the CLooG library [10] to so extended set $S_{slice}$ .

To parallelize loop nests which expose a single synchronization-free slice, time partitioning can be applied. The algorithm, presented in our paper [11], allows us to generate time partitions and corresponding fine-grained parallel code on the basis of the free schedule; all statement instances of a time partition can be executed in parallel, while partitions are enumerated sequentially. The free schedule function is defined as follows.

**Definition 4** [12]. The *free schedule* is the function that assigns discrete time of execution to each loop statement instance as soon as its operands are available, that is, it is mapping $\sigma$:*LD*→ $\mathbb{Z}$ such that

$$\sigma(p) = \begin{cases} 0 \; if \; there \; is \; no \; p_1 \in LD \; s.t. \; p_1 \to p \\ 1 + max(\sigma(p_1), \sigma(p_2), ..., \sigma(p_n)); \\ \qquad\qquad p, p_1, p_2, ..., p_n \in LD; \\ p_1 \to p, p_2 \to p, ..., p_n \to p, \end{cases}$$

where $p, p_1, p_2, ..., p_n$ are loop statement instances, *LD* is the loop domain, $p_1 \to p, p_2 \to p, ..., p_n \to p$ mean that the pairs $p_1$ and $p$, $p_2$ and $p$, ...,$p_n$ and $p$ are dependent, $p$ represents the dependence destination, while $p_1, p_2, ..., p_n$ represent the sources of dependences, *n* is the number of operands of statement instance *p* (the number of dependences whose destination is statement instance *p*). The free schedule is the fastest legal schedule [12]. In paper [11] we presented fine-grained parallelism extraction based on the power *k* of relation *R*.

The idea of the algorithm is the following [11]. Given relations $R_1$, $R_2$, ..., $R_m$, representing all dependences in a loop nest, we first calculate $R = \bigcup_{i=1}^{m} R_i$ and then $R^k$, where $R^k = \underbrace{R \circ R \circ ...R}_{k}$, "∘" is the composition operation. Techniques of calculating the power *k* of relation *R* are presented in the following publications [8], [9], [14] and they are out of the scope of this paper. Let us only note that given transitive closure $R^+$, we can easily convert it to the power *k* of *R*, $R^k$, and vice versa, for details see [9].

Given set *UDS* comprising all loop nest statement instances that are ready to execution at time *k*=0, each vertex, belonging the set $S_k$ = $R^k(UDS)$ - $R^+ \circ R^k(UDS)$, is connected in the dependence graph, defined by relation *R*, with some vertex(ices) represented by set *UDS* with a path of length *k* . Hence at time *k*, all the statement instances belonging to the set $S_k$ can be scheduled for execution and it is guaranteed that *k* is as few as possible.

## IV. Loop Tiling

Tiling is a very important iteration reordering transformation for both improving data locality and extracting loop nest parallelism. TRACO allows users generate parallel tiled code by means of algorithms based on the transitive closure of a dependence graph [13].

First, we form set *TILE(**II**, **B**)* including iterations belonging to a parametric tile as follows

*TILE*(***II**, **B***) = {[***I***] | ***B***II* +***LB*** $\leq$ ***I*** $\leq$ min( ***B****(***II*** +**1**) + ***LB*** -**1**, ***UB***) AND ***II*** $\geq$ 0}, where vectors ***LB*** and ***UB*** include the lower and upper loop index bounds of an original loop nest, respectively; diagonal matrix ***B*** defines the size of a rectangular original tile; elements of vectors ***I*** and ***II*** represent the original loop nest indices and the identifiers of tiles, respectively; **1** is the vector whose all elements have value 1.

*TILE*(***II**, **B***) represents a tile of the rectangular shape with a fixed size defined by the user.

Sets *TILE_LT* and *TILE_GT* are the unions of all the tiles whose identifiers are lexicographically less and greater than that of *TILE*(***II***, ***B***), respectively.

*TILE_LT* ={[***I***] | exists ***II***$'$ s. t. ***II***$'$ $\prec$ ***II*** AND ***II***, ***II***$'$ in *II_SET* AND ***I*** in *TILE*(***II***$'$, ***B***)},

*TILE_GT* ={[***I***] | exists ***II***$'$ s. t. ***II***$'$ $\succ$ ***II*** AND ***II***, ***II***$'$ in *II_SET* AND ***I*** in *TILE*(***II***$'$, ***B***)}.

Set *TILE_ITR = TILE - R*$^+$( *TILE_GT* ) does not include any invalid dependence target.

Set *TVLD_LT* = ( *R*$^+$(*TILE_ITR*) $\cap$ *TILE_LT*) - *R*$^+$(*TILE_GT*) includes all the iterations that i) belong to the tiles whose identifiers are lexicographically less than that of set *TILE_ITR*, ii) are the targets of the dependences whose sources are contained in set *TILE_ITR*, and iii) are not any target of a dependence whose source belong to set *TILE_GT*.

Set *TILE_VLD = TILE_ITR* $\cup$ *TVLD_LT* represents target tiles.

To generate code, we form set *TILE_VLD_EXT* by means of inserting i) into the first positions of the tuple of set *TILE_VLD* indices $ii_1, ii_2, ..., ii_d$; ii) into the constraints of set *TILE_VLD* the constraints defining tile identifiers ***II*** $\geq$ 0 and ***B***II*+***LB*** $\leq$ ***UB***.

The resulting code can be produced by means of applying any code generator to scan elements of set *TILE_VLD_EXT* in the lexicographic order, for example, CLooG [10]. TRACO implements an extended approach allowing for tiling imperfectly nested loops also.

All the presented algorithms implemented in the TRACO compiler are based on the transitive closure of a dependence relation representing all dependences in a loop nest. Loop nest tiling and iteration space slicing can be combined in order to increase program locality and the grain size of parallel code. For this purpose, we form relation *R_TILE* that describes dependences among all tiles but ignores dependences within each tile as follows.

*R_TILE*:={[***II***]->[***JJ***]: exist ***I***, ***J*** s.t. (***II**, **I***) in *TILE_VLD_EXT*(***II***) *AND* (***JJ**, **J***) in *TILE_VLD_EXT*$_i$(***JJ***) *AND* ***J*** in *R*(***I***)},

where ***II**, **JJ*** are the vectors representing tile identifiers. Such a relation can be used to extract slices comprising tiles or free-scheduling in the same way as it is described in Section III except from instead of relation $R$ relation *R_TILE* has to be used.

## V. TRACO USAGE FOR THE HYDRO-FRAGMENT CODE

In this section, we present the usage of the TRACO compiler to optimize the code of the hydrodynamics fragment of the first kernel of the Livermoore Loops suite (*k1*) [15].

```
for ( l=1 ; l<=loop ; l++ ) {
 for ( k=0 ; k<n ; k++ ) {
  x[k] = q + y[k]*( r*z[k+10] + t*z[k+11] );
 }
}
```

The following relation describes dependences in this program.

*R* := [n,loop] -> { [l,k,13] -> [l',k',13] :( k' = k and 1 <= l < l' <= loop and 0 <= k < n and l < loop and 1 <= loop and 2 <= l' ) },

where here and further on "13"states for the loop nest statement identifier, defined by the line number of this statement in the source code.

First of all, we generate parallel synchronization-free code. For this purpose, we calculate the transitive closure of relation *R*, $R^*$:

$R^*$ := [n, loop] -> { [l, k, 13] -> [l', k, 13] : l >= 1 and k >= 0 and k <= -1 + n and l' >= 1 + l and l' <= loop; [l, k, v] -> [l, k, v] }.

Next, we expose slice representatives. Because $R_{UCS}$ = $\oslash$, we have

S$_{REPR}$ =*UDS*:= {[n, loop] -> [0, i1, 13] : loop >= 17 and i1 >= 0 and 16i1 <= -1 + n }.

Now, we form set, $S_{slice}$, representing slices:

$S_{slice}$ := [n, loop, c1] -> ] [i0, c1, 13] : c1 >= 0 and c1 <= -1 + n and i0 <= loop and loop >= 2 and i0 >= 1 },

and insert in the first positions of the tuple of set $S_{slice}$ the elements of the tuple of set $S_{REPR}$(together with corresponding constraints) and apply to so extended set $S_{slice}$ CLooG to get the following parallel code.

```
if (n + loop >= 3 && loop >= 1)
#pragma omp parallel for
  for (c1 = 0; c1 < n; c1 += 1)
     if (c1 >= 0 && loop >= 2 && n >= c1 + 1)
        for (c0 = 1; c0 <= loop; c0 += 1)
        x[c1]=q+y[c1]*(r*z[c1+10]+t*z[c1+11]);
```

Below, we demonstrate how tiled code can be generated for the same example. First, we define a rectangular parametric tile of the size 16x16 as follows.

*TILE*:= [ll, kk, n, loop] -> { [l, k, 13] : l >= 1 + 16ll and l >= 1 and l <= loop and l <= 16 + 16ll and k >= 16kk and k >= 0 and k <= -1 + n and k <= 15 + 16kk and ll >= 0 and kk >= 0 and loop >= 1 and n >= 1 }.

Next, we calculate the following sets:

*TILE_LT*:= [ll, kk, n, loop] -> { [l, k, 13] : l >= 1 + 16ll and l >= 1 and l <= loop and l <= 16 + 16ll and k >= 0 and k <= -1 + 16kk and n >= 1 + 16kk and ll >= 0 and loop >= 16ll and kk >= 0 },

*TILE_GT*:= [ll, kk, n, loop] -> { [l, k, 13] : l >= 1 + 16ll and l >= 1 and l <= loop and l <= 16 + 16ll and k >= 16 + 16kk and k <= -1 + n and ll >= 0 and loop >= 16ll and kk >= 0 and n >= 1 + 16kk , *TILE_ITR*:= [n, loop, ll, kk] -> [l, k, 13] : ll >= 0 and kk >= 0 and l >= 1 + 16ll and l <= 16 + 16ll and l <= loop and k >= 16kk and k <= 15 + 16kk and k <= -1 + n },

*TVLD_LT* = $\oslash$, *TILE_VLD* = *TILE_ITR*,

*TILE_VLD_EXT*:= [n, loop] -> { [i0, i1, i2, i3, 13] : i0 >= 0 and i1 >= 0 and i2 >= 1 + 16i0 and i2 <= 16 + 16i0 and i2 <= loop and i3 >= 16i1 and i3 <= 15 + 16i1 and i3 <= -1 + n }.

Applying CLooG to set *TILE_VLD_EXT,* we generated the following tiled code (without parallelism).

```
for(c0=0; c0 <= (loop-1)/16; c0 += 1)
 for(c1=0; c1 <= (n-1)/16; c1 += 1)
  for(c2=16*c0+1; c2<=min(loop,16*c0+16); c2++)
   for(c3=16*c1; c3<=min(n-1,16*c1+15); c3++)
    x[c3]=q+y[c3]*(r*z[c3+10]+t*z[c3+11]);
```

To generate parallel synchronization-free tiled code, we calculate tile representatives (the lexicographically minimal tiles of slices) comprised in set *TILE_SOUR* and a relation *R_TILE* that describes dependences among all tiles but ignores dependences within each tile as follows. Next, the transitive closure of that relation, $R\_TILE^*$, is calculated, and finally set, *SLICE*, representing slices comprising tiles are extracted. The corresponding sets and relations for the loop nest above are as follows.

*TILE_SOUR*:= [n, loop] -> { [ i1, i3, 13] : loop >= 17 and i1 >= 0 and i3 >= 16i1 and i3 <= 15 + 16i1 and i3 <= -1 + n }, where "13"is the statement identifier,

*R_TILE:*= [n, loop] -> { [i0, i1, 13] -> [o0, i1, 13] : i0 >= 0 and i1 >= 0 and 16o0 <= -1 + loop and o0 >= 1 + i0 and 16i1 <= -1 + n and 16i0 <= -2 + loop },

$R\_TILE^*$:= [n, loop] -> { [i0, i1, 13] -> [o0, i1, 13] : i0 >= 0 and i1 >= 0 and 16o0 <= -1 + loop and o0 >= 1 + i0 and 16i1 <= -1 + n and 16i0 <= -2 + loop },

*SLICE:*= [n, loop, c1] -> { [i0, i1, i2, i3, 13] : loop >= 17 and i2 <= 16 + 16i0 and i2 <= loop and i3 >= 16c1 and i3 >= 0 and i3 <= 15 + 16c1 and i3 <= -1 + n and i3 <= 15 + 16i1 and i3 >= 16i1 and i2 >= 1 and i2 >= 1 + 16i0 }.

Applying CLooG to set *SLICE* and preprocessing the code returned by CLooG, we get the following OpenMP C parallel code, where line 1 represents the OpenMP *parallel for* directives pointing out that the *for* loop in line 2 can be executed in parallel; line 2 and line 4 include the *for* loops enumerating tile identifiers whereas line 5 and line 6 present *the for* loops scanning statement instances within a tile whose identifier is defined by the indices of the loops in lines 2 and 4.

```
1.#pragma omp parallel for
2.for (c1 = 0; c1 <= floord(n - 1, 16); c1++)
3. if (loop >= 17)
4.  for (c0 = 0; c0 <= (loop-1)/16; c0 += 1)
5.   for(c2=16*c0+1;c2<=min(16*c0+16,loop);c2++)
6.    for(c3=16*c1; c3<=min(n-1,16*c1+15); c3++)
7.      x[c3]=q+y[c3]*(r*z[c3+10]+t*z[c3+11]);
```

## VI. Related work

Well-known automatic parallelization of numerical algorithms is based on the polyhedral model, which provides an abstraction to perform high-level transformations such as loop-nest optimization and parallelization on affine loop nests. The polyhedral source to source tools: Pluto [16], POCC and PTile [17] transform C programs to expose parallelism and improve data locality simultaneously. The core transformation framework mainly works by finding affine transformations for efficient loop nest tiling and fusion, but not limited to those.

TABLE I
Numerical programs

| Benchmark | Description |
|---|---|
| advect3d | Advection Kernel for Weather Modeling |
| correl | Correlation Computation |
| dct | Discrete Cosinus Transform |
| doitgen | Multi resolution Analysis Kernel |
| dsyr2k | Symmetric rank-2k operations |
| gemver | Vector Multiplication and Matrix Addition |
| k6 | General Linear Recurrence Equations |
| tce | Tensor Contraction Expressions |

The polyhedral model approach includes the following three steps: i) program analysis aimed at translating high level codes to their polyhedral representation and to provide data dependence analysis based on this representation, ii) program transformation with the aim of improving program locality and/or parallelization, iii) code generation [18], [19], [20], [21], [22]. All above three steps are available in the approach presented in this paper. But there exists the following difference in step ii): in the polyhedral model "*a (sequence of) program transformation(s) is represented by a set of affine functions, one for each statement*" [23] while the presented approach does not find and use any affine function. It applies the transitive closure of a program dependence graph to specific subspaces of the original loop nest iteration space. At this point of view the program transformation step is rather within the Iteration Space Slicing Framework introduced by Pugh and Rosser [4]: "*Iteration Space Slicing takes dependence information as input to find all statement instances from a given loop nest which must be executed to produce correct values for the specified array elements* ". The key step in Iteration Space Slicing is calculating the transitive closure of a loop nest dependence graph.

To extract affine transformations, the polyhedral model assumes that first "time-partition constraints" are to be formed, then a solution to them has to be found. The "time-partition constraints" [18], [19], [24] represent the condition that if one iteration is depend upon the other, then the first must be assigned to a time that is no earlier than that of the second; if they are assigned to the same time, then the first has to be executed after the second. If there exist more than one linearly independent solutions to the time-partition constraints formed for a loop nest, then it is possible to derive affine transformations allowing for loop nest parallelization and program locality improvement. Otherwise, the polyhedral model fails to expose parallelism and improve program locality.

Some limitations of affine transformation are considered in paper [1]. The main drawback of the affine transformation framework is that there does not always exist two or more

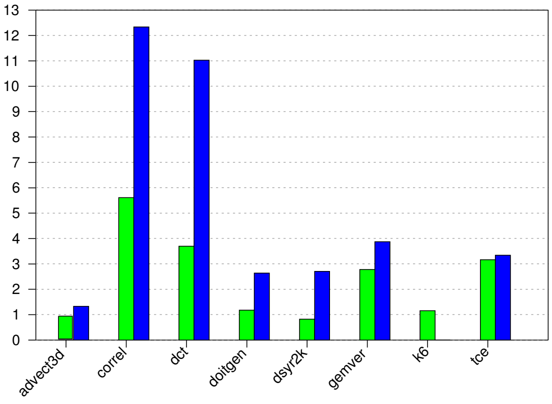

Fig. 1. Speed-up1 for tiled codes (the green bars) and speed-up2 for parallel tiled codes (the blue bars) of the studied numerical programs.

independent solutions to the time-partition constraints. For example, the studied numerical algorithm *k6* (General Linear Recurrence Equations) cannot be tiled or parallelized by PLUTO or other polyhedral tools because there exists the only solution to corresponding time-partition constraints. To extract parallelism, TRACO needs only the transitive closure of a dependence graph, so it lacks the drawbacks inherent for affine transformations.

## VII. Numerical programs

In this section, we present numerical programs chosen for carrying out experiments (Table I). We consider applications of numerical algorithms in industry and engineering: *advect3d*, *tce*, and *dct*; typical programs from compute-intensive sequences of algebra operations: *correl*, *doitgen*, *dsyr2k*, *gemver*, and *k6*. Source codes of these numerical programs are available at the TRACO website [2].

*advect3d* is the Runga-Kutta advection core from the NCOMMAS code for mesoscale weather modeling [25]. *tce* is a sequence of four nested loops, occurring in Tensor Contraction Expressions that appear in computational quantum chemistry problems [26]. Discrete cosinus transform (*dct*) is important to numerous applications in science and engineering, from lossy compression of audio and images to spectral methods for the numerical solution of partial differential equations.

The reminding benchmarks are linear algebra programs: *gemver* is a composition of BLAS operations used for householder bidiagonalization, *doitgen* is an in-place 3D-2D matrix product, and symmetric rank-2k operations *dsyr2k*. General linear recurrence equations *k6* is a kernel from the Livermore loops [15]. *correl* creates a correlation matrix and is used also in data mining [27].

The computations of *k6*, *dsyr2k*, *advect3d*, *tce*, and *gemver* are represented by perfectly nested loops, while *doitgen*, *dct*, and *correl* are represented by imperfectly nested loops.

## VIII. Experiments

We have applied TRACO to each of the benchmarks, presented in Table 1, to generate serial tiled and parallel synchronization-free tiled code. For the *k6* program, TRACO is able to generate only serial tiled code (for this benchmark, PLUTO fails to generate tiled and any parallel code).

To run programs, we have used a computer with Intel i5-4670 3.40 GHz processors (Haswell, 2013), 6MB cache and 8GB RAM. Table II presents execution time for original (*t_untiled*), serial tiled (*t_tiled*) and parallel tiled (*t_par_tiled*) applications (for 4 CPUs) for the different problem size and tile (block) size as well as the speed up of tiled code, where *speed-up1=t_untiled/t_tiled*, *speed-up2=t_untiled/t_par_tiled*, *speed-up3=t_tiled/t_par_tiled.*

Analysing the data in Table II, we may conclude that serial tiled code for each program, except from *advect3d* and *dsyr2k*, demonstrates positive speed-up (see speed-up1), for the *correl* program, speed-up is equal about 5,5. This fact can be explained by increasing tiled code locality in comparison with that of untiled code.

Serial tiled code does not increase the locality of the original *advect3d* and *dsyr2k* programs, so the corresponding serial tiled programs are not faster than the original ones.

All parallel synchronization-free tiled programs expose positive speed-up (speed-up2 and speed-up3). Two parallel programs, *dct* and *corcol,* demonstrate super linear speed-up2 ( for four CPUs, the speed-up of those programs is about 12 and 11, respectively). The reason for super-linear speed-up is that the working set of a problem is greater than the cache size when executed sequentially, but can fit nicely in each available cache when executed in parallel.

The best program speed-ups (speed-up2) are presented in a graphical way in Figure 1. All parallel tiled programs, generated by TRACO, are faster than serial tiled code – see speed-up3.

## IX. Conclusion

In this paper, we presented applying the transitive closure of dependence graphs, implemented in TRACO, for automatic producing both serial and parallel tiled code for chosen numerical applications. Loop nest computations are divided into multiple slices which are mapped to processors as threads. TRACO allows users to achieve significant speed-up of parallel numerical algorithms on shared memory machines with multi-core processors. The effectiveness of applying TRACO is comparable or better than that of other well-known optimizing compilers.

In the future, we plan to implement in TRACO techniques allowing for tiled code scalability and tile shapes different from the rectangular one, first of all parallelepiped tiles that will allow us to increase parallelism degree of parallel tiled code.

***Abstract*—The paper is devoted to discussion of the minimal cycles of the so called Kaprekar's transformations and some of its generalizations. The considered transformations are the self-maps of the sets of natural numbers possessing $n$ digits in their decimal expansions. In the paper there are introduced several new characteristics of such maps, among others, the ones connected with the Sharkovsky's theorem and with the Erdős-Szekeres theorem concerning the monotonic subsequences. Because of the size the study is divided into two parts. Part I includes the considerations of strictly theoretical nature resulting from the definition of Kaprekar's transformations. We find here all the minimal orbits of Kaprekar's transformations $T_n$, for $n = 3, ..., 7$. Moreover, we define many different generalizations of the Kaprekar's transformations and we discuss their minimal orbits for the selected cases. In Part II (ibidem), which is a continuation of the current paper, the theoretical discussion will be supported by the numerical observations. For example, we notice there that each fixed point, familiar to us, of any Kaprekar's transformation generates an infinite sequence of fixed points of the other Kaprekar's transformations. The observed facts concern also several generalizations of the Kaprekar's transformations defined in Part I.**

## I. Introduction

SUBJECT concerning the form, description and coexistence of orbits of the given map $F\colon X \to X$ became a chart-topping object of research after popularization of the Sharkovsky's theorem ([1], [8], [9], [10], [23], [27], [28]). We shall recall it to the Readers.

Let $\mathbb{N}$ denote the set of all positive integers. The following ordering of elements of $\mathbb{N}$ is called the Sharkovsky's ordering of $\mathbb{N}$:

$$\begin{gathered}3, 5, 7, 9, \dots, 2\cdot 3, 2\cdot 5, 2\cdot 7, 2\cdot 9, \dots,\\ 2^2\cdot 3, 2^2\cdot 5, 2^2\cdot 7, 2^2\cdot 9, \dots \\ 2^k\cdot 3, 2^k\cdot 5, 2^k\cdot 7, 2^k\cdot 9, \dots, 2^4, 2^3, 2^2, 2, 1.\end{gathered}\tag{1}$$

**Sharkovsky's theorem**. *The following facts hold:*

(a) *If $f\colon [0,1] \to [0,1]$ is a continuous map then there exists $n = n(f) \in \mathbb{N} \cup \{2^\infty\} \cup \{0\}$ such that the set $Per(f)$ of periods of all periodic orbits of $f$ is equal to the set of all $m \in \mathbb{N}$ located on the right side of $n$ in the Sharkovsky's order (if $n = 2^\infty$ then, by definition, $Per(f) = \{2^k\colon k = 0, 1, 2, \dots\}$, whereas, if $n = 0$ then $Per(f) := \mathbb{N}$).*

(b) *If $n \in \mathbb{N} \cup \{2^\infty\} \cup \{0\}$ then there exists a continuous map $f\colon [0,1] \to [0,1]$ such that the set $Per(f)$ is equal to the set of all $m \in \mathbb{N}$ located on the right side of $n$ in the Sharkovsky's order and for two selected cases, $n = 2^\infty$ and $n = 0$, the set $Per(f)$ is equal to the one defined above.*

In the subject-matter referring to the Sharkovsky's theorem we know a lot at the moment and many facts have been also till now discovered, like for example the description of periodic orbits of triod (see [2]), the generalizations of Sharkovsky's theorem for hereditarily decomposable chainable continua (see [22], [25], [26]) and the new order for periodic orbits of interval maps (see [5] and references therein). Another important fact (which we intend to discuss in this study as well) concerns not only the periods of a given map but also the so called orbit type. It was at first defined by S. Baldwin in [3] for maps of an interval (see also [24] and references therein) and next extended by others (for example in [4] for the maps of a circle and in [21] for the groups and the groups of graphs). We will use here the following definition [1]. If $f\colon X \to X$, where $X \subset \mathbb{R}$ has $n$-elements (minimal) orbit $\{x_0, f(x_0), \dots, f^{n-1}(x_0)\}$, where $f^k$ denotes the $k-$times composition of $f$, then this orbit induces a cyclic permutation of order $n$, called the orbit type. More precisely, if the points of this orbit are indexed in increasing order $x_1 < x_2 < \dots < x_n$, then the respective orbit type $p$ is defined by $p(k) = j$ whenever $f(x_k) = x_j$. In other words, if $x_0 = x_{k_1}$, $f(x_0) = x_{k_2}, \dots$, $f^{(n-1)}(x_0) = x_{k_n}$, then the orbit type $p$ is equal to $(k_1, k_2, \dots, k_n)$. We note that there exists $(n-1)!$ orbit types of order $n$.

We say that the orbit type guarantees a period-3 point if any continuous function with an orbit of that type possesses a three-element orbit. Eric Lundberg proved in paper [19] that

$$\lim_{n\to\infty} \frac{\gamma_n}{(n-1)!} = 1,$$

where $\gamma_n$ denotes the number of orbit types of order $n$ that guarantees a period-3 point.

Let us emphasize that almost all the above results cannot be transformed so obviously onto many equally interesting cases of maps, even so numerically attractive like the self-maps of the finite sets.

A reason for creating this paper was the information, surprising for the Authors, about the existence of the so called Kaprekar constant [16], [17], which appeared to be,

978-83-60810-66-8/$25.00©2015, IEEE

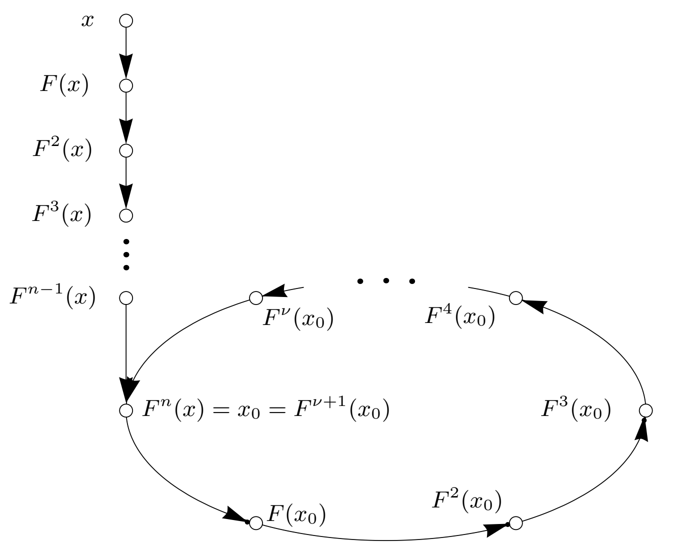

Fig. 1. Graphical illustration of a finite set $X$ and a map $F\colon X \to X$, where $X = \{F^k(x) : k \in \mathbb{N}\}$ for some $x \in X$, possessing one nontrivial and proper orbit

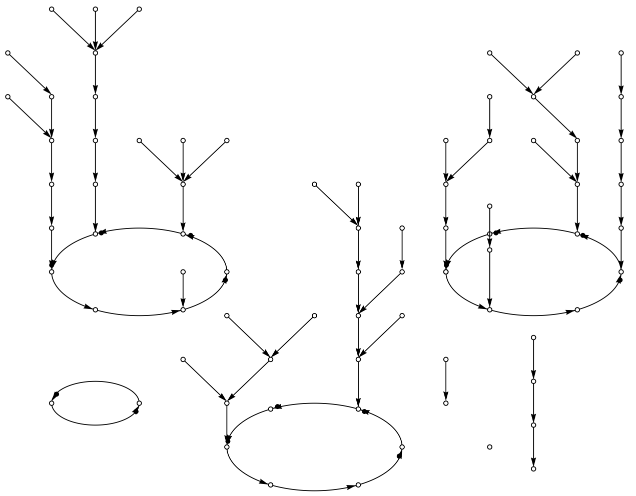

Fig. 2. Graphical illustration of any map $F : X \to X$ operating, where $X$ is a finite set of all indicated circle-points

no more no less, a single element of a single orbit of some map (we will describe this map in Section 2) onto the finite set of all natural numbers with four-digit decimal expansion. Let us notice in this moment that if $F\colon X \to X$ and $X$ is a finite nonempty set then for every $x \in X$ there exists $n \in \mathbb{N}_0$ such that $n$-th $F$-iteration of $x$, i.e. the element $F^n(x)$, belongs to some minimal orbit of $F$. This means, by definition, that certain subset of $X$ is of the form $\{x_0 = F^{\nu+1}(x_0), F(x_0), F^2(x_0), \ldots, F^\nu(x_0)\}$, where $\nu \in \mathbb{N}_0$. The above facts are illustrated in Figures 1 and 2.

Let us note that in general case there is no connection between values $n$ and $\nu$ (more precisely, for any $n, \nu \in \mathbb{N}$, for the set $X$ composed of elements – circles like in Fig.1, we construct a map described in Fig.1 proving that there is no relation between $n$ and $\nu$). However, we should remember that in the case of some specific maps (and even for the families of maps) the relation between $n$ and $\nu$ may appear!

In case when $F$ is a bijection on $X$, that is permutation on $X$, then every element of set $X$ belongs to some $F$-orbit ($F$-orbit is created by elements of each cycle of permutation $F$). Certainly, if $F$ is not a bijection on $X$ then the situation is also easy to describe, at least from the theoretical point of view, namely the set

$$\mathbb{X} := \bigcap_{k=0}^{card\, X} F^k(X)$$

is a set-theoretical union of all orbits of the map $F$, and moreover, $F$ restricted to $\mathbb{X}$ is a bijection on $\mathbb{X}$. Set $\mathbb{X}$ is the largest fixed subset of map $F$, it means if $Y \subset X$ and $F(Y) = Y$, then $Y \subset \mathbb{X}$. Henceforward we will call such set as the maxinvariant subset of $F$. The only problem in this situation is the actual form of set $\mathbb{X}$? (In Figure 2 the set $\mathbb{X}$ is equal to the union of final single points and all points located on the indicated ellipses.) Of course equally essential, although much more difficult in practice, is the description of all orbits of map $F$.

In this paper, as the input set $X$ we will take the families containing numbers 0, $10^{k-1} - 1$ and the natural numbers possessing $k$ digits in their decimal expansion, that is

$$X = X(k) = \{0\} \cup \{n \in \mathbb{N}\colon 10^{k-1} - 1 \leq n < 10^k\}$$

for each $k \in \mathbb{N}$. This additional "condition" will enable to reduce determination of the orbits of the so called Kaprekar's transformations $T_k\colon X(k) \to X(k)$ – described in the next section – to solution of some diophantine equations. Although we have learnt about orbits of many maps $T_k$, this knowledge did not help us unfortunately to answer the basic question: how many orbits do these maps possess in dependence on the value of parameter $k$ for any $k \in \mathbb{N}$? In both parts of our study we are able to answer this question only for values $k \leq 20$.

In Part II of our considerations we will present many various remarks, facts and conjectures which arose basically by observing the numerical results concerning the description of the orbits of maps $T_n$ for $n \leq 20$. We will prove, among others, that the fixed points of these maps generate the infinite sequences of the fixed points of maps $T_{a\,n+b}$, $n \in \mathbb{N}$, for some natural numbers $a$ and $b$.

Additionally, we have noticed that many from among the maps investigated by us (including the generalizations of the Kaprekar's transformation – we define them in last section – however, with regard to this paper length, we will present the appropriate considerations in a separate paper) preserve the strong Sharkovsky's order (the Sharkovsky's order, respectively). It should be understood in the following way.

**Definition 1.** *Map $T\colon X \to X$, where $X$ is a finite set, preserves the strong Sharkovsky's order if the elements of the set of cardinalities of all orbits of this map can be ordered* *in the sequence $k_1, k_2, \dots, k_n$, being the sequence of natural numbers, successive in the sense of order (1).*

**Definition 2.** *Map $T\colon X \to X$, where $X$ is a finite set, preserves the Sharkovsky's order if the elements of the set of cardinalities of all orbits of this map can be ordered in the sequences $k_1^{(r)}, k_2^{(r)}, \dots, k_n^{(r)}$, $r = 1, 2, \dots, s$, successive in the sense of order (1), and the different values of superscript $r$ correspond with the different "numbers of levels" of description (1). More precisely, the first level of description (1) is formed by the numbers*

$$3, 5, 7, 9, 11, \dots,$$

*the second level of description (1) is made by the numbers*

$$2 \cdot 3, 2 \cdot 5, 2 \cdot 7, 2 \cdot 9, 2 \cdot 11, \dots,$$

*the third level of description (1) is created by the numbers*

$$4 \cdot 3, 4 \cdot 5, 4 \cdot 7, 4 \cdot 9, 4 \cdot 11, \dots, \quad \textit{and so on},$$

*and finally "the last level" of description (1) is formed by the numbers*

$$\dots, 2^5, 2^4, 2^3, 2^2, 2, 1.$$

Reason of these definitions is also worth to recall. So, as it is easy to prove, for any one-to-one sequence $k_1, k_2, \dots, k_n$ of natural numbers there exist the sets $X_i$, $i = 1, 2, \dots, n$, (pairwise disjoint and such that $cardX_i = k_i$) and the map $T\colon \bigcup_{i=1}^{n} X_i \to \bigcup_{i=1}^{n} X_i$, for which the sets $X_i$ are the only minimal orbits.

Moreover, we have investigated the minimal cycles of the discussed here maps with regard to the Erdős-Szekeres theorem, as well as to the maximal length of monotonic intervals of the given cycle (see [30]) and, at last, by paying the special attention to the relatively new but extremely dynamic theory of "pattern avoiding permutations" (see [6], [20]).

Let us recall here at least few essential definitions and facts. Let $\mathbf{a} = \{a_i\}_{i=1}^{n}$ be a one-to-one sequence of real numbers. Each subsequence $\mathbf{b}$ of $\mathbf{a}$ having the form $\{a_l, a_{l+1}, ..., a_{l+r}\}$ for some $l, r \in \mathbb{N}_0$, $1 \le l \le l{+}r \le n$, will be called an interval of $\mathbf{a}$. A subsequence $\mathbf{b}$ of $\mathbf{a}$ is said to be a monotonic interval of $\mathbf{a}$ whenever $\mathbf{b}$ is an interval of $\mathbf{a}$ and, simultaneously, $\mathbf{a}$ is a monotonic sequence. Moreover, we will denote by $l(\mathbf{a}) := n$ the number of elements of $\mathbf{a}$ called as the length of $\mathbf{a}$, by $d(\mathbf{a})$ – the maximal number from among the numbers denoting the lengths of all decreasing subsequences of $\mathbf{a}$ and finally by $i(\mathbf{a})$ – the maximal number from among the numbers denoting the lengths of all increasing subsequences of $\mathbf{a}$.

**Erdős-Szekeres' theorem.** *Let us suppose that $\mathbf{a}$ is a finite one-to-one sequence of real numbers. Then we have*

$$d(\mathbf{a})\, i(\mathbf{a}) \ge l(\mathbf{a}).$$

The above theorem comes from the joint paper by Erdős and Szekeres concerning the Ramseys problem [12]. Next, Wituła et al. in [30] have discussed whether the given one-to-one sequence $\mathbf{a}$ of all numbers $1, 2, ..., n$ (which means that $\mathbf{a}$ can be identified with the respective permutation on set $\{1, 2, ..., n\}$) contains a monotonic interval $\mathbf{b}$ of length 3. The following fact is, among others, proven there.

**Theorem 1.** *Let $\mathbf{a} = \{a_i\}_{i=1}^{3n}$ be a permutation on $\{1, 2, ..., 3n\}$ and let $n \ge 4$. If $i(\mathbf{a}) = n$, $d(\mathbf{a}) = 3$, $a_k = 3n$ and $a_l = 1$ for some $k < l$, then $\mathbf{a}$ contains a monotonic interval $\mathbf{b}$ of length 3.*

In the next section of this paper we will present the definition of Kaprekar's transformations $T_n$ and we will formulate the conditions describing the elements of minimal orbits of $T_n$ for $4 \le n \le 7$. In fact, it will be only the necessary conditions, yet they will "reduce" enough the sets of natural numbers containing the maxinvariant subset of the respective Kaprekar's transformation, so that the final calculations will be possible to make even by hand.

## II. Kaprekar's transformations

In this section we discuss the Kaprekar's transformations

$$\begin{aligned} T_n\colon \{0\} \cup \{\alpha\colon 10^{n-1} - 1 \le \alpha < 10^n\} \to \\ \to \{0\} \cup \{\alpha\colon 10^{n-1} - 1 \le \alpha < 10^n\} \end{aligned}$$

for every $n \in \mathbb{N}$, defined in the following way. We set $T_n(0) = 0$ and let $\alpha \in \mathbb{N}$ be any $n$-digit number, the decimal expansion of which is composed of digits $0 \le a_1 \le a_2 \le \ldots \le a_n \le 9$. We take

$$\begin{aligned} T_n(\alpha) &:= \sum_{k=1}^{n} (a_k - a_{n-k+1}) 10^{k-1} = \\ &= a_n a_{n-1} \ldots a_1 - a_1 a_2 \ldots a_n. \end{aligned}$$

The orbits of operator $T_n$ will be called as the $T_n$-orbits for every $n \in \mathbb{N}$. Moreover, we will call the $k$-fold composition of operator $T_n$, for any $k, n \in \mathbb{N}$, as the $T_n$-composition. Next, the fixed points of operator $T_n$, where $n \in \mathbb{N}$, will be called as the Kaprekar's constants of $n$-th order.

Let us note that Hindu mathematician Dattathreya Ramachandra Kaprekar has started in 1949 in paper [16] the discussion on the, called now, Kaprekar's transformations $T_n$. The classical Kaprekar's constant, that is number 6174, was also announced in this paper. But only in paper [17] Kaprekar proved that after applying operator $T_4$ at most 7-times every four-digit number in base 10 leads to the same result, that is $6174 = T_4(6174)$.

Properties of operator $T_5$, acting on the five-digit integers in bases $r < 13$, were investigated by Charles W. Trigg [29], the mathematician well-known mostly for his great involvement in the issues of recreational mathematics. Next, Klaus E. Eldridge and Seok Sagong in their paper [11] from 1988 described the convergence of $\{T_3^n(x)\}_{n=1}^{\infty}$ for all three-digit numbers $x$ for any base $r \in \mathbb{N}$, $r \ge 2$. They obtained, among others, the following result.

**Theorem 2.**

a) *$T_3^n(x)$ is convergent (in usual sense) to nontrivial constant (also called the Kaprekar's constant) if and only if*

*$r$ is even. The respective Kaprekar's constant is equal to the 3-digit number $\left(\frac{r-2}{2}, r-1, \frac{r}{2}\right)$ in base $r$.*

b) *If $r$ is odd then $T_3$ possesses (except the trivial orbit) only one two-element orbit consisting of numbers $\left(\frac{r-3}{2}, r-1, \frac{r+1}{2}\right)$ and $\left(\frac{r-1}{2}, r-1, \frac{r-1}{2}\right)$ in base $r$.*

Papers [7], [15], [18] are also devoted to the discussion on Kaprekar's transformations.

We will present now the descriptions of elements of orbits of maps $T_n$ for values of $n$ equal in turn 5,6,7 and 4. These facts are partly new and originally presented.

**Theorem 3.** *Every orbit of operator $T_5$ must contain exclusively the numbers of the form $ABA \times 99$, where $0 \leq B \leq A \leq 9$.*

*Proof:* For five-digit number $n$ composed only of digits $0 \leq e \leq d \leq c \leq b \leq a \leq 9$ we have

$$\begin{aligned} T_5(n) &= (a-e)(10^4-1)+(b-d)(10^3-10) = \\ &= 99 \times ((a-e) \times 101 + (b-d) \times 10) \\ &= 99 \times ABA, \end{aligned}$$

where $0 \leq B := b-d \leq A := a-e \leq 9$. ■

**Corollary 1.** *The orbits of operator $T_5$ can be sought just and only from among the $T_5$-iteration of the following 54 numbers*

$$\begin{aligned} &101 \times 99,\ 111 \times 99,\ 202 \times 99,\ 212 \times 99,\ 222 \times 99, \\ &303 \times 99,\ 313 \times 99,\ 323 \times 99,\ 333 \times 99, \\ &\vdots \\ &909 \times 99,\ 919 \times 99,\ 929 \times 99, \ldots, 999 \times 99. \end{aligned}$$

*Moreover, each $T_5$-orbit must be the subset of the above set of numbers.*

**Remark 1.** *We have $T_5(99 \times 111) = T_5(99 \times 999)$.*

**Theorem 4.** *Each orbit of operator $T_7$ must contain only the numbers of the form*

$$AB(A+C)BA \times 99, \tag{2}$$

*where $0 \leq C \leq B \leq A \leq (A+C) \leq 9$, or*

$$A(B+1)(A+C-10)BA \times 99, \tag{3}$$

*where $1 \leq C \leq B \leq A \leq 9 < (A+C)$ and $B \leq 8$.*

*Proof:* Let $n$ be the seven-digit number composed of the following seven digits

$$0 \leq g \leq f \leq e \leq d \leq c \leq b \leq a \leq 9.$$

Then we have

$$\begin{aligned} &T_7(n) = (a-g)(10^6-1)+(b-f)(10^5-10)+ \\ &+(c-e)(10^4-10^2) = 99 \times ((a-g) \times 10101+ \\ &+(b-f) \times 1010 + (c-e) \times 100) = \\ &= \begin{cases} AB(A+C)BA \times 99, & \text{if } A+C \leq 9, \\ A(B+1)(A+C-10)BA \times 99, & \text{if } A+C > 9 \\ & \text{and } B \leq 8, \end{cases} \end{aligned}$$

where $A := a-g$, $B := b-f$, $C := c-e$. It is obvious that we have $0 \leq C \leq B \leq A \leq 9$. ■

**Corollary 2.** *Orbits of operator $T_7$ can be sought only from among the $T_7$-compositions on the following numbers (we give first the numbers defined by formula (2)):*

$$\begin{aligned} &10101 \times 99,\ 11111 \times 99,\ 11211 \times 99, \\ &20202 \times 99,\ 21212 \times 99,\ 21312 \times 99, \\ &22222 \times 99,\ 22322 \times 99,\ 22422 \times 99, \\ &30303 \times 99, \ldots, \\ &\vdots \\ &90909 \times 99, \ldots, 98989 \times 99,\ 999999 \times 99, \end{aligned}$$

*and (it is about 163 numbers described by formula (3)):*

$$\begin{aligned} &99089 \times 99,\ 99189 \times 99, \ldots, 99889 \times 99, \\ &98079 \times 99,\ 98179 \times 99, \ldots, 98679 \times 99, \\ &\vdots \\ &93029 \times 99,\ 93129 \times 99, \\ &92019 \times 99, \\ &89088 \times 99,\ 89188 \times 99, \ldots, 89688 \times 99, \\ &88078 \times 99,\ 88178 \times 99, \ldots, 88578 \times 99, \\ &\vdots \\ &84038 \times 99,\ 84138 \times 99, \\ &83028 \times 99, \\ &\vdots \\ &67066 \times 99,\ 67166 \times 99,\ 67266 \times 99, \\ &66056 \times 99,\ 66156 \times 99, \\ &65046 \times 99, \\ &56055 \times 99. \end{aligned}$$

**Theorem 5.** *Each orbit of operator $T_6$ contains only the numbers described by the following seven formulae*

$$9 \times A(A+B)(A+B+C)(A+B)A, \tag{4}$$

*where $0 \leq C \leq B \leq A \leq A+B+C \leq 9$, or*

$$9 \times A(A+B+1)(A+B+C-10)(A+B)A, \tag{5}$$

*where $0 \leq C \leq B \leq A \leq A+B \leq 8$ and $10 \leq A+B+C < 20$, or*

$$9 \times (A+1)0(A+B+C-10)9A, \tag{6}$$

*where $1 \leq C \leq B \leq A \leq 9$ and $A+B=9$, or*

$$9 \times (A+1)(A+B-9)(A+B+C-9)(A+B-10)A, \tag{7}$$

*where $0 \leq C \leq B \leq A \leq 9$ and $10 \leq A+B \leq A+B+C \leq 18$, or*

$$9 \times (A+1)(A+B-8)(A+B+C-19)(A+B-10)A, \tag{8}$$

*where* $0 \le C \le B \le A \le 9$ *and* $A+B+C \ge 19$ *(we note that then* $A+B \ge 10$*) and* $A+B \le 17$*, or*

$$9 \times 110(C-1)89, \tag{9}$$

*where* $C \ge 1$*, or*

$$9 \times 109989. \tag{10}$$

*Proof:* In order to get the presented formulae let us assume that $n$ is the natural six-digits number composed of the digits $0 \le a_6 \le a_5 \ldots \le a_1 \le 9$. Then we obtain

$$T_6(n) = 9((a_1-a_6)(10^4+10^3+10^2+10+1)+ \\ +(a_2-a_5)(10^3+10^2+10)+(a_3-a_4)10^2).$$

By taking $A := a_1 - a_6$, $B := a_2 - a_5$, $C := a_3 - a_4$ we find

$$T_6(n) = A10^4+(A+B)10^3+(A+B+C)10^2+(A+B)10+A,$$

where $0 \le C \le B \le A \le 9$. The only thing which left is to analyze the value of sums $A+B+C$ and $A+B$ which gives the thesis of theorem. ■

**Remark 2.** *Although we have as many as seven different formulae describing potential numbers belonging to the orbits of operator* $T_6$*, their description can be directly generated in easy way. However, we will omit here this description.*

**Remark 3.** *It was numerically proved by the Authors that operator* $T_6$ *possesses three fixed points (the Kaprekar's constants of sixth order):*

$$0,\ 549945,\ 631764$$

*and one 7-element orbit (we give it in a table in Part II of this paper). The information on an existing 7-element orbit is omitted in the table presented in the Polish version of Wikipedia (http://pl.wikipedia.org/wiki/Stala_Kaprekara).*

**Theorem 6.** *Orbits of operator* $T_4$ *contain only the numbers described by formulae*

$$9 \times A(A+B)A, \tag{11}$$

*where* $0 \le B \le A \le A+B \le 9$*, or*

$$9 \times (A+1)(A+B-10)A, \tag{12}$$

*where* $1 \le B \le A \le 9$ *and* $A+B \ge 10$*.*

*Proof:* Let $n \in \mathbb{N}$ be the four-digit number composed of digits $0 \le d \le c \le b \le a \le 9$. Then we have

$$\begin{aligned} T_4(n) &= (a-d)(10^3-1)+(b-c)(10^2-10) = \\ &= 9 \times \big((a-d)(10^2+10+1)+(b-c)10\big) = \\ &= \begin{cases} 9 \times A(A+B)A, & \text{if } A+B \le 9, \\ 9 \times (A+1)(A+B-10)A, & \text{if } A+B > 9, \end{cases} \end{aligned}$$

where $A := a-d$, $B := b-c$. Certainly we have $0 \le B \le A \le 9$. ■

**Remark 4.** *Formulae (11) and (12) describe the following 45 numbers*

$$\begin{array}{l} 111 \times 9,\ 121 \times 9, \\ 222 \times 9,\ 232 \times 9,\ 242 \times 9, \\ 333 \times 9,\ 343 \times 9,\ 353 \times 9,\ 363 \times 9, \\ 444 \times 9,\ 454 \times 9, \ldots, 484 \times 9, \\ 555 \times 9,\ 565 \times 9, \ldots, 595 \times 9, \\ 605 \times 9, \\ 666 \times 9,\ 676 \times 9,\ 686 \times 9^*,\ 696 \times 9, \\ 706 \times 9,\ 716 \times 9,\ 726 \times 9, \\ 777 \times 9,\ 787 \times 9,\ 797 \times 9, \\ 807 \times 9,\ 817 \times 9, \ldots, 847 \times 9, \\ 888 \times 9,\ 898 \times 9,\ 908 \times 9, \ldots, 968 \times 9,\ 999 \times 9. \end{array}$$

*where by* $^*$ *we have distinguished the Kaprekar's constant. Directly calculating (even by hand – if we are extremely dogged) we can verify that* $T_4$ *possesses only one orbit*

$$\{686 \times 9 = 6174\}.$$

*Let us recall, that this fixed point of* $T_4$*, i.e. number 6174, is called the Kaprekar's constant (of fourth order).*

## III. Final remarks

Authors of this paper, apart from the discussed here Kaprekar's transformations, have also defined and investigated the minimal orbits (cycles, respectively) of few generalizations of these transformations, like for example

— the symmetric Kaprekar's transformation

Let $a_1a_2\ldots a_n$ be the decimal expansion of number $a \in \mathbb{N}$, $10^{n-1} \le a < 10^n$. Then the $n$-th symmetric Kaprekar's transformation $M$ is defined as

$$M(a_1a_2\ldots a_n) = \sum_{k=1}^{n} |c_k - b_k| 10^{k-1}$$

where $(b_1, b_2, \ldots, b_n)$ and $(c_1, c_2, \ldots, c_n)$ are the sequences, nondecreasing and nonincreasing, respectively, composed of the digits $a_1, a_2, ..., a_n$. We include to the set of $n$-digit numbers also the number zero. Orbits of operators $M$ for the odd values $n \le 19$, although "quite easy" to calculate even by hand, surprise yet with their final form. We will present here only few quantitative pieces of information.

So, if $n = 2k+1$, $1 \le k \le 5$, then $M$ possesses only the fixed points and $k$-element orbits, for $n = 13$ operator $M$ possesses two fixed points, 0 and 65432101...6, four 2-element cycles, eleven 3-element cycles and 827 cycles of length 6 (sic). For $n = 15$ the operator $M$ possesses 44 fixed points, 342 different 2-elements orbits and 2678 different 4-elements orbits. For $n = 17$ the operator $M$ possesses only 6 fixed points, 32 different 2-element orbits and 6060 different 4-element orbits. Finally, for $n = 2^k$ the operator $M$ possesses only trivial orbit $= \{0\}$ for every $k \in \mathbb{N}$.

— nonoptimal Kaprekar's transformations
One of the examples of this transformation, called by us the $Q$-Kaprekar's transformation, is defined as

$$Q_n(A) := (a_n - a_2)10^{n-1} + (a_{n-1} - a_1)10^{n-2} + \\ + \sum_{k=1}^{n-2}(a_k - a_{n-k+1})10^{k-1},$$

where $0 \leq a_1 \leq a_2 \leq \ldots \leq a_n \leq 9$ are the all digits of decimal expansion of number $A$. We note that, in contrast to the Kaprekar's transformation $T_4$, the transformation $Q_4$ possesses two 2-element orbits: $\{2187, 6543\}$ and $\{3285, 5274\}$ and the trivial fixed point. Next, $Q_5$ possesses the trivial fixed point and the 2-element orbit $\{52974, 54963\}$ (in contrast, transformation $T_5$ has four different orbits). Transformations $Q_6$ and $T_6$ have both three fixed points and, respectively, the 8-element orbit and the 7-element orbit. Transformations $Q_7$ and $T_7$ possess both the trivial fixed point and one 8-element orbit (but of different orbit types).

— general Kaprekar's transformations
We take that the natural number $A$, $10^{n-1} \leq A < 10^n$, possesses the following decimal expansion $A = d_1 d_2 \ldots d_n$. Let $a_1 := \max\{d_1, d_2, \ldots, d_n\}$, $a_2 := \max\{d_2, d_3, \ldots, d_n\}$ and in general $a_k := \max\{d_k, d_{k+1}, \ldots, d_n\}$, for $k = 1, 2, \ldots, n$. The announced general Kaprekar's transformations are defined by relations

$$d_{\sigma,\pi}(A) := \sum_{k=1}^{n} |d_{\sigma(k)} - d_{\pi(k)}| 10^{n-k},$$

$$d_{\sigma,\pi}^{weak}(A) := \left| \sum_{k=1}^{n} (d_{\sigma(k)} - d_{\pi(k)}) 10^{n-k} \right|,$$

and

$$D_{f,g}(A) := \sum_{k=1}^{n} |d_{f(k)} - d_{g(k)}| 10^{n-k},$$

$$D_{f,g}^{weak}(A) := \left| \sum_{k=1}^{n} (d_{f(k)} - d_{g(k)}) 10^{n-k} \right|,$$

$$R_f(A) := \sum_{k=1}^{n} |a_k - a_{f(k)}| 10^{n-k},$$

$$R_f^{weak}(A) := \left| \sum_{k=1}^{n} (a_k - a_{f(k)}) 10^{n-k} \right|,$$

for any permutations $\sigma$, $\pi$ on set $\{1, 2, \ldots, n\}$ and for any functions $f, g\colon \{1, 2, \ldots, n\} \to \{1, 2, \ldots, n\}$.

***Abstract*—Observations of ultra-high energy neutrinos became a priority in experimental astroparticle physics. Up to now, the Pierre Auger Observatory did not find any candidate on a neutrino event. This imposes competitive limits to the diffuse flux of ultra-high energy neutrinos in the EeV range and above.**

**The prototype Front-End boards for Auger-Beyond-2015 with Cyclone® V E can test the neural network algorithm in real pampas conditions in 2015. Showers for muon and tau neutrino initiating particles on various altitudes, angles and energies were simulated in CORSIKA and OffLine platforms giving pattern of ADC traces in Auger water Cherenkov detectors. The 3-layer 12-10-1 neural network was taught in MATLAB by simulated ADC traces according the Levenberg - Marquardt algorithm. New sophisticated trigger implemented in Cyclone® V E FPGAs with large amount of DSP blocks, embedded memory running with 120 - 160 MHz sampling may support to discover neutrino events in the Pierre Auger Observatory.**

## I. Introduction

OBSERVATION of ultrahigh energy cosmic rays (UHECR) of energy 1−100 EeV ($10^{18}$ − $10^{20}$ eV) has stimulated much experimental as well as theoretical activity in the field of astro-particle Physics [1]. Although many mysteries remain to be solved, such as the origin of the UHECRs, their production mechanism and composition, we know that it is very difficult to produce these energetic particles without associated fluxes of ultrahigh energy neutrinos (UHE$\nu$s) [2]. In the "bottom-up" scenarios, protons and nuclei are accelerated in astrophysical shocks, while pions are produced by cosmic ray interactions with matter or radiation at the source [3]. In the "top-down" models, protons and neutrons are produced from quark and gluon fragmentation with a production of much more pions than nucleons [4]. Furthermore, protons and nuclei also produce pions due to the Greisen-Zatsepin-Kuzmin (GZK) cutoff [5]. The ultrahigh energy cosmic rays (UHECR) flux above $\sim 5\times 10^{19}$ eV is significantly suppressed according to expectations based on the UHECRs interaction of with the cosmic microwave background (CMB) radiation [6]. For primary protons, the photo-pion production is responsible for the GZK effect, thus UHE$\nu$s are produced from decayed charged pions. However, their fluxes are doubtful [4] and if the primaries are heavy nuclei, the UHE$\nu$s should be strongly suppressed [7].

Neutrinos can show directly sources of their production due to no deflection by magnetic fields. Unlike photons they travel inviolate from the sources carrying an impression of the production model. UHE$\nu$s can be detected with arrays of detectors at ground level that are currently being used to measure extensive showers produced by cosmic rays [8]. The main challenge is an extraction from the background, induced by regular cosmic rays, showers initiated by neutrinos. Due to a very small neutrino cross-section for interactions, higher probability of a detection is at high zenith angles [9] due to a bigger atmosphere slant depth provides thicker target for neutrino interactions. Inclined showers starting a development deeply in the atmosphere can be a signature of neutrino events.

## II. Triggers

Each water Cherenkov detector of the surface array has a 10 $m^2$ water surface area and 1.2 m water depth, with three 9-inch photomultiplier tubes (PMTs) looking through optical coupling material into the water volume, which is contained in a Tyvek reflective liner. Each PMT provides signals, which are digitized by 40 MHz 10-bit Analog to Digital Converters (ADCs).

Triggers are generated for signals above amplitude thresholds. The trigger for the surface detector array is hierarchical. Two levels of trigger (called T1 and T2) are formed at each detector. T2 triggers are combined with those from other detectors and examined for spatial and temporal correlations, leading to an array trigger (T3). The T3 trigger initiates data acquisition and storage. Two independent trigger modes are

978-83-60810-66-8/$25.00©2015, IEEE

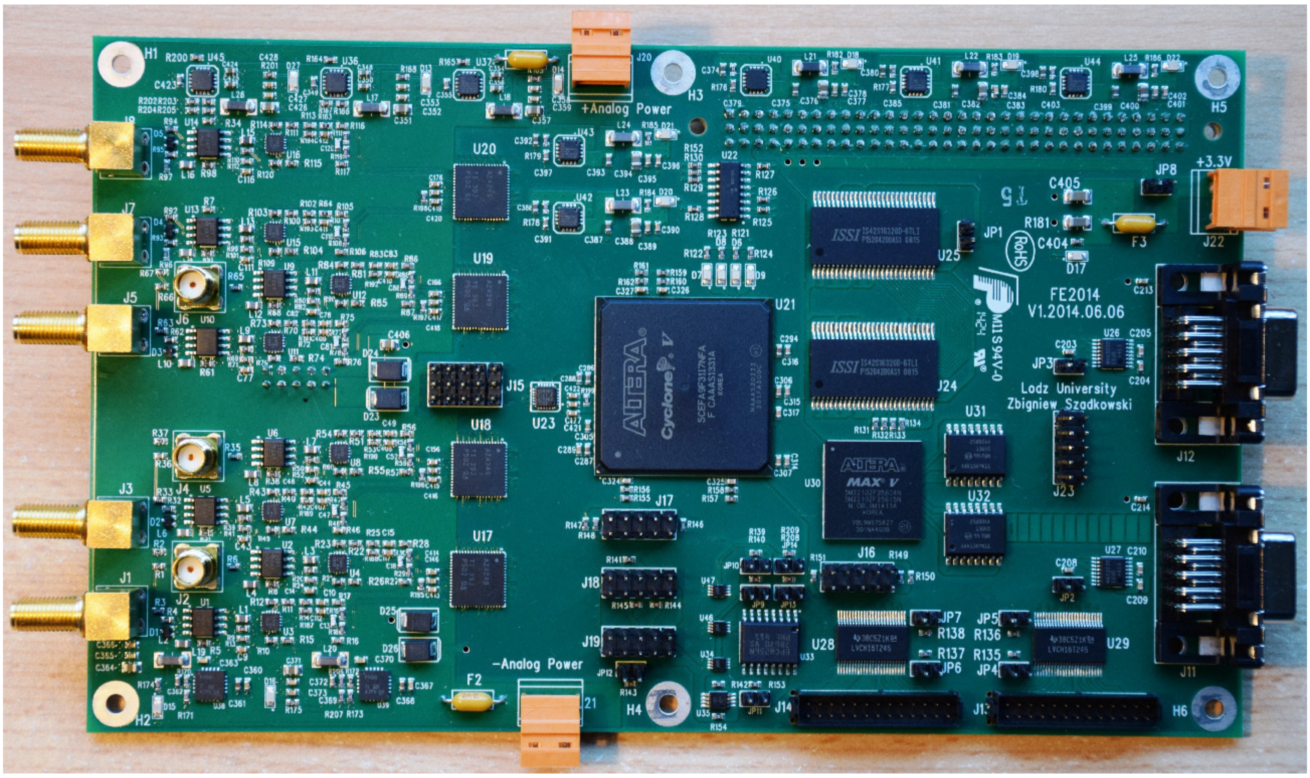

Fig. 1. The Front-End Board developed for the Auger-Beyond-2015 upgrade design used also for the ANN algorithm tests.

implemented as T1. The 1st T1 mode is a simple threshold trigger (TH) which requires the coincidence of the three PMTs each above 1.75 $I_{VEM}^{peak}$. The Vertical Equivalent Muon (VEM) is a unit used for a calibration corresponding to ∼50 ADC-units for 40 MHz sampling frequency. This trigger is used to select large signals that are rather concentrated in time. The 2nd mode is designated the "Time-over-Threshold" trigger (ToT) and at least 13 time-bins in 120 ADC bins of a sliding window of 3 $\mu$s are required to be above a threshold of 0.2 $I_{VEM}^{peak}$ in coincidence in 2 out of 3 PMTs. This trigger is intended to select sequences of small signals spread in time. From the point of view of short pulses characteristic for very inclined "old" showers as well as for relatively short signals for inclined "young showers the ToT trigger is useless.

FPGAs currently used in the Pierre Auger surface detectors analyze signal amplitudes in a time domain. Much higher efficiency can provide spectral triggers based i.e. on Discrete Cosine Transform [10] [11] [12]. Triggers based on an artificial neuron networks is an alternative approach focusing on specific patterns of ADC traces registered in Pierre Auger water Cherenkov detectors [13].

## III. ADC TRACES ANALYSIS

With the SD of the Pierre Auger Observatory we can detect and identify UHE neutrinos in the EeV range and above [14]. Due to much larger cross-section than neutrinos, the 1st interaction for protons, heavier nuclei and even photons usually appears shortly after entering the atmosphere. However, neutrinos can generate showers initiated deeply into the atmosphere. Vertical showers initiated by protons or heavy nuclei have a considerable amount of electromagnetic component at the ground ("young" shower front). However, at high zenith angles ($\theta \geq 75$) (thicker than about three vertical atmospheres), UHECRs interacting high in the atmosphere generate shower fronts dominated by muons at ground ("old" shower front), which generate narrow signals (short ADC traces) spreading over typically tens of nano-seconds in practically all the stations of the event. These traces can be recognized with 16-point DCT algorithm as well as with 16-point input AAN.

Calculations show [15] that "young" showers are spread in time over hundreds of nano-seconds. For the "old" showers practically only the muonic components survives. It gives a short bump in the SD. The "young" showers contains also some electromagnetic component, which enlarge in time an ADC traces. However, muonic components of "young" showers is ahead of the electromagnetic one and gives an early bump. The rising edge of the bump is not so sharp as for the "old" ones, but the signal next is also relatively fast attenuated, till the electromagnetic component starts to give its own contribution. The ANN approach can focus on the early bump, to select traces potentially generated by neutrinos.

On the other hand, independent simulations of showers in CORSIKA [16] an next calculation of water Cherenkov detectors (WCDs) response in OffLine package [17] showed

TABLE I
DISTANCES FROM THE PLACE OF THE FIRST INTERACTION TO DETECTOR FOR PROTONS AND MUON NEUTRINOS IN DEPENDENCE OF ZENITH ANGLE. ALL THE DISTANCES ARE IN $g/cm^2$. BECAUSE OF THE GEOMETRY NOT ALL THE DISTANCES ARE AVAILABLE FROM EVERY ANGLE.

| | | 500 | 1000 | 2000 | 3000 | 4000 | 5000 | 10000 |
|---|---|---|---|---|---|---|---|---|
| 80° | p | | | + | + | + | | |
| 80° | $\nu$ | + | + | + | + | + | | |
| 85° | p | | | + | + | + | + | |
| 85° | $\nu$ | + | + | + | + | + | + | |
| 89° | p | | | + | + | + | + | + |
| 89° | $\nu$ | + | + | + | + | + | + | + |

that for neutrino showers (initiated either by $\nu_\mu$ or $\nu_\tau$) for relatively big zenith angle (i.e. 70°) and low altitude (9 km) (to be treated as "young" showers before a maximum of development) give relatively short ADC traces and they can be analyzed also by 16-point pattern engines [13].

## IV. CORSIKA AND OFFLINE CALCULATIONS

The main motivation of an ANN implementation as a shower trigger is a fact that up to now the entire array did not registered any neutrino-induced event. The probably reasons are: a) a very low stream of neutrinos and b) amplitudes of ADC-traces are small and probably are below of threshold of standard 3-fold coincidence trigger. The main idea was to use ANN approach as a pattern recognition technique.

The input data for the ANN are simulated traces of protons and muon neutrinos, which hit the atmosphere in high zenith angles - 80°, 85° and 89°, respectively. The chosen energies of primary particles are $3 \times 10^8$, $10^9$, $3 \times 10^9$ and $10^{10}$ GeV, respectively. The distances from the place of the first interaction to the detector used for simulations are dependent of the angle and the type of particle (Table I). We decided not to simulate protons which are very close to detector, because the probability that proton will not interact on long way to detector is very low. Additionally, traces produced by this kind of interactions may include also electromagnetic part of the shower. These traces would look completely different than the rest and may significantly decrease the efficiency of the ANN.

There are 120 different categories. These categories are used as input by the CORSIKA simulation platform. The CORSIKA program simulates the cosmic ray shower initiated by the specific particle. The result of this simulation is distribution of the position and energies of the particles on the level of the detector. Simulations are relatively fast. All of the 120 categories had been simulated in a week. The simulated cosmic ray showers are the input for the OffLine package, which provides a response of the water Cherenkov detector and generates the ADC traces (signal waveforms). These simulations are very time consuming. As a result we got simulated traces from the photo-multipliers, as if they were triggered by standard T1 trigger. We have proven that 16-point input is sufficient for the ANN pattern recognition [13]. The next step was to find in the 16-point trace, which corresponds to triggered events. To clearly see the beginning of the event we decided that two first points should be on the pedestal level. Afterwards we subtracted the pedestal level from all used data. These extracted points we could finally use for training and testing our neural network.

For a training procedure, we decided to use half of the data available for the testing procedure. We arrange data, to have proton and neutrino traces alternately. The proton traces were treated as negative signals ("0" for the ANN) and the neutrino traces were treated as positive ones ("1" for the ANN). This step allowed the ANN to teach faster and get less errors while training. The testing procedure consists on assigning specific value to the trace. This value depends on the coefficients of the trained ANN. If the value is greater than the threshold, the trace is treated as a neutrino trace, otherwise it is treated as a proton trace. The efficiency of the neutrino recognition with specific threshold level can be defined as number of neutrino traces recognized correctly divided by the number of all neutrino traces. The proton mistakes level is defined as number of proton traces treated as neutrino traces divided by the number of all proton traces.

The testing procedure was divided into two stages. First, we wanted to find out if we could use the data from the specific category to distinguish muon neutrinos and protons for all the angles or all the energies. Simulated data contains only three different angles: 80°, 85° and 89°, respectively, but we do not expect the zenith angle of the particle would be exactly like them. If the ANN trained on the specific category with angle 85° can distinguish neutrinos and protons also for 89° and 80° with acceptable efficiency, we assumed it could distinguish protons and neutrinos also for full angle range: 80° - 89°. The same is for energies. The ANN had been also trained by the data of the specific energy and then it was tested on the other values of the chosen parameter. The second step of the testing procedure consisted on training the ANN by the randomly taken data from all categories. In this case we used 30% of the whole data for training the ANN. The result from this step should be better than in previous one, because the data used for teaching was taken from the wider set of data.

The efficiency of the ANN strongly depends on the data used for training. The positive and negative signals should be as different as possible, to increase the distinction of proton and neutrino traces. Our first results (Fig. 9 continuous line) shows, that ANN does not work properly. There was no separation between protons and neutrinos. When we looked at the data we used for teaching the ANN, we found that some of the neutrino and proton traces looked very similar to each other. Moreover the simulated traces produced by neutrino shower with various distances to the detector, but with the same energy and angle was diametrically different. The same effect we observed in the other angles and energies (Fig. 2) and in the traces produced by protons (Fig. 7). This effect is directly connected with the electromagnetic (EM) part of the shower. If the distance to the detector is short, the EM part of the shower gives second component in the traces, additional to standard muonic one. At high zenith angles the proton showers should not have the EM component, because it should disappear after 2000 - 3000 $g/cm^2$. Old

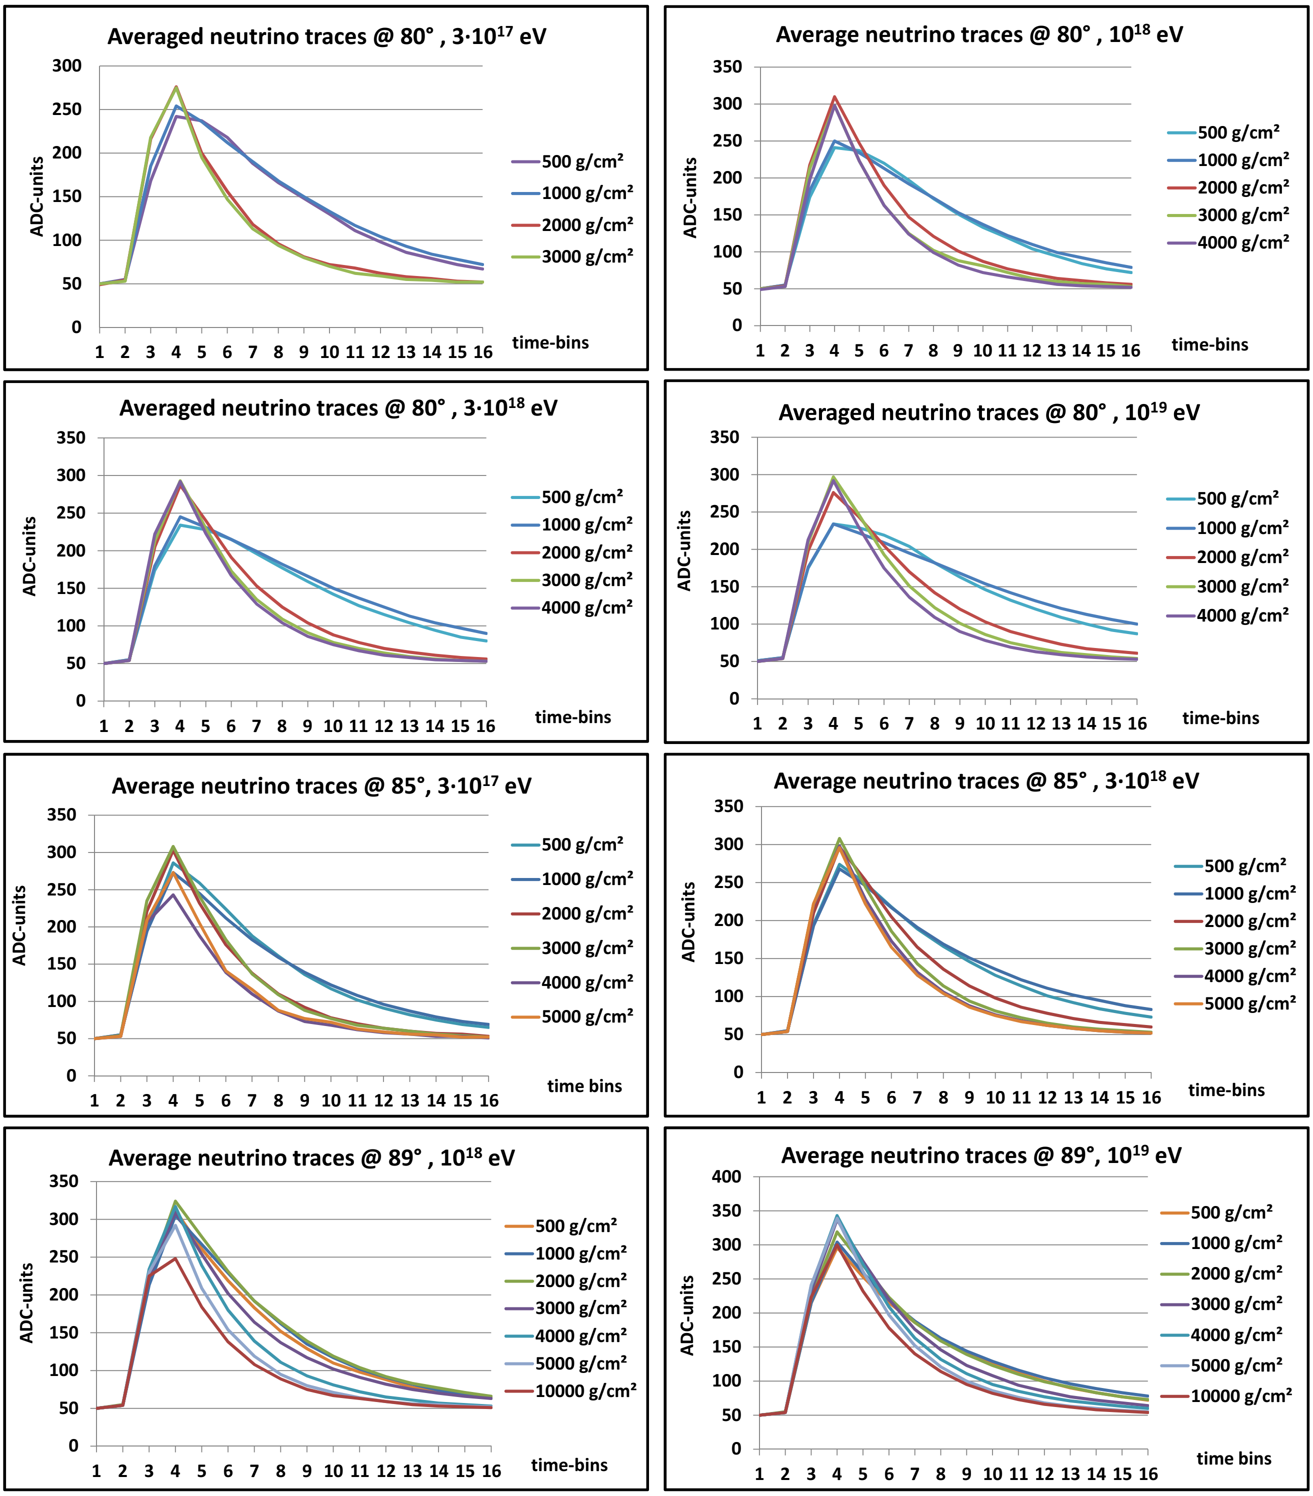

Fig. 2. Plots contain averaged neutrino signal waveforms (ADC traces) for various angles, energies and initialization points. The exponents of the traces at distances 500 and 1000 $g/cm^2$ are different than on the rest of distances. This effect does not depends on the energy and slightly depends on the angle.

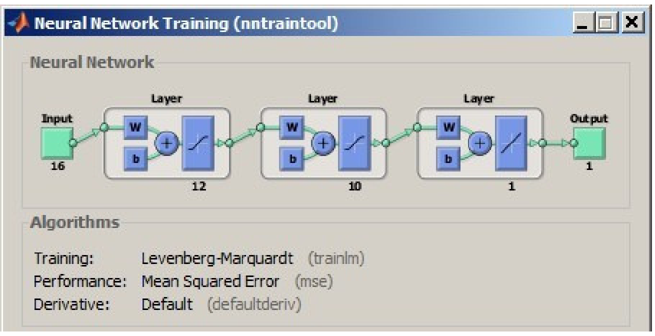
neutrino showers looked like old proton neutrino showers, so we decided to separate the data and focus on recognizing only the young neutrino showers, where the EM component was still visible. We also decided to remove proton showers with visible EM component, because traces they generated looked similar to traces generated by young neutrino showers.

Moreover, for this showers the probability to occur on this angles was low. The data we decided to keep were all neutrino traces with distances 500 and 1000 $g/cm^2$ and all proton traces with two maximal distances for each angle. Fig. 5 shows the average traces for data at 80° after the separation. Neutrino and proton traces have completely different shapes and it would be easier to recognize the neutrino traces when ANN is learned and tested on this data. Fig. 6 shows the histogram of the average exponents of rejected and accepted proton and neutrino categories. We can observe that the exponents of the rejected neutrino categories corresponds with exponents of the accepted proton categories. This was probably the main reason of low distinction of protons and neutrinos by ANN. Additionally, average exponents of the accepted proton and neutrino categories are separated.

## V. MATLAB ANALYSIS



Training: Levenberg-Marquardt (trainlm)
Performance: Mean Squared Error (mse)
Derivative: Default (defaultderiv)

Fig. 4. Training performance for the 3-layer network 12-10-1

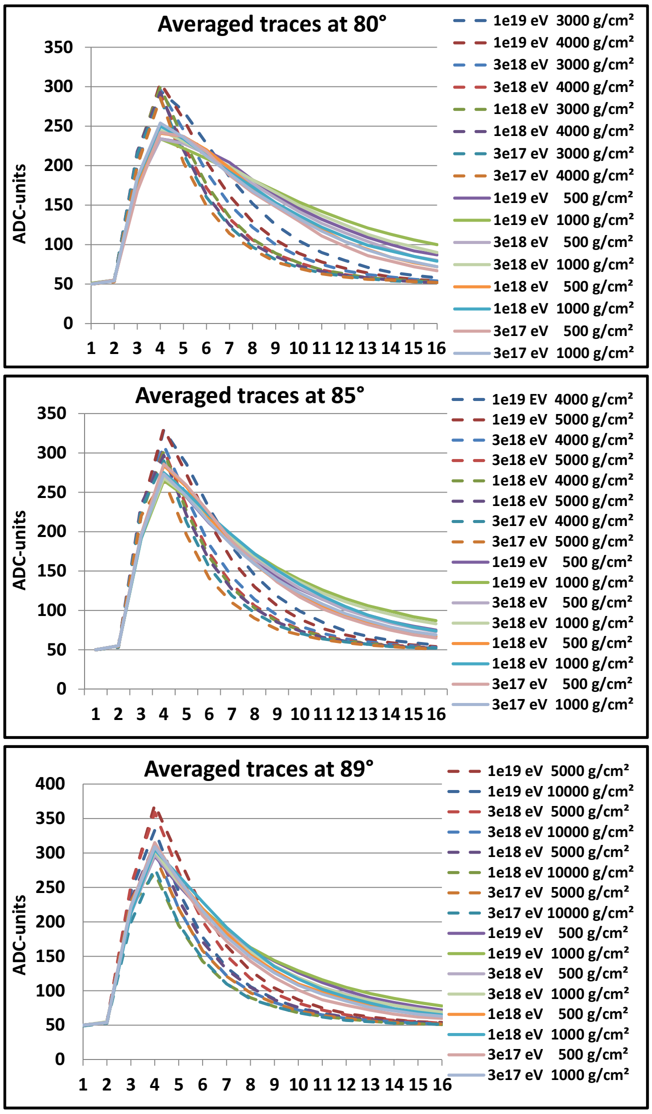

Fig. 5. The plot showing the differences between the traces produced by old proton showers (dashed line) and young neutrino showers (continuous line).

On Fig. 8a we can see how the angular efficiency behaves. In the case, when the ANN was tested on all categories, the ANN was learned using the specific category with parameters: angle 85°, energy $3\times10^{18}$ eV, distance to detector 2000 $g/cm^2$ both for protons and neutrinos. The separated case used 80°, $3\times10^{18}$ eV and 500 $g/cm^2$ as positive signals (neutrinos) and 80°, $3\times10^{18}$ eV and 4000 $g/cm^2$ as negative signals (protons). For the case, which use all categories for tests, the efficiency seems to be independent of the angle. The case, which use only traces produced by young neutrino and old proton showers ("separated" case) shows the efficiency changes slightly, when we change the angle. On Fig. 8b we can see that in both cases the efficiency of the ANN is independent of the energy (in the used energy range). Fig. 9 shows the comparison between both cases. The ANN tested on non-separated traces has problems with distinguishing the proton and neutrinos on every level of the threshold. The effectiveness of finding neutrino traces and the level of proton mistakes differs only slightly. The second ANN, tested on the separated traces, can recognize protons and neutrinos with acceptable efficiency. The proton mistakes level is much lower than efficiency of finding the neutrino traces, moreover the efficiency of finding neutrino traces is higher than in the previous case. Finally, Fig. 10 shows the difference of the non-separated and separated cases, when the data taken for training the ANN was taken randomly from all traces, appropriate for specific case. We can see that, the distinguishing the proton and neutrino traces increased in both cases, but the recognition of the neutrinos and protons is much better when we teach the ANN with the data from separated traces. In this case the neutrino efficiency to proton mistakes level ratio is greater than two, when in the other case this ratio is on the level of 1.3. This ratio is very important, because it shows if the ANN works or not. The ratio on the level of one means the ANN does not work, because the neutrino to proton traces quotient is the same as in the whole data. The data triggered as neutrino would be processed off-line in next steps. Lower level of proton mistakes and greater efficiency of recognizing neutrino traces means that amount of data to process off-line would be smaller, but neutrino traces would appear more frequently in it.

## VI. FPGA Implementation

A 16-input neuron for 14-bit data and 14-bit coefficients is shown on Fig. 11. An neuron output drives a neural transfer function - a tansig, which calculates a layer output from its net input. It can be implemented as ROM in embedded FPGA memory. We selected 14-bit input, 14-bit-output tansig implementation in RAM: a 2-port function with blocked writing left port to keep a reasonable compromise between a calculation accuracy and a memory size. The same array of coefficients is used for two independent neuron transfer functions.

The 12-10-1 network (Fig. 3) offers the best performance (Fig. 4) with a minimal resource occupancy, however, it requires 23 neurons. Due to the limited amount of DSP blocks, we could use this network for a single PMT only. The Quartus compiler allows a compilation with arbitrarily selected implementations of the multipliers: either in the DSP blocks or in logic elements only. An implementation of the multipliers in the Adaptive Logic Modules (ALMs) is much more resource-consuming (1247 ALMs instead of 107 ALMs + 8 DSP blocks). However, such a selection allows the implementation of a more complicated network, which provides a similar registered performance (keeps approximately the same speed). The 3-channel 12-10-1 network needs 36 neurons (1st layer implemented in the DSP blocks) + 33 neurons implemented in 41151 ALMs (36.5% of 5CEFA9F31I7).

## VII. Conclusion

We run CORSIKA simulation for proton, iron, $\nu_\mu$ and $\nu_\tau$ primaries. Output data collected on 1450 m (the level of the Pierre Auger Observatory) was an input for OffLine providing the ADCs response in the WCDs. Obtained ADC traces were thus used to teach the 12-10-1 neural network implemented already in the 5CEFA7F31I7 FPGA on the Cyclone® V development kit. This FPGA is smaller version of the chip

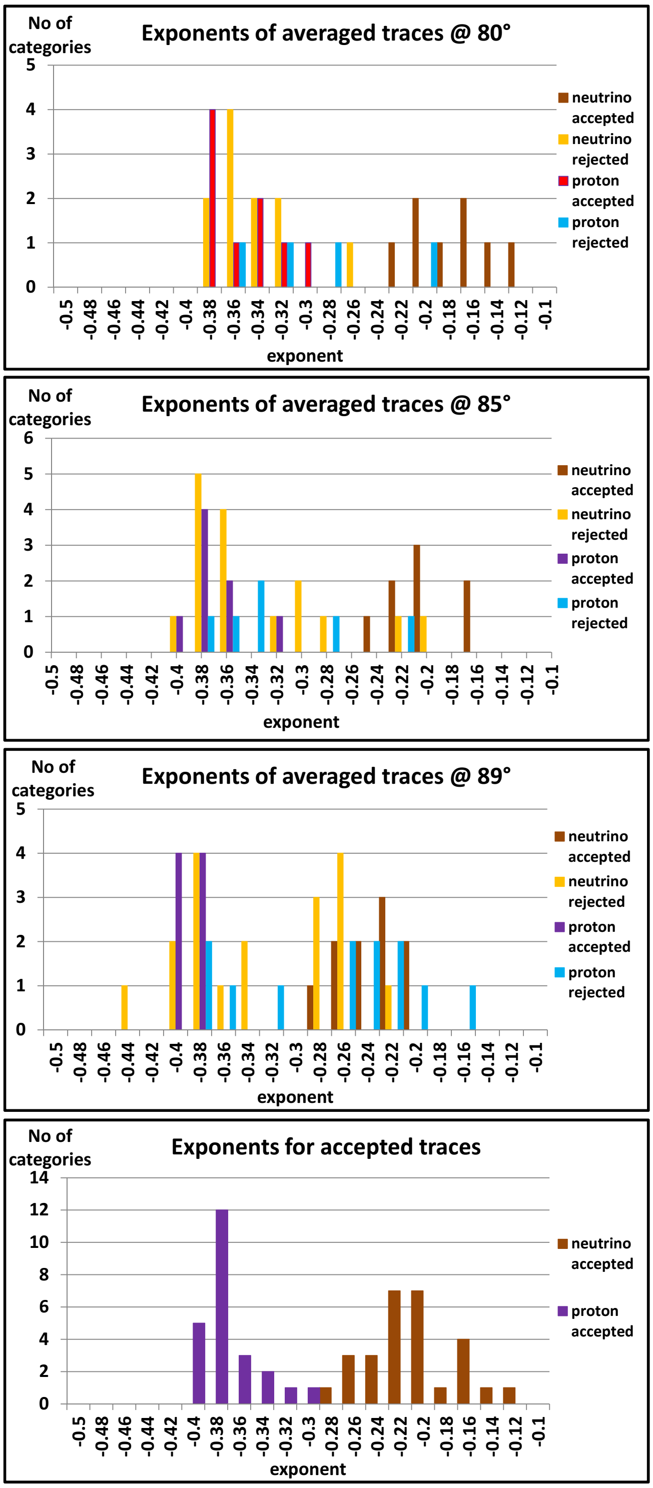

Fig. 6. A histogram of exponents of rejected and accepted traces for protons and neutrinos. The accepted neutrino traces exponents are separated from the accepted proton traces exponents. The rejected neutrino traces looks very similar like traces made by old proton showers. This may cause problems with ANN training and may increase the level of the proton traces recognized as neutrino traces by ANN.

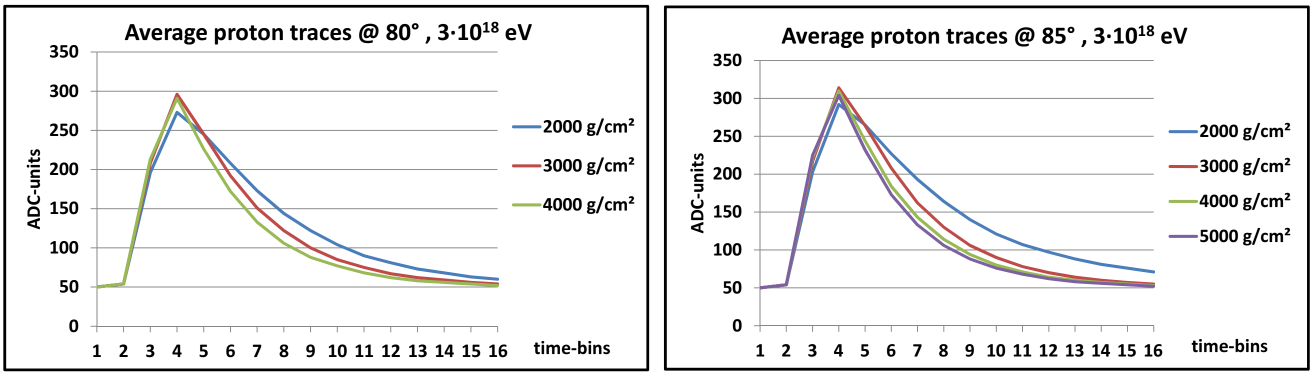

Fig. 7. Plots showing average traces for protons for different distances. As in Fig. 2 the shortest distances have different exponents than the rest.

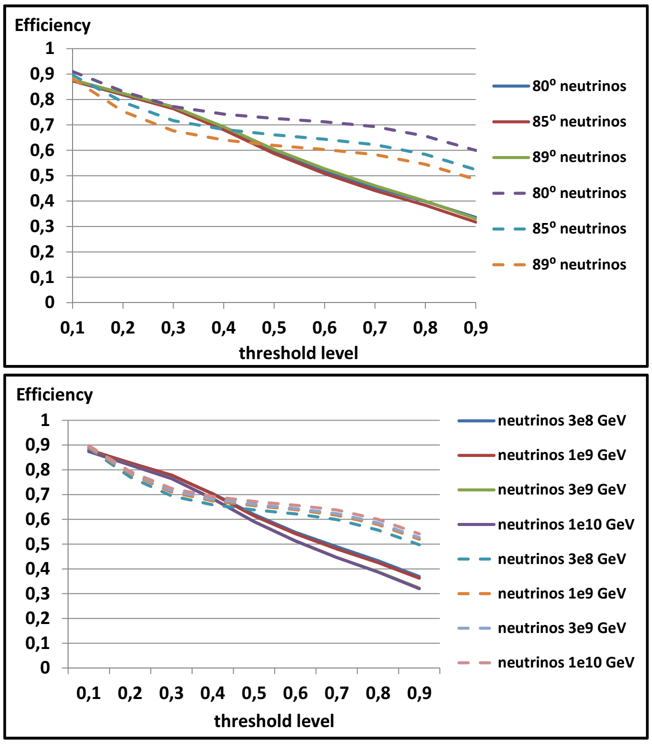

Fig. 8. The angular dependency of a neutrino efficiency as a function of a threshold level for angles (top) and energies (bottom). The continuous lines denote the data for testing were gathered from all traces. The dashed lines represent the case with separated traces.

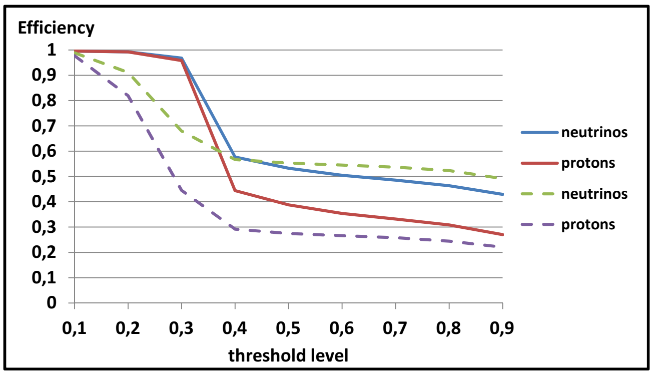

Fig. 9. The efficiency of the neutrinos recognition and proton mistakes level in function of threshold level for the non-separated (continuous lines) and separated traces (dashed lines) used for testing the ANN. The data taken for training are the same as in the Fig 8.

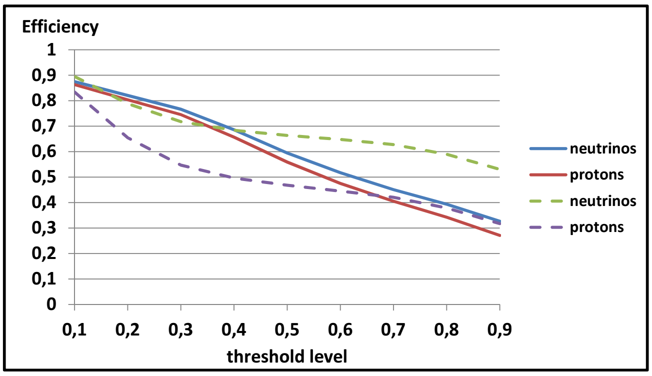

Fig. 10. The efficiency of the neutrino traces recognition and proton mistakes level in function of threshold level for the non-separated (continuous line) and separated traces (dashed line) used for testing the ANN. The traces used for training the ANN were randomly taken from all categories of non-separated or separated traces respectively.

being designed for the Front-End Board for Auger-Beyond-2015 task.

Preliminary results show that the ANN algorithm can detect neutrino events currently neglected by the standard Auger triggers.

The recognition efficiency of the neutrino traces by the ANN algorithm strongly depends on the differences between the data used for the ANN training. If we teach the ANN with the data containing only traces produced by young neutrino and old proton cosmic air showers we can reach the acceptable level of recognition. Moreover, we can distinguish protons and neutrinos, which means the ANN works on very promising level.

***Abstract*—The paper presents the first results from the trigger based on the Discrete Cosine Transform (DCT) operating in the new Front-End Boards with Cyclone V FPGA deployed in 8 test surface detectors in the Pierre Auger Engineering Array.**

**The patterns of the Analog-to-Digial Converter (ADC) traces generated by very inclined showers were obtained from the Auger database and from the CORSIKA simulation package supported next by OffLine reconstruction Auger platform which gives a predicted digitized signal profiles. Simulations for many variants of the initial angle of shower, initialization depth in the atmosphere, type of particle and its initial energy gave a boundary of the DCT coefficients used next for the on-line pattern recognition in the FPGA.**

**Preliminary results have proven a right approach. We registered several showers triggered by the DCT for 120 MSps and 160 MSps.**

## I. Introduction

THE AIM of the Pierre Auger Observatory [1] is measuring of cosmic rays at the ultra-high energy with sufficient statistics and resolution. 1680 water Cherenkov surface detectors (SD) are distributed over an area of 3000 km$^2$ for measuring the charged particles associated with extensive air showers (EAS) and 24 telescopes with 30 × 30 degrees of field of view and 12 m$^2$ mirror area each to observe the fluorescent light produced by charged particles in the EAS during operation on clear moonless nights. The simultaneous observation of EAS by the ground array and the fluorescent light known as a "hybrid" event [2] [3] improves the resolution of the reconstruction considerably and, thanks to the calorimetric nature of the fluorescent light emitted, provides energy measurements virtually independent of hadronic interaction models. Each SD station is equipped in three 9-inch photomultiplier tubes (PMTs) reading out the Cherenkov light from the 12 $m^3$ of purified water contained in each tank. Two independent trigger modes are implemented in the SD to detect, in a complementary way, the electromagnetic and muonic components of an air-shower [4]. The first mode is a simple threshold trigger, which requires the coincidence of the three PMTs each above 1.75 $I^{peak}_{VEM}$. This trigger is used to select large signals that are not necessarily spread in time. The second mode takes into account that, for other than very inclined showers or signals from more vertical showers very close to the shower axis, the arrival of particles and photons at the detector is dispersed in time, at least 13 bins in 120 time bins of a sliding window of 3 $\mu$s are required to be above a threshold of 0.2 $I^{peak}_{VEM}$ in coincidence in two of any 3 PMTs.

Very inclined showers generated by hadrons and starting their development early in the atmosphere produce a relatively thin muon pancake (∼1m thickness) on a detection level. Ultra-relativistic charged particles trespassing the water in a surface detector generate the Cherenkov light detected next in photo-multipliers (PMT). A direct light gives a peak with a very short rise time and fast exponential attenuation. The DCT trigger allows recognition of ADC traces with specific shapes The standard trigger requires 3-fold coincidences in a single time bin. The present sampling frequency in the surface detectors is 40 MHz. The new Front-End Board developed for the Auger-Beyond-2015 surface detector upgrade allows a sampling up to 250 MSps (120 MSps and 160 MSps were used in tests).

Neutrinos can generate showers starting their development deeply in the atmosphere, known as "young" [5] [6]. They contain a significant amount of an electromagnetic component, usually preceded by a muon bump. Simulations show [7] that it is often fully separated from the electromagnetic fraction and the 16-point DCT algorithm can also be used..

A probability of 3-fold coincidences of direct light corresponding to a standard Auger trigger is relatively low. Much more probable are 2-fold coincidences of a direct light. The 3rd PMT is next hit by reflected light, but with some delay. By fast sampling (120-160 MSps) this delay gives signal in the next time bins. The standard T1 trigger ceases giving a sufficient rate for horizontal and very inclined showers. The rate drops down below an acceptable level. We had to modify the T1 trigger to get approximately standard trigger rate.

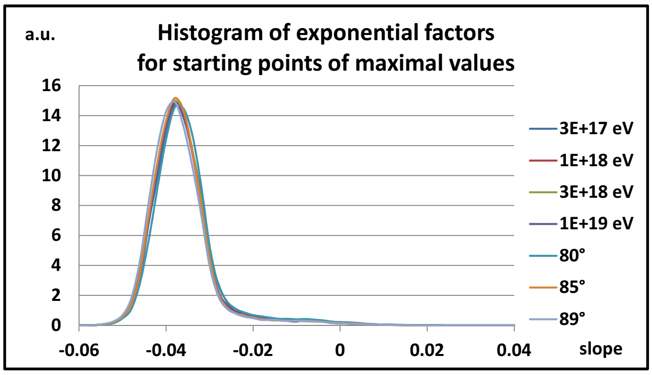

Fig. 1. Histogram of exponential factors for traces starting from the maximal values.

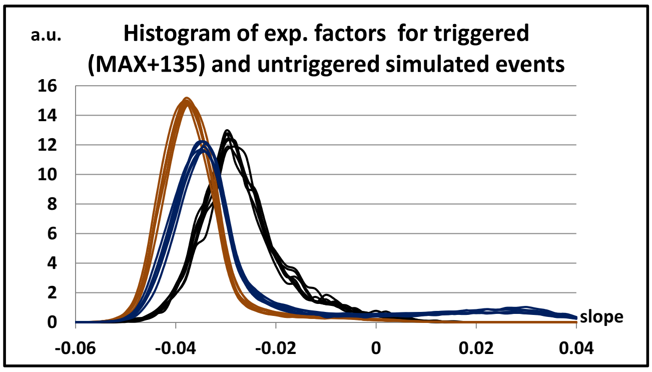

Fig. 2. Histogram of exponential factors for triggered traces starting from the maximal values (as in Fig. 1 - red), from the standard T1 threshold = 1.75 VEM (135 ADC-units)(blue) and for non-triggered (black) events.

Cherenkov light generated by very inclined showers crossing the Auger tank can reach the PMT directly without reflections on Tyvec® liners (a special material with 95% of reflectivity). Especially for "old" showers the muonic front is very flat. This together corresponds to very short direct light pulse falling on the PMT and in consequence very short rise time of the PMT response. For vertical or weakly inclined showers, where the geometry does not allow reaching the Cherenkov light directly on the PMT, the light pulse is collected from many reflections on the tank walls. Additionally, showers developing for not so high slant depth are relatively thick. These give a signal from a PMT as spread in time and relatively slow increasing. A very short rise time together with a relatively fast attenuated tail could be a signature of very inclined showers. We observe numerous very inclined showers crossing the full array but which "fire" only few surface detectors. For that showers much more tanks should have been hit. Muonic front produces PMT signals either too low for 3-fold coincidences or desynchronized in time. This may be a reason of "gaps" in the array of activated tanks.

Two-fold coincidences of DCT coefficients allow triggering signals currently being ignored due to either too high amplitude threshold or due to their de-synchronization in time causing a tank geometry. Three DCT engines implemented into Cyclone® V E 5CEFA9F31I7N FPGA used ~60% of DSP blocks generate the spectral trigger, when in at least 2 channels 8 DCT coefficients simultaneously are inside the acceptance lane. Additional veto signal (analyzing the amplitude) controls a trigger rate to avoid a saturation of a transmission channel. Both lab and long-term field measurements on the test tank confirm a high efficiency of the recognition of expected patterns of ADC traces.

Auger data (40 MSps) show that hadron induced showers with dominant muon component (investigated in a zenith angle of $70-90°$) give an early peak with a typical rise time mostly from 1 to 2 time bins and exponentially attenuated tail. Very inclined showers with well defined shape can be detected by a pattern recognition technique, in particular by a spectral trigger based on the Discrete Cosine Transform [8] [9] [10] [11]. The DCT trigger cannot be implemented into currently used Front-End Boards with ACEX® [12] and Cyclone® [13] FPGAs due to a lack of DSP blocks. New Front-End Board with Cyclone® V E FPGA successfully passed tests on the field collecting Auger data even with 160 MHz sampling [9]. The DCT trigger was tested with 120 and 160 MHz. Scaled to the 1st harmonics DCT coefficients are independent of the amplitude. They are determined by the shape only. This causes that the DCT trigger could also be accidentally generated by very low noise pulses with the required characteristics. In order to cut this type of the spurious triggers, the spectral trigger was also supported by the "veto" amplitude threshold of ~20 ADC-counts. Pulses above this threshold are analyzed next with the DCT engines.

Due to noise and other factors which can distort the shape of the PMT pulse, strict conditions imposed on all coefficients are too strong. The DCT trigger has been generated if a subset of DCT coefficients (similar to the Occupancy in the ToT) has been simultaneously "fired". Simulations performed for various artificial level of additional noise (0 - 6 ADC-counts) showed that even a significant noise contribution does not violate an efficiency of the DCT trigger. A little bit higher noise in Cyclone® V E Front-End in comparison to a noise level in the previous FEB generations with 40 MHz sampling should not be a significant factor. The new 160 MHz sampling Cyclone® V E Front-End Boards are not equipped in the anti-aliasing filters. This keeps a flexibility for various possible sampling frequencies, however, registered shape is not smoothed and provides even very short one time-bin peaks (6.25 ns) corresponding to reflections from Tyvec walls. Such a very precisely reconstruction of timing in the ADC traces violates in some sense a fundamental assumption on a smooth exponential attenuation of the tail. We had to introduce some corrections to take into account also this effect. The CORSIKA and OffLine simulations do not show that the reflections may significantly reduce an efficiency of this approach. However, the Auger simulation/reconstruction packages assume 60 MHz cut-off Nyquist filter, which in real Cyclone® V E Front-End has not been introduced. Thus, the simulations (available only for the "official" 120 MHz sampling frequency) give rather hints for higher 160 MSps sampling and real DCT

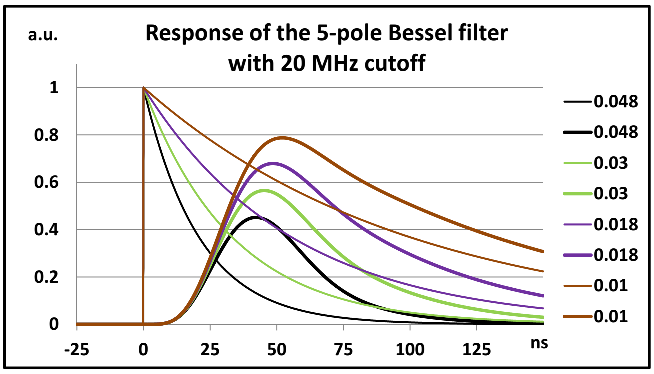

Fig. 3. Pulses as a response on a unity jump with an exponential attenuation with the factors $\alpha$ = 0.048, 0.03, 0.018 and 0.01, respectively.

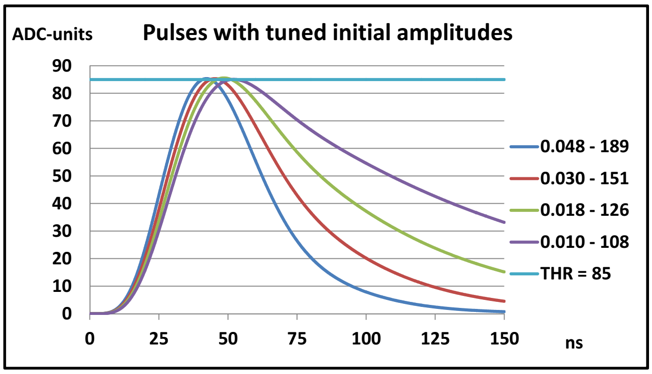

Fig. 4. Pulses filtered by the 5-pole Bessel filter with 20 MHz cutoff with amplitudes: 189, 151, 126 and 108 ADC-units, respectively for 0.048, 0.03, 0.18 and 0.01 exponential factors.

trigger implementation required several step by step optimizations.

## II. CORSIKA and OffLine simulations

We simulated the surface detector response on proton induced showers for energy $3 * 10^{17}$ eV, $10^{18}$ eV, $3 * 10^{18}$ eV and $10^{19}$ eV and for angles 80°, 85° and 89°. The initial points were selected for 2, 3, 4, 5 and 10 $kg/cm^2$, if the angle allowed on this geometrical configuration. ADC traces were collected as triggered (3-fold coincidences in a single time bin) and non-triggered (the standard T1 trigger condition not obeyed, traces registered in neighboring detectors). The standard T1 threshold 1.75 VEM was set in simulations.

Data from standard 40 MHz sampling simulation was used for an optimization of the condition of the DCT trigger for 120 and 160 MSps. Data for 16-point DCT trigger for 160 and 120 MSps corresponds to 100 and 133 ns of ADC trace, respectively. These intervals correspond to 4 and 5 time bins for the standard 40 MSps sampling. As expected proton induced showers generate ADC traces with rapid jump from a pedestal level with relative fast exponentially attenuated tails. We investigated exponential factors of traces in the interval of 125 ns (5 time-bins) selecting parts of traces starting from the maximum value (MAX for triggered (Fig. 1) and non-triggered) and from the standard threshold level (135 ADC-units for triggered only). According to Fig. 2 we see that ranges of exponential factors depend on amplitudes of signals. Traces investigated from the maximum values (variant A)(red curves on Fig. 2) shows faster attenuation than investigating from the T1 threshold level (variant B). Non-triggered traces (with amplitudes lower than T1 threshold level at least in one channel) show much slower attenuation (variant C). For we get the following ranges for attenuation factors $\alpha$ in the function ADC = exp(-$\alpha$*t), where t in nanoseconds.

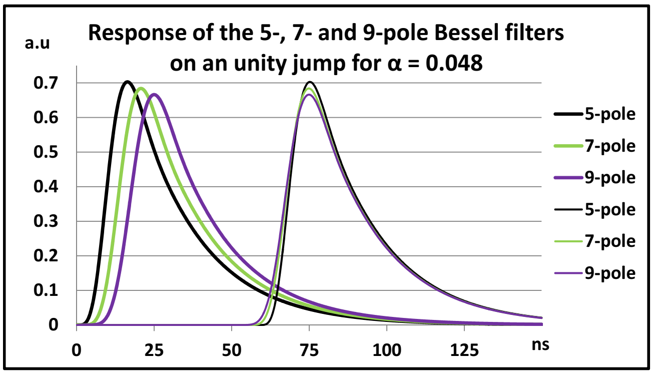

Fig. 5. Response on an unity jump of Bessel filters with 5,7,and 9 poles, respectively. The left curves show response on a jump for 0 ns. The right curves are adjusted to get maximum in the same time bin.

- variant A : 0.048 - 0.030 : ∼89-90% of traces
- variant B : 0.048 - 0.010 : ∼83-86% of traces
- variant C : 0.042 - 0.014 : ∼89-91% of traces

The variant B gives the worst estimation, however, it is not unexpected, as traces may still rise after crossing the T1 threshold. This variant is presented to show the dependence of the exponential factor on the amplitude of signal.

## III. 5-pole Bessel filter with 20 MHz cutoff

According to the Nyquist theorem digitized ADC data should be filtered by the anti-aliasing filter before their processing. For the 40 MSps sampling the cutoff of the filter is 20 MHz. The ACEX® and Cyclone® FEBs were equipped in 5-pole Bessel filters. The Bessel filter provides a maximally flat group/phase delay (maximally linear phase response), which preserves the wave shape of filtered signals in the passband. Higher order of the filter gives steeper frequency characteristic for stop-band, however it requires more sophisticated filter circuit with relatively low values of capacitors. The parasitic PCB capacity became no negligible factor. The transfer function H(s) for the 5-pole Bessel filter with 20 MHz cutoff is as follows:

$$H(s) = \frac{K}{(s-p)(s-z_1)(s-z_1^*)(s-z_2)(s-z_2^*)} \qquad (1)$$

where $K = 3.1336e + 40$, $p = -0.11642e9$, $z_1 = -0.07421e9 + 0.114e9 * j$, $z_2 = -0.10701e9 + 0.005563e9 * j$.

Let us calculate the response of the Bessel filter on the unity jump with the exponential attenuation tails with $\alpha$ = 0.048, 0.03, 0.018 and 0.01, respectively. The Laplace transform for the function x(t) = exp(-$\alpha$*t) is X(s) 1/(s+$\alpha$). The factor $\alpha$ is given for time in nanoseconds. The signal response we get with the inverse Laplace transform:

$$y(t) = Y(s)^{-1} = (H(s) * X(s))^{-1} \tag{2}$$

$$\begin{aligned} Y(t) &= (A * sin(z'_{Im,1} * t) + B * cos(z'_{Im,1} * t) * e^{z'_{Re,1} * t} \\ &+ (C * sin(z'_{Im,2} * t) + D * cos(z'_{Im,2} * t) * e^{z'_{Re,2} * t} \\ &+ E * e^{p' * t} + F * e^{-\alpha * t} \end{aligned} \tag{3}$$

where: $p' = p * 10^{-9}$ $z'_{1,2} = z_{1,2} * 10^{-9}$

Fig. 3 shows responses on an unity jump of the input signal with various exponential attenuation factors. We can see that:

- pulses are delayed on 40 - 50 ns,
- an amplitude of pulses depends on the exponential factor.

A dependence of output signal amplitude on an exponential factor causes that short pulses have to have higher amplitudes to be above the threshold level. Fig. 4 shows pulses with tuned amplitudes to reach at least the T1 threshold level (1.75 VEM ~85 ADC-units).

Let us notice that for all investigated values of $\alpha$ we get : $\alpha < |z_{Re,1}| < |z_{Re,2}| < |p|$. This causes that the exponential term $e^{-\alpha * t}$ attenuates slower than other terms in Eq. 3and practically it only survives for $t$ >~50 ns (after a maximum). So, the attenuation (exponential) factor for a output tail remains the same as in the input signal with rapid jump and exponential tail.

This means that all estimations of attenuation factors for ADC traces from the shower simulations remains valid and the Bessel filter does not affect the attenuation characteristics after the maximum of pulse. The rise time still depends significantly on an order of the filter and the cutoff frequency.

## IV. BESSEL FILTERS FOR THE SDE UPGRADE

According to golden rules the new Front-End electronics with the sampling frequency of 120 MHz should be equipped in the 60 MHz cutoff anti-aliasing filter. Higher order of the filter provides sharper frequency characteristic in the stop-band, but it introduces slightly bigger suppression and few nanoseconds additional delay (Fig. 5).

Fig. 5 shows that 9-pole filter in comparison to 5-pole one:

- introduces bigger delay,
- suppresses stronger the signal,
- provides the same attenuation factor for tails.

5-pole Bessel filter for the upgrade design seems to be enough. Nevertheless, the test system installed in the Auger Engineering Array is considered to verify various configurations for sampling frequencies, data resolutions, trigger conditions etc. The sampling frequencies determine the cutoff in the anti-aliasing filters. For 120 MSps the cutoff should equals 60 MHz. On the other hand this cutoff would be too low for the 160 MSps. The hardware implementation of the Bessel filter on the PCB is difficult (parasitic capacitors have to be taken into account, a tolerance of components should be better than 1%. For resistors it is no problem, however for capacitors it is. Namely, a dynamic switching of cutoff frequencies in hardware filters is impossible. A requirement of wide spectrum of sampling frequencies excludes any fixed filter to be implemented on the PCB.

For this reason the Front-End has been designed without internal anti-aliasing filter at all.

## V. RISE TIMES OF THE SIGNAL WAVEFORMS

Fig. 5 suggests that a rise time of a unity jump takes at least 2-3 time-bins (20 - 25 ns) for the 120 MSps. This is fully confirmed by the CORSIKA + Offline simulations. Fig. 6a shows a contribution of signals waveforms with 1-, 2- and more time bins, respectively. The contribution of 1-time-bin is

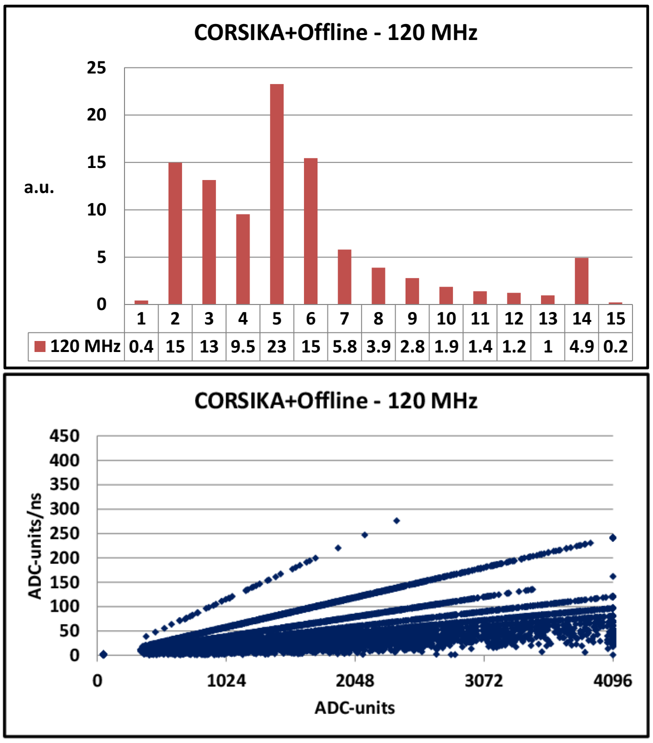

Fig. 6. A histogram showing a contribution of rise times for 1-,2- and more time bins for CORSIKA + Offline simulations with 120 MHz sampling frequency (upper graph) as well as a slope distribution of rising edges of signal waveforms vs. an amplitudes for 120 MSps (lower graph). Branches correspond to 1-, 2- and more time bins slopes from a pedestal level to maximum a maximum value.

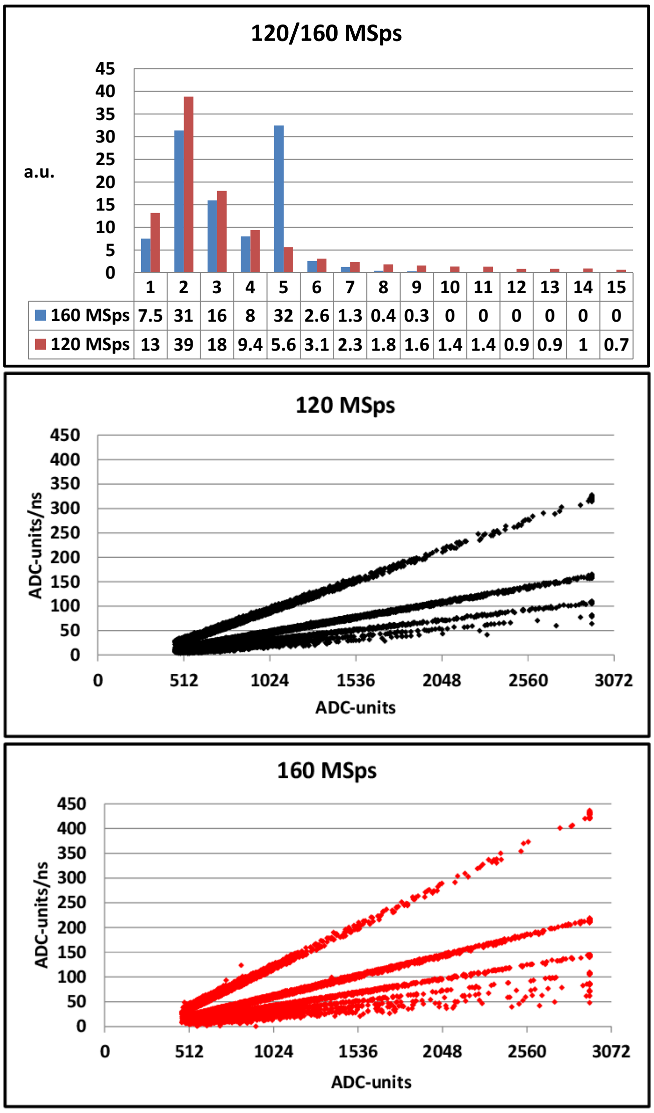

| | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 | 11 | 12 | 13 | 14 | 15 |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| 🟦 160 MSps | 7.5 | 31 | 16 | 8 | 32 | 2.6 | 1.3 | 0.4 | 0.3 | 0 | 0 | 0 | 0 | 0 | 0 |
| 🟥 120 MSps | 13 | 39 | 18 | 9.4 | 5.6 | 3.1 | 2.3 | 1.8 | 1.6 | 1.4 | 1.4 | 0.9 | 0.9 | 1 | 0.7 |

Fig. 7. A histogram showing a contribution of rise times for 1-,2- and more time bins for real measurements with 120 and 160 MSps (upper graph) as well as a slope distribution of rising edges of signal waveforms vs. an amplitudes for 120 MSps (middle graph) and 160 MSps (lower graph). Branches correspond to 1-, 2- and more time bins slopes from a pedestal level to a maximum value.

negligible (∼0.4%). Real measurements without anti-aliasing filters give much bigger 1-time-bin contribution: 13% for 120 MSps and 7.5% for 160 MSps (Fig. 7a).

Fig. 6b and Fig. 7b show slope distributions for simulations and real measurements, respectively, both for 120 MHz sampling frequency. We see that anti-aliasing filter introduces a significant inclination of the signal rising edges, which may dramatically affect a timing analysis based on rising times distributions and important for e.g. splitting of muon "pancakes" generated in very inclined showers. Charged muons are deflected in the Earth magnetic field and create two sub-showers. A precise timing analysis allows a significant improvement of a geometrical shower reconstruction.

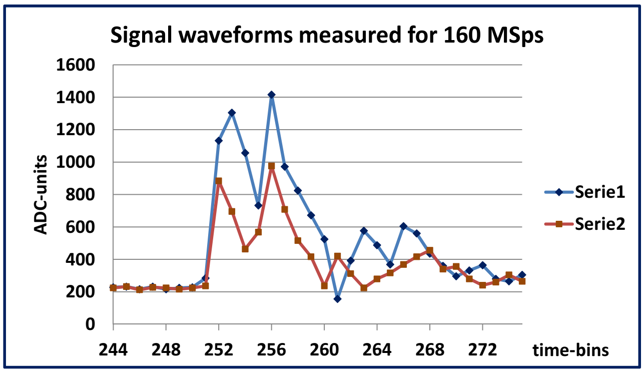

Fig. 8. Samples of signal waveforms registered with 160 MSps, which manifest light reflections from the Tyvec® walls.

Fig. 7c shows that for the 160 MSps a contribution signal waveforms with 1-time-bin rising edges is still high. It means a real rise time of many signal from the pedestal level to the maximal value may be even shorten than an interval of a single time bin.

Rising times for 160 MSps reach even ∼440 ADC-units/ns, which is 2-3 times faster than with even 5-pole Bessel filter. This may suggest that the rising edge is in fact steeper and with

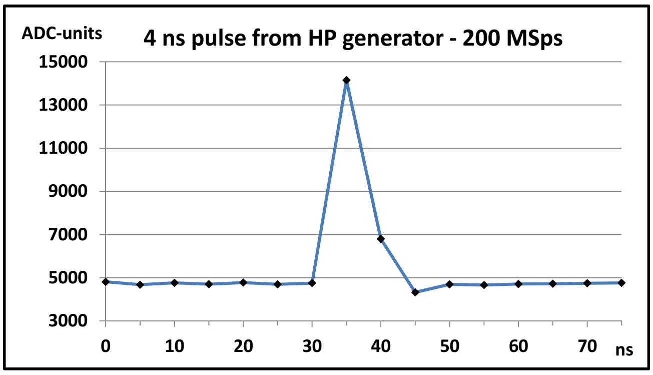

Fig. 9. A signal waveform for 4 ns pulse from the HP generator for the sampling frequency 200 MHz.

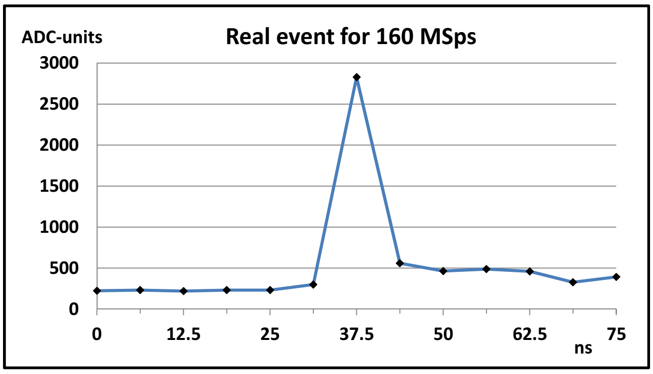

Fig. 10. A signal waveform of a real very short pulse registered for 160 MSps.

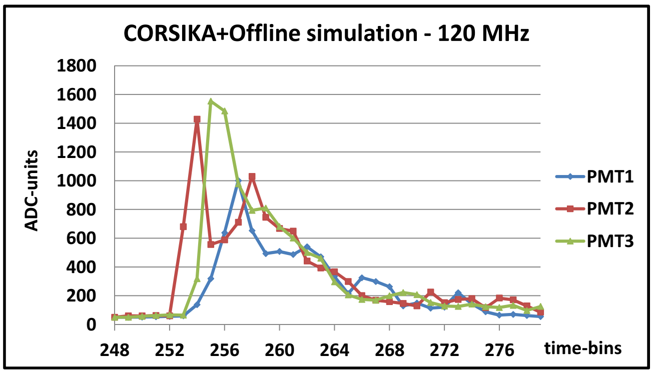

Fig. 11. Samples of signal waveforms simulated by the CORSIKA and Offline packages with 120 MSps, which manifest light reflections from the Tyvec® walls.

a faster sampling frequencies we would get still non-negligible amount of events located on the 1-time-bin branch.

A significant contribution of events with 5-time-bin rising edge comes from a light reflections from a Tyvec® walls (see samples of measured signal waveforms on Fig. 8 and simulated on Fig. 11). 3-4 time-bins for 160 MSps correspond to 18.75 - 25 ns and to 4 - 5 m of an additional geometrical distance for a light by n = 1.333 for a pure water.

The Front-End Board with Cyclone® V E is able to register even a 1-time-bin very short pulse. Fig. 9 shows a very short 4 ns pulse registered in the lab for a signal provided from the HP generator. ADC was working with 200 MHz sampling frequency. A similar pulse (Fig. 10) has been registered in real conditions for a signal obtained from PMTs of the tested surface detector. If the Front-End Board had been equipped in the anti-aliasing filter such pulses would have been strongly suppressed and probably not registered due to too low amplitude below a detection threshold.

## VI. DCT TRIGGER CONFIGURATIONS

16-point DCT algorithm for 120, 160 or 200 MHz sampling frequencies corresponds to 125, 93.75 or 75 ns, respectively, of sliding windows. We are interested in signal waveforms with a jump from a pedestal level to a maximum value and with the exponentially attenuated tails. As a pattern we can select 2, 3 or more time bins (Fig. 12) on a pedestal level following by the jump. DCT coefficients significantly depend on an amount of initial (pedestal level) time bins (Fig. 13).

The DCT coefficients are scaled to the $1^{st}$ harmonics. For the variant of 4 time bins, the DCT[1] is sometimes (for a particular tail slope $\alpha$ = 0.16667) very close to zero and as denominator in a scaling arbitrary units (a.u.) gives a huge value of a fraction (Fig. 14). So, the 4 time-bin variant provides an almost negligible sensitivity for $\alpha \neq 0.16667$.

For 160 and 200 MHz sampling frequencies 3 time-bins variants manifest the same undesirable coefficient characteristics similar to shown on Fig. 13c due to an almost singularity because of DCT[1]. for final test we select 3 time-bin variant for 120 MSps and 2 time-bin variants for 160 and 200 MSps, respectively.

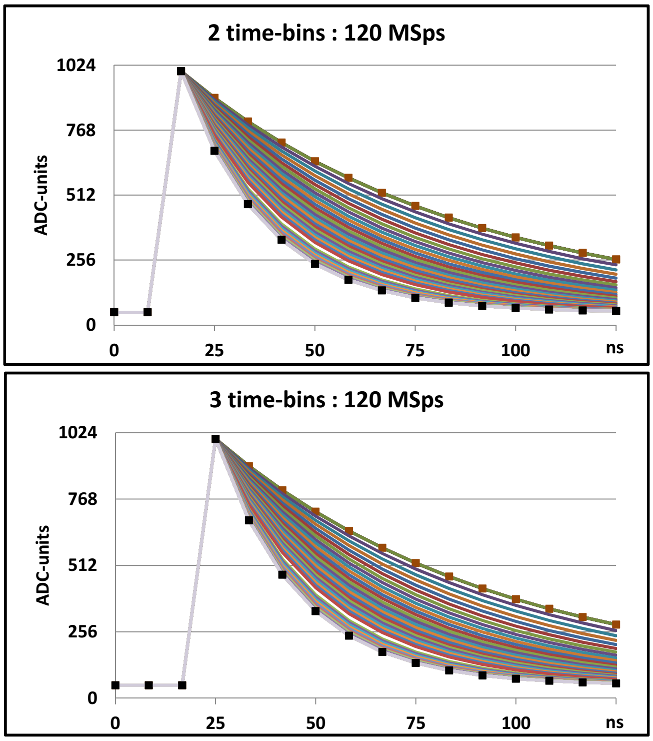

Fig. 12. Shapes of signal waveforms (for 120 MSps) giving the DCT trigger. The upper graph corresponds to an analysis of a signal waveform, where a jump appears on the $2^{nd}$ time-bin, the lower one for the $3^{rd}$ one.

DCT coefficients are preliminary calculated in an external C program for various $\alpha$ slopes. They are stored in the FPGA ROM and multiplexed in real time to keep arbitrary selected DCT rate (~6 Hz). In order to provide a sufficient calculation precision with a reasonably resources occupancy the DCT coefficients for ROM are selected as 12-bit fixed-point data.

For 160 and 200 MSps the DCT[8]/DCT[1] is almost independent of the tail slopes and are almost zeroed. We will neglect this coefficients as almost insensitive on signal waveform shapes.

The AHDL code for the FPGA contains a sigma-delta algorithm multiplexing several variants of bordering slopes to keep the stable DCT trigger rate in huge daily temperature variation [14]. This algorithm has been already successfully tested in Nov. 2014

## VII. CONCLUSIONS

We planned to deploy 7 Front-End Boards in a hexagon of the surface detectors in the Pierre Auger Engineering Array. As we see from Fig. 13 and Fig. 14 a configuration with 4 time-bins on a pedestal level is not suitable for a detection. A scaling fails due to a small DCT[1] coefficient for 15th k index. The variant with 3 time bins seems to be more appropriate, although 2 time bin variant also was tested in 2014 and passed successfully tests on the FEB with Cyclone III.

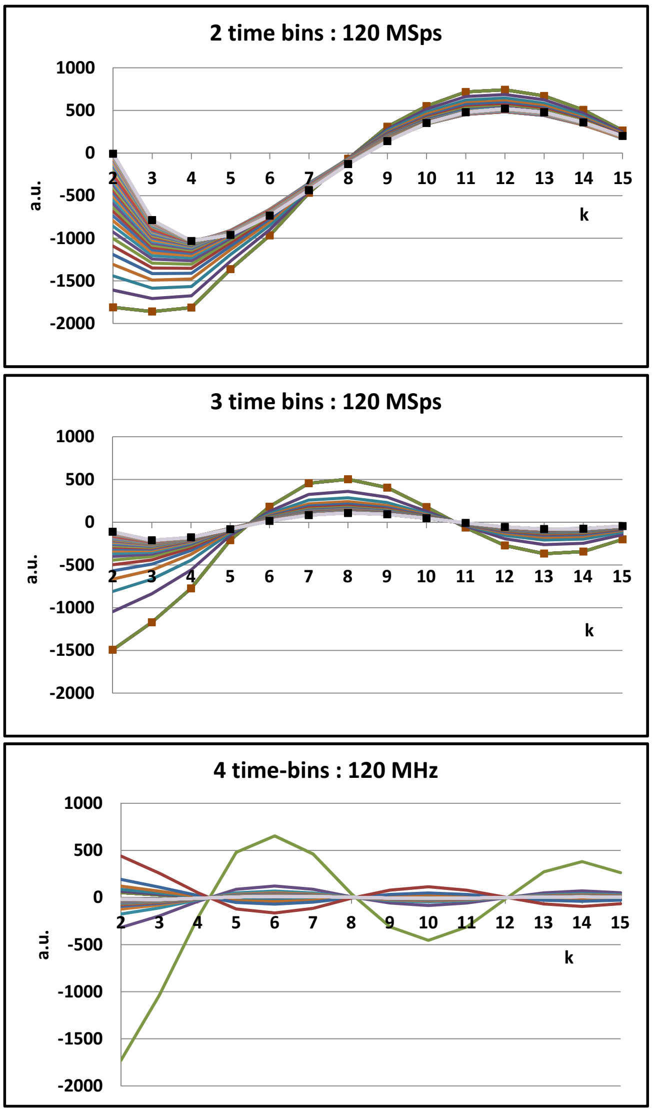

Fig. 13. DCT coefficients (for 120 MSps) giving the DCT trigger. The upper graph corresponds to an analysis of a signal waveform, where a jump appears on the $2^{nd}$ time-bin, the middle one for the $3^{rd}$ one and the lower graph for the $4^{th}$ one.

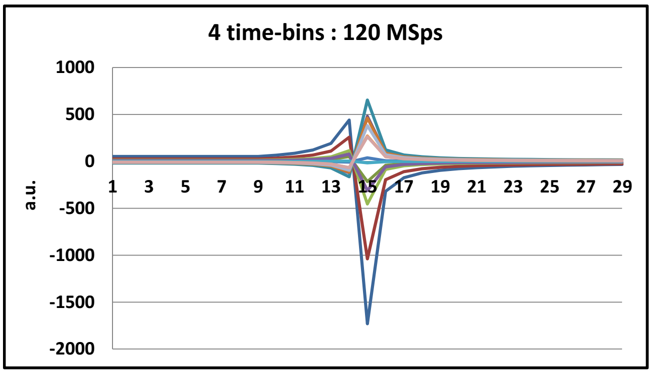

Fig. 14. DCT coefficients (for 120 MSps) vs. index of the tail slope. For k=15 the DCT[1] is close to zero (as denominator in a scaling) and DCT[k]/DCT[1] become huge values in comparison the other scaled DCT cofficients.

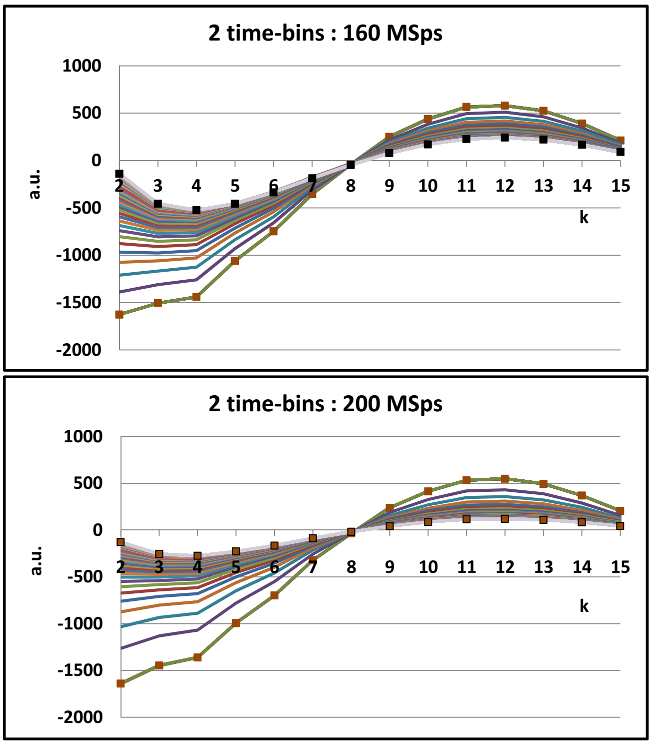

Fig. 15. DCT coefficients for 160 and 200 MSps giving the DCT trigger.

***Abstract*—Let**

$$f(n) = \begin{cases} 1 & \text{if} \quad n = 1 \\ 2^{2^{n-2}} & \text{if} \quad n \in \{2,3,4,5\} \\ \left(2+2^{2^{n-4}}\right)^{2^{n-4}} & \text{if} \quad n \in \{6,7,8,\dots\} \end{cases}$$

**We conjecture that if a system**

$$T \subseteq \{x_i + 1 = x_k,\ x_i \cdot x_j = x_k :\ i,j,k \in \{1,\dots,n\}\}$$

**has only finitely many solutions in positive integers $x_1,\dots,x_n$, then each such solution $(x_1,\dots,x_n)$ satisfies $x_1,\dots,x_n \leqslant f(n)$. We prove that the function $f$ cannot be decreased and the conjecture implies that there is an algorithm which takes as input a Diophantine equation, returns an integer, and this integer is greater than the heights of integer (non-negative integer, positive integer, rational) solutions, if the solution set is finite. We show that if the conjecture is true, then this can be partially confirmed by the execution of a brute-force algorithm.**

***Index Terms*—bound for integer solutions, Diophantine equation, finite-fold Diophantine representation, height of a solution, integer arithmetic.**

IN THIS article, we present a conjecture on integer arithmetic which implies a positive answer to all versions of the following open problem:

**Problem.** *Is there an algorithm which takes as input a Diophantine equation, returns an integer, and this integer is greater than the heights of integer (non-negative integer, positive integer, rational) solutions, if the solution set is finite?*

The height of a rational number $\frac{p}{q}$ is defined by $\max(|p|,|q|)$ provided $\frac{p}{q}$ is written in lowest terms. The height of a rational tuple $(x_1,\dots,x_n)$ is defined as the maximum of $n$ and the heights of the numbers $x_1,\dots,x_n$.

**Theorem 1.** *Only $x_1 = 1$ solves the equation $x_1 \cdot x_1 = x_1$ in positive integers. Only $x_1 = 1$ and $x_2 = 2$ solve the system $\{x_1 \cdot x_1 = x_1,\ x_1 + 1 = x_2\}$ in positive integers. For each integer $n \geqslant 3$, the following system*

$$\begin{cases} x_1 \cdot x_1 = x_1 \\ x_1 + 1 = x_2 \\ \forall i \in \{2,\dots,n-1\}\ x_i \cdot x_i = x_{i+1} \end{cases}$$

*has a unique solution in positive integers, namely $\left(1,2,4,16,256,\dots,2^{2^{n-3}},2^{2^{n-2}}\right)$.*

**Theorem 2.** *For each positive integer n, the following system*

$$\begin{cases} \forall i \in \{1,\dots,n\}\ x_i \cdot x_i = x_{i+1} \\ x_{n+2} + 1 = x_1 \\ x_{n+3} + 1 = x_{n+2} \\ x_{n+3} \cdot x_{n+4} = x_{n+1} \end{cases}$$

*is soluble in positive integers and has only finitely many integer solutions. Each integer solution $(x_1,\dots,x_{n+4})$ satisfies $|x_1|,\dots,|x_{n+4}| \leqslant \left(2+2^{2^n}\right)^{2^n}$. The maximal solution in positive integers is given by*

$$\begin{cases} \forall i \in \{1,\dots,n+1\}\ x_i = \left(2+2^{2^n}\right)^{2^{i-1}} \\ x_{n+2} = 1 + 2^{2^n} \\ x_{n+3} = 2^{2^n} \\ x_{n+4} = \left(1 + 2^{2^n} - 1\right)^{2^n} \end{cases}$$

*Proof.* The system equivalently expresses that $(x_1 - 2) \cdot x_{n+4} = x_1^{2^n}$. By this and the polynomial identity

$$x_1^{2^n} = 2^{2^n} + (x_1 - 2) \cdot \sum_{k=0}^{2^n-1} 2^{2^n-1-k} \cdot x_1^k$$

we get that $x_{n+3} = x_1 - 2$ divides $2^{2^n}$ and $x_{n+4} = \dfrac{x_1^{2^n}}{x_1 - 2}$. Hence, $x_1 \in \left[2 - 2^{2^n}, 2 + 2^{2^n}\right] \cap \mathbb{Z}$, the system has only finitely many integer solutions, and $|x_1|,\dots,|x_{n+4}| \leqslant \left(2+2^{2^n}\right)^{2^n}$. □

In [10, p. 719], the author proposed the upper bound $2^{2^{n-1}}$ for positive integer solutions to any system

$$T \subseteq \{x_i + x_j = x_k,\ x_i \cdot x_j = x_k :\ i,j,k \in \{1,\dots,n\}\}$$

978-83-60810-66-8/$25.00©2015, IEEE

which has only finitely many solutions in positive integers $x_1, \dots, x_n$. The bound $2^{2^{n-1}}$ is not correct for any $n \geqslant 8$ because the following system

$$\begin{cases} \forall i \in \{1,\dots,k\} \; x_i \cdot x_i &= x_{i+1} \\ x_{k+2} + x_{k+2} &= x_{k+3} \\ x_{k+2} \cdot x_{k+2} &= x_{k+3} \\ x_{k+4} + x_{k+3} &= x_1 \\ x_{k+4} \cdot x_{k+5} &= x_{k+1} \end{cases}$$

provides a counterexample for any $k \geqslant 3$. In [11, p. 96], the author proposed the upper bound $2^{2^{n-1}}$ for modulus of integer solutions to any system

$$T \subseteq \{x_k = 1, \;\; x_i + x_j = x_k, \;\; x_i \cdot x_j = x_k : \;\; i,j,k \in \{1,\dots,n\}\}$$

which has only finitely many solutions in integers $x_1, \dots, x_n$. The bound $2^{2^{n-1}}$ is not correct for any $n \geqslant 9$ because the following system

$$\begin{cases} \forall i \in \{1,\dots,k\} \; x_i \cdot x_i &= x_{i+1} \\ x_{k+2} &= 1 \\ x_{k+3} + x_{k+2} &= x_1 \\ x_{k+4} + x_{k+2} &= x_{k+3} \\ x_{k+4} \cdot x_{k+5} &= x_{k+1} \end{cases}$$

provides a counterexample for any $k \geqslant 4$. Let

$$f(n) = \begin{cases} 1 & \text{if} \quad n = 1 \\ 2^{2^{n-2}} & \text{if} \quad n \in \{2,3,4,5\} \\ \left(2 + 2^{2^{n-4}}\right)^{2^{n-4}} & \text{if} \quad n \in \{6,7,8,\dots\} \end{cases}$$

**Conjecture.** *If a system*

$$T \subseteq \{x_i + 1 = x_k, \;\; x_i \cdot x_j = x_k : \;\; i,j,k \in \{1,\dots,n\}\}$$

*has only finitely many solutions in positive integers $x_1, \dots, x_n$, then each such solution $(x_1, \dots, x_n)$ satisfies $x_1, \dots, x_n \leqslant f(n)$.*

Theorems 1 and 2 imply that the function $f$ cannot be decreased. Let $\mathcal{R}ng$ denote the class of all rings $\boldsymbol{K}$ that extend $\mathbb{Z}$, and let

$$E_n = \{x_k = 1, \;\; x_i + x_j = x_k, \;\; x_i \cdot x_j = x_k : \;\; i,j,k \in \{1,\dots,n\}\}$$

Th. Skolem proved that any Diophantine equation can be algorithmically transformed into an equivalent system of Diophantine equations of degree at most 2, see [6, pp. 2–3] and [2, pp. 3–4]. The following result strengthens Skolem's theorem.

**Lemma 1.** *([10, p. 720]) Let $D(x_1, \dots, x_p) \in \mathbb{Z}[x_1, \dots, x_p]$. Assume that* $\deg(D, x_i) \geqslant 1$ *for each $i \in \{1, \dots, p\}$. We can compute a positive integer $n > p$ and a system $T \subseteq E_n$ which satisfies the following two conditions:*

`Condition 1.` *If $\boldsymbol{K} \in \mathcal{R}ng \cup \{\mathbb{N}, \; \mathbb{N} \setminus \{0\}\}$, then*

$$\forall \tilde{x}_1, \dots, \tilde{x}_p \in \boldsymbol{K} \; \Big(D(\tilde{x}_1, \dots, \tilde{x}_p) = 0 \Longleftrightarrow$$

$$\exists \tilde{x}_{p+1}, \dots, \tilde{x}_n \in \boldsymbol{K} \; (\tilde{x}_1, \dots, \tilde{x}_p, \tilde{x}_{p+1}, \dots, \tilde{x}_n) \textit{ solves } T\Big)$$

`Condition 2.` *If $\boldsymbol{K} \in \mathcal{R}ng \cup \{\mathbb{N}, \; \mathbb{N} \setminus \{0\}\}$, then for each $\tilde{x}_1, \dots, \tilde{x}_p \in \boldsymbol{K}$ with $D(\tilde{x}_1, \dots, \tilde{x}_p) = 0$, there exists a unique tuple $(\tilde{x}_{p+1}, \dots, \tilde{x}_n) \in \boldsymbol{K}^{n-p}$ such that the tuple $(\tilde{x}_1, \dots, \tilde{x}_p, \tilde{x}_{p+1}, \dots, \tilde{x}_n)$ solves $T$.*

*Conditions 1 and 2 imply that for each $\boldsymbol{K} \in \mathcal{R}ng \cup \{\mathbb{N}, \; \mathbb{N} \setminus \{0\}\}$, the equation $D(x_1, \dots, x_p) = 0$ and the system $T$ have the same number of solutions in $\boldsymbol{K}$.*

For a positive integer $n$, let $S(n)$ denote the successor of $n$.

**Lemma 2.** *Let $T$ be a finite system of equations of the forms: $x = 1$, $x + y = z$, and $x \cdot y = z$. If the equation $x = 1$ belongs to $T$, then the system $T \cup \{x \cdot x = x\} \setminus \{x = 1\}$ has the same solutions in positive integers.*

**Lemma 3.** *Let $T$ be a finite system of equations of the forms: $S(x) = y$, $x + y = z$, and $x \cdot y = z$. If the equation $x + y = z$ belongs to $T$ and the variables $z_1$, $z_2$, $\widetilde{z_1}$, $\widetilde{z_2}$, $\widetilde{v}$, $u$, $t$, $\widetilde{t}$, $v$ are new, then the following system*

$$T \cup \{z \cdot x = z_1, \;\; z \cdot y = z_2, \;\; S(z_1) = \widetilde{z_1}, \;\; S(z_2) = \widetilde{z_2}, \;\; \widetilde{z_1} \cdot \widetilde{z_2} = \widetilde{v},$$

$$z \cdot z = u, \;\; x \cdot y = t, \;\; S(t) = \widetilde{t}, \;\; u \cdot \widetilde{t} = v, \;\; S(v) = \widetilde{v}\} \setminus \{x + y = z\}$$

*has the same solutions in positive integers and a smaller number of additions.*

*Proof.* According to [5, p. 100], for each positive integers $x, y, z$, $x + y = z$ if and only if

$$S(z \cdot x) \cdot S(z \cdot y) = S((z \cdot z) \cdot S(x \cdot y))$$

Indeed, the above equality is equivalent to

$$\left(z^2 \cdot x \cdot y + 1\right) + z \cdot (x + y) = \left(z^2 \cdot x \cdot y + 1\right) + z^2$$

□

Lemmas 1–3 imply the next theorem.

**Theorem 3.** *If we assume the Conjecture and a Diophantine equation $D(x_1, \dots, x_p) = 0$ has only finitely many solutions in positive integers, then an upper bound for these solutions can be computed.*

**Corollary 1.** *If we assume the Conjecture and a Diophantine equation $D(x_1, \dots, x_p) = 0$ has only finitely many solutions in non-negative integers, then an upper bound for these solutions can be computed by applying Theorem 3 to the equation $D(x_1 - 1, \dots, x_p - 1) = 0$.*

**Corollary 2.** *If we assume the Conjecture and a Diophantine equation $D(x_1, \dots, x_p) = 0$ has only finitely many integer solutions, then an upper bound for their modulus can be computed by applying Theorem 3 to the equation*

$$\prod_{(i_1, \dots, i_p) \in \{1,2\}^p} D((-1)^{i_1} \cdot (x_1 - 1), \dots, (-1)^{i_p} \cdot (x_p - 1)) = 0$$

**Lemma 4.** *([10, p. 720]) If there is a computable upper bound for the modulus of integer solutions to a Diophantine equation with a finite number of integer solutions, then there is a computable upper bound for the heights of rational solutions to a Diophantine equation with a finite number of rational solutions.*

**Theorem 4.** *The Conjecture implies that there is a computable upper bound for the heights of rational solutions to a Diophantine equation with a finite number of rational solutions.*

*Proof.* It follows from Corollary 2 and Lemma 4. □

The Davis-Putnam-Robinson-Matiyasevich theorem states that every recursively enumerable set $\mathcal{M} \subseteq \mathbb{N}^n$ has a Diophantine representation, that is

$$(a_1, \dots, a_n) \in \mathcal{M} \Longleftrightarrow$$
$$\exists x_1, \dots, x_m \in \mathbb{N} \quad W(a_1, \dots, a_n, x_1, \dots, x_m) = 0 \qquad \texttt{(R)}$$

for some polynomial $W$ with integer coefficients, see [2]. The polynomial $W$ can be computed, if we know the Turing machine $M$ such that, for all $(a_1, \dots, a_n) \in \mathbb{N}^n$, $M$ halts on $(a_1, \dots, a_n)$ if and only if $(a_1, \dots, a_n) \in \mathcal{M}$, see [2]. The representation (R) is said to be finite-fold, if for any $a_1, \dots, a_n \in \mathbb{N}$ the equation $W(a_1, \dots, a_n, x_1, \dots, x_m) = 0$ has only finitely many solutions $(x_1, \dots, x_m) \in \mathbb{N}^m$. Yu. Matiyasevich conjectures that each recursively enumerable set $\mathcal{M} \subseteq \mathbb{N}^n$ has a finite-fold Diophantine representation, see [1, pp. 341–342], [3, p. 42], and [4, p. 745]. Matiyasevich's conjecture implies a negative answer to the Problem, see [3, p. 42].

**Theorem 5.** *(cf. [10, p. 721]) The Conjecture implies that if a set $\mathcal{M} \subseteq \mathbb{N}$ has a finite-fold Diophantine representation, then $\mathcal{M}$ is computable.*

*Proof.* Let a set $\mathcal{M} \subseteq \mathbb{N}$ has a finite-fold Diophantine representation. It means that there exists a polynomial $W(x, x_1, \dots, x_m)$ with integer coefficients such that

$$\forall b \in \mathbb{N} \ \Big(b \in \mathcal{M} \Longleftrightarrow \exists x_1, \dots, x_m \in \mathbb{N} \quad W(b, x_1, \dots, x_m) = 0\Big)$$

and for any $b \in \mathbb{N}$ the equation $W(b, x_1, \dots, x_m) = 0$ has only finitely many solutions $(x_1, \dots, x_m) \in \mathbb{N}^m$. By Corollary 1, there is a computable function $g \colon \mathbb{N} \to \mathbb{N}$ such that for each $b, x_1, \dots, x_m \in \mathbb{N}$ the equality $W(b, x_1, \dots, x_m) = 0$ implies $\max(x_1, \dots, x_m) \leqslant g(b)$. Hence, we can decide whether or not a non-negative integer $b$ belongs to $\mathcal{M}$ by checking whether or not the equation $W(b, x_1, \dots, x_m) = 0$ has an integer solution in the box $[0, g(b)]^m$. □

In this paragraph, we follow [9] and we explain why Matiyasevich's conjecture although widely known is less widely accepted. Let us say that a set $\mathcal{M} \subseteq \mathbb{N}^n$ has a bounded Diophantine representation, if there exists a polynomial $W$ with integer coefficients such that

$$(a_1, \dots, a_n) \in \mathcal{M} \Longleftrightarrow \exists x_1, \dots, x_m \in \{0, \dots, \max(a_1, \dots, a_n)\}$$
$$W(a_1, \dots, a_n, x_1, \dots, x_m) = 0$$

Of course, any bounded Diophantine representation is finite-fold and any subset of $\mathbb{N}$ with a bounded Diophantine representation is computable. A simple diagonal argument shows that there exists a computable subset of $\mathbb{N}$ without any bounded Diophantine representation, see [1, p. 360]. The authors of [1] suggest a possibility (which contradicts Matiyasevich's conjecture) that each subset of $\mathbb{N}$ which has a finite-fold Diophantine representation has also a bounded Diophantine representation, see [1, p. 360].

For a positive integer $n$, let $\tau(n)$ denote the smallest positive integer $b$ such that for each system

$$T \subseteq \{x_i + 1 = x_k, \ x_i \cdot x_j = x_k : \ i, j, k \in \{1, \dots, n\}\}$$

with a finite number of solutions in positive integers $x_1, \dots, x_n$, all these solutions belong to $[1, b]^n$. By Theorems 1 and 2, $f(n) \leqslant \tau(n)$ for every positive integer $n$. The Conjecture implies that $f(n) = \tau(n)$ for every positive integer $n$.

**Theorem 6.** *(cf. [9, Theorem 4]) If a function $h \colon \mathbb{N} \setminus \{0\} \to \mathbb{N} \setminus \{0\}$ has a finite-fold Diophantine representation, then there exists a positive integer $m$ such that $h(n) < \tau(n)$ for every integer $n > m$.*

*Proof.* There exists a polynomial $W(x_1, x_2, x_3, \dots, x_r)$ with integer coefficients such that for each positive integers $x_1, x_2$,

$$(x_1, x_2) \in h \Longleftrightarrow$$
$$\exists x_3, \dots, x_r \in \mathbb{N} \setminus \{0\} \quad W(x_1, x_2, x_3 - 1, \dots, x_r - 1) = 0$$

and for each positive integers $x_1, x_2$ at most finitely many tuples $(x_3, \dots, x_r)$ of positive integers satisfy $W(x_1, x_2, x_3 - 1, \dots, x_r - 1) = 0$. By Lemmas 1–3, there is an integer $s \geqslant 3$ such that for any positive integers $x_1, x_2$,

$$(x_1, x_2) \in h \Longleftrightarrow$$
$$\exists x_3, \dots, x_s \in \mathbb{N} \setminus \{0\} \quad \Psi(x_1, x_2, x_3, \dots, x_s) \qquad \texttt{(E)}$$

where $\Psi(x_1, x_2, x_3, \dots, x_s)$ is a conjunction of formulae of the forms $x_i + 1 = x_k$ and $x_i \cdot x_j = x_k$, the indices $i, j, k$ belong to $\{1, \dots, s\}$, and for each positive integers $x_1, x_2$ at most finitely many tuples $(x_3, \dots, x_s)$ of positive integers satisfy $\Psi(x_1, x_2, x_3, \dots, x_s)$. Let $[\cdot]$ denote the integer part function, and let an integer $n$ is greater than $m = 2s + 2$. Then,

$$n \geqslant \left[\frac{n}{2}\right] + \frac{n}{2} > \left[\frac{n}{2}\right] + s + 1$$

and $n - \left[\frac{n}{2}\right] - s - 2 \geqslant 0$. Let $T_n$ denote the following system with $n$ variables:

$$\begin{cases} \multicolumn{4}{c}{\text{all equations occurring in } \Psi(x_1, x_2, x_3, \dots, x_s)} \\ \forall i \in \left\{1, \dots, n - \left[\frac{n}{2}\right] - s - 2\right\} & u_i \cdot u_i & = & u_i \\ & t_1 \cdot t_1 & = & t_1 \\ \forall i \in \left\{1, \dots, \left[\frac{n}{2}\right] - 1\right\} & t_i + 1 & = & t_{i+1} \\ & t_2 \cdot t_{\left[\frac{n}{2}\right]} & = & u \\ & u + 1 & = & x_1 \text{ (if } n \text{ is odd)} \\ & t_1 \cdot u & = & x_1 \text{ (if } n \text{ is even)} \\ & x_2 + 1 & = & y \end{cases}$$

By the equivalence (E), the system $T_n$ is soluble in positive integers, $2 \cdot \left[\frac{n}{2}\right] = u$, $n = x_1$, and

$$h(n) = h(x_1) = x_2 < x_2 + 1 = y$$

Since $T_n$ has at most finitely many solutions in positive integers, $y \leqslant \tau(n)$. Hence, $h(n) < \tau(n)$. □

Below is the excerpt from page 135 of the book [7]:

*Folklore. If a Diophantine equation has only finitely many solutions then those solutions are small in 'height' when compared to the parameters of the equation.*

*This folklore is, however, only widely believed because of the large amount of experimental evidence which now exists to support it.*

Below is the excerpt from page 12 of the article [8]:

*Note that if a Diophantine equation is solvable, then we can prove it, since we will eventually find a solution by searching through the countably many possibilities (but we do not know beforehand how far we have to search). So the really hard problem is to prove that there are no solutions when this is the case. A similar problem arises when there are finitely many solutions and we want to find them all. In this situation one expects the solutions to be fairly small. So usually it is not so hard to find all solutions; what is difficult is to show that there are no others.*

That is, mathematicians are intuitively persuaded that solutions are small when there are finitely many of them. It seems that there is a reason which is common to all the equations. Such a reason might be the Conjecture whose consequences we have already presented.

For a positive integer $b$, let $\Phi(b)$ denote the Conjecture restricted to systems whose all solutions in positive integers are not greater than $b$. Obviously,

$$\Phi(1) \Leftarrow \Phi(2) \Leftarrow \Phi(3) \Leftarrow \dots$$

and the Conjecture is equivalent to $\forall b \in \mathbb{N} \setminus \{0\}\ \Phi(b)$. The Conjecture is true for $n = 1$ and $n = 2$. Therefore, the sentence $\Phi(4)$ is true. For each positive integer $n$, there are only finitely many systems

$$T \subseteq \{x_i + 1 = x_k,\ x_i \cdot x_j = x_k :\ i, j, k \in \{1, \dots, n\}\}$$

Hence, for each positive integer $n$ there exists a positive integer $m$ such that the Conjecture restricted to systems with at most $n$ variables is equivalent to the sentence $\Phi(m)$.

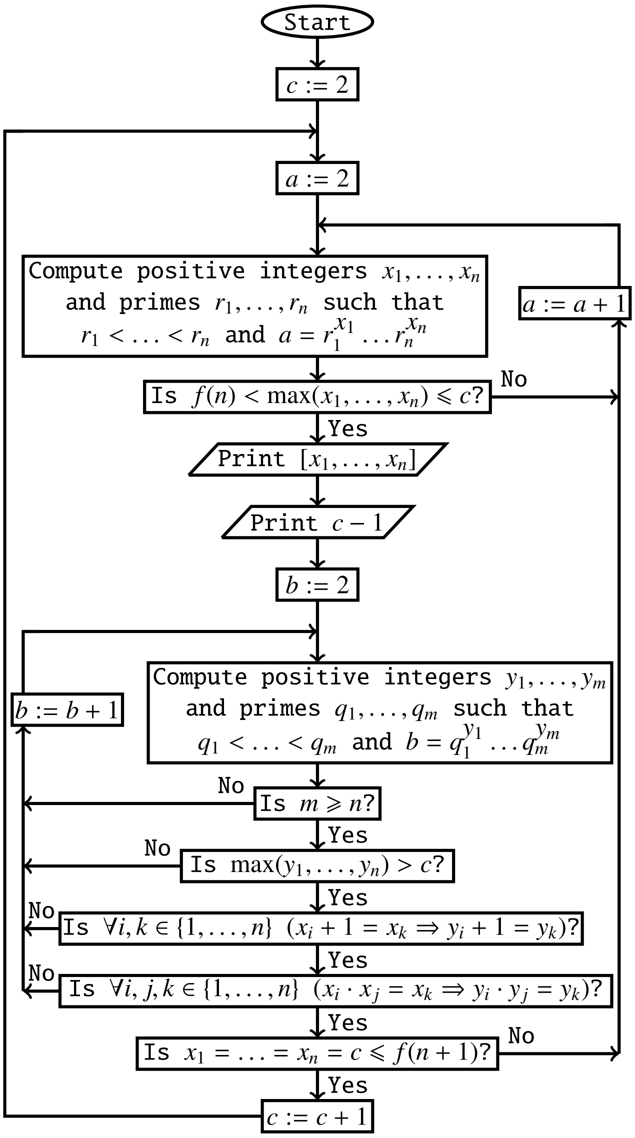
**Theorem 7.** *The Conjecture is equivalent to the following conjecture on integer arithmetic: if positive integers $x_1, \dots, x_n$ satisfy $\max(x_1, \dots, x_n) > f(n)$, then there exist positive integers $y_1, \dots, y_n$ such that*

$$\Big(\max(x_1, \dots, x_n) < \max(y_1, \dots, y_n)\Big) \wedge$$

$$\Big(\forall i, k \in \{1, \dots, n\}\ (x_i + 1 = x_k \Longrightarrow y_i + 1 = y_k)\Big) \wedge$$

$$\Big(\forall i, j, k \in \{1, \dots, n\}\ (x_i \cdot x_j = x_k \Longrightarrow y_i \cdot y_j = y_k)\Big)$$

The execution of the following flowchart never terminates.



Start
$c := 2$
$a := 2$
Compute positive integers $x_1, \dots, x_n$ and primes $r_1, \dots, r_n$ such that $r_1 < \dots < r_n$ and $a = r_1^{x_1} \dots r_n^{x_n}$
$a := a + 1$
Is $f(n) < \max(x_1, \dots, x_n) \leqslant c$?
No
Yes
Print $[x_1, \dots, x_n]$
Print $c - 1$
$b := 2$
Compute positive integers $y_1, \dots, y_m$ and primes $q_1, \dots, q_m$ such that $q_1 < \dots < q_m$ and $b = q_1^{y_1} \dots q_m^{y_m}$
$b := b + 1$
No
Is $m \geqslant n$?
Yes
No
Is $\max(y_1, \dots, y_n) > c$?
Yes
No
Is $\forall i, k \in \{1, \dots, n\}$ $(x_i + 1 = x_k \Rightarrow y_i + 1 = y_k)$?
Yes
No
Is $\forall i, j, k \in \{1, \dots, n\}$ $(x_i \cdot x_j = x_k \Rightarrow y_i \cdot y_j = y_k)$?
Yes
Is $x_1 = \dots = x_n = c \leqslant f(n + 1)$?
No
Yes
$c := c + 1$

**Theorem 8.** *If the Conjecture is true, then the execution of the flowchart provides an infinite sequence $X_1, c_1, X_2, c_2, X_3, c_3, \dots$ where $\{c_1, c_2, c_3, \dots\} = \mathbb{N} \setminus \{0\}$, $c_1 \leqslant c_2 \leqslant c_3 \leqslant \dots$ and each $X_i$ is a tuple of positive integers. Each returned number $c_i$ indicates that the performed computations confirm the sentence $\Phi(c_i)$. If the Conjecture is false, then the execution provides a similar finite sequence $X_1, c_1, \dots, X_k, c_k$ on the output. In this case, for the tuple $X_k = (x_1, \dots, x_n)$ an appropriate tuple $(y_1, \dots, y_n)$ does not exist, $\{c_1, \dots, c_k\} = [1, c_k] \cap \mathbb{N}$, $c_1 \leqslant \dots \leqslant c_k$, the sentences $\Phi(1), \Phi(2), \Phi(3), \dots, \Phi(c_k)$ are true, and the sentences $\Phi(c_k + 1), \Phi(c_k + 2), \Phi(c_k + 3), \dots$ are false.*

*Proof.* Let $p_n$ denote the $n^{\text{th}}$ prime number ($p_1 = 2$, $p_2 = 3$, etc.), and let $c$ stands for any integer greater than 1. The function $f$ is strictly increasing and there exists the smallest positive integer $n$ such that $c \leqslant f(n+1)$. Hence, if positive integers $x_1, \dots, x_i$ satisfy $f(i) < \max(x_1, \dots, x_i) \leqslant c$, then $i \leqslant n$ and $2 \leqslant p_1^{x_1} \dots p_i^{x_i} \leqslant p_1^c \dots p_n^c$. Therefore, if the sentence $\Phi(c)$ is true, then the flowchart algorithm checks all tuples of positive integers needed to confirm the sentence $\Phi(c)$. □

The following *MuPAD* code implements a simplified flowchart's algorithm which checks the following conjunction

$$\Big(m \geqslant n\Big) \wedge \Big(\max(y_1, \dots, y_n) > c\Big) \wedge$$

$$\Big(\forall i,k \in \{1,\dots,n\}\ (x_i + 1 = x_k \Longrightarrow y_i + 1 = y_k)\Big) \wedge$$

$$\Big(\forall i,j,k \in \{1,\dots,n\}\ (x_i \cdot x_j = x_k \Longrightarrow y_i \cdot y_j = y_k)\Big)$$

instead of four separate conditions.

We attempt to confirm the sentence $\Phi(256)$. Since the execution of the flowchart algorithm (or its any variant) proceeds slowly, we must confirm the sentence $\Phi(256)$ in a different way. For integers $a_1, \dots, a_n$, let $P(a_1, \dots, a_n)$ denote the following system of equations:

$$\begin{cases} x_i + 1 &= x_k \quad (\text{if } a_i + 1 = a_k) \\ x_i \cdot x_j &= x_k \quad (\text{if } a_i \cdot a_j = a_k) \end{cases}$$

**Lemma 5.** *For each positive integer n, there exist positive integers $a_1, \dots, a_n$ such that $a_1 \leqslant \dots \leqslant a_n = \tau(n)$ and the system $P(a_1, \dots, a_n)$ has only finitely many solutions in positive integers. Each such numbers $a_1, \dots, a_n$ satisfy $a_1 < \dots < a_n$.*

*Proof.* If $a_1 < \dots < a_n$ does not hold, then we remove the first duplicate and insert $a_n + 1$ after $a_n$. Since $a_n + 1 > a_n = \tau(n)$, we get a contradiction. □

Let $\mathcal{F}$ denote the family of all systems $P(a_1, a_2, a_3)$, where integers $a_1, a_2, a_3$ satisfy $1 < a_1 < a_2 < a_3$.

**Theorem 9.** *The Conjecture is true for $n = 3$.*

*Proof.* By Lemma 5, there exist positive integers $a_1$, $a_2$, $a_3$ such that $a_1 < a_2 < a_3 = \tau(3)$ and the system $P(a_1, a_2, a_3)$ has only finitely many solutions in positive integers. If $a_1 = 1$, then $a_2 = 2$ and $a_3 \in \{3, 4\}$. Let $a_1 > 1$. Since $a_1 < a_2 < a_3$, we get $a_1 \cdot a_1 < a_1 \cdot a_2 < a_2 \cdot a_2$. Hence,

$$\operatorname{card}\Big(P(a_1, a_2, a_3) \cap \Big\{x_1 \cdot x_1 = x_3,\ x_1 \cdot x_2 = x_3,\ x_2 \cdot x_2 = x_3\Big\}\Big) \leqslant 1$$

Each integer $a_1$ satisfies $a_1 + 1 \neq a_1 \cdot a_1$. Hence,

$$\operatorname{card}\Big(P(a_1, a_2, a_3) \cap \Big\{x_1 + 1 = x_2,\ x_1 \cdot x_1 = x_2\Big\}\Big) \leqslant 1$$

Since $a_1 < a_2 < a_3$, the equation $x_1 + 1 = x_3$ does not belong to $P(a_1, a_2, a_3)$. By these observations, the following table shows all solutions in positive integers to any system that belongs to $\mathcal{F}$.

| | $\emptyset$ | $\{x_1{\cdot}x_1{=}x_3\}$ | $\{x_1{\cdot}x_2{=}x_3\}$ | $\{x_2{\cdot}x_2{=}x_3\}$ |
|---|---|---|---|---|
| $\emptyset \cup$ | any triple $(s,t,u)$ solves this system | any triple $\left(s,t,s^2\right)$ solves this system | any triple $(s,t,s{\cdot}t)$ solves this system | any triple $\left(s,t,t^2\right)$ solves this system |
| $\{x_1{+}1{=}x_2\} \cup$ | any triple $(s,s{+}1,u)$ solves this system | any triple $\left(s,s{+}1,s^2\right)$ solves this system | any triple $(s,s{+}1,s{\cdot}(s{+}1))$ solves this system | any triple $\left(s,s{+}1,(s{+}1)^2\right)$ solves this system |
| $\{x_1{\cdot}x_1{=}x_2\} \cup$ | any triple $\left(s,s^2,u\right)$ solves this system | $\notin \mathcal{F}$ | any triple $\left(s,s^2,s^3\right)$ solves this system | any triple $\left(s,s^2,s^4\right)$ solves this system |
| $\{x_2{+}1{=}x_3\} \cup$ | any triple $(s,t,t{+}1)$ solves this system | any triple $\left(s,s^2{-}1,s^2\right)$ solves this system | $\notin \mathcal{F}$ | $\notin \mathcal{F}$ |
| $\{x_1{+}1{=}x_2,$ $x_2{+}1{=}x_3\} \cup$ | any triple $(s,s{+}1,s{+}2)$ solves this system | only the triple $(2,3,4)$ solves this system | $\notin \mathcal{F}$ | $\notin \mathcal{F}$ |
| $\{x_1{\cdot}x_1{=}x_2,$ $x_2{+}1{=}x_3\} \cup$ | any triple $\left(s,s^2,s^2{+}1\right)$ solves this system | $\notin \mathcal{F}$ | $\notin \mathcal{F}$ | $\notin \mathcal{F}$ |

The table indicates that the system

$$\left\{x_1 + 1 = x_2,\ x_2 + 1 = x_3,\ x_1 \cdot x_1 = x_3\right\} =$$

$$\left\{x_1 + 1 = x_2,\ x_2 + 1 = x_3\right\} \cup \left\{x_1 \cdot x_1 = x_3\right\}$$

has a unique solution in positive integers, namely $(2,3,4)$. The other presented systems do not belong to $\mathcal{F}$ or have infinitely many solutions in positive integers. □

**Corollary 3.** *Since the Conjecture is true for $n \in \{1,2,3\}$, the sentence $\Phi(16)$ is true.*

**Theorem 10.** *The sentence $\Phi(256)$ is true.*

*Proof.* By Corollary 3, it suffices to consider quadruples of positive integers. The next *MuPAD* code returns 63 quadruples $(a_i,b_i,c_i,d_i)$ of positive integers, where $a_i < b_i < c_i < d_i \leqslant 256$ and $\max(a_i,b_i,c_i,d_i) = d_i > 16$. These quadruples have the following property: if positive integers $a,b,c,d$ satisfy $a < b < c < d \leqslant 256$ and $\max(a,b,c,d) = d > 16$, then there exists $i \in \{1,\dots,63\}$ such that $P(a,b,c,d) \subseteq P(a_i,b_i,c_i,d_i)$.

Of course, the Conjecture restricted to integers $n \in \{1,2,3,4\}$ is intuitively obvious and implies Theorem 10. Formally, the Conjecture remains unproven for $n = 4$. We explain why a hypothetical brute-force proof of the Conjecture for $n = 4$ is much longer than the proof of Theorem 10. By Lemma 5, it suffices to consider only the systems $P(a,b,c,d)$, where positive integers $a,b,c,d$ satisfy $a < b < c < d$.

`Case 1:` $a = 1$. Obviously,

$$\mathrm{card}\Big(\Big\{x_1 + 1 = x_2\Big\} \cap P(a,b,c,d)\Big) \leqslant 1$$

and

$$\mathrm{card}\Big(\Big\{x_3 + 1 = x_4\Big\} \cap P(a,b,c,d)\Big) \leqslant 1$$

Since $b + 1 < b \cdot b$, we get

$$\mathrm{card}\Big(\Big\{x_2 + 1 = x_3,\ x_2 \cdot x_2 = x_3\Big\} \cap P(a,b,c,d)\Big) \leqslant 1$$

Since $b \cdot b < b \cdot c < c \cdot c$, we get

$$\mathrm{card}\Big(\Big\{x_2 \cdot x_2 = x_4,\ x_2 \cdot x_3 = x_4,\ x_3 \cdot x_3 = x_4\Big\} \cap P(a,b,c,d)\Big) \leqslant 1$$

The above inequalities allow one to determine $(1+1) \cdot (1+1) \cdot (2+1) \cdot (3+1) = 48$ systems which need to be solved.

`Case 2:` $a > 1$. Obviously,

$$\mathrm{card}\Big(\Big\{x_2 + 1 = x_3\Big\} \cap P(a,b,c,d)\Big) \leqslant 1$$

Since $a + 1 < a \cdot a$, we get

$$\mathrm{card}\Big(\Big\{x_1 + 1 = x_2,\ x_1 \cdot x_1 = x_2\Big\} \cap P(a,b,c,d)\Big) \leqslant 1$$

Since $c + 1 < a \cdot c$, we get

$$\mathrm{card}\Big(\Big\{x_3 + 1 = x_4,\ x_1 \cdot x_3 = x_4\Big\} \cap P(a,b,c,d)\Big) \leqslant 1$$

Since $a \cdot a < a \cdot b < b \cdot b$, we get

$$\mathrm{card}\Big(\Big\{x_1 \cdot x_1 = x_3,\ x_1 \cdot x_2 = x_3,\ x_2 \cdot x_2 = x_3\Big\} \cap P(a,b,c,d)\Big) \leqslant 1$$

Since $a \cdot a < a \cdot b < b \cdot b < b \cdot c < c \cdot c$, we get

$$\mathrm{card}\Big(\Big\{x_1 \cdot x_1 = x_4,\ x_1 \cdot x_2 = x_4,\ x_2 \cdot x_2 = x_4,$$
$$x_2 \cdot x_3 = x_4,\ x_3 \cdot x_3 = x_4\Big\} \cap P(a,b,c,d)\Big) \leqslant 1$$

The above inequalities allow one to determine $(1+1) \cdot (2+1) \cdot (2+1) \cdot (3+1) \cdot (5+1) = 432$ systems which need to be solved.

*MuPAD* is a computer algebra system whose syntax is modelled on *Pascal*. The commercial version of *MuPAD* is no longer available as a stand-alone product, but only as the *Symbolic Math Toolbox* of *MATLAB*. Fortunately, the presented codes can be executed by *MuPAD Light*, which was offered for free for research and education until autumn 2005.

***Abstract*—An algorithm for extracting material shape and spatial information from non-uniform background, and for generating object skeletons for statistical two-dimensional experiments using random walk approach, is presented. This finds applications in textile analysis and microscopic analysis of various materials like hairs and allows for further precise determination of textile yarn dimensions as well as other geometrical characteristics like a fractal dimension.**

## I. Introduction

HEMP fibers can be used for a variety of textile products, e.g. clothing or home textiles, but also for technical purposes in fiber composites. For all applications, it is important to determine the fiber lengths and diameters (averaged along with a standard deviation), a task which can be handled by optical equipment and respective software (e.g. [1,2]). Another important factor, however, is the identification of the degree of bifurcation, which influences the spinning process, the fiber-matrix bond strength etc. For this property there is no standard measurement procedure available. Our article aims at presenting a novel method to define the bifurcation of fibers, based on the evaluation of microscopic fiber images based on random walk analysis. The hemp fibers investigated in our study are pre-treated by hammer milling or by combing. Afterwards, the fibers are separated chemically by alkaline cooking [3].

Photographic images of different magnifications were taken using a digital optical microscope VHX-600D by Keyence with an objective VH-Z20R. Captured images were then processed giving monochromatic representative maps. Next, random walk statistical experiments on these maps were carried out. Subsequent chapters describe all mentioned steps, before conclusions are finally provided.

## II. Image Processing

The algorithm described here consists of two denoising and four extraction steps. In the first step, the image is being smoothed using a median filter [4]. This step slightly reduces fine-grained noise and also improves the efficiency of filters used in the first extraction step of the algorithm. The next step is an unsharp masking where it is necessary to define the proportional factor k of the operation [5]. This step can be defined as follows:

$$A_{um}=A_{mf}-Gauss\left(A_{mf}\right)$$
$$A_{um}=k\cdot A_{um}+A_{mf} \quad , \qquad (1)$$

where $A_{um}$ is the unsharp masked image, $A_{mf}$ is the median filtered image, and *Gauss* is the Gaussian filter [4], for which we use the Gaussian filter kernel $k = 0.4$. The window size and the standard deviation parameter σ equal 3. The parameters were chosen experimentally.

The first extraction step is an algorithm that can be split into two functional parts: a background sampling, and a background removal. The algorithm removes the background using a special filter that uses a background sample. The filter window is defined as a vector $h=\{h_1, h_2, h_3, h_4\}$, where $h_1$ is the average intensity, $h_2$ is the standard deviation of intensity, $h_3$ is the maximum intensity, and $h_4$ the minimum intensity. Contrary to the results of Ref. 6, all the values from $h_1$ to $h_4$ are calculated from a Moore neighborhood of each pixel. This improves the filter's quality as consecutive neighborhoods partially overlap each other.

In the first functional part, the algorithm sums Euclidean distances from reference vector, created from upper left corner of the background sample ($h_{ref}$), to reference vectors of all the other pixels from the sample ($h_{ib}$). Next, the algorithm calculates the reference pattern $\bar{d}$ that can be expressed as follows

$$\bar{d}=\frac{\sum_{i=0}^{i=M\cdot N} d\left(h_{ref},h_{ib}\right)}{s} \quad , \qquad (2)$$

where $s$ is the experimentally chosen value, $M$ is the number of rows in the background sample, and $N$ is the number of columns in the background sample.

There are two options for choosing the $s$ value. The default value is $1/4\,MN$, which makes $\bar{d}$ an average of all the distances, taking into consideration the window size = 3.

978-83-60810-66-8/$25.00©2015, IEEE

The other option is to divide by an experimentally chosen value to either increase or decrease the algorithm's sensitivity. For the pictures presented in this article we chose the second option. Thus, it was necessary to divide the sum by a number smaller than $1/4MN$ . This choice increased the filter's sensitivity, since the background in our images was far less uniform than in the images in [6]. Once the $s$ value is properly chosen, the algorithm will give similarly good results for other images provided their background has the same texture and the lighting conditions are similar. This procedure will be proved in the next section of this paper.

In the second part of the algorithm, the distance between reference vectors, generated for each pixel of the image, is compared to the previously calculated reference pattern. The filter function is defined as

$$\begin{matrix} A_{dn}\ if\ \ d\left(h_{ref},h_i\right)\ge \bar{d} \\ 0\ if\ \ d\left(h_{ref},h_i\right)< \bar{d} \end{matrix}\ , \qquad (3)$$

where $h_{ref}$ is the reference vector created from the upper left corner of the sampled region, $h_i$ is the $i$-th region of the whole image, and $A_{dn}$ is the denoised image. When the distance is greater than the reference pattern, we leave the processed image untouched, otherwise we remove the currently sampled pixel. Eventually any objects in the image are separated from the background.

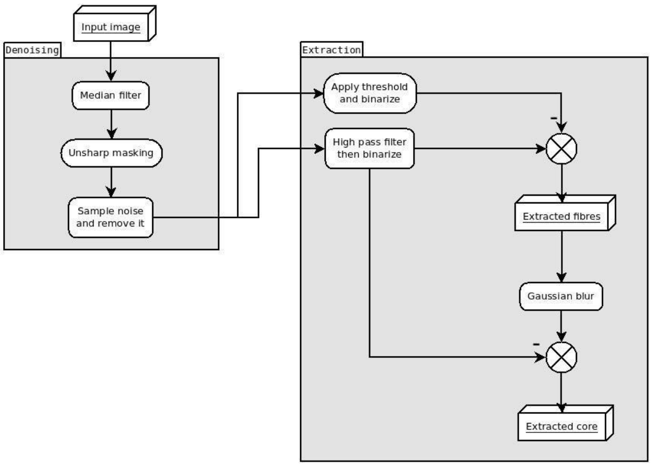

Fig. 1 Pipeline of the algorithm

The algorithm requires several parameters to be specified in order to process input images with expected quality. These parameters are: the background sample, the extraction threshold, the sensitivity, the median filter size, the unsharp-masking proportional-factor, the Gaussian filter window size, and the Gaussian and high-pass filter window-size. For the purpose of this paper, however, we analyzed all the parameters and chose to present only those which have the greatest impact on image quality. The results comparing influence of parameters for the same input image are presented in Fig. 2. In Fig. 3 only input images and final results needed for random walk experiments are depicted.

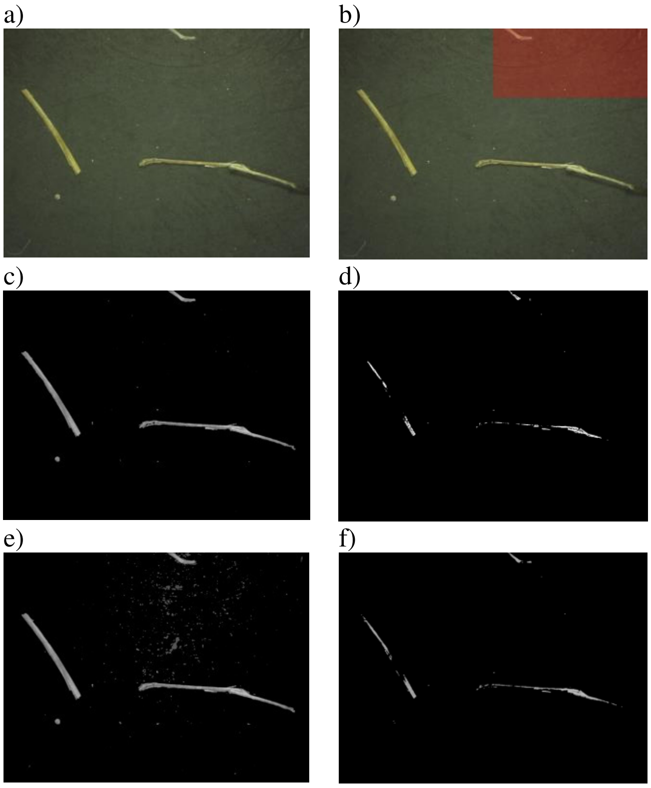

Fig. 2 A first exemplary set with optimally chosen parameters (segmentation threshold = 100, $s$ = 0.06 · width · height): input image for processing (a), background sample (b), image separated from background (c), second result set for image separated from the background with too high sensitivity, the same background sample as above (segmentation threshold = 100, s = 0.05 · width · height) (d), third set of results for the image separated from the background with too low sensitivity, the same background sample as above (segmentation threshold = 100, $s$ = 0.07 · width · height) (e), a fourth set of results for the image separated from the background with bad noise sample (segmentation threshold = 100, $s$ = 0.06 · width · height) (f).

As it is seen in the examples, the presented parameters have very high impact on the image quality. Although the parameter $s$ needs to be chosen experimentally, different input images having similar background texture and lighting conditions are being processed properly. This proves the algorithm's applicability in microscopic photography and industrial photography, where different objects are photographed in similar, but not necessarily identical conditions.

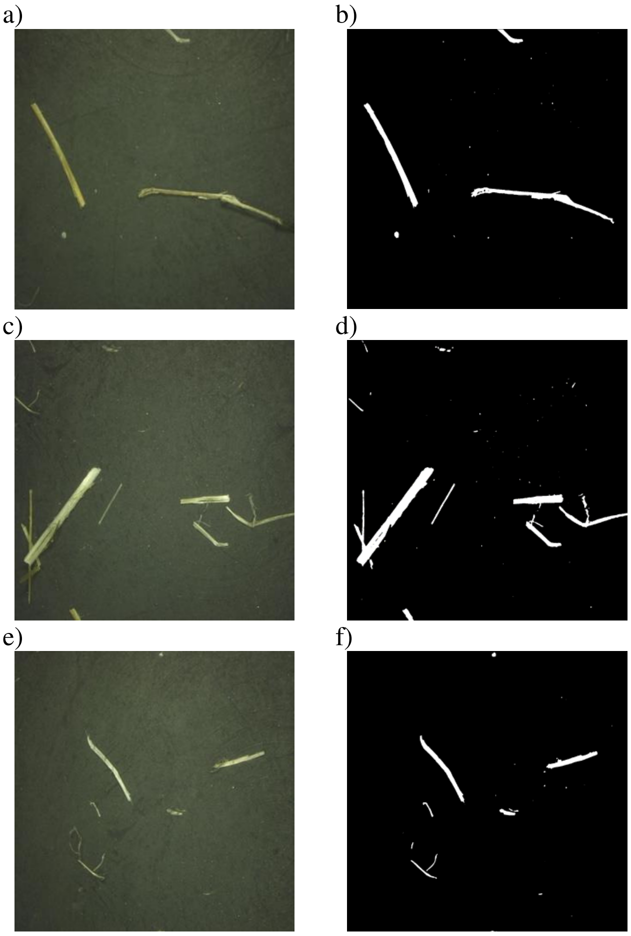

Fig. 3 Different examples of input images (a, c, e) and final results of monochrome maps needed for random walk experiments (b, d, f), respectively

## III. Random Walk Experiments

In this chapter the use of the image statistical analysis to examine the time series of the displacement of the random walker is discussed. Let us consider a uniform two-dimensional 'black' plane. A random walk can be applied and a walker is allowed to move randomly (with the same probability) up, down, to the left or to the right by a unit length in a unit time. This is the Markovian type random walk and the direction of the $n$-th step is chosen at random and does not depend on directions of previous ones. Here the mean square displacement of the probe $\left\langle R^2(n)\right\rangle$ is linearly dependent on the number of steps $n$ (time) which is proportional to the squared averaged random walk distance:

$$\left\langle R^2(n)\right\rangle \propto n. \tag{4}$$

Similarly, the pictures under investigation can be examined by means of the random walk procedure. At every iteration, a random direction is being chosen and then the algorithm proceeds one step into the chosen direction. However, the position at the $n$-th step depends on the previous positions due to the non-uniformity of the texture. Finally, the mean squared displacement is no longer the linear function of $n$ [7-9], but the following relation appears for large n:

$$\left\langle R^2(n)\right\rangle \propto n^{2H}, \tag{5}$$

where $H$ is the self-similarity coefficient called Hurst exponent [7,10]. From Hurst exponent distribution, unambiguous information about yarn hairness, and in general, information about yarn quality can be obtained. Such quantitative evaluations are on demand for textile industry. In practice, for a random walk on two-dimensional monochromatic pictures the typical result is $H < 1/2$; however, the information obtained for the exponent distribution is a unique information of a given picture (Fig. 4). Details about this type of analysis, applied for knitted fabrics, can be found in [11].

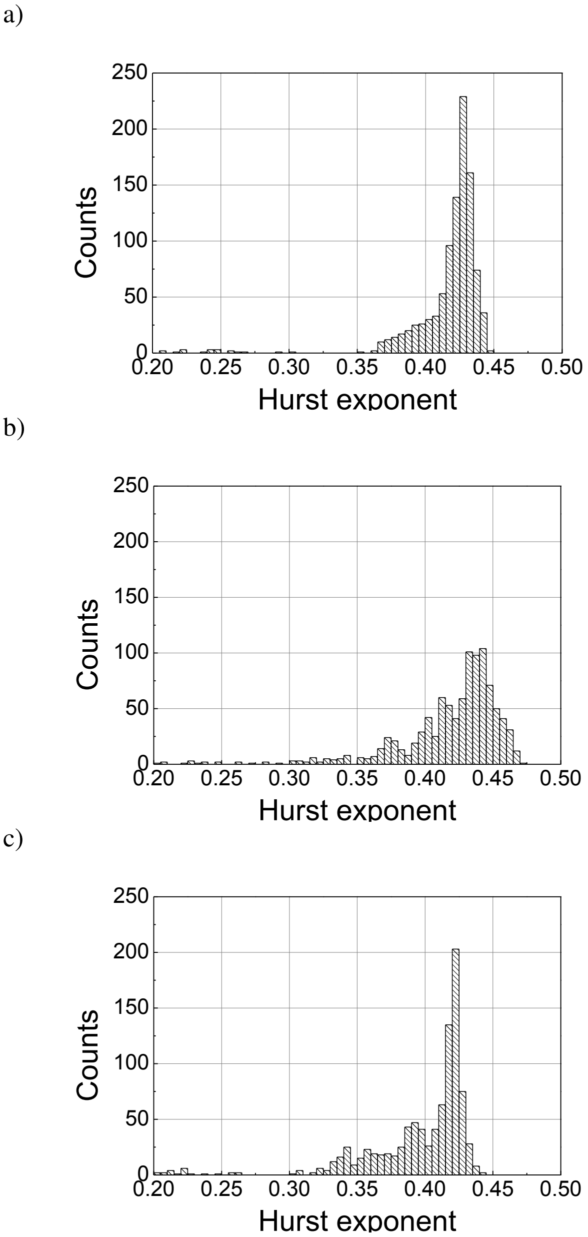

Fig. 4 Results of random walk experiments (a, b, c) carried out on the three monochromatic images from Fig. 3 (b, d, f), respectively

## IV. Conclusions

The paper gives an overview of the necessary steps used to create reliable monochromatic images from microscopic images by separating objects under examination from the background. This algorithm was applied on microscopic pictures of hemp fibers. Comparison between random walks performed on the monochromatic pictures gives a quantitative measure of differences between the hemp fibers, dependent on the fiber diameters and bifurcations which are important parameters in fiber manufacturing processes such as spinning or composite production. Thus, the image processing algorithm presented here is a fundamental requirement in the optical evaluation of fiber quality using the self-similarity coefficient.

***Abstract*—Floating-point additions in concurrent execution environment are known to be hazardous, as the result depends on the order in which operations are performed. This problem is encountered in data parallel execution environments such as GPUs, where reproducibility involving floating-point atomic addition is challenging. This problem is due to the rounding error or cancellation that appears for each operation, combined with the lack of control over execution order. In this article we propose two solutions to address this problem: work reassignment and fixed-point accumulation. Work reassignment consists in enforcing an execution order that leads to weak reproducibility. Fixed-point accumulation consists in avoiding rounding errors altogether thanks to a long accumulator and enables strong reproducibility.**

## I. Introduction

Efficient exploitation of modern multicore architectures relies on a hierarchical structuration of computation as well as execution concurrency. This affects determinism and numerical reproducibility making software development tedious. For example, GPUs manage several thousands of concurrent threads thanks to hardware resources such as warp and block schedulers. The design complexity of those processors is such that thread scheduling is mostly unknown and can be considered unpredictable. A common workaround is to enforce interaction between tasks using memory consistency with synchronization mechanisms such as locks, atomics or barriers.

Atomic operations are designed to perform a read-modify and write operation in one instruction. For example, atomicAdd() reads a word at a given address, adds a number to it, and writes the result back to the same address. The operation is atomic in the sense that it is guaranteed to be performed without interference from other threads. In other words, no other thread can access this address until the operation is complete. Although atomic operations can address the problem of memory consistency, they do not solve the problem of numerical reproducibility when dealing with floating-point numbers. This is a major issue as non-determinism of floating-point calculations in parallel programs causes validation and debugging issues, and may even lead to deadlocks [1].

The numerical non-reproducibility of floating-point atomic additions is due to the combination of two phenomena: rounding-error and the order in which operations are executed. This problem can be depicted with the simplified following CUDA kernel which computes the sum of $N$ floating-point numbers stored in table *i_val* according to their address *i_adr* in a table *res* located in global memory.

```
__global__ void GlobalSum(float *i_val,
             int *i_adr, float *res, int N){
  int gid =  blockDim.x*blockIdx.x+threadIdx.x;

  for(uint i=0; i<N; i+=GridDim.x*blockDim.x)
     atomicAdd(&res[i_adr[i+gid]],
             i_val[i+gid]);
}
```

Listing 1.  Floating-point atomic accumulation

The problem with this simple code, is that we do not have any information on the order in which threads will acquire access to the datum *Res*. For example, on a set of $N = 2^{16}$ values with a condition number[1] of $10^8$ and a single output address, we measured that out of over 1000 runs with 1 block of 1024 threads on a GTX680 we obtain 1000 different results.

One can argue that in the case where there is a single accumulator, weak reproducibility could be achieved by replacing atomicadd with standard addition combined with a reduction algorithm. However this solution does not hold when some threads are not producing any value (not executing the atomic addition), or when there are multiple accumulator, as in the bin counting or histogram problem as encountered in Nbody [3],

[1] The condition number characterizes the numerical stability of a problem [2].

978-83-60810-66-8/$25.00©2015, IEEE

Real-time simulation [4], accurate reduction scheme [5], or SQL query [6]. In these applications, floating-point atomic addition is used to accumulate values while preserving memory consistency.

In this article, we will use two concepts regarding numerical reproducibility in the context of data parallelism. *Weak numerical reproducibility* consists in being able to reproduce the same result between two executions when input parameters are identical. *Strong numerical reproducibility* consists in being able to reproduce the same results between two executions independently of the execution parameters or the architecture. Strong numerical reproducibility can be further subdivided in two classes of algorithms. Those which are producing correctly rounded results such as the one based on long accumulators [7], and others which provide reproducible results without any guaranty on accuracy [8].

Following these two definitions, we propose two solutions to address reproducibility involving floating-point atomics addition in the context of GPU programming by attacking the problem at its two roots. The first solution, work reassignment, consists in enforcing an evaluation order by overloading the block index assignment. With this solution, results are identical among runs for identical execution parameters. It is considered weakly reproducible as the number of threads per block affects the evaluation scheme and therefore the result. The second solution, fixed-point accumulation, avoids the rounding errors that occur during floating-point addition by using a long accumulator. As the addition is now exact, thus associative, the result is independent on the evaluation order or the hardware. In addition, the result is as accurate as possible as the accumulation is performed exactly. This solution is considered strongly reproducible.

The rest of this article is organized as follow. Section II introduces the necessary background about floating-point arithmetic and model of execution of GPUs. Section III presents the first solution we propose, based on block reordering. Section IV presents the second solution based on long accumulators. Section V analyses the theoretical cost of both methods and Section VI presents performance measurements on Nvidia GPUs.

## II. Background

### A. Floating-point arithmetic

Floating-point (FP) numbers approximate real numbers with a significand, an exponent, and a sign. The IEEE-754 standard, which was revised in 2008, specifies floating-point formats and operations. In this paper, we consider the `binary32` or single precision format. The floating-point number system can represent a wide range of numbers with nearly-constant precision.

Floating-point addition is not associative, due to the rounding error that occur when adding numbers with different exponents. It leads to the absorption of the lower bits of the sum. For example the exact mathematical result of $(1 + 2^{100} - 2^{100})$ is equal to 1 whereas the computed result is either 0 or 1 depending on the order of operations. Thus, the final accuracy of a floating-point summation depends on the order of evaluation. More details can be found in the main references related to floating-point arithmetic [9], [10]. This problem of numerical reproducibility linked to the order of floating-point operations, is amplified when executed in massively parallel environments like GPUs.

### B. GPU execution model

In this article we consider CUDA capable Nvidia GPUs used for the execution of tasks exhibiting data parallelism. These tasks are divided in threads operating in SIMT mode and executed by specific hardware. We must distinguish the software and hardware organization of threads. From the developer point of view, threads are divided into three hierarchical levels: a *grid* of *blocks* of *threads*. The same code, or kernel, is executed by multiple threads running in parallel on different data. *Threads* are grouped in set of *block_size* elements in order to make so-called *blocks*. Blocks are packed in set of *grid_size* elements in order to make a so-called *grid*. Threads in a block and blocks of a grid are uniquely identified by their coordinates in the blocks and the grid. In this model, threads in a block and the blocks of a grid are virtually launched in parallel, which implies that no assumption shall be made regarding the execution order.

In CUDA terminology, GPU hardware consists of CUDA cores organized hierarchically. These CUDA cores are grouped in streaming multiprocessors (SMs). The number of SMs varies depending on the architecture of the GPU and the CUDA compute capability. An additional and transparent level of grouping is introduced at the hardware level: the warp. These warps, corresponding to 32 threads, are created, managed, launched and executed by SIMT units. Multiprocessors share the instruction fetch, decoding and control logic across all the threads in a warp, so they run in lock-step [11].

Blocks are dispatched among the available multiprocessor by the block schedulers. This step consists in launching a new block with a unique identifier according to available resources. The number of concurrent blocks depends on the number and version of SMs and the resources such as registers and shared memory required by the executed kernel. This step impacts determinism as no assumption can be made on how indexes are generated and is subject to variations from one run to another [12].

Traditional thread synchronization primitives used in concurrent programming such as mutexes, barriers, and semaphores are limited on GPU to intra-block synchronizations. Atomic operations provide basic support for inter-block communication. Atomic instructions were first introduced on Nvidia hardware with compute capability 1.1, and atomic addition operating on 32-bit floating-point values in global and shared memory were introduced with compute capability 2.0. Atomic floating-point operations are necessary, first to provide the substrate for high performance floating-point operations, and second, to preserve the memory consistency necessary to deal with thousands of threads in flight.

The variety and performance of synchronization primitives available on GPUs have continuously increased over the years. This has lead to numerous works that have been focusing on efficient inter-block synchronization. For example, in [13] Volkov et al. propose a global software synchronization method that does not use atomic operations to accelerate dense linear-algebra constructs. In [14], [15], Xiao and Feng propose a mechanism for inter-block communication via global memory. In [16], Stuart and Owens are evaluating various implementations of barriers, mutexes and semaphores applied to Nvidia's GPU. Collange et al. use long accumulators to enable reproducible floating-point reductions [7]. However, none of those works have addressed the problem of reproducible atomic floating-point addition.

## III. Enforcing execution order

As discussed in the introduction, atomic operations enforce memory consistency, but not execution order. This means that atomic additions ensure that all data will be considered, but do not guarantee the order of operations. This is problematic for floating-point addition. The first solution we propose is to enforce an execution order for atomic addition, similarly to what can be achieved using a reduction algorithm. Threads and blocks are spawned and scheduled by hardware, following unspecified and implementation-specific policies. Thus, no assumption can be made on their real execution order. Therefore, we cannot rely on CUDA thread and block identifiers used at software level. Such solution would leads to an inefficient execution scheme and most likely to a deadlock situation [15].

The proposed solution uses two key concepts. The first one is based on a new software assignment of the block index, in order to guarantee a fine control over blocks effectively executed by the hardware. The second concept is based on atomic locks in order to ensure uniqueness of accesses at block level. We extend the solution proposed in [17] in order to control the order of execution. The lock used is similar to a fetch-and-add mutex algorithm in which the block index corresponds to the token acquired by a block.

### *A. Block re-ordering*

Block synchronization is challenging, as the CUDA programming model does not support it. The only safe solution consists on splitting kernels into subkernels, as a kernel launches involves an implicit synchronization barrier. Alternatively, resident kernel techniques take advantage of the fact that once launched, a block continue its execution until completion, freeing resources only at the end. For example, the block barrier proposed by Feng in [14] is working only when the number of launched blocks is less than the number of blocks that could be executed concurrently on the hardware. In case this assumption is not met, deadlocks may occur. For example, consider a GPU and a kernel such that only 8 blocks can run concurrently. If the kernel is launched on more than 9 blocks, then at least 1 block will not be scheduled. In that case running blocks will be waiting on the barrier for every block to complete, which will never happen as resources taken by those running block will never be released for others to complete.

In our case, we want to ensure that blocks are executed in a reproducible manner. This requires defining an execution order, which corresponds to a statically known order. This order can be, for example, the one corresponding to their block index. Besides requiring a known order, we need to prevent deadlock situation, which involves restrictions on the real scheduling of blocks.

The proposed solution consists in overriding the index generated by the block scheduler. This can be done by using a global variable *oBlkId* set to 0 at kernel launched which will be queried by one thread of each block at the beginning of the execution. The resulting index is stored in a shared variable *sBlkIdx* accessible by every thread of the block they belong to, and can be used as the new block index. An overview of the code is given in listing 2.

```
// Shared BlockIdx within a block
__shared__ uint sBlkIdx;

// Reindexing Block
struct BlkIdx{
  // New ordered index for BlockIdx
  uint *oBlkId;

  BlkIdx(void){
    cudaMalloc((void**) &oBlkId, sizeof(uint));
    cudaMemset(oBlkId, 0, sizeof(uint));
  }

  ˜BlkIdx(void){
    cudaFree( ordBlockId );
  }
  __device__ uint get_ordered_blockId(){
    if (threadIdx.x == 0)
      sBlkIdx = atomicInc(oBlkId, gridDim.x-1);

    __syncthreads();
    return sBlockIdx;
  }
};
```

Listing 2. Block reindexing

Thanks to this new block index, we can ensure a known execution order for block, which will be deadlock-free. With this technique, we chain together running blocks following a well-defined order. Therefore the overhead is solely concentrated in the access to the global index *sBlockIdx*. We now have to set a floating-point atomic addition which is reproducible within each block, which we will describe next.

### B. Atomic completion

Threads of blocks are scheduled as set of 32 consecutive threads, or warps. Again, as we do not have any control over the execution order of threads, we need to make sure that threads of a given block are always scheduled in a similar fashion when they are atomically accessing the destination address.

A solution is to encapsulate the atomic addition within a fetch-and-add mutex (FA) algorithm similarly to the one described in listing 3. With this solution, each thread of a given block is waiting for its turn on a variable shared at block level. These results ultimately to a serialization of each atomic addition at both thread-level and block-level as there are launched in an order corresponding to their global identifier. This solution is simple and provides strong numerical reproducibility. However accesses cannot happen concurrently and will perform poorly. We should mention that a syncthreads barrier is required at the end of the outer loop to ensure that no warp will go faster than any other warp with lower thread identifier.

```
struct Lock{
  uint *g_lock;

  Lock(void){
    cudaMalloc( (void**) &g_lock, sizeof(uint));
    cudaMemset( g_lock, 0, sizeof(uint));
  }

  ~Lock(void){
    cudaFree( g_lock );
  }

  __device__ void acquire_lock(int goalval){
    if (threadIdx.x == 0)
      while(atomicAdd(g_lock, 0) != goalval);
    __syncthreads();
  }

  __device__ void release_lock(){
    __syncthreads();
    if (threadIdx.x == 0){
      (*g_lock) = ((*g_lock)+1)%(gridDim.x);
    }
  }
};
```

Listing 3. Fetch-and-Add mutex

To improve performance of the previous solution, we can relax the constraint on the execution order in order to allow the atomic additions within a block to be replaced by simple additions executed in parallel. This results in a reduction scheme that only depends on the block size and is therefore considered as weakly reproducible. This solution requires 6 steps as described in listings 4. First, floating-point atomic data and addresses are stored in parallel in two tables located in shared memory. Then, both tables are sorted using the corresponding destination address as sorting key. In our implementation we used a bitonic sort as it preserve the order in case of equality. Once data are sorted according to their address, we perform a segmented sum for data with identical address. Then additions to the destination adresses are done in parallel for each different addresses within a block. We should mention that the number of additions is bounded by the number of threads per block. Those additions do not require atomic operations as atomic access is guaranteed with a FA lock on the new block identifier.

```
__device__ void ordered_concurrent_ AtomicAdd(
        float *dest, float val, Lock &lock){
  int tidx = threadIdx.x;
  // 1: Store in shared mem
  s_adr[tidx] = dest;
  s_val[tidx] = val;
  __syncthreads();

  // 2: Sort Element
  bitonicSort( s_adr, s_val);

  // 3: Segmented Sum
  segmented_sum_per_block(s_adr, s_val);

  // 4: Aquire the lock in order
  lock.acquire_lock(sBlockIdx);

  // 5: Final write in
  if (threadIdx.x < blockDim.x-1){
    if (s_adr[tidx] != s_adr[tidx+1]){
      *(s_adr[tidx]) += s_val[tidx];
    }
  }else{
      // For the last thread !
      *(s_adr[tidx]) += s_val[tidx];
  }
  // 6: Release the lock
  lock.release_lock();
}
```

Listing 4. Second solution: Serialization of atomic access at block level

## IV. Making addition associative

To achieve numerical reproducibility of atomic addition, we have seen in section III a solution based on enforcing an execution order. This section describes an alternative solution that consists in avoiding rounding errors to compute the correctly-rounded result.

To enforce strong reproducibility, we replace floating-point additions by fixed-point additions, which are associative. To avoid losing any precision compared to the floating-point format, we use a fixed-point accumulator that covers the whole range of values representable in the considered floating-point format. For instance, an accumulator with 127 integral bits and 127 fractional bits covers the range of single-precision floating-point. Such counter is known as a long accumulator or superaccumulator [18].

While the use of such a wide accumulator may seem extremely costly at first sight, three considerations make its performance actually attractive in the context of atomic operations:

- First, the average complexity of adding one floating-point value to a superaccumulator does not depend on the width of the superaccumulator [7]. Assuming the accumulator is represented as a vector of machine words (32-bit in the single-precision case), an accumulation generally only affects two words in the vector. Although carries may need to be propagated, the probability that a carry propagates across multiple words quickly gets negligible assuming low-order digits follow a uniform distribution [19].
- Second, updates to individual words of the superaccumulator can happen in any order without bearing any impact on the result, as long as all carries are detected and eventually propagated (including carries that occur during carry propagation). This enable regular integer atomic operations to update each part of the accumulator independently, without the need to implement any locking or coarser-grain transactions. Carries are detected *a posteriori* from the older value returned by the atomic operation and the value that was accumulated. Carries that occur are iteratively propagated to the higher-order words of the superaccumulator. Atomic operations from other threads may modify the superaccumulator during carry propagation; however, it bears no impact on the final result as all carry are eventually propagated in an arbitrary order.
- Third, this solution only requires hardware support for atomic integer addition, and does not need support for atomic floating-point addition. Therefore, the long accumulator allows to design reproducible atomic addition for any floating-point representation format (e.i. half, single or double precision of the IEEE-754 standard). By contrast, current GPUs only support floating-point atomic operations on single-precision data. The only difference lies in the size of the long accumulator.

We propose a thread-safe generalization of the long accumulation algorithm [20]. This accumulation algorithm is illustrated on Figure 1. The exponent and mantissa are extracted from the input number. High-order bits $e_h$ of the exponent are used to select the words that are affected in the superaccumulator. Lower-order bits $e_l$ select a cutoff point to split the mantissa into (at most) two parts, $m_h$ and $m_l$, whose weights are aligned with the words of the superaccumulators. This has the effect of shifting the mantissa to align it with the superaccumulator words. Words $m_h$ and $m_l$ are independently accumulated atomically to their respective accumulator words. Carries are detected and propagated using independent atomic operations.

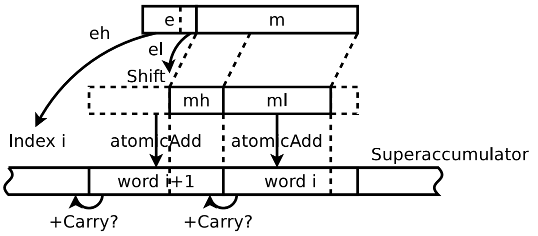

Fig. 1. Accumulation of a floating-point number to a superaccumulator.

## V. Cost

In this section we details the memory and operation cost of the two proposed solutions.

### A. Work reassignment

The solution based on enforcing an execution order requires one integer for the global index, one for the lock and one integer in shared memory for each block to store the shared index. In addition to these elements it requires a table of $N$ integers and $N$ floating-point numbers in shared memory per block to store temporary values, with $N$ corresponding to the number of threads per block.

In terms of computational overhead, this solution first requires to get a new block index at the beginning of the kernel. This involves one atomic instruction. Then, the kernel is left unmodified except when floating-point atomic additions need to be performed. In that case, each atomic addition is replaced by a write of both the address and the value to shared memory, plus a bitonic sort and a segmented sum per block over $N$ elements achieved in $O(log(N))$.

Then, threads of each block are waiting for their turn by spinning over the lock index. Once this condition is met, threads with the last address to be written send their write to global memory along the normal store path. As mentioned before these writes do not require atomic addition and can be done in parallel with an increased probability that global memory accesses are coalesced as data are sorted according to their destination addresses. For these reasons, this solution will perform well when many threads of the same block attempt to atomically add a value to the same location.

### B. Fixed-point accumulation

The fixed-point accumulator solution adds overhead in storage, computation, memory transfers and adds an extra rounding step. The most obvious cost of a long accumulator is its memory overhead. An accumulator able to represent exactly every single-precision floating-point value requires 280 bits of storage, as opposed to 32 bits using a floating-point accumulator. Likewise, a double-precision long accumulator needs about 2100 bits. Fortunately, long accumulators often contain sparse data: when accumulating numbers of the same order of magnitude, only a small part of the accumulator will be accessed, while the remaining part stays null. The hot parts can fit inside caches and benefit from fast cached atomic operations, while the cold part will remain in the large, off-chip memory.

Adding a floating-point value to a long accumulator also requires extra computations. The algorithm described in section IV extracts the exponent and mantissa of the floating-point number, then splits the mantissa by scaling and rounding it twice. However, binning algorithms are memory intensive and their performance is usually not limited by computations. This means the computational of long accumulation may be hidden by the memory access delays.

In terms of memory accesses, fixed-point accumulation requires two atomic operations per number in the common case, while a floating-point accumulation will only need one atomic add on platforms that support it in hardware. On the other hand, conflicts are reduced as atomic accesses span a larger memory area.

Finally, the fixed-point result has to be rounded to floating-point at the end of the accumulation. Rounding involves finding the first significant bit, then scanning the rest of the accumulator to compute the round, guard and sticky bits, that are necessary for IEEE-754 compliant rounding. The rounding phase can be performed in parallel between accumulators as they have no dependencies.

## VI. RESULTS

We tested both methods on a GTX480, a GTX560 and a GTX680 architectures with characteristics described in Table I. We made comparisons for a number of output addresses ranging from 1 (which corresponds to an accumulation) to 16384 different addresses randomly generated. Each thread was responsible for the accumulation of one floating-point value at a given address in global memory. Each kernel was launched with 100 blocks of 512 threads.

We compared the proposed methods against the *unordered solution* which consists in atomically adding the generated data at a given address as described in listing 1. For comparison purposes, we also included the fully sequential solution (block and warp sequential). Both block and warp sequential and block sequential methods relies on enforcing an execution order whereas superaccumulators avoid rounding errors altogether.

Figure 2(a), 2(b) and 2(c) describes the execution time on the GTX480, GTX560 and GTX680 respectively. One can observe that the execution time of the unordered solution quickly decreases as the number of output addresses increases. This is due to reduced contention : as the atomic accesses are spread across a wider range of accesses, the probability of conflicts decreases and the global performance improves. On the other hand, both sequential methods exhibit an execution time that is almost insensitive to the number of output addresses. The solution based on the long accumulator has an execution cost that decreases on the GTX480 and GTX560 and quickly increases after 64 to 128 different addresses. The decrease is due to concurrent accesses that can happen simultaneously as the number of different accumulators increases. However after a certain bound, the overhead of the accumulator do not compensate the gain obtained by the increase in concurrent accesses.

On the GTX 680, the unordered algorithm is always best according to figure 2(c), which is consistent with the fact that atomic operations were improved on this architecture compared to previous generations. Atomic performance is less sensitive to conflicts. The long accumulator also benefits from the improving atomic performance.

On GTX480 and GTX560, one can notice that the block sequential solution can even be faster than the unordered solution for small numbers of output addresses. This is because the small number of atomic access compensates the overhead of the segmented summation and sorting. By contrast, for the unordered solution almost every atomic access generated by each thread is conflicting on the output address, leaving no room for concurrent execution.

Out of these results, we can observe that enforcing strong numerical reproducibility is between 1.3 and 21 times more expensive than the unordered summation, whereas weak numerical reproducibility corresponds to 0.4 to 10 times the execution time of the unordered summation.

We should mention that the solution based on enforcing execution order uses block-wide synchronization barriers. This implies that atomics using the weakly reproducible solution need to be invoked from uniform control-flow regions. Every thread has to execute the instruction FPatomicAdd, otherwise the behavior is unspecified.

## VII. Conclusion

Atomic operations are very helpful in data parallel programming to enforce memory consistency. However when dealing with floating point values, this concurrency can lead to high variability, even when input data and execution parameters are identical. This behavior, due to rounding errors combined with the lack of control over execution order, is problematic as it causes validation and debugging issues, as well as producing hard-to-diagnose bugs in distributed environments.

In this article we propose two solutions to tackle this problem, each one addressing one source of the problem. We have described a first solution that enforces an execution order at block level thanks to new block synchronization primitive. We have shown that this solution is competitive in terms of performance (0.4-10 times) with the traditional hardware-based solution which is not reproducible. However, numerical reproducibility is ensured only for similar execution parameters as this solution depends on the number of threads per block and is therefore considered weakly reproducible.

We have proposed another solution based on a very long accumulator, which eliminates every rounding error and makes floating-point addition associative. This solution avoids the need to enforce an execution order and provides strong numerical reproducibility. It provides a correctly-rounded result with optimal accuracy. We have shown that this solution is between 1.3 and 21 times more expensive than the unordered solution. On the other hand, this solution does not require hardware support for floating-point atomic addition and can be applied to any floating-point representation format.

# 2nd International Workshop on Cyber-Physical Systems

PROLIFERATION of computers in everyday life requires cautious investigation of approaches related to the specification, design, implementation, testing, and use of modern computer systems interfacing with real world and controlling their environment. Cyber-Physical Systems (CPS) are physical and engineering systems closely integrated with their typically networked environment. Modern airplanes, automobiles, or medical devices are practically networks of computers. Sensors, robots, and intelligent devices are abundant. Human life depends on them. Cyber-physical systems transform how people interact with the physical world just like the Internet transformed how people interact with one another.

The event is a continuation and extension of 2006-2010 Real-Time Software FedCSIS workshops and 2013 IWCPS. The objective of the workshop is to assemble and develop a community with main interest in cyber-physical systems.

## Topics

Due to an extensive scope of the topics, the workshop will accept papers in the following areas:

- Control Systems
  - embedded/networked/intelligent
  - wireless sensing/actuation
  - adaptive/predictive
- Scalability/Complexity
  - modularity
  - design methodology
  - legacy systems
  - tools
- Interoperability
  - concurrency
  - models of computation
  - networking
  - heterogeneity
- Validation and Verification
  - assurance
  - certification
  - simulation
- Cyber-security
  - intrusion detection
  - resilience
  - privacy
  - attack vectors
- Applications of CPS
  - robotics
  - transportation
  - military
  - medical
  - consumer
  - manufacturing
  - power systems
- CPS Education
  - curriculum development
  - web-based laboratories
  - academic courses
  - pedagogy issues

## Event Chairs

**Grega, Wojciech,** AGH University of Science and Technology, Poland

**Kornecki, Andrew J.,** Embry Riddle Aeronautical University, United States

**Nigro, Libero,** Università della Calabria, Italy

**Szmuc, Tomasz,** AGH University of Science and Technology, Poland

**Zalewski, Janusz,** Florida Gulf Coast University, United States

## Program Committee

**Angiulli, Fabrizio,** University of Calabria

**Babiceanu, Radu,** ERAU

**Cicirelli, Franco,** Università della Calabria, Italy

**Crespo, Alfons,** Universitat Politecnica de Valencia, Spain

**Golatowski, Frank,** University of Rostock, Germany

**Gomes, Luis,** Universidade Nova de Lisboa, Portugal

**Halang, Wolfgang A.,** Fernuniversitaet, Germany

*Abstract*—**Cyberphysical systems, with their interdependence between physical behaviour and digital control, need insights from frequency domain control engineering, state space control engineering and discrete formal systems theory for their proper description. Neglecting any of these, results in descriptions that omit essential details. Hybrid Event-B is a formalism that enables all the relevant detail to be assimilated. A case study based on yaw control for the KURT e-vehicle is used as a testbed to explore the effective interaction between the various needed disciplines in exploring a specific design issue, the formalisation of yaw control discretization, using Hybrid Event-B.**

## I. Introduction

TODAY, the low cost, small size, low energy consumption and wide availability of digital processors, together with the ready availability of a wide variety of stadardised control components, makes the embedding of computing components and digital control into what was previously purely analogue equipment, ubiquitous. This has now given rise to the burgeoning field of cyberphysical systems, in which computing systems are intimately connected to equipment that acts in the physical space. Increasingly, the impact of such systems is safety critical, and in such cases, the techniques by which the systems are developed demand scrutiny — at least in those spheres where it is recognised that safety and dependability (more precisely, their potential lack) merit certification processes that have to be successfully passed before systems can be deployed in the field. In reality, what is required to be certified often lags well behind what is attempted and shown to be feasible technically.

An essential element of many such certification processes is a verifiable audit trail of mathematical models of the system and of their relevant properties. Ideally, all models and properties should be verifiably consistent with one another, and demonstrably possess the properties needed for safe operation. In the case of cyberphysical systems this ideal is challenging, for the following reasons.

Traditionally, control design is done in the frequency domain [1], [2], [3]. This readily yields the quantities needed by the engineer, using a mixture of rigorous results and design heuristics. Although the rigorous results often do not hold with mathematical precision in reality (e.g. needed bandwidth assumptions), the degree of inexactitude is not harmful in practice. A major element of this approach is the use of simulation to judge the suitability of a design, using tools like Modelica [4].

Traditionally, computing systems, which proceed by discrete steps, are modelled and analysed within a discrete state space — there is no notion of frequency domain for an arbitrarily constructed discrete space. Since there is an enormous variety in the aspects of behaviour that can be modelled by the discrete steps of a computing system, correspondingly, depending on what the elements of the state space represent, we find an enormous variety of approaches to the formalisation of computing systems [5].

Following on from this observation, traditionally, formalisms for computing systems (e.g. the many surveyed in [5]) do not engage with continuous mathematics at all. To address this shortcoming in the context of cyberphysical systems, two different approaches are seen. In the first, the formalism does not engage with continuous mathematics, stays essentially discrete, and incorporates facts concerning continuous aspects of the modelled system as inputs or axioms. In the second, special purpose formalisms are designed to include continuous phenomena in suitable ways alongside the discrete ones.

More recently, a more rigorous approach to control has emerged within 'mathematical control theory' [6], [7], [8], that emphasises the state based approach to control. This perspective is able to relate more directly to the state based perspective of computing formalisms in a way that the frequency domain perspective (although equivalent to it via transform theory) would struggle to do. Moreover, the rigour of the proofs in mathematical control theory typically matches much better with the style of argument in computing formalisms, both being ultimately grounded in set theory. Then again, much of the useful engineering information that is evident and easily manipulated in the frequency domain, and is inferred smoothly from simulation, can become greatly obscured in the state based approach. Thus there is a conflict between the usual approaches to the various disciplines that contribute to the cyberphysical systems agenda.

In this paper we examine a case study that hosts an encounter (we hesitate to say collision) between the various approaches and issues mentioned. Although it is a simplified case study, it is not a toy, in that it is drawn directly from a genuine system, the KURT e-vehicle from Altreonic. We specifically look at yaw control and its stability in KURT. We embed the abridged development in the Hybrid Event-B (HEB) formalism [9], [10], and focus on the formal description and properties of the discretization step from a high level continuous design to a lower level time triggered discrete one.

978-83-60810-66-8/$25.00©2015, IEEE

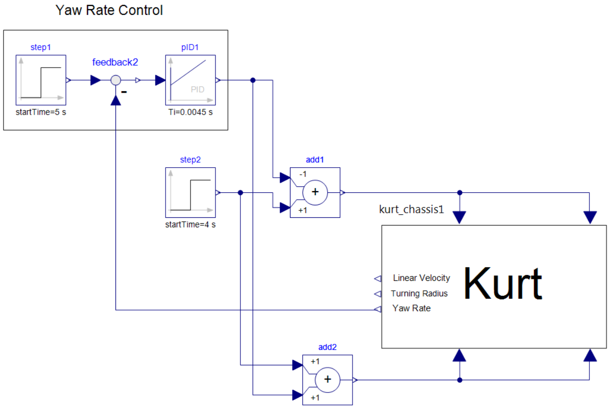

Fig. 1. KURT simulation: Modelica yaw rate control configuration.

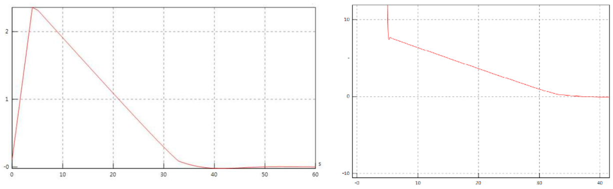

Fig. 2. KURT simulation: left, vehicle linear velocity (m/s) vs. simulation Time (s); right, vehicle turning radius (m) vs. simulation time (s).

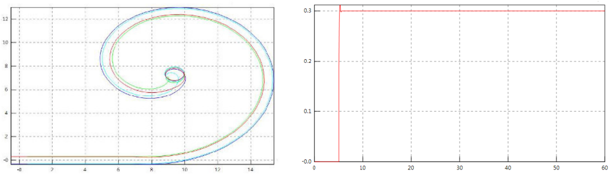

Fig. 3. KURT simulation: left, vehicle trajectory in Y vs. X axis (m); right, vehicle yaw rate response (rad/s) vs. simulation time (s).

From a rigorous point of view, discretization steps introduce copious amounts of low level detailed technical complexity. In order to keep the account within reasonable bounds, we do take some shortcuts in the development, commenting on the pros and cons as we go.

The rest of this paper is as follows. In Section II we overview KURT, and describe a Modelica simulation that was used to validate a number of design parameters for yaw control. In Section III we overview the HEB formalism, stressing the aspects that are most important for us. Section IV reformulates yaw control in HEB, and Section V examines the stability of the model in a state space based way. Section VI discusses the issues raised by going from a continuous to a discretized formulation in a formal manner. Section VII concludes.

## II. Yaw Control in the KURT E-Vehicle

The KURT e-Vehicle is an innovative vehicle concept based on a modular, scalable and fault tolerant architecture. The propulsion system of KURT utilises four independently controlled in-wheel motors and employs a differential steering technique combined with a drive-by-wire architecture. In its simplest form such a steering technique entails steering the vehicle by creating a difference in linear velocity between the left and right side of the vehicle. Such approaches are often utilised in unmanned robotic platforms as well as heavy earth moving machinery. In the absence of a mechanical steering mechanism, such as articulated steering, these vehicles are often referred to as skid-steer vehicles. The advantages of utilising a 4-wheel drive differential steered concept includes minimising the mechanical complexity of the steering mechanism as well as increased manoeuvrability. However, reducing mechanical complexity demands a more intelligent propulsion control system which in turn will be deployed on an embedded target platform. The employed steering control strategy will therefore do well by minimising implementation complexity specifically with regards to aspects such as required processing power and number of sensors. To this end a control strategy has been devised for the KURT e-Vehicle whereby the effective yaw rate of the vehicle is utilised as the control parameter.

According to the kinematic relations [11] of a differential steered vehicle, yaw rate is related to linear velocity and instantaneous turning radius, and can be relatively easily measured with inexpensive MEMS based sensors. The added benefit of yaw rate control is related to safety, more specifically, with regards to maintaining stability of the combined vehicle and driver centre of gravity (COG) when executing turning manoeuvres. In a drive-by-wire, and specifically a steer-by-wire system, there is not necessarily provision for a feedback mechanism which serves to cause the driver to limit the turning radius when executing a turn in accordance with the linear velocity of the vehicle. Simply put, if a turn is taken too sharply at too high speed the vehicle can topple over. Therefore, by controlling the yaw rate of the vehicle when executing a turn, the effective turning radius can be controlled. This in turn permits preventing the centrifugal force component from getting large enough to cause the vehicle to overturn.

A basic propulsion and steering control strategy is as follows: the throttle command issued by the user is interpreted as a thrust request which is translated into a torque command and is applied equally to all four wheels; a steering command issued by the user is translated into a yaw rate request which serves as the set point to a closed loop PID controller. The output of the PID controller is added to the torque command of the wheels on one side and subtracted on the opposite side. The side to which it is added or subtracted depends on whether the steering request is to the left or to the right. When steering to the left the output of the PID controller will be subtracted from the torque command of the wheels on the left and added to the torque commands of the wheels on the right. When steering to the right the situation will be reversed.

In order to simulate the proposed control strategy, a dynamic model of a skid-steer vehicle was created in Modelica [4]. For the purposes of this investigation, the model does not include complex tyre and surface interactions, but rather models the wheels as point masses, on which the propulsion, rolling resistance and friction forces act.[1] The vehicle is represented with a simple H-shaped geometry with a single point mass located equidistant from the rear and front wheel

[1] Tyre and surface interactions result in friction forces (and are even necessary to control the vehicle properly).

representing the combined vehicle and payload mass. It is also the yaw rate of this mass that is measured and utilised in the steering control loop. The PID steering controller was designed by applying the Cohen-Coon tuning method [12], [13], [14]. A typical yaw control simulation setup is depicted in Fig. 1.

The kurt_chassis1 component from Fig. 1 resembles the dynamic model of the skid-steer vehicle. The model receives four inputs namely the thrust applied to the left rear and front wheel masses as well the thrust applied to the right rear and front wheel masses. The model provides three outputs of which the yaw rate is of primary concern. The step input source element step2 simulates a thrust request issued by the user. The steering PID controller is implemented by pID1 of which the output is subtracted from the output of step2 by add1 and added to the output of step2 by add2. The output of add1 is applied equally to the left wheel masses whereas the output of add2 is applied equally to the right wheel masses. The purpose of step1 is to simulate a steering request issued by the user in the form of a yaw rate request. The output of step1 serves as the set point to the closed loop controller with the yaw rate output of the kurt_chassis1 being the measured variable. The simulation setup therefore represents a steering request to turn left. The simulation sequence commences by issuing a constant thrust request ($thr = 15\,\mathrm{N}$) for a duration of 4 seconds during which no steering request is present ($yrr = 0\,\mathrm{rad/s}$). At $t = 4$ seconds the thrust command is removed ($thr = 0\,\mathrm{N}$) and at $t = 5$ seconds a constant steering request is issued ($yrr = 0.3\,\mathrm{rad/s}$). The simulation continues to run until $t = 40$ seconds.

The vehicle is therefore expected to accelerate from $t = 0$ to $t = 4$ seconds after which it will decelerate. From $t = 5$ seconds onwards the vehicle is expected to turn to the left. According to the kinematic relations the turning radius of the vehicle is expected to decrease proportionally to the linear velocity provided that the yaw rate is held constant. Figs. 2 and 3 depict the results obtained from the simulation run. The RHS of Fig. 3 shows the step response of the measured yaw rate. From the results it is seen that the controller is sufficiently capable of maintaining a constant yaw rate with acceptable overshoot (4%) and settling time (0.1 seconds). From Fig. 2 it is seen that the turning radius decreases in proportion to the linear velocity in accordance with the kinematic relations. Fig. 3 also shows the trajectory of the four wheel masses. The trajectory indicates the vehicle follows a spiral path as the linear velocity and the turning radius decreases. Correlating the trajectory with the turning radius it is observed that the rear wheels progressively digress from the trajectory of the front wheels as the turning radius decreases. From $t = 32$ seconds onwards the vehicle starts to rotate around its own centre of mass resulting in near zero turning radius.

## III. An Outline of Hybrid Event-B

In this section we outline HEB, relating it to the more familiar Event-B [15]. The bulk of the material refers to a single machine. However, our models involve three machines: for the user, for KURT's behaviour, and for the control system, so we include what we need for multiple machines below.

### A. Single Hybrid Event-B Machines

In Fig. 4 we see a schematic HEB machine. It starts with declarations of time and of a clock. Time is a first class citizen in that all variables are functions of time (which is read-only), explicitly or implicitly. Clocks are assumed to increase like time, but may be set during mode events. Variables are of two kinds. There are mode variables (like $u$) which take their values in discrete sets and change their values via discontinuous assignment in mode events. There are also pliant variables (such as $x, y$), declared in the PLIANT clause, which typically take their values in topologically dense sets (normally $\mathbb{R}$) and which are allowed to change continuously, such change being specified via pliant events.

Next are the invariants. These resemble invariants in discrete Event-B, in that the types of the variables are asserted to be the sets from which the variables' values *at any given moment of time* are drawn. More complex invariants are similarly predicates that are required to hold *at all moments of time* during a run.

Then, the events. The *INITIALISATION* has a guard that synchronises time with the start of any run, while all other variables are assigned their initial values as usual.

Mode events are analogues of events in discrete Event-B. They can assign all machine variables (except time). The schematic *MoEv* of Fig. 4, has parameters $i?, l, o!$, (input, local, and an output), and a guard *grd*. It also has the after-value assignment specified by the before-after predicate *BApred*, which can specify the after-values of all variables (except time, inputs and locals).

Pliant events are new to HEB. They specify the continuous evolution of the pliant variables over an interval of time. Fig. 4 has a schematic pliant event *PliEv*. There are two guards: *iv*, for specifying enabling conditions on the pliant variables, clocks, and time; and *grd*, for specifying enabling conditions on the mode variables.

The body of a pliant event contains three parameters $i?, l, o!$, (again, input, local, and output) which are functions of time, defined over the duration of the pliant event. The behaviour of the event is defined by the COMPLY and SOLVE clauses. The SOLVE clause contains direct assignments, e.g. of $y$ and output $o!$ (to time dependent functions); and differential equations, e.g. specifying $x$ via an ODE (with $\mathcal{D}$ as the time derivative).

The COMPLY clause can be used to express any additional constraints that are required to hold during the pliant event via the before-during-and-after predicate *BDApred*. Typically, constraints on the permitted ranges of the pliant variables, can be placed here. The COMPLY clause can also be used to specify properties at an abstract level, e.g. stating safety properties for the event without going into detail.

Briefly, the semantics of a HEB machine consists of a set of *system traces*, each of which is a collection of functions of time, expressing the value of each machine variable over the duration of a system run.

Time is modeled as an interval $\mathcal{T}$ of the reals. A run starts at some initial moment of time, $t_0$ say, and lasts either for a finite time, or indefinitely. The duration of the run, $\mathcal{T}$, breaks up into a succession of left-closed right-open subintervals: $\mathcal{T} = [t_0 \ldots t_1), [t_1 \ldots t_2), [t_2 \ldots t_3), \ldots$. Mode events (with their discontinuous updates) take place at the isolated times corresponding to the common endpoints of these subintervals $t_i$,

    END
  END
```

Fig. 4. A schematic Hybrid Event-B machine.

and in between, the mode variables are constant, and the pliant events stipulate continuous change in the pliant variables.

We insist that on every subinterval $[t_i \ldots t_{i+1})$ the behaviour is governed by a well posed initial value problem $\mathcal{D}xs = \phi(xs\ldots)$ (where $xs$ is a relevant tuple of pliant variables). Within this interval, we seek the earliest time $t_{i+1}$ at which a mode event becomes enabled, and this time becomes the preemption point beyond which the solution to the ODE system is abandoned, and the next solution is sought after the completion of the mode event.

In this manner, assuming that the *INITIALISATION* event has achieved a suitable initial assignment to variables, a system run is *well formed*, and thus belongs to the semantics of the machine, provided that at runtime:

(1) Every enabled mode event is feasible, i.e. has an after-state, and on its completion enables a pliant event (but does not enable any mode event).[2]

(2) Every enabled pliant event is feasible, i.e. has a time-indexed family of after-states, and EITHER:
   (i) During the run of the pliant event a mode event becomes enabled. It preempts the pliant event, defining its end. ORELSE
   (ii) During the run of the pliant event it becomes infeasible: finite termination. ORELSE
   (iii) The pliant event continues indefinitely: nontermination.

Thus, in a well formed run mode events alternate with pliant events. The last event (if there is one) is a pliant event (whose duration may be finite or infinite). In reality, there are several semantic issues that we have glossed over in the framework just sketched. We refer to [9] for a more detailed presentation (and to [10] for the extension to multiple machines). The presentation just given is quite close to the modern formulation of hybrid systems. See e.g. [16], [17] — or [18] to get a perspective stretching further back.

If, from Fig. 4, we erase time, clocks, pliant variables and pliant events, we arrive at a skeleton (conventional) Event-B machine. This simple erasure process illustrates (in reverse) the way that HEB has been designed as a clean extension of the original Event-B framework. The only difference of note is that, now —at least according to the (conventional) way that Event-B is interpreted in the physical world— (the mode) events (left behind by the erasure) execute *lazily*, i.e. *not* at the instant they become enabled (which is, of course, the moment of execution of the previous event).

### B. Multiple Hybrid Event-B Machines

The principal objective in modelling complex systems in the B-Method is to start with small simple descriptions and to refine to richer, more detailed ones. This means that, at the highest levels of abstraction, the modelling must **abstract away from concurrency**. By contrast, at lower levels of abstraction, the events describing detailed individual behaviours of components become visible. In a purely discrete event framework, like conventional Event-B, there can be some leeway in deciding whether to hold all these low level events in a single machine or in multiple machines — because all events execute instantaneously, isolated from one another in time (in the usual interpretation).

In HEB the issue is more pressing. Because of the inclusion of continuous behaviour, *all* components are always executing *some* event. Thus an integrated representation risks hitting the combinatorial explosion of needing to represent each possible combination of concurrent activities within a separate event, and so there is a much stronger incentive to put each (relatively) independent component into its own machine, synchronised appropriately. Put another way, there is a very strong incentive to **not abstract away from concurrency**.

The same impulse is reinforced when we wish to construct systems out of components, e.g. a plant and a controller. There, it is also convenient to conceive the pieces separately and combine them appropriatelty. The key concept in achieving this is the INTERFACE. This is a syntactic contruct (adapted from the idea in [19]) that includes the declarations of a set of variables, the invariants that involve them, and also their initialisations. A community of machines may have access to the variables declared in an interface if each machine CONNECTS to the interface. All events in the machines must

[2] If a mode event has an input, the semantics assumes that its value only arrives at a time strictly later than the previous mode event, ensuring part of (2) automatically.

Fig. 5. A Hybrid Event-B system for yaw control.

preserve all of the invariants in the interface, of course. An important point is that *all* invariants involving the interface's variables must be in the interface.

Multi-machine HEB systems need more than what we have just described, namely (at least) synchronisation and instantiation mechanisms. These, and other issues, are discussed in [10]. What we have mentioned will suffice for this paper.

## IV. A Hybrid Event-B Model of Yaw Control

In this section we take the model discussed in Section II and re-express it as a Hybrid Event-B PROJECT. The project itself appears in Fig. 5, where its overall structure is defined in the PROJECT *Kurt_Prj* file. This indicates the pieces that the system is constructed from. These consist of the INTERFACE *YawCtrl_IF* and the MACHINEs *KurtUser_Mch*, *Kurt_Mch* and *YawCtrl_Mch.*

The interface SEES the CONTEXT *Kurt_Ctx* which contains the definitions of all the constants and static mathematics that the project will need, and more importantly, it is also the home of any AXIOMS (concerning these static elements) that we may rely on for verification. The interface then names the (pliant) variables shared by the machines that connect to it, lists their invariants, and defines their intialisations. Table 1 lists the variables, and describes how they relate to the elements of the KURT simulation model in Fig. 1.

The three machines *KurtUser_Mch*, *Kurt_Mch* and *YawCtrl_Mch* are formal definitions of the three actors in the dynamics.

The *KurtUser_Mch* machine describes the behaviour of the user who drives KURT. The machine CONNECTS to the *YawCtrl_IF* interface, to access needed variables, and it has a single pliant event *SteerKurt*. This applies a constant thrust from time 0 to time 4 $thr(t) := \Theta(4-t)$, and a constant yaw request from time 5 onwards $yrr(t) := \Theta(t-5)$, where $\Theta$ is the Heaviside step function. This is consistent with the description in Section II.

Machine *Kurt_Mch* describes the intrinsic behaviour of the KURT e-vehicle. It also CONNECTS to *YawCtrl_IF*. In this simple model it is assumed that KURT will emit a measured yaw rate *yrm* whose derivative is proportional to the difference of the thrusts applied to left and right wheel sets $tar(t) - tal(t)$, and which is thus (via a positive constant $C_K$) proportional to the differential thrust $stc(t)$ (see Fig. 1):

$$\frac{d}{dt} yrm(t) = C_K \, stc(t) \tag{3}$$

Machine *Kurt_Mch* expresses this in HEB notation.

Machine *YawCtrl_Mch* describes the controller that turns the user's steering commands into thrust commands to KURT's wheels. Of course it CONNECTS to *YawCtrl_IF*. At its heart is the PID controller in Fig. 1 which calculates the differential steering thrust command $stc(t)$ from the value, integral and derivative of the yaw rate error $yer(t)$:

$$stc(t) = K_P \left[ yre(t) + \frac{1}{T_I} \int_0^t yre(s)\, ds + T_D \frac{d}{dt} yre(t) \right] \tag{4}$$

The formalism of HEB does not permit us to write this directly since (aside from implicit constraints in the COMPLY clause), it allows direct assignment and differential equations only, in the SOLVE clause. The formulation in the *YawCtrl_Mch* machine unwinds (4) into an acceptable form. Thus, separate variables are introduced for the proportional, integral and derivative of $yre(t)$: $yreP(t), yreI(t), yreD(t)$ (variable $yre(t)$ itself is not an element of the *Kurt* project). On this basis, equation (4) turns into the following lines of the SOLVE clause of the *YawControl* pliant event:

$$\begin{aligned} yreP(t) &:= yrr(t) - yrm(t) && (5)\\ yreD(t) &:= \mathcal{D}\, yreP(t) && (6)\\ \mathcal{D}\, yreI(t) &:= yreP(t) && (7)\\ stc(t) &:= K_P[yreP(t) + yreI(t)/T_I + T_D\, yreD(t)] && (8) \end{aligned}$$

The remaining assignments in the SOLVE clause of the *YawControl* event, quite faithfully mirror the relevant functions and connections of the yaw control model in Fig. 1, when the interpretation is mediated via the information in Table 1.

## V. Formal Properties of Yaw Control

Some properties can be easily checked from the text of Fig. 5. For instance, each of the variables of the *YawCtrl_IF* interface appears exactly once in the left hand side of any of the assignments or ODEs in any of the pliant events in the project. Since all these pliant events run concurrently, this property is a prerequisite for consistency.

The next obvious thing is the observation that all of the assignments and equations of the *Kurt* project are linear. This means that an analytic solution to the system's behaviour is within reach, which we examine now.

### A. Stability Analysis of the Simulation

Given that there are step functions in the system inputs $thr$ and $yrr$ at $t = 4$ and $t = 5$, the behaviour splits naturally into three intervals: $[0 \dots 4), [4 \dots 5), [5 \dots \infty)$.

During $[0 \dots 4)$ the vehicle accelerates from 0: thus $thr = 15 = tal = tar$, and all other variables remain at 0. During $[4 \dots 5)$, the thrust is switched off $thr = 0 = tal = tar$. So all variable values are 0. (In the simulation of Section II the vehicle begins to slow, although this depends on frictional forces not included in our formal model.)

**Table 1: Variables Used in the Yaw Control Models**

| Variable | Meaning |
|---|---|
| *yrr* | Yaw Rate Request (output of step1) |
| *yrm* | Yaw Rate Measured (output of Kurt) |
| *yre* | Yaw Rate Error, i.e. $yre = yrr - yrm$ (output of feedback2) |
| *yreD* | Time Derivative of Yaw Rate Error (derivative of output of feedback2) |
| *yreP* | Proportional Steering Yaw Rate Error, i.e. $yreP = yre$ (output of feedback2) |
| *yreI* | Time Integral of Yaw Rate Error (integral of output of feedback2) |
| *stc* | (Differential) Steering Thrust Command (output of pID1) |
| *thr* | Thrust Request (output of step2) |
| *tal* | Thrust Applied Left (output of add1) |
| *tar* | Thrust Applied Right (output of add2) |

Turning starts at $t = 5$, and we must solve the system of equations in the *Kurt* project. The *KurtBehaves* event in the *KurtMch* machine implies that $yrm(t)$ is the time integral of $C_K stc(t)$ up to a constant of integration $L_P$. This can be substituted into the right hand side of (5) which then yields $yreP(t)$. Differentiating this, in turn yields $yreD(t)$ via (6). Integrating it instead, yields $yreI(t)$ via (7), up to another constant of integration $L_I$. Substituting these relationships into (8) yields the integral equation:

$$\begin{aligned} stc(t) &= K_P(0.3 - L_P) - C_K K_P \int_5^t stc(s)\, ds \\ &\quad + \frac{K_P}{T_I}\left[(0.3 - L_P)(t-5) - L_I - C_K \int_5^t\!\!\int_5^s stc(u)\, du ds\right] \\ &\quad - C_K K_P T_D\, stc(t) \qquad (9) \end{aligned}$$

Differentiating this twice yields the homogeneous ODE:

$$\left(T_D + \frac{1}{C_K K_P}\right)\frac{d^2}{dt^2}stc(t) + \frac{d}{dt}stc(t) + \frac{1}{T_I}stc(t) \;=\; 0 \qquad (10)$$

The only solutions of (10) are exponential. Putting in the ansatz $stc(t) = Re^{\lambda t}$ and integrating twice yields candidates for the integral terms in the RHS of (9). Since (9) must be an identity, equating coefficients of $e^{\lambda t}$ and of the linear terms allows $L_P$, $L_I$ and $R$ to be determined from initial conditions. And with $stc(t)$ determined, we can easily calculate the behaviour of all the other system variables if we wish.

For mechanical stability, we need the real part of either value of $\lambda$ to be negative. This yields two constraints on the family of constants in the *Kurt* system, each being of the form $expr > 0$. However, up to positive constant factors and an additional factor of $T_I$, one $expr$ is the reciprocal of the other. Therefore, the two cannot be consistent unless $T_I > 0$, whence we get:

$$T_I > 0 \quad \text{and} \quad T_D + \frac{1}{C_K K_P} > 0 \qquad (11)$$

We can add these as AXIOMS to the context *Kurt_Cxt*:

AXIOMS
$T_I > 0$
$T_D + 1/(C_K K_P) > 0$

With axioms like these included in the project, new invariants become provable. Specifically, because $yreP(t)$ in $[5 \dots \infty)$ is bounded by a negative exponential displaced by a constant, its maximum is finite, so that we can add:

INVARIANTS
$yreP(t) \leq yreP_{MAX}$

to the interface *YawCtrl_IF*, where $yreP_{MAX}$ can be calculated explicitly.

### B. More General Stability Analysis

The above analysis accurately reflected —though from a formal vantage point— the kind of evaluation that can be achieved by a simulation based approach, such as we had in Section II. In this section, we extend the formal analysis to the case of a more arbitrary yaw rate request input $yrr(t)$, provided it stays within specified bounds. We illustrate thereby the greater reach of a more symbolically based approach, in cases where the calculational challenges remain tractable.

With a relatively arbitrary $yrr(t)$, we can redo the derivation of the previous section. We arrive at an analogue of (10) in which the LHS is as before and the RHS is modified:

$$\begin{aligned} \ldots &= \frac{1}{C_K}\left(T_D\frac{d^3}{dt^3}yrr(t)+\frac{d^2}{dt^2}yrr(t)+\frac{1}{T_I}\frac{d}{dt}yrr(t)\right) \\ &\equiv inh(t) \end{aligned} \tag{12}$$

We see that the inhomogeneous term $inh(t)$ depends solely on the derivatives of $yrr(t)$.

Introducing the vector $\mathbf{stc}(t) = [stcP(t) \quad stcD(t)]^{\mathrm{T}}$ where $stcP(t) \equiv stc(t)$ and $stcD(t)$ is the time derivative of $stcP(t)$, we can write the second order ODE (12) as a first order system:

$$\frac{d}{dt}\mathbf{stc}(t) = \mathbf{A}\,\mathbf{stc}(t) + \mathbf{b}(t) \tag{13}$$

where:

$$\mathbf{A} = \begin{bmatrix} 0 & 1 \\ -H/T_I & -H \end{bmatrix} \quad \text{and} \quad \mathbf{b}(t) = \begin{bmatrix} 0 \\ H\,inh(t) \end{bmatrix} \tag{14}$$

and $H = C_K K_P/(1+C_K K_P T_D)$, (the latter being the reciprocal of the constant appearing in (11)).

The form of (13) is standard (see, e.g. [20], [21], [22] and many other places), so the system can be integrated by applying a routine procedure. For $t \geq 5$ we have:

$$\mathbf{stc}(t) = e^{\mathbf{A}(t-5)}\mathbf{stc}(5) + \int_5^t e^{\mathbf{A}(t-s)}\mathbf{b}(s)\,ds \tag{15}$$

Since $\mathbf{b}(t)$ consists solely of derivatives of $yrr(t)$, we can integrate by parts repeatedly. To do so we introduce the notation $\mathbf{yrr}(t) = [0 \quad yrr(t)]^{\mathrm{T}}$, and we observe that:

$$\begin{aligned} &\int_5^t e^{\mathbf{A}(t-s)}\frac{d^k}{ds^k}\mathbf{yrr}(s)\,ds = \\ &\quad \left[e^{\mathbf{A}(t-s)}\sum_{j=0}^{k-1}\mathbf{A}^{k-j-1}\frac{d^j}{ds^j}\mathbf{yrr}(s)\right]_5^t \\ &\quad + \mathbf{A}^k\int_5^t e^{\mathbf{A}(t-s)}\mathbf{yrr}(s)\,ds \end{aligned} \tag{16}$$

So as not to have to deal with a large collection of boundary terms coming from (16), we now hypothesise a turning episode in which $yrr(t)$ starts at zero (for $t = 5$), smoothly increases and then smoothly decreases back to zero (for $t > 9$ say). Dropping the boundary terms, we get, in the $t > 9$ region:

$$\begin{aligned} \mathbf{stc}(t) &= e^{\mathbf{A}(t-5)}\mathbf{stc}(5) + \\ &\frac{1}{C_K}\left(\frac{1}{T_I}\mathbf{A}+\mathbf{A}^2+T_D\mathbf{A}^3\right)\int_5^t e^{\mathbf{A}(t-s)}\mathbf{yrr}(s)\,ds \end{aligned} \tag{17}$$

A result like (17) allows us to estimate in a symbolic manner the steering thrust command required for turning episodes corresponding to $yrr(t)$'s that behave in ways characterised by some generic pattern. For example we may be able to confirm that for the class of turning episodes considered, the magnitude of the steering command will not breach the physical boundaries engineered into the system.[3]

If this strategy is pursued, then the properties assumed for $yrr(t)$ can be introduced axiomatically in the interface *YawCtrl_IF*. Technically, constants would be introduced in *YawCtrl_IF*, e.g. a constant *YRR* naming a function of time, which would be endowed with the properties required to be assumed for $yrr(t)$, expressed via axioms. Then the behaviour of $yrr(t)$ would be set equal to *YRR* in machine *KurtUser_Mch*.

The properties concerning $yrr(t)$ derivable from this basis could be dealt with in various ways. For persistent properties, the most natural approach would be to recast them as invariants of the system. Properties not of this kind cold be expressed as THEOREMS in the syntax. Both kinds would then need to be proved.

### C. On Mechanical Verification

The previous two sections gave examples of what could be addressed within a formal development framework capable of treating continuous behaviour as first class citizen. But writing a desirable property is one thing, and mechanically discharging a proof of it is another. While proper mechanical support for HEB is, as yet, an aspiration, achieving the power to do the kind of mathematics indicated in a reasonable time would require the import of the capabilities of existing tools like *Mathematica* [23]. Such an approach is entirely practical, and would provide a good level of additional assurance, beyond what can be achieved by explorations of system behaviour via simulation.

For applications requiring an even higher level of assurance, the user would have to program the rules and tactics for the relevant portion of mathematics directly, so that the details of the derivation could be exposed to scrutiny, in contrast to tools like *Mathematica*, where the internal reasoning algorithms are commercial secrets. The capability to approach the verification task in both ways is part of the planned tool support for HEB.

## VI. Discretizing Hybrid Event-B Yaw Control

A major issue in turning a conceptual design into a reality in today's engineering environment, is going from the original continuous control model to a discretized control model. This is because, with today's components, analogue control is prohibitively expensive when compared to its discrete counterpart. (There are, of course, many other reasons for preferring discrete control which are well known, such as the flexibility of software, and the lack of drift in digital components.)

In some approaches, the design is initiated directly in the discrete sphere, bypassing the continuous world altogether. However, that forces the problem of deciding the sampling frequency, to be confronted immediately. The advantage of starting in the continuous world is that this issue is postponed in favour of engagement with the primary design challenges, which are most clearly viewed in the continuous world. This is what we do here, starting with the continuous model, and then contemplating the discretized version.

[3] A more realistic simulation of KURT than shown in Section II includes limiters to do just that.

Fig. 6. A discretized Hybrid Event-B system for yaw control.

### A. Continuous and Discretized Systems

From a formal development standpoint, the most desirable relationship between a system model and its more idealised predecessor, is a refinement. Typically, a refinement enriches a more idealised model with detail taking it ‘closer to implementation’. The enriched model is proved consistent with its predecessor (normally, via a formal simulation relation). Done properly, a refinement has the potential to preserve valuable properties established earlier, in the new model. Unfortunately, in the context of the discretization issue, this strategy, applied naively, fails. The reasons are as follows.

A continuous description of a system contains an ‘infinite’ amount of information: i.e. the values of all system variables over a continuum of times. Any implementable sampling method will unavoidably ‘forget’ all but a tiny fraction of this information, i.e. all but the sampled values themselves. If the system response to the environment depends on the information it has about the system's behaviour, it is more or less inevitable that, in principle, the quality of a sampled system's response will be inferior compared with the continuous case. Thus the discretization process is not an enrichment of the continuous model but an impoverishment, and refinement, as a technique, struggles to cope with it, since the impoverishment degrades the information available for the consistency proof rather than enhancing it.

Still, the news is not all bad. Typically, the interaction between the system and the environment/plant is two way (closed loop). If, overall, both the continuous and discrete versions of the combined system are stable (with suitable choices of parameters etc.), then a reaction in the discretized system that is in some way undesirably increased compared to what it would be in the continuous system under similar circumstances, can be compensated for by the environment of the discretized system, which can increase suitably its input to the system to steer overall behaviour towards the desired regime. Doing this successfully depends on a number of things: good understanding of both system and environment; the deviations spoken of being moderate in magnitude; the overall system (in both the continuous and discrete versions) being stable; suitable choices of parameters being made.[4] See [16]

[4] Suitable parameter choice is heavily dependent on insight from the frequency domain. We return to this point below.

for a relevant technical discussion. However, if the interaction between the system and the environment is one way (open loop), it is much easier to see less acceptable devations.

### B. The Discretized Model

In Fig. 6 there is a discretized version of the previous continuous yaw control model. Each syntactic construct is replaced by its discretized counterpart; e.g. *Kurt_Prj* is replaced by *KurtD_Prj* which **REFINES –??–** it. The question marks qualifying the REFINES claim refer to a certain level of ignorance concerning the precision of the relationship between the continuous and discretized versions that we must endure, and that affects many components of the two models. We discuss this point in detail in Section VI-D.

In this exercise, for simplicity, we keep all the model constants (such as $C_K, K_P$ etc.) the same.[5] In addition, there is a further constant $T$, which represents the sampling period. For simplicity, $T$ is axiomatized to be $1/N$'th of a unit of time, so that the external stimuli to the system can remain the same as in the continuous model (and both, moreover, are open loop).

Variables $var_D$ are the discretized counterparts of their earlier predecessors $var$, sampled and updated every $T$ time units. Now, the semantics of Hybrid Event-B imposes a specific interpretation on the assignments that occur in mode events, e.g. $var_D := expr(var_D)$. When such an assignment is executed at a time $kT$ say, the LHS of the assignment denotes the new value $var_D(kT)$, which we write as $var_{D,k}$. However, the RHS is evaluated using the limiting value of $var_D$ just before $kT$. If we assume that $var_D$ does not change during any sampling interval, then the RHS is in fact $expr(var_{D,k-1})$, so the assignment implements the difference equation $var_{D,k} = expr(var_{D,k-1})$. We return to this point below.

In order to implement simple approximations to derivatives and integrals (done via backward differences and accumulated sums, respectively), preceding values of some variables need to be recorded: $var_D^{pr}$. (As with the model constants, the literature contains many approaches that tackle these issues in more sophisticated ways; see e.g. [24], [25], [26].)

We discuss the machines, one by one. The simplest is *KurtUserD_Mch*. This genuinely REFINES the earlier *KurtUser_Mch* machine in a manner which is easy to see. Namely, the original and discretized variables $thr$ and $yrr$ vs. $thr_D$ and $yrr_D$ have identical behaviours in the sole (pliant) event of the two machines *SteerKurt*. This is formalised via the equalities $thr_D = thr$ and $yrr_D = yrr$ in the invariants of the interface.

Next we have *KurtD_Mch*. This has both a pliant event *KurtBehavesPli* and a mode event *KurtBehavesMo*. The pliant event (continuously) skips. This models the zero order hold that characterises a simple sampling scheme. The pliant event REFINES –??– the *KurtBehaves* event of *Kurt_Mch*. The mode event models the periodic updates to $yrm_D$ at the sampling times, obtained by replacing the differential equation of the *KurtBehaves* event with a discretized approximation of the corresponding integral equation via $yrm_D := yrm_D + C_K T stc_D$. This is to be interpreted as discussed above, which means that the assignment represents the difference equation $yrm_{D,k} = yrm_{D,k-1} + C_K T stc_{D,k-1}$.

Then we have *YawCtrlD_Mch*. The conventions already described hold here too. Thus there is a pliant event *YawControlPli* that skips while it REFINES –??– the *YawControl* event of *YawCtrl_Mch*, and a mode event *YawControlMo* that models the periodic updates to the discretized counterparts of all the variables modified by *YawControl*. At this point a subtlety needs to be pointed out.

In a pliant event, there is no difference between the (parallel) direct assignments $x, y := y, z$ and $x, y := z, z$ because of the equality semantics of direct (instantaneous) assignment. However, when the two assignments are naively discretized, they turn into $x_D, y_D := y_D, z_D$ and $x_D, y_D := z_D, z_D$ respectively, which are to be interpreted as we discussed above. The first of these corresponds to the difference equation $x_{D,k}, y_{D,k} = z_{D,k-2}, z_{D,k-1}$, because the LHS and RHS of such assignments refer to values one sampling period apart, as noted above. Thus a chain of $n$ dependent equalities in a pliant event —which in the pliant event relate values at the same time point— can generate an $n$'th order difference equation upon discretization. This can have detrimental effects on the quality of the approximation and on its stability due to the use of older and older values — as is discussed extensively within numerical analysis, e.g. [27], [28].

In order to minimise the impact of this, we can back substitute to make use of values that are as fresh as possible.[6] Note that every different choice of scheme for doing the back substitutions results in a discretization scheme that is correspondingly different, amounting to a different design decision regarding what discretization means.

We can go further, designing the difference equations that we wish to use for the discretization *a priori*, and independently of the 'obvious' discretizations of the continuous model, and then work back to derive the discrete assignments that would implement them.

In the context of these remarks, the main impact on the *YawCtrlD_Mch* machine is to alter the detailed expressions that occur on the RHS of the assignments of the mode event. The assignment that is of most interest is the assignment for $stc_D$, where the feedback from the control strategy is most felt. Its RHS is enclosed in heavy quotes to allude to this.

### C. Discretized Stability Analysis

Let $k \in \mathbb{N}$ index the number of $1/N$'ths of a time unit elapsed since $t = 5$. We address the discretization of $stc_D$ in more detail. In the light of all the possibilities just discussed, we proceed as follows.

Looking at the assignments for $yrm_D$ and $yreP_D$ that appear in Fig. 6 and dropping the inhomogeneous terms, it is not difficult to derive the difference equation $yreP_{k+1} = -C_K T \sum_{r=0}^{k} stc_{D,r}$. Deriving the analogous expression for $yreI_D$ involves a double summation. Dealing with these directly in the assignment for $stc_D$ is certainly inconvenient. However, if we take second differences of the $stc_D$ assignment, the summations

[5] In many discretization approaches, model constants are adjusted, in order to better approximate the continuous model.

[6] This amounts to using the $x_D, y_D := z_D, z_D$ form in the earlier example.

cancel, and we obtain:

$$\begin{aligned} stc_{D,k+3} - 2stc_{D,k+2} + stc_{D,k+1} \; = \\ -C_K K_P [T_D(stc_{D,k+2} - 2stc_{D,k+1} + stc_{D,k}) \\ + T(stc_{D,k+2} - stc_{D,k+1}) + T^2 stc_{D,k+2}/T_I] \quad (18) \end{aligned}$$

which is much more amenable to analysis. Inserting the ansatz $stc_{D,k} = RW^k$ into (18) yields:

$$\begin{aligned} D(W) \; \equiv \; W^3 + C_K K_P [T^2/T_I + T + T_D - 2/C_K K_P] W^2 \\ + C_K K_P [1/C_K K_P - 2T_D - T] W + C_K K_P T_D \; = \; 0 \quad (19) \end{aligned}$$

This is a cubic equation for $W$. For stability in the system as a whole, we need $|W| < 1$ for all the solutions of $D(W) = 0$. Standard resources for cubics such as e.g. [29], [30], show the technical burden of trying to analyse this directly.

We observe that because of the sign of the $W^3$ term in (19), if all the roots of $D(W) = 0$ are real and of modulus $< 1$, then (1) $D(+1) > 0$, (2) $D(-1) < 0$, and if $D'$ is the derivative of $D$, then (3) the roots $r_\pm$ of $D'(W) = 0$ satisfy $-1 < r_- < r_+ < +1$, (4) $D(r_-) > 0$, (5) $D(r_+) < 0$. Since $D'(W) = 0$ is a quadratic it is a lot easier to handle. (We note that the constraints cited can be related to the Sturm technique for finding regions containing real roots of an arbitrary polynomial [31].)

Although the general form of the coefficients of (19) makes it cumbersome to test for the conditions (1)-(5) in full generality, we note that we are predominantly interested in the region $T \to 0$. If any necessary conditions do not hold in the limit of vanishing sampling interval, then they cannot be of interest for any engineering purpose. The $T \to 0$ limit simplifies the coefficients considerably.

Beyond this, we can rely on the physical properties of the system to simplify the case analysis further. From the Cohen-Coon tuning analysis of Section II, it emerges that $T_D \approx 10T$ and $T_I \approx 4T_D$. As well, the kinematics of the problem mean that $C_K$ is positive, and it also follows that $K_P$ is positive. So all the constants in our problem space are positive.

All of these observations make the corresponding tests relatively straightforward to carry out. Tests (1) and (2) are straightforward evaluations. The former yields a triviality while the latter yields the constraint:

$$1 > C_K K_P T_D \qquad (20)$$

which turns out to be necessary for the small $T$ limit to be feasible. Constraint (3) gives rise to a number of further conditions. However, in the small $T$ limit, they are all subsumed by the stronger condition (20).

The expressions for the roots $r_\pm$ of $D'(W) = 0$ are the standard formulae for a quadratic, and turn out to be expressions in the combination $C_K K_P T_D$. Accordingly, it is easiest to use (20) to substitute numerical values for $C_K K_P T_D$ and thence to check conditions (4) and (5). It turns out that values of $C_K K_P T_D$ around approximately 0.5 permit (4) and (5) to be satisfied in the small $T$ limit. We thus conclude that there is a stable regime in the small $T$ region, and hence furthermore, that there is a still larger region of stability when a pair of roots of $D(W) = 0$ fuses and bifurcates into a pair of complex roots (which will be close to the real axis for some range of values of the parameters).

We concede that the above analysis was somewhat *ad hoc*. More significantly, it was purposely confined entirely within the state space formulation of the problem. This is important to the extent that the HEB approach is lodged in the state space domain for reasons which were explained in the Introduction.

By contrast, most discretizations of continuous designs in engineering practice take place within the frequency domain. As mentioned previously, there are various approaches described in the literature cited earlier. Happily, one of them coincides with what we derived: the discrete equivalence approach. In that approach, a zero order hold is introduced into the model at the right point, standard $z$-transform elements are introduced for the PID components, and a transfer function is calculated by combining all of these. The poles of the transfer function give the characteristic frequencies of the system, which are checked for stability. It turns out that the denominator of the transfer function (which is a rational function in the $z$ plane), coincides exactly with (19) aside from the change of variable.

In the conventional approach to discretization, stability is analysed using the Jury test [32], [26], [8], which is applied in the $z$ domain. This generates a sequence of tests, all of which have to be passed to deduce stability (which is the property $|z| < 1$ for the characteristic frequencies). Happily once more, the first few of these coincide with the first few of the *ad hoc* tests we did above. All of this shows not only the desirability, but the feasibility of greater cooperation between the two formulations of control within the formal HEB approach.

### *D. Relating the Continuous and Discretized Models*

The cornerstone of any formal development technique like (Hybrid) Event-B is the idea of relating successive models via a formal refinement relation, which relates a more abstract model to a more concrete one. In practice this is always a simulation relation, which amounts to the statement: *IF* the invariants hold at a given moment *THEN* they hold after any update (mode or pliant) of the concrete variables — for a suitable choice of update of the abstract variables. Thus, suitably initialised, the implicational structure can be cascaded inductively into a statement that holds true at all times. Evidently, for the described approach to have force, the invariants mentioned must express a desired relationship between the two families of variables that is also expected to hold at all times.

Establishing this, when viewing discretization as an instance of refinement, proves to be very demanding in all but the simplest cases. A trivial case of discretization treated this way occurs in [9] — no technical difficulties occur there. From our own development, an equally trivial case of refinement occurs between machines *KurtUser_Mch* and *KurtUserD_Mch*, since in the INVARIANTS section of the *YawCtrlD_IF* interface we find the joint invariants $thr_D = thr$ and $yrr_D = yrr$, which express the equality of the relevant pairs of variables. Since the original and discretized variables are defined to behave in exactly the same way in their respective machines, establishing the required properties is indeed trivial, and *KurtUserD_Mch* is a genuine refinement of *KurtUser_Mch*.

For the other machines in the model, the situation is a lot less clear cut. The detailed behaviour of the continuous and discretized variables in each corresponding pair is known a lot less precisely. In particular, there is a significant lack of detail compared with what is stated regarding *thr* and *yrr* and their counterparts. A number of points arise concerning this.

Firstly, given a linear and third order discretization scheme, with sufficient additional effort an analytic solution could in principle be obtained for the various variables involved, at least in the form of summations over powers of the roots. The effort involved would be considerable, yet the perspicacity of the solution obtained would not be a given. With a relatively opaque formulation of the solution, its relationship with the analytic solution to the continuous system (which we did not pursue to its conclusion either) would also not be clear. This would lead to further technical difficulties in formulating relevant joint invariants for corresponding pairs of variables. It is not evident that they would enjoy the same level of precision that we were able to indicate for *thr* and *yrr*.

Secondly, the effort expended in achieving the goals indicated (if actually expended) would only apply for the single pair of abstract and concrete system trajectories given by the specific driving inputs specified by *thr* and *yrr* in *KurtUser_Mch* and its counterpart. They would not necessarily apply for any other inputs. But, for dependability, we would want a generic result that applied to a whole family of trajectories that was large enough to include all that could be expected to arise in practice. For that, much more generic and powerful results would be needed. And this mismatch between what typical formal techniques routinely demand, and what the analysis of control systems can routinely supply, rapidly grows greater the more complex the application system becomes.

Based on these observations, the relationships that we have quoted in the *YawCtrlD_IF* interface between continuous and discretized versions of our variables (excepting *thr* and *yrr*) is approximate equality. Some justification for this lies in the fact that we were able to show that both systems were stable (for suitably chosen static parameters).

For us, approximate equality meant $|var_D - var| < B_{var}$, for corresponding variable pairs and constants $B_{var}$. When the stability properties are sufficiently strong, such results can become provable in principle; see e.g. [16]. Still, it is not unquestionably the case that these results can be related directly to problem domain quantities, because of their reliance on existential properties.

The claim that $|var - var_D| < B_{var}$ can serve as a suitable joint invariant depends crucially on knowing that the dynamics is such that the difference between continuous and discretized versions of variables always strictly decreases, i.e. that we always have behaviour consistent with asymptotic stability, *regardless of the behaviour of any external input*. However, in Section VI-A, we acknowledged the possibility of impoverished information from sampling allowing the discrepancy between variables to grow, even if temporarily. In such cases, the arguments in [16] will not hold.

In cases like that, it is often not too hard to prove *local properties*, i.e. properties concerning a single sampling interval, that assert not-too-bad divergence. The downside of such properties though, is that they do not cascade inductively into statements that hold at all times.

A variation on the refinement technique that is focused on such local properties is retrenchment [33], [34], [35], [36]. It provides a formal framework in which such local properties can be expressed, and additionally, related to properties controlled by refinement (see particularly [35]). A judicious combination of refinement and retrenchment could prove to be the best approach to the technical difficulties mentioned.

Of course, we are not the first authors to discuss the challenges posed by discretization. As well as standard discrete control references such as [32], [26], [25], [37], [8], there are more specialised treatments aimed at specific aspects, e.g. [38], [39], [40], [41]. Frequently they focus on a frequency domain approach or on statistical properties. It is probably fair to say though, that there is no detailed treatment that is an ideal match to the needs of a formal approach to control systems design and development.

## VII. Conclusions

In the preceding sections, we took a simplified though non-trivial version of the yaw control problem for the KURT e-vehicle, and used it as a testbed for complementing and strengthening the assurance obtainable via conventional engineering approaches, by using a formal modelling and refinement approach to the development. The vehicle for the latter was the Hybrid Event-B formalism [9], [10], a formalism designed to capture hybrid system behaviour in way that is compatible with established formal development approaches from the computing sphere, and with state based approaches from the control sphere.

One immediate consequence of this is the evident tension between the state based perspective of formal approaches (which need to deal with arbitrarily structured state spaces) and the frequency domain based perspective of conventional engineering design. The frequency domain approaches, typically based on Laplace transforms and *z*-transforms, turn functional properties into algebraic ones — the latter are usually much easier to manipulate in practice, and thus are strongly favoured in practical engineering. The simplification of the design process coming from the use of algebraic techniques is amplified by the use of specific stimuli (such as response to step function inputs), and of simulation, as preferred techniques to gauge the appropriateness of a design. Of course, to quote a familiar truism, simulation can only show the presence of faults, not their absence, so enhancing the development methodology with formal techniques which potentially have broader coverage is a worthwhile aim.

Doing this seriously though, quickly invites back the technical obstacles that the algebraic and simulation based approaches strove to avoid. We rapidly saw this in our examination of the discretization of PID control in the KURT e-vehicle application — the technical difficulties inherent in moving from a relatively perspicuous continuous design to a suitable discretized version quickly proliferated.

These observations readily propose a series of topics that it would be very worthwhile to develop more fully in order to increase the utility of a combined approach.

[I] A closer cooperation is needed between, on the one hand, the state space methods typical in state based control and formal approaches, and on the other hand, the frequency domain based approaches so widely used in conventional engineering. Normally, discussions take place exclusively within one domain or the other, but a greater interaction could improve the feasibility of a combined approach. For this, and depending on the specific goals of a given analysis, more contact points would be identified between state space and frequency methods, such that the solution to a state space question could be derived in the frequency domain. However, it has to be appreciated that only certain questions translate well between the two domains.

[II] With issues such as discretization, it is clearly impractical to tackle each development from first principles in a practical methodology. A family of suitable generic results is needed that can be applied in a wide variety of contexts to inform the formal strand of the development. Similar remarks apply to other aspects of the development methodology — we could mention topics such as sensitivity and robustness, besides stability, which we concentrated on.

[III] To facilitate the efficient incorporation of the relevant kinds of formal derivation (done by hand in an *ad hoc* manner in this paper) additional special purpose syntactic support could be provided within the Hybrid Event-B formalism, especially in the context of mechanised tool support.

Besides these issues concerned with the technical interaction between different approaches, lies the application level scope of the formal modelling and refinement. We confined our attention to stability in an ideal environment, thereby neglecting many things. In reality, friction and sensitivity to external influences in the equipment affect the behaviour of the system. If these are not modelled properly, then the rigour of a formal refinement becomes spurious. Likewise statistical fluctuations in both the equipment and the environment of operation impacts the behaviour, and needs to be taken into account.

The traditional engineering approach to such questions is again via the frequency domain. It is assumed that influences such as these are each characterised by a suitable frequency domain response profile, often determined experimentally where needed. With a characterisation of that kind to hand, the controller can be designed to filter out stimuli that are undesired, and to respond appropriately to those that are important. With such a bandwidth limited frequency domain controller design, the Nyquist theorem and engineering heuristics give a good guide to the sampling frequency needed for a dependable discretization. However, this kind of frequency domain derivation is rather far from the state space approaches that could be directly placed in a formal development framework. All of these topics provide fertile territory for further work, to be pursued in other publications.

***Abstract*—Reactive programs often control safety-critical systems, thus it is essential to verify their safety requirements. ESTEREL is a synchronous programming language for developing control-dominated reactive systems, and XEVE is a verification environment that analyzes circuit descriptions generated from ESTEREL programs. However, a circuit generated by the ESTEREL compiler from non-pure ESTEREL program often displays behaviors which may violate safety properties even when the source program does not. We introduce an automatic abstraction process for ESTEREL programs developed to tackle this problem. When the process is applied to a program augmented with observers to monitor the program's behavior, it results in a pure program that preserves the behavior of the source program, replacing value-carrying objects with pure signals. We have built a prototype tool that implements the abstraction and used it to purify control programs and robotic systems.**

***Index Terms*—Verification, Abstraction, Reactive Systems, ESTEREL.**

## I. INTRODUCTION

*Reactive systems* are computer systems that continuously react to their environment at a speed determined by the environment. Most industrial real-time systems are reactive [3]. ESTEREL[1] is an imperative concurrent language for the development of industrial-strength reactive systems, which is especially well-suited for control-dominated reactive systems such as real-time process control systems, embedded systems, communication protocols, peripheral drivers, human-machine interfaces, and others [4]. ESTEREL belongs to the family of *synchronous languages*— languages that are based on the synchrony hypothesis, which states that a program instantaneously reacts to its input. Control is assumed to takes no time and thus output is broadcast right when the input arrives. The notion of simultaneity is captured by the concept of *event*, which is a set of simultaneous occurrence of (possibly valued) signals [3]. ESTEREL offers significant advantages over traditional languages used in industrial settings [5], such as verification (due to the precise mathematical semantics and the existence of verification tools and techniques), reduction of testing (automatic verification covers safety requirements), high-level abstraction, and better code structuring. A full definition of the language, as of version 5.91, can be found in [4].

ESTEREL programs communicate with their environment by means of signals and sensors. Signals can be used both for input and output, and may convey values; sensors can only be input and always convey values. A signal can be either present or absent; no such concept exists for sensors. A signal that carries values is called a *valued signal*, and a signal that does not convey values is called a *pure signal*.

Reactive systems are often used to control safety-critical systems. Hence they require rigorous design methods, and formal verification must be considered [3]. A complete, consistent and precise specification is constructed, often employing formal language to avoid ambiguity. While this process is very potent in detecting errors already at the formal specification development phase [6], there still is a risk that there would be inconsistencies between the formal specification and the eventual product. Even while the specification is formally verified, the product itself may still be erroneous, and we want to verify that the program satisfies its safety properties.

*Verification by observers* [7] is an approach to verify code. *Observers* are program modules monitoring the program, testing that a property is satisfied and broadcasting specific signals when the property is violated. The observers are composed in parallel to the original program, and the resulting program is compiled using an ESTEREL compiler into a finite automaton. The properties of the automaton are verified using tools such as the X ESTEREL VERIFICATION ENVIRONMENT (XEVE) [7], reducing the verification problem to reachability problem in finite automata – finding if there exists an execution trace from the initial state to a state emitting one or more of those special observer signals.

The XEVE verification environment requires the program to be compiled into Berkeley Logic Interchange Format (BLIF), a logic-level hardware hierarchical circuit description in a textual form; however, ESTEREL compiler, as of version

This work has been partially supported by GIF (grant No. 1131-9.6/2011). The paper is based on the master's thesis of the first author. For the thesis and the prototype tool see [1]. This paper extends a very short paper we have published in [2].

[1] We refer to ESTEREL v5.92, which we use for teaching. The toolset and the documentation are available at http://www-sop.inria.fr/esterel.org/filesv5_92/.

5.91[2], can either compile pure ESTEREL programs into BLIF files without changing their semantics, or, using the `-soft` option, abstract the data and compile only the control aspect into BLIF [9]. Pure ESTEREL programs only handle pure signals, i.e., they involve no valued signals, types, constants, functions, procedures, tasks, or variables [9]. In this work we collectively refer to valued signals, sensors, and variables as *valued objects*. The problem is that XEVE may fail to verify properly circuits generated from observed programs in which data is involved in the control when using the `-soft` option. The reason is that the abstraction might add behaviors not displayed by the original program, possibly including behaviors in which observer signals are emitted. Based on the false observation, the user might reject a program which is actually correct. For example, consider the following program:

```
module SpuriousError
   output Error;
   var v := 1 : integer in
      if (v <> 1) then
         emit Error
      end if;
      pause
   end var
end module
```

This program declares a variable `v` and initializes it to 1. It is obvious that the signal `Error` is never emitted because the condition tested by the `if` statement is never fulfilled. We can compile this program into a BLIF file using the `-soft` option, yet XEVE suggests that `Error` is possibly emitted, probably since the role of the data in the control flow is ignored and every transition dependent on run-time values is always enabled.

Many control schemes, however, receive numerical inputs, conduct numerical calculations, and emit numerical outputs. Example for such schemes are signal processors and closed-loop feedback controllers. We *purify* such programs to allow automatic verification of their properties. This is a transformation of ESTEREL programs handling valued objects into pure ESTEREL programs. It abstracts an unbound, concrete system that handles data by replacing objects that take values from theoretically-infinite domains with pure signals to receive a finite system. The abstraction preserves the external observable behavior of the original program, i.e. there is a correspondence in terms of inputs, outputs, and timings between the two programs. The difference between the two programs is that the abstract program uses pure signals where the original one employs valued signals, sensors, and variables.

Our approach is largely based on *predicate abstraction* [10]. Predicate abstraction is an automatic mapping of an unbounded system (the *concrete system*) to a finite system (the *abstract system*). An abstract system is defined by a concrete system and a finite set of predicates. Its states correspond to truth assignments to these predicates. The predicates define the *abstraction function*, which maps the states of the concrete system to the states of the abstract system. A state of the abstract system is reachable if it is an abstraction of a reachable concrete state. A user who wants to prove certain invariants supplies them as part of the predicate set. If the predicates stating the invariants are true in all reachable abstract states, then it means that the invariants hold in any reachable state of the concrete system. Applying this idea to ESTEREL, we automatically derive predicates about current and previous values of valued objects, of the form "the value of object $x$ is in the range $I$". Each such predicate is translated to a pure signal. We can say that a state of the concrete system where such predicate is held is abstracted to a state of the purified program where the corresponding signal is present.

Usually, abstraction-based proof techniques are sound but not complete, since the abstraction is done such that every property proven to be satisfied by the abstract system has a concrete version which holds on the concrete system, yet the other way around is unnecessarily true [10]. However, verification using our abstraction technique is both sound and complete, since the abstract program adds no new behaviors to those displayed by the concrete program; in particular every pure signal is emitted by the observer-augmented concrete program if and only if it is emitted by its purified version. The abstraction alters the semantics of a few operations; however, these changes remain internal, i.e. the interaction with the environment is unaffected.

We suggest an algorithm that automatically purifies a certain group of programs and we characterize the class of programs verifiable using our technique. The main contribution of this work is extending the class of programs verifiable using observers with XEVE. We have implemented a prototype tool that purifies ESTEREL programs based on the algorithm described in Section II. This section also presents a running example of a *proportional controller*. We discuss the challenges we have faced when abstracting variables in Section III. The programs to which the method is applicable must comply with certain constraints, which are discussed in Section IV. Section V characterizes the class of programs to which the solution can be applied and provides test cases. We conclude and provide suggestions for future work in Section VI.

## II. ESTEREL PROGRAM PURIFICATION

The XEVE verification environment takes as input BLIF files. Compiling an ESTEREL program into this format preserves the program's behavior only if the source code is pure. Hence, we have to substitute valued objects with pure signals and to modify the statements controlling the flow of the program and manipulating these objects to use pure signals instead. In this section we explain how to transform a program that complies with certain necessary constraints, into a pure program preserving the behavior of the original program.

We describe only the fundamentals of the algorithm.[3] We use a running example to demonstrate our method. It shows the application of our method to a *proportional controller*. This

[2] We chose to focus on ESTEREL v5 since it is free, suitable for teaching, and can be verified using the free XEVE tool which is part of the ESTEREL v5_92 distribution, whereas ESTEREL v7 [8] is commercial. XEVE is used in the industry [7].

[3] Due to lack of space we omit some details. The full description can be found in [1].

is a closed-loop feedback controller whose control signal is proportional to the *error* – the difference between the *set point*, also known as the *reference* (the ideal point) and the measured quantity under control, i.e., the control signal is calculated by multiplying the *error signal* by a *gain* [11]. Following is the ESTEREL code before its purification:

```
module PropMotor:
   input SampleTime;
   sensor Speed : double;
   output MotorForce : double;
   output AC_ON, AC_OFF;
   loop
      % proportional controller for the motor force
      present SampleTime then
         emit MotorForce (3.0 * (100.0 - ?Speed))
      end present;
      await SampleTime
   end loop ||
   loop
      % bang-bang controller for the cooling sub-system
      present MotorForce then
         if ?MotorForce > 270.0 or
            ?MotorForce < -270.0 then
            emit AC_ON
         else
            if ?MotorForce > -30.0 and
               ?MotorForce < 30.0 then
               emit AC_OFF
            end if
         end if
      end present;
      await tick
   end loop
end module
```

In addition to the proportional controller, the example uses a *bang-bang controller* that is composed in parallel and controls a cooling system. Bang-bang controllers are feedback controllers that switch abruptly between two states [11]. The controller receives a measured quantity of interest, and outputs a certain value if that quantity is above a certain threshold, and a different value otherwise.

The example displays a control system for a motor. The set point is 100 km/h; the measured quantity is the motor's current speed, received by the `Speed` sensor; the gain is 3.0. The output signal, `MotorForce`, is the force that the motor should produce, and is obtained by multiplying the difference between 100 km/h and the current speed by the gain. The motor is cooled by an air conditioning unit when exerting more than a certain amount of force (270.0). The air conditioning stops when the amount of force exerted by the motor drops below a certain threshold (30.0) (the difference between the thresholds is deliberate and used for hysteresis[4]). To start the air conditioning, it emits the `AC_ON` signal, and to stop the air conditioning, it emits `AC_OFF`.

We want to verify several safety properties of the given program using observers that monitor the system's behavior and emit special signals once one of these properties is violated. The observers are assembled in threads parallel to the main program. We would be able to verify that these signals are never emitted by compiling the observer-augmented program into BLIF format; however, we cannot do so as long as the program handles data other than pure signals.

The algorithm removes from the program all variables, sensors, and valued signals. Instead, we represent their values using pure signals. Each Boolean-valued object needs only one signal – that we call a *value signal* – to represent its value (present when true, absent when false). Since a Boolean signal actually has three states (absent, present and true, present and false) it takes another signal, which we call a *presence signal*, to denote whether the simulated Boolean signal is considered present or absent.

As for numerical-valued objects whose values range over infinite domains, we partition their domains into non-overlapping intervals, which we hereby call *ranges*, in such way that two goals are achieved. The first one is being able to decide any condition containing an occurrence of some numerical valued object by knowing the range within which that object's value resides. For example, the condition $?s > 3.0$ for a sensor $s$ ($?s$ is the current value of $s$) can be decided if the information whether $?s \in (-\infty, 3.0]$ or $?s \in (3.0, +\infty)$ is available. The second goal is maintaining relationships between dependent objects. For instance, for the assignment $v := a * ?x + b$, where $v$ is a variable, $x$ is a valued signal and $a$ and $b$ are literal constants, we can determine the range within which the $v$'s value would reside following the assignment based on the range of $x$. E.g., for $v := 2 * ?x + 1$ where $?x$ is in (1,3], the value of $v$ is in $(2 \cdot 1 + 1, 2 \cdot 3 + 1] = (3, 7]$. Note that actually we calculate the ranges for $x$ given the partition for $v$.

Our prototype tool works in two stages that run in a sequence by a shell script. In the first stage a standalone tool parses the source ESTEREL program according to v5_91 grammar specification found in [4] and outputs an intermediate file containing a list of syntax rules it identifies. The second stage is another program that reads that file and constructs a parse tree representation of the program. The tree data structure holds the information about all objects and statements of the source program, such that it is possible to reconstruct the program entirely from the tree. During the construction of the tree items that are of interest to the abstraction process, such as valued objects or statements that manipulate or test data are identified and stored in collections from which the abstraction algorithm can efficiently access them later. The abstraction is performed on the tree. The tool automatically calculates the predicates and performs the abstraction, implementing the algorithm discussed in this work. At the final step, a pure, abstract program is written to a target file based on the transformed tree. For sake of readability, we have edited in the paper the code produced by the tool.

After the source program is parsed, the abstraction algorithm starts with a pre-processing step to simplify the program when needed. Currently it expands each `sustain` statement (a statement emitting a specified signal in every instant once started and remains active forever) for a valued signal by a loop in which that signal is emitted in every instant, such that we can handle these statements just like instantaneous signal emissions (`emit` statements). This is also the place to perform other pre-processing activities; for example, for the simplicity

[4] Hysteresis can be introduced by setting "dead zones" of no reaction around the set point in bang-bang controllers to avoid rapid on-off cycling [11].

of the algorithm, we require the user to guarantee a few preconditions the source program must fulfill (see Section IV) in order to apply the tool/algorithm to it; these assumptions can be obtained automatically by performing some pre-processing steps on the original program. This step can be expanded in future versions to include them as well.

We implement some interval-scalar arithmetic operations required by this algorithm. Let *I* be an interval, and *a* and *b* be scalars:

- Multiplication of an interval by a scalar: $a \cdot I$ (equivalent to scaling an interval), and
- Addition of a scalar to an interval: *I* + *b* (equivalent to translating an interval).

Additionally, we define a *product* of two partitions $P_1$ and $P_2$ as $\{I_1 \cap I_2 | I_1 \in P_1 \wedge I_2 \in P_2\}$. This is a "mutual refinement" of $P_1$ and $P_2$ by one another. We denote the partition of the domain of a numerical valued object *x* by PARTITION(*x*). The partitioning process starts from statements that assign a constant value to a valued object (i.e. *var* := *const* or emit *val_sig* (*const*) ). The object's domain is partitioned according to the assigned constant. Suppose, e.g. that at some stage of the partitioning process PARTITION(*v*) = {(–∞, 1), [1, 1], (1, +∞)} for a variable *v*, once considering an assignment *v* := 2.0, PARTITION(*v*) is refined to {(–∞, 1), [1, 1], (1, 2), [2, 2], (2, +∞)}. This refinement allows us to refer later to *v* = 2 (equivalent to *v* ∈ [2, 2]) as a predicate in our abstract system, which is true once the assignment takes place in the original program. Note that this is the product of {(–∞, 1), [1, 1], (1, +∞)} and {(–∞, 2), [2, 2], (2, +∞)}.

Next, we consider the Boolean data expression in which a valued object occurs. Let (*a**D*+*b*) *R c* be a Boolean data expression, where *a*, *b* and *c* are literals ($a \neq 0$), *D* is either the current or the previous (i.e. pre(?*x*)) value of *x*, all have the same data type, and *R* is a relational operator. We denote $k = \frac{c-b}{a}$. If *a* divides $c - b$ (i.e. $\lfloor k \rfloor = k$) or *x* is floating-point real, the partition of *x* is refined with the partition {(–∞, *k*), [*k*, *k*], (*k*, +∞)}; otherwise, *x*'s partition is refined with $\{(-\infty, \lfloor k \rfloor], [\lceil k \rceil, +\infty)\}$. During the partitioning process we distinguish integer objects from float and double objects. For integer objects, non-integer values are illegal, therefore – an interval that does not contain integers is irrelevant. Also, non-integer values can be excluded from ranges computed for integer objects. When we compute ranges for an object of type integer, if an interval (range) end is neither at $+\infty$ nor at $-\infty$, we round it to the nearest integer inside the interval, and close the end. For example, if we compute a range $(-10, 3.5]$ for an integer object, then this range contains exactly the same values as [–9, 3] in the integer domain, hence $(-10, 3.5]$ is replaced by [–9, 3].

The partitioning process continues based on dependency between valued objects. We consider a valued object *y* to be *dependent* on another valued object *x* if *x*'s current or previous value occurs in an assignment to, or an emission of, another valued object *y* (the data expression is of the form *a* * *D* + *b* where *a* and *b* are literals and *D* denotes *x* for a variable *x*, ?*x* for a sensor *x*, or either ?*x* or pre(?*x*) when *x* is a signal). Suppose *y*'s partition is $\{Y_1, Y_2, ..., Y_n\}$, then *x*'s partition is refined with $\{{}^1\!/_a \cdot Y_1 - {}^b\!/_a, {}^1\!/_a \cdot Y_2 - {}^b\!/_a, ..., {}^1\!/_a \cdot Y_n - {}^b\!/_a\}$. The order by which these dependencies are considered is detailed in Section IV.

There are two valued objects in the example: the sensor Speed and the output signal MotorForce. Since MotorForce is set with Speed's transformed value, MotorForce's ranges are computed before Speed's ranges. MotorForce is computed the following nine ranges: {(–∞, –270.0), [–270.0, –270.0], (–270.0, –30.0), [–30.0, –30.0], (–30.0, 30.0), [30.0, 30.0], (30.0, 270.0), [270.0, 270.0], (270.0, +∞)}. We denote them by $R_1^{\text{MotorForce}}$, ..., $R_9^{\text{MotorForce}}$, respectively. The only valued signal emission found in the entire program is: emit MotorForce (3.0 * (100.0 – ?Speed)). Let us denote this statement by $E_1$. Once executed, ?MotorForce = –3.0 * ?Speed + 300.0. Since Speed = 100.0 – MotorForce / 3, the partitioning provides the following ranges for Speed: {(–∞, 10.0), [10.0, 10.0], (10.0, 90.0), [90.0, 90.0], (90.0, 110.0), [110.0, 110.0], (110.0, 190.0), [190.0, 190.0], (190.0, +∞)}, denoted by $R_1^{\text{Speed}}$, ..., $R_9^{\text{Speed}}$. Note that when this emission is executed, MotorForce is in $R_1^{\text{MotorForce}}$ if and only if Speed is in $R_9^{\text{Speed}}$, MotorForce is in $R_2^{\text{MotorForce}}$ if and only if Speed is in $R_8^{\text{Speed}}$, and so forth.

Each range is matched with a pure *range signal*. For a valued object *x*, for which PARTITION(*x*) = $\{R_1^x, R_2^x, ..., R_n^x\}$, the ranges' corresponding signals are named R1_*x*, R2_*x*, etc. A configuration of the abstract, purified program in which R*i_x* is present corresponds to a configuration of the original, concrete program where the value of *x* is in $R_i^x$. In other words, an event in which R*i_x* is present in the abstract program stands for an event in which the value of *x* resides within range $R_i^x$ in the concrete program. In addition, if *x* in the source program is a signal, an occurrence of any of its range signals in the abstract program means that *x* is present in the corresponding configuration of the concrete program.

When we declare range signals for a numerical input signal or a numerical sensor (replacing the original signal or sensor definitions), we also declare an exclusion relation[5] among the range signals, such that the environment would not be able to provide more than one range for each original valued object at the same instant. As for sensors, since every sensor is ever-present and always carries a value, a thread is composed in parallel to the program, emitting the range signal for its first range when its other range signals are absent.

The declarations of sensor Speed and valued output signal MotorForce in the example are replaced with the following declarations:

```
input    R1_Speed, R2_Speed, R3_Speed, R4_Speed,
         R5_Speed, R6_Speed, R7_Speed, R8_Speed,
         R9_Speed;
relation R1_Speed # R2_Speed # R3_Speed # R4_Speed #
         R5_Speed # R6_Speed # R7_Speed # R8_Speed #
         R9_Speed;
output   R1_MotorForce, R2_MotorForce, R3_MotorForce,
```

[5] An *exclusion relation*, also known as *incompatibility*, is a declaration that asserts that no two signals listed by the relation declaration can be present simultaneously in the environment [4].

```
         R4_MotorForce, R5_MotorForce, R6_MotorForce,
         R7_MotorForce, R8_MotorForce, R9_MotorForce;
```

To implement Speed's "ever-presence" property, we compose the following code segment in a parallel thread:

```
loop
   present not ( R2_Speed or R3_Speed or R4_Speed or
                 R5_Speed or R6_Speed or R7_Speed or
                 R8_Speed or R9_Speed ) then
      emit R1_Speed
   end present;
   await tick
end loop
```

The original variable assignment and valued signal emission statements are replaced by emit statements, emitting pure local signals to denote the execution of their respective statements. The effect of the assignments and the emit statements from the program is simulated by parallel components, calculating the range signal that should be emitted every instant for each numerical valued object of the program, to represent its state in every instant. For a variable, the simulation code tests whether a signal denoting an assignment to that variable has occurred in the previous instant, and if so – it emits the range signal representing that variable's state following the assignment. If no "assignment" is performed, then the previous range signal is emitted once again. For full details regarding variable simulation using pure signals, see Section III. For a valued signal, the simulation code works similarly, with two differences: the previous range signal emitted need not be emitted in an instant if no "emission" takes place in that instant, and every emission operation can be handled independently.

We need to translate the emission of MotorForce in the example to range signal terms. The original emit statement is replaced with emit E1. A new code segment is composed in a thread running in parallel to the current module's body, emitting the correct range signal for MotorForce in response to E1's presence. The local signal E1 must be declared as well, and its scope must include both the transformed module's original threads and the new thread shown below.

```
... || [ loop
            present E1 then
               present R1_Speed then
                  emit R9_MotorForce
               end present;
               present R2_Speed then
                  emit R8_MotorForce
               end present;
               ...
               present R9_Speed then
                  emit R1_MotorForce
               end present;
               await tick
         end loop ] || ...
```

Variable abstraction also employs pure signals and resembles valued signal abstraction; however, it is different because a variable can store values for future instants and can change value multiple times in every instant. It is elaborated on in Section III.

We now discuss transforming expressions. ESTEREL features three types of expressions [4]: *data expressions*, which are built by combining basic objects using operators and function calls; *signal expressions*, which are Boolean expressions over signal statuses; and *delay expressions*[6], which are used by temporal statements such as await[7] and abort[8].

Signal expressions consist of: signal identifiers, which may appear within pre operators (meaning their status from the previous instant); parentheses; and logical operators (and, or and not). They are tested by present statements (conditional statements testing signal statuses instead of data) or occur within delay expressions used by temporal statements. These expressions are transformed as follows:

- An identifier of a signal *S* having a numerical data type, whose ranges are $R_1^S, R_2^S, ..., R_n^S$, is replaced by the subexpression (R1_*S* or R2_*S* or ... or R*n*_*S*).
- An identifier of a signal whose data type is boolean is replaced by the identifier of its respective presence signal.

In our example, there is a present statement testing whether MotorForce is present before testing its value. Accordingly, we replace the MotorForce identifier with a chain of or operators over the range signals representing MotorForce in the purified program: present (R1_MotorForce or R2_MotorForce or ... or R9_MotorForce) then...

Numerical data expressions whose values are assigned to variables or carried by signals are handled by the variable assignment and valued signal emission simulation mechanisms. Hence we would like to focus on Boolean data expressions, whose values are not only used in variable assignments and signal emissions, but also in if statements.

Boolean data expressions are recursively translated to signal expressions. They are tested at each instant in a loop composed in parallel to the program. If the expression is true, a special signal is broadcast and is used in the purified code:

1) To calculate the results of simulated assignments to boolean-typed variables and emission of boolean-typed signals; and
2) To simulate the evaluation of Boolean data expressions by if statements. An if statement testing a Boolean data expression $B_i$ is replaced with a present statement that tests its corresponding signal B*i* in the transformed program.

In the example there are two Boolean data expressions. We translate the first, ?MotorForce > 270.0 or ?MotorForce < -270.0, into the signals expression R9_MotorForce or R1_MotorForce and create a thread that runs in parallel to the module's original threads. The new thread contains a loop in which the signal B1 is emitted in every instant in which this signal expression is satisfied. Afterwards, if ?MotorForce > 270.0 or

[6] A delay expression is an expression defining a delay that begins when the temporal statement bearing it starts and elapses in some later instant, possibly in the same instant in which the delay starts (delays that may elapse immediately are called *immediate delays*, and they start with the immediate keyword). There are three types of delays (standard, immediate, and count delays), but all delay expressions use signal expressions.

[7] The await statement pauses program execution until a delay elapses [4].

[8] The abort statement kills its body when a delay elapses [4].

`?MotorForce < -270.0 then...` can be replaced by the statement `present B1 then...`.

Additional transformations include removing the original interface and local declarations for the valued objects and modifying input relations. There are two types of input relations offered by ESTEREL: *exclusion relations* and *implication relations*. Exclusion relations, shown earlier as means to ensure that no two range signals representing a numerical input signal, assert that no two signals listed by the relation declaration can be present in the environment simultaneously. If the original program contains an exclusion relation where a numerical valued signal appears, than the declaration is expanded to include all range signals representing it. Identifiers of valued Boolean signals are replaced by the identifiers of their respective presence signals. Implication relations, which are relations of the form `relation` *A* `=>` *B*, asserting that if *A* is present then *B* must be present, are harder to transform, as they require a different solution for each case. For example:

- If *A* is a valued signal and its type is numerical while *B* is pure, then the relation is broken-down to a series of declarations for each range signal representing *A*, stating that an occurrence of any range signal of *A* implies that *B* is present.
- If *A* is pure and *B* is valued and numerical, then we add a thread containing a loop, where in every instant we check if *A* is present, and if so we ensure that if no other range signal representing *B* is present, then `R1_`*B* is internally-emitted. The reason that we cannot use implication in this case is that we want to allow any range signal representing *B* to appear if *A* is present, and not necessarily one particular range signal.

The full list appears in [1].

We want to verify the following properties in the example:

1) The program never simultaneously emits the signals `AC_ON` and `AC_OFF`. Such a situation “confuses” the external controller of the air conditioner. When an occurrence of both signals in the same instant happens, the observer emits `ErrorACConflict`.
2) The air conditioning is not off when the force exerted by the motor is greater than 270.0 in either direction. In case of violation, the observer emits the signal `ErrorNoAC`.

Hereby is the observer code – expressed in terms of the abstract program:

```
signal AC_isOn, AC_isOff in
   loop
      % no air condition conflict: ON and OFF not emitted
      % at the same instant
      present AC_ON and AC_OFF then
           emit ErrorACConflict
      end present;
      % air condition is never off when motor force is
      % greater than 270 or lower than -270
      present AC_isOff and
              (R1_MotorForce or R9_MotorForce)
        then emit ErrorNoAC
      end present;
      await tick
   end loop ||
   [ abort
         sustain AC_isOff
      when immediate AC_ON;
      loop
         present AC_OFF then
            emit AC_isOff
         else
            present AC_ON then
               emit AC_isOn
            else
               present pre(AC_isOff) then emit AC_isOff
               end present;
               present pre(AC_isOn) then emit AC_isOn
               end present
            end present
         end present;
         await tick
      end loop ]
end signal
```

The declaration of the output signals `ErrorACConflict` and `ErrorNoAC` joins the interface of the module. This observer code consists of one parallel thread in charge of emitting the observer signals in every instant in case of a property violation, and another parallel thread calculating auxiliary signals. The auxiliary signals indicate whether the air conditioning is on or off, depending on the most recent control signal to the air conditioning subsystem emitted by the program. Composing the observer code in parallel with the main program's body, and running XEVE on the resulting program, neither `ErrorACConflict` nor `ErrorNoAC` are ever emitted.

When applying our technique to abstract programs that satisfy the technique's requirements, verification using observers is both sound and complete [1]. We proved it by showing that an abstract program has the same reactive behavior as the concrete program, up to communicating with the environment by means of pure signals instead of the original valued signals and sensors. There is a loss of information and the abstract program allows theoretically more behaviors than the concrete program, in the sense that the abstract program provides ranges of possible values for the outputs given ranges of possible values for the inputs. However, the two programs make the same control decisions under the same circumstances and emit corresponding outputs, in particular with respect to pure signals, including, but not limited to, the observer signals, hence the soundness and completeness of the proof technique as a whole. The proof starts by defining for every event of the concrete program a corresponding event of the abstract system. The proof that the two systems behave in the same way given corresponding timed input sequences is statement-wise. On the one hand, statements that do not handle valued objects remain unchanged by the abstraction. On the other hand, statements that handle them are altered or replaced, hence the proof focuses on them. We identify four groups of statements that concern valued objects: statements that declare local signals and variables; statements that test data, i.e. make control decisions based on the data (namely `if` statements); statements that test signals, i.e. make control decisions based on statuses (presence or absence) of signals; and statements that manipulate data. We investigate, for every statement, the behavior of the construct replacing it in the abstract program. The full details appear in [1].

## III. Variable Abstraction

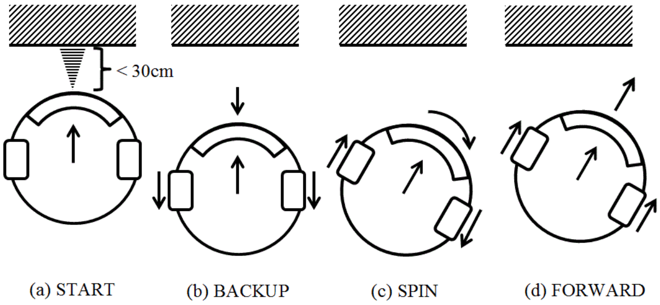
As we do for valued signals, we replace variables with local pure signals representing their current values. Employing pure signals for representing variables in the abstract program has a major drawback. ESTEREL supports multiple assignments to a variable in a single instant, as it does not contradict the synchrony hypothesis [4]; however, unlike variables, a pure signal may have only one status at each instant – it may either be present or absent, not both.

In the current version of the algorithm, we impose two restrictions on programs supported by the abstraction in addition to those listed in Section IV: (i) each variable is assigned at most once on every instant – after it is read[9] by all statements referencing it in that instant; and (ii) initializing a variable takes an instant (as a result of the previous constraint). Given these assumptions, we have implemented variable simulation[10] in the abstract program as follows:

- A local pure signal is declared for each assignment statement in the concrete program: `A1`, `A2`, `A3`, etc.
- Every assignment statement is replaced by an `emit` statement emitting the corresponding pure signal.
- For every variable $v$ a concurrent thread is added to the program in which there is a loop that emits in every instant the pure signal representing the current value of $v$.
- The code in this loop checks the previous status of signals indicating an assignment to $v$. If one of these signals has been emitted during the previous instant, it calculates the pure-signal representation of $v$'s value in the current instant based on the statuses of the pure signals representing the values of valued objects from the previous instant. If no signal indicating an assignment to $v$ has been present in the previous instant, the pure signals representing $v$'s previous value are re-emitted in the current instant; since no assignment to $v$ means that it retains its previous value.

This implementation with its implied restrictions is suitable for a certain group of programs, such as programs using a variable to manage a state machine: at the beginning of each reaction the current state is checked by reading the state variable, the reaction depends on the state and the input, and at the end of the reaction, if the program changes state or mode of operation, it assigns a new value to the state variable.

For example, in [1] we show a translation to ESTEREL of an *Escape* behavior for autonomous mobile robots based on a program taken from [11]. In this example, once a robot encounters an obstacle it backs off a predefined distance, rotates a predefined angle, and then returns to its previous occupation (e.g. cruising). We add a range detector such that the robot can escape an obstacle based on proximity without actually having to collide with it. The program uses a state variable, and in every reaction responds according to the current sensor reading and the current state. A reaction ends with assigning a new value to the state variable when transitioning to a new state. Figure 1 illustrates the implementation.



(a) START (b) BACKUP (c) SPIN (d) FORWARD

Figure 1: Robot Escape Behavior (with range detection).

To represent the behavior's state, we use an `integer` variable called `State`. The states are enumerated from 1 to 4. The partition of the integers domain to ranges for `State` is $\{(-\infty, 0], [1, 1], [2, 2], [3, 3], [4, 4], [5, +\infty)\}$ since `State` is assigned the values of 1, 2, 3 and 4, and is also tested to be equal to either one of them.

In the purification process we replace every statement assigning a value to `State` in the concrete program (see the source code in [1]) with a signal emission; e.g., the first assignment `State := 1` is replaced with `emit A1`; the second assignment `State := 2` is replaced with `emit A2`; and so forth. We compose in parallel to the original program a thread containing a loop that emits at every instant the range signal representing `State`'s current value:

```
|| loop
      % for each signal denoting an assignment to State
      % the next range signal for State is emitted
      present pre(A1) then
         emit R2_State
      else present (A2) then
         emit R3_State
      else ...
      else
         % if no assignment has occurred in the previous
         % instant then State's previous range signal
         % is emitted
         present pre (R1_State) then
            emit R1_State
         end present;
         present pre(R2_State) then
            emit R2_State
         end present;
         ...
```

The choice whether to postpone the effect of an assignment to the next reaction or to respond to it immediately affects only the constraint we have to impose, because either way our abstraction allows at most one assignment to a variable in every reaction. In the first option we allow one assignment at the end of the reaction after all statements use the value assigned to it in a previous instant, whereas the second option

[9] Reading a variable refers to an evaluation of a data expression containing an occurrence of that variable.

[10] By variable simulation we refer to the code that the abstraction adds to the program that simulates operations carried-out on a variable, i.e. assigning new values to it, in terms of the pure signals employed by the abstract program to represent the value of that variable.

allows one assignment at the beginning of the reaction and using that value henceforth, until the start of the next reaction where the variable is assigned again with a new value.

The difference between variable assignment in the concrete program, which is done immediately, and the variable assignment simulation in the abstract program, where the assignment is postponed to the next instant, has no externally-visible implications for programs that satisfy the two constraint mentioned above, since we require the concrete program not to use the new value of an assigned variable until the next instant. However, this approach severely confines the use of variables. One approach that we considered for allowing free use of variables was adding a delay immediately following an assignment, in order to "buy time" for the variable to update, i.e. giving the simulation code time to detect the signal notifying on the change and respond by emitting the new pure signals representing the variable's new value. However, this transformation, which in practice breaks-down seemingly one reaction into a series of reactions, can change the timing and semantics of the program significantly. In particular, it violates the assumption that every signal retains the same status throughout the entire reaction. For example, have a look at the following program segment:

```
emit O;
present O then
   v := 1
end present;
present O then
   v : = 2
end present;
```

Since `O` is present during the instant in which this code segment is executed, the two signal tests are satisfied and `v` is assigned consecutively the values of 1 and 2. Therefore, in the end of this program segment, `v` has the value of 2. Suppose we add a delay after assignment to `v` to comply with the assumptions above, e.g. by waiting for an arrival of some signal `DELAY` after each assignment statement. We get the following code:

```
emit O;
present O then
   v := 1;
   await DELAY
end present;
present O then
   v : = 2;
   await DELAY
end present;
```

In this program segment `v` is assigned the value of 1 since `O` is present before the first arrival of the `DELAY` signal. If we assume that `O` is not emitted by any parallel thread, then `v` is not assigned the value of 2 since `O` is absent after the arrival of `DELAY`.

We suggest an improvement to our algorithm, a workaround that enables us to assume that every variable is assigned at most once in every instant. This requires implementing a pre-processing step, combined with an alternative implementation of variable simulation that responds immediately to signals notifying on assignments to the original variable.

The pre-processing step will transform the concrete program such that each variable is assigned at most once in every reaction. We call the target form SINGLE ASSIGNMENT PER REACTION (SAPR). It is inspired by *Static Single Assignment* (SSA) form. An SSA form is a representation of a program involving separating each variable *v* in the program into several variables $v_i$ such that each variable is assigned only once [12]. In this work we refer to the variables $v_i$ as *instances* of *v*. The SAPR form is distinguished from SSA form in the sense that every variable is assigned at most once in every instant but not necessarily once in the entire program code. An additional difference is that SSA form employs Φ-functions: in a node in the control flow graphs having incoming edges from two other nodes where there are two different valid instances of some variable (for example, such node could be a statement following an `if` statement having two branches – `then` and `else`, each of which manipulates a certain variable `L` from the original program code, such that new instances are created in each branch for `L` – `L1` and `L2` respectively), the SSA form defines a new variable (e.g. `L3`) and assigns to it a Φ-functions standing for the value of valid variable instance at the entrance to that node (i.e. `L3` ← Φ(`L1`, `L2`)). In the SAPR transformation we need an equivalent of a Φ-function where the control converges back at terminations of branching statements and traps. We use special variable instances which are assigned the value of the valid variable instances at the ends of branches and before `exit` statements escaping traps.

For example, suppose that in the program investigated in Section II we wanted to limit the value of control signal to a maximum of 50 in either direction, and wanted to break-down the calculation of the control signal to several steps using variables, we could have used the following code:

```
var Error, CtrlSigVal : double in
   Error := 100.00 - ?Speed;
   CtrlSigVal := Error * 3.0;
   if CtrlSigVal > 50.0 then
      CtrlSigVal := 50.0
   end if;
   if CtrlSigVal < -50.0 then
      CtrlSigVal := -50.0
   end if;
   emit MotorForce(CtrlSigVal)
end var
```

This code segment employs two variables: `Error`, which contains the error, i.e. the difference between the set point (the target speed – 100) and the current speed; and `CtrlSigVal`, which contains the value of the control signal, obtained by multiplying the error (the value of `Error`) by the gain (3). If the product of the error and the gain is smaller than –50, then it is set to –50, and if it is larger than 50 it is set to 50. Below is the SAPR form, guaranteeing that in each instant each variable is assigned at most once:

```
var Error_0, Error_1,
    CtrlSigVal_0, CtrlSigVal_1,
    CtrlSigVal_2, CtrlSigVal_3,
    CtrlSigVal_4, CtrlSigVal_5 : double in

```

In the transformed code segment we create a variable instance for every assignment statement. Once assigned, a variable instance substitutes the variable from the original program wherever it appears in data expressions from that point on, until the next assignment to the original variable, where another variable instance is used. `if` statements, which have no `else`-branch in the original program, are added with an `else`-branch. A new variable instance is created to hold the valid value upon leaving the `if` statement, and it is assigned at the end of each branch. This exemplifies the reason why `else`- and `then`-branches are introduced when missing – if a variable is manipulated in one branch and not in another then still at the end of the `if` statement there is one variable instance replacing the original variable and holding the right value. In [1] we elaborate on the transformation and provide the full example, including simulation results.

## IV. Discussion

Our method supports only programs that compile and execute without errors and that comply with several assumptions and constraints, which are described in this section. These constraints are required for maintaining relationships between valued objects and for replacing numerical and Boolean calculations with pure signal operations. However, our method still is useful for a large set of control and robotic programs. Various robot behaviors appearing in [11] can be implemented in Esterel, processing pure signals or requiring sufficiently simple calculations, thus our method can be applied to them.

In [1] we list assumptions about the input program that exist mainly for the simplicity of the solution. These assumptions usually concern Esterel syntactic sugaring instructions. However, they do not reduce the expressive power of Esterel, as each assumption can be attained by replacing the original construct by a semantically-equivalent construct, either manually or automatically. For example, we require that the program will consist of only one module. When the program consists of several modules, one module calls another using the `run` statement. The `run` statement instantiates one module within another module by syntactically replacing the `run` statement with the body of the instantiated sub-module, exporting the data declarations of the instantiated sub-module to the parent module, and discarding the interface declaration of the instantiated sub-module [4]. By replacing any `run` statement in a program having multiple modules with the instantiated sub-module's code, we can comply with this assumption.

Unfortunately, we have some real constraints that limit the family of programs to which our abstraction is applicable.

*a) We do not support external code, i.e., code written in the host language:* The Esterel v5 compiler translates the program into a program or circuit written in a host language chosen by the user, for example C. The programmer can declare abstractly and use various function, procedures, tasks, constants and data types to be implemented in the host language and linked to the code generated by the Esterel compiler [4]. Being outside the scope of the Esterel program, its behavior cannot be taken into consideration, as our method verifies the Esterel code.

*b) We do not support cyclic dependencies between values of numerical valued objects:* In order to maintain relationships between targets and sources of assignments (as well as valued signal emissions) of numerical valued objects, we restrict the numerical data expressions used to affine transformations of values of numerical valued objects (see constraint 3 in the list below in this section). We refine a valued object $x$'s partition of (−∞, +∞) to ranges for every assignment of $x$'s value to a valued object $y$, according to the data expression, defining an equation with $x$ and $y$ which is satisfied once that assignment is executed.

Since the order of partitioning is derived from the dependencies between valued objects, if there exist cyclic dependencies[11] between valued objects then the order of partitioning cannot be determined, since no strict ordering of the partitions calculated can reflect the dependencies between the objects.

Even when an object's value is transformed and set to itself directly (e.g. `v:=3*v+1` for a variable $v$), the partitioning process should theoretically refine the partition of that object's domain to ranges over and over again, infinitely many times. One solution we considered was to allow self-assignments, in the following form: Let $P = \{R_1, R_2, ..., R_n\}$ be a partition of $(-\infty, +\infty)$ for some valued object $x$. Suppose we do not take self-assignments into consideration when partitioning, but rather leave the current partition, and define assignment as "transitioning" $x$ from its previous value's bounding range(s) to a union of ranges bounding $x$'s value following the assignment. If $x$ occurs in a formula $F$ testing $x$'s value, and an assignment causes the bound of $x$'s value to contain both ranges satisfying $F$ and ranges not satisfying $F$, we cannot decide if $F$ is satisfied. For example, suppose we compute for an integer variable $v$ the ranges [1, 8], [9, 9] and [10, 12] (among others) and we have a conditional testing the expression $v$ = 9. Consider the assignment $v$ := $v$ + 1. If $v$ is in [1, 8], and the assignment is executed, then in the next instant it can be in either [1, 8] or [9, 9], thus we cannot decide if the condition $v$ = 9 is satisfied.

To determine the order by which the partitioning process inspects valued objects when partitioning by dependency, a directed graph of valued object dependencies $G = \langle V, E\rangle$ is created in the following manner. Our inputs include the set VALOBJ of valued objects in the source program, and the set of all variable assignments and valued signal emissions

[11] The term *cyclic dependency* in Esterel usually refers to a situation where there exists an instantaneous circular dependency between a signal and itself [4] (also known as a *causality cycle*). Esterel programs that contain an instantaneous dependency cycle, for which the number of solutions is not exactly one, are considered invalid. In this section we discuss a different kind of dependency, however: a dependency between the current value of an object and its previous one, from which it is calculated. We use the terms *causality cycle* and *causality problem* to refer explicitly to a causality cycle.

which appear in the original program. $V$ and $E$ are defined as follows. For each numerical valued object define a vertex: $V = \{x \mid x \in$ VALOBJ and $x$ is of type `integer`, `float`, or `double`$\}$. The set $E$ of edges in $G$ is calculated using the following procedure.

1. $E \leftarrow \emptyset$
2. For each two numerical valued objects $v$ and $u$ in $V$:
   - 2.1. If the current or previous value of a numerical valued object $u$ is assigned to $v$ (i.e., if $v$ is a variable and there exists an assignment $v$ := *exp* or if $v$ is a signal and there exists an emission `emit` $v$(*exp*), where *exp* is a data expression with an occurrence of $u$), stretch a directed edge from $u$ to $v$; that is, add $(u, v)$ to $E$.
   - 2.2. If $G$ contains cycles, halt the process with an error message.

The order by which the process partitions the domains of valued objects is a post-order of this graph. That is, a valued object $v$'s partition is computed after the partition is computed for all numerical objects to which $v$ is assigned.

Hereby is a summary of the constraints on the programs to which our method is applicable. These compromises are basically due to two limitations:

1) One way to allow automatic methods to check a non-trivial property is to reduce the power of the language or, equivalently, reduce the class of program verifiable using the method; and
2) Technical issues with aspects of our abstraction process conflicting with the synchrony hypothesis.

The constraints are:

1) All valued objects are of type `boolean`, `integer`, or floating-point real (i.e. strings and user-defined types are not allowed);
2) All numerical formulas used in Boolean data expressions are of the form $(a{\star}D{+}b)\ R\ k$ where $R$ is an relational operator, $D$ is the current or previous value of a numerical valued object (sensor, valued signal or variable of type `integer`, `float` or `double`) and $a$, $b$ and $k$ are some literal constants;[12]
3) All numerical data expressions used in assignments and valued signal emissions are of the form $a{\star}x{+}b$, where $x$ is an occurrence of a valued object (in its current or previous value), and $a$ and $b$ are constant literals, all of which of the same domain;
4) All delayed expressions in temporal statements may not be count delays;
5) No repeat loops;[13]
6) No combined signals and no valued traps;
7) No cyclic dependencies between numerical valued objects or self-assignments (except in loop-free program segments); and
8) During one instant, the program does not access more than one incarnation of a local valued signal or a variable.

Currently the algorithm and tool support accessing the values of valued signals only during reactions in which they are present; however, this can be handled by adding signals to represent the latest value of a signal from the last time it occurs. This solution will be implemented in future versions.

The set of programs to which our method is not applicable includes, but not limited to, programs employing counters (due to a dependency of the counter by its previous value); programs performing calculations which are more complicated than allowed by constraints 2 and 3 (e.g., containing operations such as dividing by the value of some object or comparing one numerical valued object to another); and programs requiring extension in the host language. By design, Esterel's data definition facilities are minimal, since data-handling is not the primary concern in control-dominated reactive programming [4]. A major advantage of this approach is high portability of the code. To program complex systems, the programmer has to put a significant effort in implementing data handling capabilities in the host language. Without supporting host language extensions, our technique is limited to simpler, control-centric programs.

A *Proportional-Integral-Derivative (PID) controller* [11] is an example of a controller to which our method is not applicable. This controller has three terms: proportional (proportional to the error signal), derivative (proportional to the derivative of the control signal, i.e. the rate of change in the error signal over time), and integral (proportional to the integral of the error signal, i.e. the summation of error over time). To calculate the integral term, the system needs to sum of the error over time, essentially creating a cyclic dependency. However, in the high level at which robot behaviors are programmed in behavior-based robotics, proportional controllers, which our method supports, are nearly always sufficient [11]. Moreover, PID controllers are not the usual application of Esterel. Esterel, as a *state-based formalism*[14], is better suited for problems where control flow is prevalent, e.g. systems that jump between different functioning modes [13]. Another style of synchronous programming, where the system's behavior is represented as a set of recurrent equations, characterizing languages such as Signal and Lustre, is well-adapted to problems where data-flow is prevalent [13], hence being more natural for implementing PID controllers where the transfer function is repeatedly calculated.

We currently investigate means to lift some of these constraints. Some research directions appear in Section VI.

[12] Currently we support only linear equations and inequalities in one variable, for future work see Section VI.

[13] Esterel v5 offers several loop constructs: `loop`, `loop-each` and `every` (temporal loops) and `repeat`. A `repeat` loop executes a finite number of times, unlike the others, which can loop forever [4]. We do not support only the `repeat` statement.

[14] A state-based formalism uses a state transition diagram where arrows are labeled with communication actions to represent the system's behavior. The diagram can be explicit in visual formalisms such as in Statecharts or implicit in imperative formalisms such as Esterel and CSML [13].

### *State-Space Complexity Evaluation*

The complexity of the number of pure signals that the abstraction adds to the program is $O\left(N_{Bool} + N_{num} \cdot (B_{atomic} + A_{const}) + A + E + B\right)$ when there is at most one relation between every two valued objects; $N_{Bool}$ is the number of Boolean valued objects, $N_{num}$ is the number of numerical valued objects, $B_{atomic}$ is the number of atomic Boolean data expressions having occurrences of numerical valued objects, $A_{const}$ is the number of assignments of constant values to numerical valued objects, and *A*, *E*, and *B* are the numbers of variable assignments, valued signal emissions, and Boolean data expressions respectively. For more complicated situations in which there can be two or more relations between two numerical valued objects we provide a recurrence relation in [1].

In general, an automaton generated from an ESTEREL program may suffer from size explosion [14]. Increasing the number of input and output signals may significantly enlarge the sets of states and transitions of the automaton produced from the purified program compared to the one generated from the original program. In two of the examples presented in [1, Chapter 5] the number of states remains the same following the purification and for one example the number of states increases from 6 to 16. However, one must remember that the abstraction is done for verification purposes only. Moreover, a typical ESTEREL application yields a fairly small number of states, usually between 10 and 100 [14].

## V. Case Studies

The constraints described in the previous section provide an accurate characterization of the family of programs to which the method can be applied. The example in Section II demonstrates the applicability of the method to two classes of control systems within this set: bang-bang controllers and proportional controllers. Another example demonstrating the application of the method to a bang-bang controller is a temperature controller system maintaining a constant temperature in a chamber using a thermometer, a timer, and two boilers [1]. We present there also the application of our method various robot programs:

- Border-following robots using one or two light sensors.
- Bang-bang implementation of the *Home* robot behavior: a robot homes on a destination marked by a beacon using differential sensing. It is based on a program appearing in [11]. We use our technique to verify that the robot does not run over the beacon, assuming that when the robot is too close then the light intensity picked by the sensor is greater than a given threshold.
- *Escape* behavior: once colliding with an obstacle, a robot goes back a predefined distance, rotates a predefined angle and then continues moving forward. It is also based on a program that is described in [11] (though modified to use a range detector and escape once detecting a close obstacle). We verify that the robot never reaches a non-reactive state, in which it fails to find a reaction and emits an error signal.

The last two examples (Home and Escape behaviors) demonstrate the application of the method to mobile robot programming following the *reactive control paradigm*. This paradigm, based on animal models of intelligence, decomposes the overall action of the robot by behavior, allowing handling multiple goals and multiple sensors, increasing robustness and extensibility [15]. By combining various behaviors and control algorithms, complicated control systems to which our method is applicable can be derived. The full code for the examples, including original program code, abstract program code, and observer code are provided in [1].

The abstraction we propose has an advantage over complete data abstraction performed when providing the `-soft` flag to the ESTEREL compiler, since it avoids adding behaviors not displayed by the original program. For example, consider the following code portion switching on and off an actuator based on a numerical input through a sensor `S`:

```
if ?S < 90.0 then emit On end if;
if ?S > 110.0 then emit Off end if
```

The ESTEREL compiler generates with the `-soft` flag a circuit in which both conditions can be satisfied at the same time, therefore it can emit both `On` and `Off` at the same reaction. However, using our abstraction, in the purified program no two range signals representing `S` can occur simultaneously, therefore both conditions cannot be satisfied at the same time.

## VI. Conclusion

Combining the verification power of XEVE with the transformation of non-Pure ESTEREL programs into Pure ESTEREL programs, we can verify safety properties of a larger family of programs. We provided examples for various categories of programs that can be verified.

There still is a large set of programs to which we cannot apply our method, e.g. those involving complicated calculations and counters. By giving up completeness, the full potential of the technique developed is realized. Applying the technique to parts of the program that fulfill the constraints while letting the ESTEREL compiler remove the rest of the data when compiling the program into a circuit can produce a more precise over-approximation than total control-based abstraction. This is especially useful when the system consists of several subsystems, some of which fulfilling the constraints while others not. In [1] we provide an example of a system comprised of a PID controller and a limit switch. The limit switch shuts the process down by cutting off the PID controller's output once an undesired limit is reached. After the measured value drops back to the safe zone, the switch can be manually reset in order to reactivate the control system. An observer helps to verify safety properties of the system by emitting a special signal whenever the program emits the output signal while the measured value is higher than some critical threshold. Not only that the calculations performed by the PID controller are not supported by our technique, but also the program takes the set point, clock interval, and gains from constants defined in the host language. The abstraction performed by the ESTEREL compiler alone produces a circuit which XEVE reports to possibly emit the observer signal. However, using our technique to abstract the safety limit switch and the observer, which comply with the requirements of our techniques, and letting the compiler abstract the rest of the program creates a circuit which never emits the observer signal, as XEVE guarantees.

The current version of the algorithm supports only linear equations and inequalities in formulas occurring in Boolean data expressions. We plan to extend the class of supported formulas, for example to handle also univariate polynomial equations and inequalities whose the roots can found analytically, i.e. polynomials of second, third, and forth degrees; the roots can be used to partition the domain of the valued object (which serves as the variable of the formula) to intervals.

One alternative approach to perform the analysis and the abstraction is based on the constructive semantics of ESTEREL [16]. ESTEREL statements are divided into two groups: *kernel statements*, forming a primitive core of the language, and *derived statements*, which are definable as combinations of kernel statements, whose purpose is to make programming more convenient. The semantics of an ESTEREL program is obtained by structural induction on the statements which it consists of. Considering the constructive semantics of ESTEREL, it is essentially enough to define the abstraction process and prove its correctness for kernel statements to obtain a process and a proof that applies to the entire ESTEREL syntax. Yet it would require to implement a much more complicated abstraction technique, that not only finds and transforms items of interest, but also breaks-down the program to kernel statements. Our approach focuses on the occurrences of valued objects in the program, leaving the rest of the program untouched.

The TEMPEST [17] toolset provides a compiler for linear temporal logic formulas representing safety properties to observers in ESTEREL language. The automaton compiled from the observer-augmented program can be verified using other tools from the TEMPEST package. When the control flow of the program to be verified is independent of valued objects (i.e., there are no conditionals testing run-time values of valued objects), the control structure can be fully determined at compile-time, therefore the verification is both sound and complete. However, when the program's control structure depends on run-time values, the technique is sound but not complete, since the ESTEREL compiler considers all paths, including those that are unreachable due to data values [18, Section 4].

We plan to incorporate the power of TEMPEST with our method to extend both the class of verifiable properties and the class of programs to which those techniques can be applied. TEMPEST should be able to successfully verify programs where the control structure is independent on the run-time values of valued objects; therefore, TEMPEST should be directly applied to programs not complying with the constraints which our method requires, while actually not querying values of objects in conditionals. Hybrid versions may be suggested, such as purifying only valued objects on which the control-flow depends directly or indirectly, while leaving the rest of the valued objects untouched (as long as the valued objects on which the control flow depends satisfy our constraints). This, however, cannot be verified using XEVE. An additional possible research direction is extending the language used in TEMPEST to express safety properties querying the run-time values of valued objects, such as "variable $V$ can never be greater than 20". In certain cases, this might be obtained by purifying together the parallel composition of the main program and the observer component.

[1]*Abstract*—**How to educate future engineers, so that they acquired new skills and competences to become developers of Cyber Physical Systems (CPS)? The paper demonstrates a curriculum framework that was developed and successfully implemented some years ago, as an outcome of two international projects undertaken by a consortium of the European and American universities. The projects had focused on special category of CPS - Real-Time CPS. Examples of laboratory environment supporting education in the field of Real Time CPS are given in the paper.**

CYBER Physical System is an example of advanced complex technological system interfacing with physical plant and with computing environment running software intensive and most often time critical application. CPS's are often safety-critical. In case of missed time deadlines or component failures CPS may result in violating safety constraints and event life-threatening consequences. We refer to such systems as Real-Time Cyber-Physical Systems (R-TCPS).

Car airbag system is a good example of such system. When a cyber-physical safety system in a car detects a crash, the airbag must inflate in tens of milliseconds to avoid injuries of the driver. The success of the airbag system relies upon the crash sensors working accurately and extremely quickly but also upon algorithms processing in real time. Such a time-critical and safety critical functionality requires specific engineering solutions.

Typically, the challenges of R-TCPS are viewed as separate problems of data measurement, transfer, distributed control, real time operating systems, etc. Domain experts contribute individual components of a design, but they often lack cross-disciplinary knowledge of how these components interact and what impact their behavior may have on other components. As the prevalence and sophistication of cyber-physical systems increases, so does the need for developers with sufficient cross-disciplinary education. In summary, designing of R-TCPS require a multi-disciplinary and integrating knowledge, covering a broad area, from control theory to real-time computing.

The problem addressed in this paper is education: how to educate future developers of R-TCPS that would often work in multinational companies interacting with fellow engineers from different countries?

The following ABET Engineering Criteria Program Educational Outcomes were formulated for accreditation process of CPS education [1]:

- Ability to apply mathematical models of physical systems, cyber systems, and their composition.
- Ability to design and conduct simulations and tests of a cyber-physical system and to analyze the results.
- Ability to apply good engineering practices in the design of a system that mixes cyber and physical components subject to constraints including safety, security, cost, and dependability.
- Ability to function effectively on multi-disciplinary teams spanning cyber and physical domains.
- Ability to identify, formulate and solve engineering problems that have both cyber and physical aspects.
- Understanding of the professional and ethical responsibilities of the design of life- and safety-critical systems.
- Ability to communicate effectively across cyber and physical domains.
- Understanding of how design decisions in the cyber domain may affect the physical domain and visa-versa.
- Recognition of the need for, and ability to engage in life-long learning.
- Knowledge of contemporary issues with cyber-physical systems.
- Ability to select and use appropriate techniques, skills, and modern engineering tools that span the cyber and physical domains.

Most of the ABET criteria were addresses by two-year long ILERT project: International Learning Environment for Real-Time Software Intensive Control Systems (RSIC) started in 2006 [2]. The project was sponsored by the Fund for Improvement of Postsecondary Education (FIPSE) of the U.S. Department of Education and the European Commission. The project was implemented in a consortium

[1] The work presented in this paper was supported by the AGH University of Science and Technology, grants number 11.11.120.768, 11.11.120.396 and by the U.S. Department of Education FIPSE grants P116J060005 and P116J080025.

of one American (ERAU - Embry Riddle Aeronautical University, Daytona Beach, FL) and three European universities (AGH - AGH University of Science and Technology, Krakow, Poland; UJF - Université Joseph Fourier, Grenoble, France; and BUT - Brno University of Technology, Brno, Czech Republic). The academic departments leading the project represented computing, control, and telecommunication disciplines.

Based on own research and the industry surveys, the consortium faculty confirmed that modern computer control systems are heavily software-centric, implementing reactive and time critical software, where safety is the issue and the margin for error is narrow. Examples include aircraft avionics, air traffic control, space shuttle control, medical and automotive equipment, power stations and more. It is vital for future software developers to understand the basic real-time applications concepts such as the issues of timing, concurrency, inter-process communication, resource sharing, interrupts, and handling external physical devices. Generally, challenge is the situation where the physical systems operating in Newtonian (absolute) time must interface with computational systems and networks evolving in cyber time.

The purpose of ILERT project was defined as follows [2]: … {four university partners} *propose a study leading to establishment of a RSIC international, multidisciplinary curriculum framework focusing on important aspect of the computer/system/control/software engineering education. We plan to explore the mechanism for involving students from multilingual geographically separated institutions in a coordinated educational experience exposing them to the problems, methods, solution techniques, infrastructure, technologies, regulatory issues, and tools in the domain of dependable real-time safety-critical software-intensive control systems*.

The consortium members were deeply convinced that engineering curricula require continuous modifications to prepare students for the technological challenges of the modern workplace. Rapid progress of computing technologies is the major reason that the academic programs like electronics, computer and software engineering, robotics, and control engineering need continuous updates and integration of knowledge.

An additional issue was the internationalization and globalization of complex systems development. Several large companies, specifically in the aerospace industry, engage international teams working in geographically diverse locations often using diverse standards, guidelines, and processes. It is advantageous for future engineers to understand the implications of international collaboration and to appreciate cultural differences.

Successful ILERT project was subsequently continued by Dependable Systems International Research and Education Experience (DeSIRE2) project which started in 2008 [3]. Two American universities joined the consortium but only one continued and contributed to the project (UCF – University of Central Florida, Orlando, FL). The objective of this implementation project was to establish a platform for a sustained and consistent mobility exchange of students engaged in R-TCPS oriented programs. The target of the programs was to deliver on the labor market graduates, capable of working efficiently in multidisciplinary teams and participating in international collaboration on industrial R-TCPS projects, which require conformance to specific standards mandated by regulatory authorities.

This paper summarizes the results of both projects, as an example of a Real-Time Cyber-Physical Systems education framework.

## I. First Project: Curriculum Design

The first project (ILERT) started with a research phase, including the analysis of industry requirements related to graduates in the proposed domain. The collected data were analyzed and the results were used to help identify academic program learning objectives and outcomes, thus preparing a base for creation of a new curriculum framework [3].

The subsequent steps included:

- Defining learning objectives and outcomes, identifying the curriculum framework, exploring the partners' programs common features, laboratory infrastructure, identification of the curricula contents, and analysis of the educational process assessment. One needs to note, that the existence of common characteristics did not imply automatic commonality of the ways how individual institutions pursued common educational objectives. Universities often find their own methods to let shared content shape the development of procedure and instructional delivery.
- Defining the roles of the project partners and focus of interest. Considering the four universities strengths in various areas such as control, software engineering, telecommunication, and embedded systems, the consortium defined as their point of interest Real-time Software-intensive Control (RSIC) - a subset of RT-TCPS domain.
- Curriculum development included two complementary groups of activities. The first one, more general, had focused on methodology and process of creation of a unique and curriculum framework in the area of real-time software-intensive control, which combines elements of control, software, and computer engineering programs. Such curriculum was in high demand by industry as shown in earlier industry surveys and interviews. The second was a practical case study adapting a selected RSIC curriculum unit acceptable for engineering programs in four organizations. The curricula were reviewed to prioritize and integrate the various elements in order to meet the learning objectives and demands of interdisciplinary specialization in Real-Time Software-Intensive Control serving RSIC. An appropriate sequence of courses was proposed.

- Credit transfer and accreditation issues. The development of new curriculum framework in information technologies may require new approaches to validate and accredit learning. Existing and emerging structures for accreditation, quality control and credit transfer (such as the European Credit Transfer and Accumulation Scheme) were analyzed and coordinated. The proposed curriculum units, focusing on the objectives and outcomes of the educational activity, were developed according to the U.S. Accreditation Board of Engineering and Technology (ABET) standards as well as the applicable standards of Ministry of Higher Education in the European countries.
- Students mobility. Based on the developed curricula, students' mobility between partners institutions was proposed, opening possibility of collaborating and enrolling in the same course offered concurrently in four partner sites.

The project identified six RSIC Framework areas [4]: Software Engineering, Digital Systems, Computer Control, Real-Time Systems, Networking, and Systems Engineering.

1. Software Engineering: software engineering concepts and practices, lifecycle models, project management, processes, software modeling and formal representation; software requirements; software architectural and module design; software construction methods and practices, testing and quality assurance; software maintenance, notations and tools.
2. Digital Systems: methods, techniques, and tools used to support the design of combinational and sequential digital circuits and the design of fault tolerant and advanced networked hardware components.
3. Computer Control: concepts of feedback control, continuous vs. discrete models of dynamic systems, simulation, controller design, implementation of control algorithms in real-time, integrated control design and implementation (hardware-in-the-loop), security aspects, implementation for physical processes.
4. Real-Time Systems: timing and dependability properties of software intensive systems, RTOS concepts and applications, concurrency, synchronization and communication, scheduling, reliability and safety aspects.
5. Networking: data communication, network topology, analysis and design, information security, algorithms, encryption, bus architectures, wireless, distributed control and monitoring.
6. System Engineering: system engineering concepts, principles, and practices; system engineering processes (technical and management), system requirements, design, integration, and testing; special emphasis on the development of a RSIC system and the integration of RSIC system elements.

The basic organizational unit for this framework was RSIC "component". A RSIC component was defined as a curriculum unit covering theory, knowledge, and practice - supporting the RSIC objectives and outcomes. The proposed RSIC Curriculum Framework did not specify the way in which component topics might be formed into modules or courses reflecting the RSIC concept. Component topics were focused in one or two courses, or spread among several courses, along with other non-RSIC topics. For each component more detailed didactic aspects were defined such as: the prerequisite knowledge, component learning objectives, information about required facilities and equipment, and guidelines and suggestions for course design and delivery.

In addition to the above six RSIC Framework areas, additional institutional, regional, or national requirements in areas of "general education" were required to be added to the curricula as, for example, requirements for oral and written communication, for arts and humanities, or for the social sciences. These areas also supported the RSIC curriculum objectives and outcomes related to ethical and professional responsibility, effective communications skills, ability to work as part of a team, and lifelong learning. Each ILERT partner analyzed how the framework could be applied to their program. The challenge was to maintain the program integrity and at the same time include all necessary elements of the RSIC Framework.

## II. Second Project: Student Exchanges

Subsequently, another project received support from both FIPSE and European Commission under umbrella of Atlantis Program designed to support trans-Atlantic student mobility exchanges between Europe and USA. The objective of Dependable Systems International Research and Educational Experience project (DeSIRE2) [4] was to train engineering students to achieve global competency and to provide exposure for the students to work in international settings with foreign partners, to get opportunity for exploring the host country language and customs, and to make available instruction the students in the areas not available in the home school.

The learning objectives and outcomes of DeSIRE2 project were to prepare specialists to solve problems in a multidisciplinary way utilizing wide range of CPS domains. The expected graduate student competencies provided by completion of the DeSIRE2 program were as follows:

- Demonstrate professionalism in work and grow professionally through continued learning.
- Demonstrate understanding of analysis and design to implement software-intensive systems.
- Demonstrate understanding of analysis and design to implement control systems.
- Apply advanced software engineering techniques to implement real-time concepts.
- Implement a rigorous quality assurance process.
- Implement hardware/ software integration.

- Demonstrate knowledge of the principles and techniques needed for the analysis and design of a system form dependability perspective.
- Assume a variety of roles in teams of diverse membership.

According to the initial plans, the student mobility was to be distributed between the original six consortium partner universities: three from the EU in cooperation with three universities from the US. During the first year of the project a multilateral Memorandum of Understanding (MoU) was signed by partners' schools. The memorandum stipulated the conditions of: mobility exchange period, tuition and enrollment, student eligibility, student and faculty mobility, and student selection. Due to legal issues, the third American university left consortium in the first year not contributing to the mobility exchanges.

Each consortium university partners had a dedicated unit in their organizational structure handling foreign students' exchanges and supporting the recruitment. Students received support in both pre- and post-mobility activities. The project contact faculty at each university served as the focal point to advise, guide, and help both local and the visiting students.

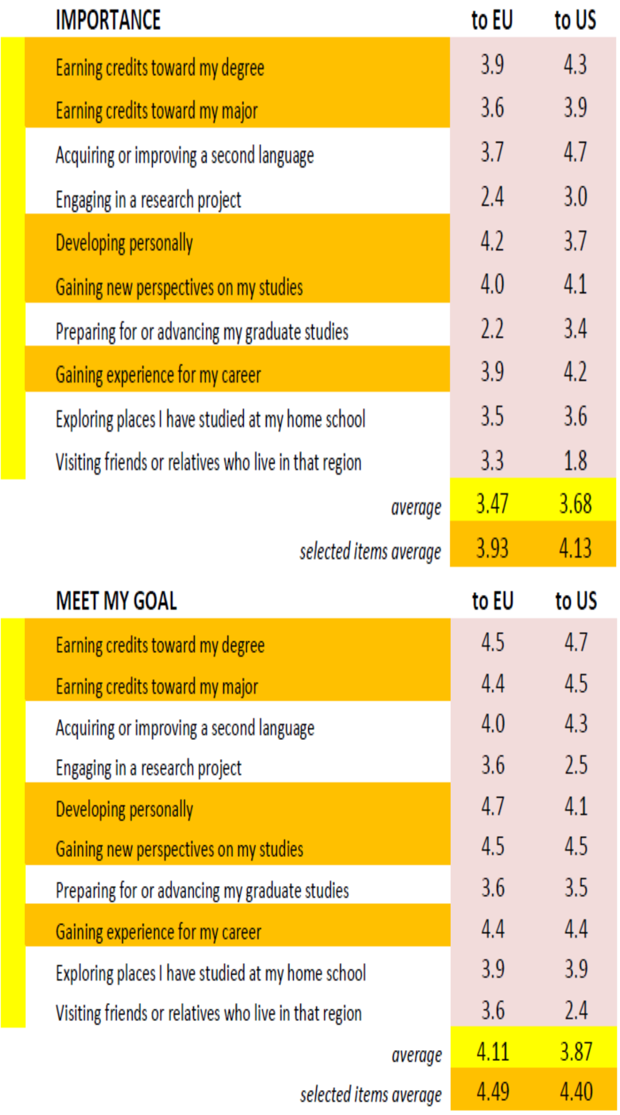
Individual program of study was developed for each candidate. The reason was that students from partner universities have had different capabilities and knowledge base due to the differences of their local academic programs. Therefore, it was necessary to shift from courses forcing the "one size fits all" approach to courses accommodating individual learning paths. Such paradigm shift was supported by the "component" approach described in the Section 2.

Due to the individual nature of each exchange and necessity to find appropriate selection of courses, the task of creating an individual learning path for a single exchange was rather complicated. The logistic of the mobility exchange required a candidate student to register for course work at the home institution in coordination with the local mobility exchange project contact faculty, who helped the student to find an appropriate set of courses in one of the overseas partners' schools. The main objective was to focus the individual plan of study in the area related to DeSIRE2 project specialization. The students then took the course overseas, with the grade passed back to the home school international office and recorded with the school registration office (or a dean office) for inclusion in the student's official record. The administrative issues such as course equivalency, satisfying the student's program core requirements, prerequisite requirements etc., were usually approved by the Faculty Dean and appropriate graduate program coordinator in advance before commencement of the mobility exchange. The approved courses were counted towards a degree at the home institution. The mechanism of ECTS/US credits equivalents, as defined by the MoU, was applied.

The consortium partners exchanged 36 students (nineteen from US studying in Europe and seventeen EU students studying in the US) achieving nearly balanced mobility exchanges participation. It needs to be noted that the consortium faced significant challenge recruiting American students. The major obstacles were constraints of academic calendar, missing opportunities of earning while abroad and thus related financial issues, and difficulties with finding appropriate set of courses to be credited to the student transcript [5].

The project requested students to complete post-mobility survey. The sample of students engaged in the mobility is still statistically insignificant, but the post-mobility surveys they filed provide interesting observations. At the project completion we collected total of 30 surveys (83% return rate): 15 from European students studying in the USA and 15 from the American students studying in Europe.

On a scale of 1 (negative) to 5 (positive), the level of satisfaction related to the program merit, in terms of importance and meeting the goals, are for American students in Europe 3.93 and 4.49 respectively, while for European students in the USA they are 4.13 and 4.40 (Figure 1).

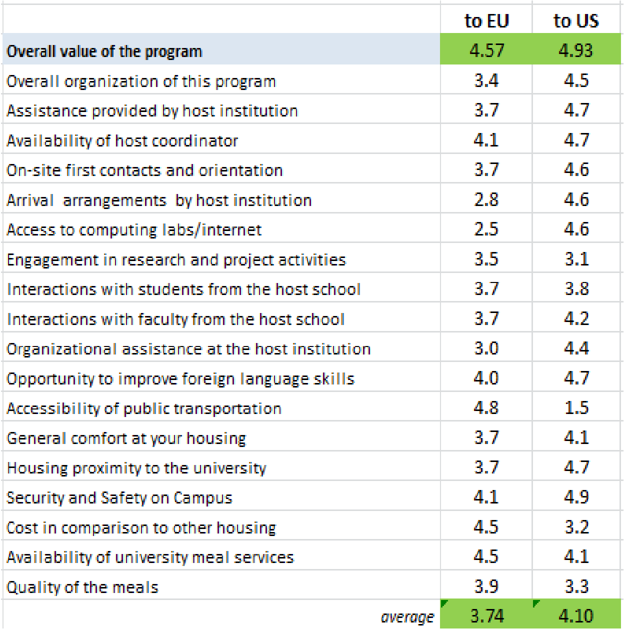


| IMPORTANCE | to EU | to US |
|---|---|---|
| Earning credits toward my degree | 3.9 | 4.3 |
| Earning credits toward my major | 3.6 | 3.9 |
| Acquiring or improving a second language | 3.7 | 4.7 |
| Engaging in a research project | 2.4 | 3.0 |
| Developing personally | 4.2 | 3.7 |
| Gaining new perspectives on my studies | 4.0 | 4.1 |
| Preparing for or advancing my graduate studies | 2.2 | 3.4 |
| Gaining experience for my career | 3.9 | 4.2 |
| Exploring places I have studied at my home school | 3.5 | 3.6 |
| Visiting friends or relatives who live in that region | 3.3 | 1.8 |
| *average* | 3.47 | 3.68 |
| *selected items average* | 3.93 | 4.13 |

| MEET MY GOAL | to EU | to US |
|---|---|---|
| Earning credits toward my degree | 4.5 | 4.7 |
| Earning credits toward my major | 4.4 | 4.5 |
| Acquiring or improving a second language | 4.0 | 4.3 |
| Engaging in a research project | 3.6 | 2.5 |
| Developing personally | 4.7 | 4.1 |
| Gaining new perspectives on my studies | 4.5 | 4.5 |
| Preparing for or advancing my graduate studies | 3.6 | 3.5 |
| Gaining experience for my career | 4.4 | 4.4 |
| Exploring places I have studied at my home school | 3.9 | 3.9 |
| Visiting friends or relatives who live in that region | 3.6 | 2.4 |
| *average* | 4.11 | 3.87 |
| *selected items average* | 4.49 | 4.40 |

Fig.1. DeSIRE mobility exchanges: importance and meeting goals

The satisfaction survey results show that the overall value of the program was nearly perfect 4.93 for European students visiting USA and 4.57 for Americans in Europe. The averages of the relevant survey items are: 4.10 for the European students in USA and slightly lower 3.74 for the Americans in Europe (Figure 2). Statistical t-test analysis allows us to state with 88% confidence that the experiences of European students in USA seem to be more positive that their counterpart in Europe.



| | to EU | to US |
|---|---|---|
| **Overall value of the program** | 4.57 | 4.93 |
| Overall organization of this program | 3.4 | 4.5 |
| Assistance provided by host institution | 3.7 | 4.7 |
| Availability of host coordinator | 4.1 | 4.7 |
| On-site first contacts and orientation | 3.7 | 4.6 |
| Arrival arrangements by host institution | 2.8 | 4.6 |
| Access to computing labs/internet | 2.5 | 4.6 |
| Engagement in research and project activities | 3.5 | 3.1 |
| Interactions with students from the host school | 3.7 | 3.8 |
| Interactions with faculty from the host school | 3.7 | 4.2 |
| Organizational assistance at the host institution | 3.0 | 4.4 |
| Opportunity to improve foreign language skills | 4.0 | 4.7 |
| Accessibility of public transportation | 4.8 | 1.5 |
| General comfort at your housing | 3.7 | 4.1 |
| Housing proximity to the university | 3.7 | 4.7 |
| Security and Safety on Campus | 4.1 | 4.9 |
| Cost in comparison to other housing | 4.5 | 3.2 |
| Availability of university meal services | 4.5 | 4.1 |
| Quality of the meals | 3.9 | 3.3 |
| *average* | 3.74 | 4.10 |

Fig.2. DeSIRE mobility exchanges: satisfaction survey

Due to the demanding nature of engineering courses conducted in English in three European partner universities, the issue of the language instruction was not a priority. However, the exchange students engaged in language and/or cultural instruction classes, participated in a variety of activities to learn the host country, interacted with their peers from the host school, and in general were satisfied with the opportunity to travel and explore different cultures. The native Slavic languages in two European partner universities were rather difficult to learn for the American students – except those with the specific country heritage that may already know the language (being typically an additional initiative to apply for the mobility exchange)

Additionally, faculty mobility exchanges were conducted to support: lectures delivery at the host institutions related to the objectives of the project, pre-mobility orientations and program promotion at host institutions, face-to-face meetings with mobility candidates and active mobility students, and planning/co-ordination meetings with the host university faculty and administration.

A dedicated website supporting the student exchange was maintained and systematically upgraded, containing up-to date information about the project objectives, activities, outcomes, progress and deliverables. One of the requirements of the mobility exchange completion was for the students to create personal blogs reflecting their experiences. The blogs were linked from the project website (http://www.desire.agh.edu.pl/).

All students engaged in the program had very positive impression of their mobility stay and appreciated the opportunity provided by the project funding. In general the students expressed positive feedback related to the general study abroad experience. Only few comments from post-mobility surveys addressed the actual classroom experience.

- To Europe:
  - *...academic system is a little harder than US because of the lack of assignments and the dominant influence of the exams (midterm and final) on your grade for the class* (ERAU->UJF).
  - *...enjoyed very much the curriculum and the hands on approach of the courses, especially the opportunity to practice our newly gained knowledge through the academic project. I believe that this experience thought me a lot on more than just academic knowledge but it also allowed me to grow on a more personal level* (UCF->UJF).
- To USA:
  - *...engineering and software departments are also very good here. There is lot of interesting projects, classes. Another great thing is that the teachers are mostly people that are working or worked in the field they are now teaching, i.e. I had Software Project Management class with the instructor from Boeing Company – a real software project manager* (AGH->ERAU)
  - *... this was a real experience for me abroad. It brought me a lot of knowledge in certain class and a new method of working* (UJF->ERAU).

## III. Implementation Examples

Hands-on learning approach was proposed for the majority of RSIC components. This approach involves learning experience which enhances student's ability to think critically. The student must plan an experiment to test a hypothesis, put the experiment into motion, see the experiment to completion, and then be able to explain and interpret the experiment's results. Another hands-on experience has been engagement in a team project requiring students to analyze the problem, specify system requirements, find appropriate solution, resulting in designing and implementing a small scale cyber-physical system. Two selected examples are provided below.

### *A. Example 1: CPS Laboratory Experiment*

The example of lab environment supporting education in Real-Time Cyber-Physical Systems is provided below [6].

The goal of this educational module (lectures and practical training) is to familiarize students with industrial Ethernet IP technology studying a model of an industrial Allen Bradley Networked Programmable Logic Controller (PLC) connected through different gateways to the physical system (model of air lift). The system uses distance measurements and implements control signals in a similar way to typical industrial process. Students became familiar with essential characteristics of data transmission networks and with the influence of the network parameters on control quality of the physical system. Students also work with several standard testing methods and items of industrial equipment.

The Ethernet IP laboratory, shown in Figure 4 consists of six data transmission nodes: CompactLogix L35E Programmable Logic Controller, POINT_IO: 1734-AENT, PowerFlex 40 inverter, WAGO 750-341 Coupler, Internet Camera (WebCam), and PanelView 600 Plus – Touch Panel.

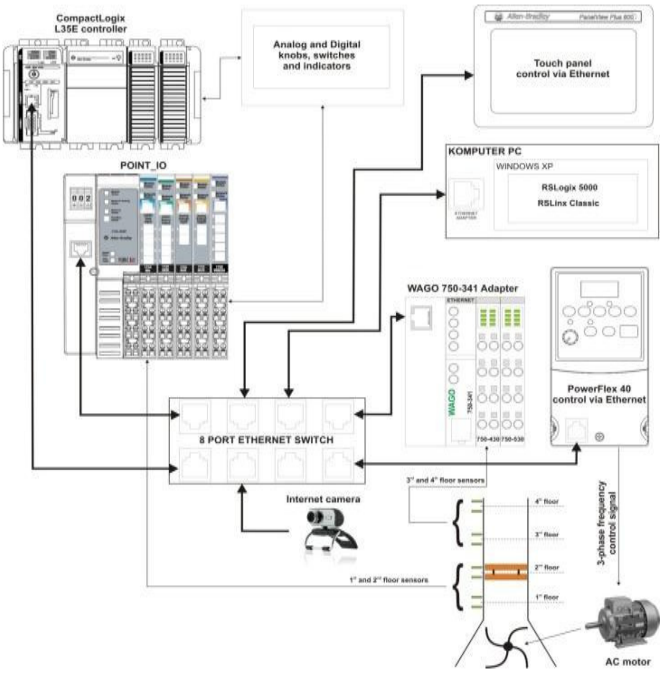


Fig.3. Laboratory Setup

A standard personal computer is used as a development and Ethernet monitoring platform and the web camera generates noise imitating the network data traffic.

The major issues for consideration by the students were: (a) analyze the Ethernet/IP packets and Ethernet network parameters (throughput, round trip time etc.) by utilizing the Wireshark application, (b) diagnose and analyze the jitter for a several scan times and the RPI parameter (Request Packet Interval), and (c) find the effects of load Ethernet network on stabilization of the position of the Aero-lift.

The physical system used in the module is Aero-lift. The test-rig contains the blower based on three-phase drive controlled by the inverter, a pipe for vertical motion of the cart and eight discrete sensors to measure the cart position (see Figure 4). The Aero-lift is an example of the dynamic system sensitive for sampling time and latency in data transmission. With this set-up a number of consequences caused by the inaccurate settings for Ethernet modules and I/O blocks can be observed.

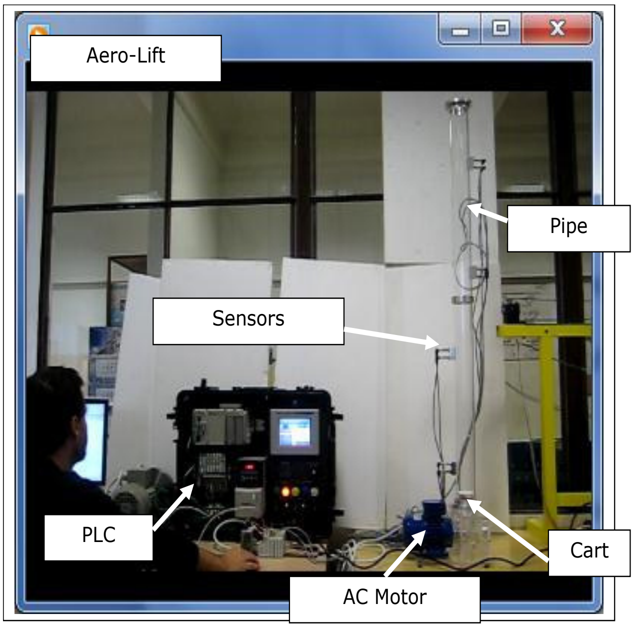

Fig.4. Physical system used in the laboratory setup

The offered laboratory demonstrates all the features and includes all components expected for Cyber Physical Systems: industrial equipment reflecting real physical plant, computing environment, time critical software, and distance data transfer. The laboratory shows that traditional real-time performance guarantees are insufficient for CPS when system components are spatially distributed and connected via data transmission networks.

## *B. Example 2: Teamwork Development of a CPS*

The consortium members recognized the demand for efficient development of quality RSIC/ CPS systems and need for an international learning environment. An innovative learning approach was implemented involving students from multilingual, geographically separated institutions in a coordinated educational experience in laboratory CPS development [7]. The project was realized as a component of the ILERT engaging on-site students and faculty of universities from four countries (USA, Poland, France, and Czech Republic).

The technical objective of the project was to develop real-time software packages for two robots (physical system) that cooperate in searching for a target in a simple maze. The target search in the maze was designed to simulate a practical example a rescue problem.

The two robots were considered to work within the limited operating area. The robots were assigned different roles: The "Leader" Robot starts in one of the four corners and, according the implemented algorithm, it is searching for the black square that is positioned in the center of the maze. The "Follower" Robot starts in one of the four corners (which may be different that the starting corner of the

Leader Robot) and according the information received from the Leader robot it attempts to find the black corner is a shortest possible time. The use of rigorous software development process was emphasized and the comprehensive documentation was expected as an integral part of the project's outcomes. Team cooperation and related intensive inter- and intra-team communication was also assumed. Each team was responsible for their developed components from the initial phases of analysis and design through component implementation to integration and testing.

The two major Project Learning Objectives were focusing on the Process and Product:

- Process - effective work in multicultural and multidisciplinary teams including such aspects as team organization and planning, team communication, and project management.
- Product - development of an RSIC system resulting in developing real-time embedded software, hardware and software system integration, implementation of digital control in real time, design/implement communication protocols.

To meet the above objectives, international students' teams have worked on robotic design and control experiments with LEGO MINDSTORMS NXT kits.

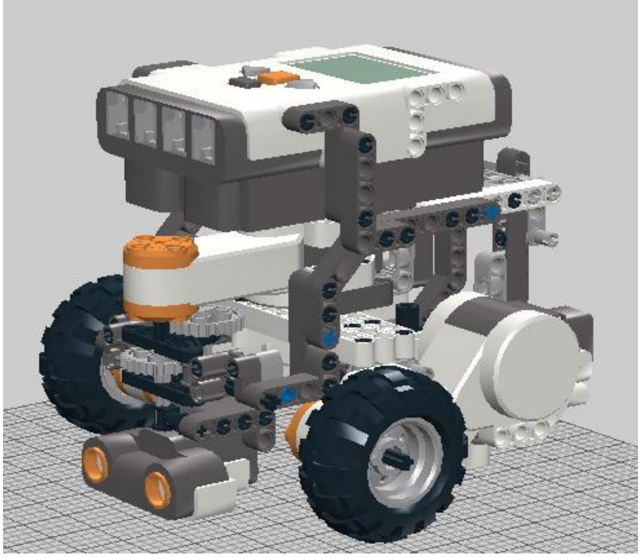

Fig.5. Design of three wheels robot construction

The basic problem was an accurate and precise motor control. The error in the motor control can affect the correct navigation and robot movements. From the educational viewpoint it was not so important that the robot moves, but how precise it operated and what was the accuracy of the controlled devices.

LEGO-MINDSTROMS NXT kit (Fig. 5) was selected as a common platform for students' teams. The used LEGO platform proved flexible enough to achieve both technical learning objectives. A Web-based Project Management System (WebPMS) was used to improve communication and test Internet based tools for inter-university collaboration.

The programming solutions related to LEGO NXT were implemented in open source NXC (Not Exactly C) - a text-based language for MINDSTORMS® NXT robot microcontroller. The language supports multitasking on standard LEGO firmware. With freely available BrixCC Integrated Development Environment (IDE) it was possible to create quite complex and advanced data acquisition and control algorithms operating concurrently and in real-time, including file management and communication features. A custom Bluetooth communication program was designed and implemented so the robot(s) movements could be monitored and displayed on the host.

## IV. Conclusion

Cyber-Physical Systems are a novel category of engineering systems, involving closely interacting physical and computational components. In the CPS, control algorithms, embedded hardware, real-time software, and communication are closely intertwined while the digital cyber components are connected interacting with the physical real-world processes. Due to interaction with the environment and people, the issues of dependability and performance while meeting the functional requirements are of primary concern. It is critical that the future CPS developers are proficient in these multidisciplinary projects while being able to work with professionals representing different skills and organizational affiliations.

The laboratory environment delivers required features and includes all components expected for Cyber Physical Systems: physical plant, computing environment, software intensive and time critical, distance data transition.
CPS technology challenges included: CPS data acquisition, data precision, time dependencies, the critical elements of modern CPS, quality assurance and integration; data and information analytics, control algorithms and rigorous software development process. In particular, assures compliance with an important CPS education criterion formulated by ABET: "ability to function effectively on multi-disciplinary teams spanning cyber and physical domains".

The international consortium of universities, with support of the U.S. Department of Education FIPSE and the European Commission projects, has been engaged in the CPS related educational activities at graduate levels since 2007. The objective of these educational activities was to educate students in the principles and design issues in CPS and to develop student competency to be comfortable working in an international setting collaborating across the nations' boundaries. It was found that it has been easier to achieve these multi-disciplinary and integration-focused knowledge and skills required for the CPS education when engaging a group of universities, rather than when attempting to achieve them within a single university. Students' feedback confirms that they truly enjoyed the program, and they expressed great interest in future participation in the CPS related activities.

To continue potential future cooperation after project completion and expiration of the multilateral agreement, the participating universities signed bi-lateral agreements stipulating continuing cooperation in the area of the CPS, with both faculty and student exchanges.

□

*Abstract*— **Time Petri Nets (TPN) are a well-known formalism for modelling time-dependent systems with timing constraints. This paper proposes an approach based on a stochastic extension of TPN (sTPN), which enables both qualitative assessment of feasible temporal behaviors through model checking, and quantitative evaluation of a probability measure of a given behavior, by statistical model checking. The experimental work rests on the use of the latest version of the UPPAAL toolbox which supports both exhaustive non deterministic analysis and statistical model checking of system properties. The approach is demonstrated through an example.**

## I. Introduction

The development of safety-critical software systems is challenged by the needs of addressing both functional and temporal correctness issues. Violation of timing constraints can have important consequences in the practical domain (e.g., economy, medicine, cyber physical control systems, etc.). Therefore, it is highly recommended the use of formal tools for modelling and analysis of concurrent and timed software.

From the point of view of analysis, both qualitative verification and quantitative evaluation of system properties are nowadays advocated by engineers and developers. Whereas qualitative verification of a system model tries to identify feasible behaviors, quantitative evaluation aims to associate them a measure of occurrence probability.

Qualitative verification is often based on the exhaustive enumeration of all the possible execution states of a model, organized in the so called model *state graph*, and on checking desired properties through efficient traversal algorithms on the state graph. To avoid an infinite growth of the state graph, each state node is implemented as a couple: a *discrete data part*, and *a dense time part*. The time component typically stores in a compact way (*zone*) all the clock (timer) inequalities which hold in the state. As a consequence, a state is in reality a *state class* which subsumes an infinite number of states which could be reached by only changing the clock values (firing times of transitions).

Despite the use of state classes, depending on the system model, the state graph can suffer of state explosion problems. In addition, the construction and navigation of the state graph can become undecidable when a complex combination of modelling factors (non-deterministic time of actions, sporadicity of process arrival, message passing, stochastic aspects etc.) occurs. In these cases, the study of system properties can only be approximated, e.g., through simulation.

Qualitative non deterministic verification based on model checking [1] has been demonstrated by Time Petri Nets [2]-[5] and Timed Automata [6] based tools, e.g. [7]-[12]. Quantitative evaluation of system behavior is supported by recent extensions to the ORIS tool [8] and by latest versions of UPPAAL [9]-[11] which include a statistical model checker (SMC) [13].

This paper proposes an original approach to qualitative and quantitative evaluation of systems with timing constraints which is based on the Time Petri Net (TPN) formalism which is very often used for modelling real-time and embedded systems, communication protocols etc. To permit both non-deterministic analysis and stochastic analysis of system properties, a stochastic extension of TPN (sTPN) [14] is also considered. The contribution of the paper consists in a mapping of TPN/sTPN onto UPPAAL so as to exploit, on a same model, both the exhaustive model checker and the stochastic model checker.

Whereas the support of sTPN in the ORIS tool is based on the concept of *stochastic state class* and *stochastic state graph*, i.e., a density probability distribution function is attached to each state class which characterizes the possible stochastic evolutions from it, i.e., estimating the probability of the outgoing state transitions, the use of sTPN in UPPAAL rests on batches of simulation runs and statistics inference of desired results from these runs. As a consequence, ORIS can provide a greater resolution on the probability measures. However, this paper argues that the proposed approach based on UPPAAL has the following strengths: (1) it is based on a popular and efficient toolbox, (2) it does not incur in an infinite stochastic state graph nor suffer of stochastic state explosion problems as discussed in [14] (3) it in any case can provide quantitative measures of probability which are valuable from the engineering point of view.

The paper is structured as follows. Section II provides basic definitions of TPN and sTPN formalisms. Section III

□ This work was not supported by any organization

describes a modelling example. Section IV gives an overview to non-deterministic analysis and stochastic analysis enabled by UPPAAL. Section V discusses the developed structural translation from TPN/sTPN to UPPAAL. Section VI illustrates the application of the proposed approach to a thorough property assessment of the model described in Section III, by detailing qualitative and quantitative analysis. Section VII concludes the paper by indicating directions of on-going and future work.

## II. Time Petri Nets Definitions

A basic TPN is a tuple $(P, T, B, F, M_0, I_{nh}, EFT^s, LFT^s)$ where:

- $P$ is a finite nonempty set of places;
- $T$ is a finite nonempty set of transitions;
- $P \cap T = \emptyset$;
- B is the backward incidence function, $B: P \times T \to \mathbb{N}$, where $\mathbb{N}$ denotes the set of natural numbers;
- $F$ is the forward incidence function, $F: P \times T \to \mathbb{N}$;
- $I_{nh}$ is the set of inhibitor arcs, $I_{nh} \subset P \times T$ where $(p,t) \in I_{nh} \Rightarrow B(p,t) = 0$;
- $M_0$ is the initial marking function, $M_0: P \to \mathbb{N}$, which associates with each place a number of tokens;
- $EFT^s: T \to R^+$ is a function which associates each transition with a (finite) earliest static firing time. $R^+$ denotes the set of non-negative real numbers;
- $LFT^s: T \to R^+ \cup \{\infty\}$ is a function which associates each transition with a (possibly infinite) latest static firing time. In any case it must be $LFT^s \geq EFT^s$.

Differently from [13], in this work TPNs admit both inhibitor arcs and non-unitary arc weights.

The state of a TPN is a pair $s =< m, \tau >$ where $m: P \to N$ is the net marking, and $\tau: T \to R^+$ associates each transition with a (dynamic) *time-to-fire* (clock or timer). The state evolves according to the *firability* and *firing* clauses.

A transition $t$ is *enabled*, as in classic Petri nets, if each of its input places contains sufficient tokens, i.e., iff

$$\forall\, p \in P, (p,t) \in I_{nh} \Rightarrow M(p) = 0\ \wedge \\ B(p,t) > 0 \Rightarrow M(p) \geq B(p,t)$$

Transition $t$ is *firable* if it is enabled and its time-to-fire $\tau(t)$ is not higher than that of any other enabled transition.

When $t$ fires, the state $s =< m, \tau >$ is replaced by a new states $s' =< m', \tau' >$ where marking $m'$ is derived from $m$ by the withdrawal of tokens from the input places and the deposit of tokens in the output places. More precisely, the firing process consists of the two (atomic) phases:

$$m_{int}(p) = m(p) - B(p,t) \text{ (withdraw phase)} \\ m'(p) = m_{int}(p) + F(p,t) \text{ (deposit phase)}$$

Transitions which are enabled in the intermediate marking $m_{int}$ (and then also in $m$) *and* in the final marking $m'$ are said *persistent* to the $t$ firing. Transitions which are enabled in $m'$ but not in $m_{int}$ are said *newly enabled*.

A transition which is multiple enabled in a state $s$ is supposed to consume its enablings one at a time (*single server* semantics). Therefore, after its own firing, would $t$ be still enabled, it is regarded as a newly enabled one.

For any transition $t_p$ which is persistent to the firing of $t$, its time-to-fire is reduced, in the new state $s'$, as follows:

$$\tau'(t_p) = \tau(t_p) - \tau(t)$$

For any newly enabled transition $t_{ne}$ its time-to-fire is constrained to occur not deterministically in its static time interval:

$$EFT^s(t_{ne}) \leq \tau'(t_{ne}) \leq LFT^s(t_{ne})$$

### A. Stochastic extensions

An sTPN [14] specializes a basic TPN as follows. The set of transitions is partitioned into two subsets: $T = T_1 \cup T_2$, where $T_1 \subseteq T$ is the subset of *timed transitions*, $T_2 \subset T$ is the set of *immediate transitions*. Besides its static time interval, a timed transition is attached a probability density distribution function $PDF: T_1 \to R^+$, which is constrained in the static time interval $[EFT^s, LFT^s]$ of the transition. It is also said the static time interval is the *support* of the pdf. An immediate transition is attached a real positive weight $\pi: T_2 \to R^+$.

The semantics interpretation of an sTPN is as follows. Immediate transitions (as in Generalized Stochastic Petri Nets –GSPN- [15]) always fire *before* any timed transition, and consumes no time. The set of simultaneously enabled immediate transitions in the current state constitutes a *random switch*, i.e., each immediate transition $t_i$ is firable with probability

$$Prob(t_i) = \frac{\pi(t_i)}{\sum_{t_j \in T_2 \text{ and } t_j \text{ is enabled}} \pi(t_j)}$$

The time-to-fire $\tau(t)$ of a timed transition $t$ is stochastically defined, at its enabling instant, by sampling the $PDF(t)$ with the constraint:

$$EFT^s(t) \leq PDF(t) \leq LFT^s(t)$$

As an example, the $PDF$ of a timed transition can be (default) a uniform distribution function which picks up a value in the static time interval of the transition, or a negative exponential distribution function. However, in the general case, a timed transition can follow a generally distributed function constrained in the support time interval.

Firing of a timed transition follows the same rules as in basic TPNs.

## III. A Modelling Example

Fig. 1 depicts a TPN model [14] made up of two (almost identical) production cells, identified by suffixes 1 and 2, which operate sequentially and cyclically.

Each cell admits two parallel activities named JobA (t1, t7) and JobB (t2, t8). JobA requires the use of a resource res (places p2 and p9) which may fail during the usage. In the case of failure, JobA is not completed, and a recovery action recA (t5 and t11) is instead executed which replaces the normal behavior provided by JobA. A failed resource is repaired by a repair transition (see t3 and t9). The execution of a production cell is started by the start transition (t0, t6). A cell logically terminates its current production phase when a token is generated in the couple of termination places (p5, p6) or (p12, p13).

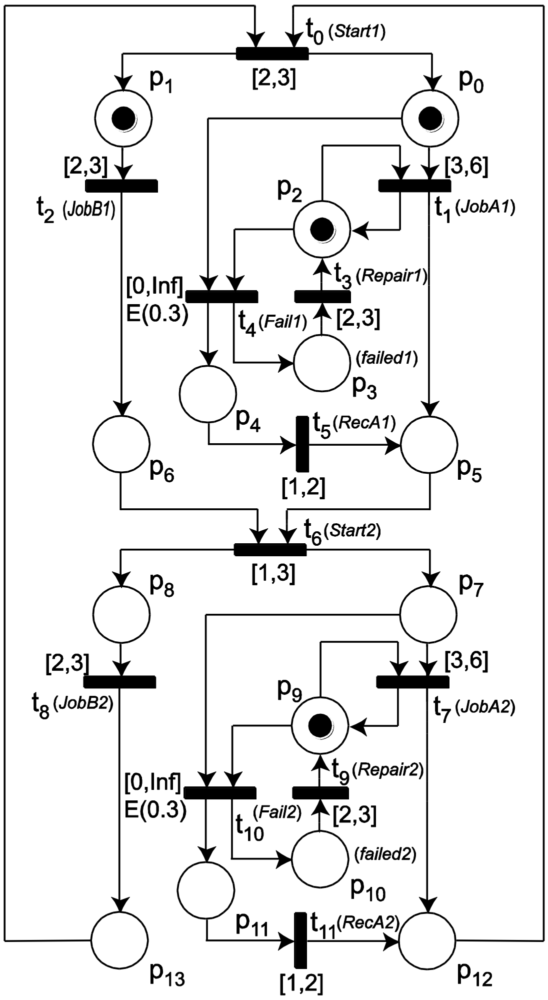

Fig. 1 A TPN/sTPN model with two production cells

All the transitions in Fig. 1 are supposed, in the stochastic interpretation, to be served by a uniform distribution in the associated static time interval, with the exception of the failure transitions (t4, t10) which have a support interval of [0,∞] and an exponential distribution function whose rate is $\lambda = 0.3$, as witnessed by the notation E(0.3) attached to the transitions.

The use of [0,∞] as the time interval of a failure transition is noteworthy. In both non-deterministic and stochastic interpretations the failure cannot occur later than 6 time units measured from the time instant in which the failure transition gets enabled. This happens because of the [3,6] time interval of the JobA transition, which forbids the failure to occur later than 6. In the stochastic interpretation, however, something subtle occurs. Due to the exponential distribution E(0.3), the failure is expected to happen with a very low probability, as the sample chosen from the E(0.3) pdf can be much greater than 6 and thus later with respect to the completion time of the JobA activity. All of this reflects the different concerns of non-deterministic analysis and stochastic analysis (see later in this paper).

## IV. Uppaal Concepts

The popular and efficient Uppaal toolbox [9]-[10] allows modelling and verification of time-dependent systems. An Uppaal model consists of a network of timed automata (TA) [6]. TA are designed as *template processes*, which can have parameters, can be instantiated, and consist of *atomic actions*.

TA are extended with local or global integer (and boolean) variables and arrays of integers, clocks and channels. In latest versions of the toolbox, C-like functions and structures are also permitted. Time is dense and can be controlled by means of *clock* variables. Clocks can only be reset and compared against nonnegative integer constants.

All the clocks of a model increase automatically with the same rate of advancement of the hidden system time. TA synchronize to one another by CSP-like channels (*rendezvous*) which carry no data values.

Asynchronous communication is provided by broadcast channels where a single sender can synchronize with a (possibly empty) group of receivers. The sender of a broadcast signal in no case is blocked. Locations (states) of an automaton are linked by *edges* (transitions).

Every edge can be annotated by a *command* with three (optional) elements: (i) a *guard*, (ii) a *synchronization* (? for input and ! for output) on a channel, and (iii) an *update* consisting of a set of clock resets and a list of variable assignments. Channel synchronization implies the commands of the sender and of the receiver(s) are jointly executed. However, the update of an output command is executed *before* that of a matching input command.

An atomic action consumes no time and refers either to the execution of an internal command of one automaton or to a joint execution of the multiple commands during a synchronization among two or more TA.

A clock *invariant* can be attached to a location as a *progress* condition. The timed automaton can remain into the location as long as its invariant holds. Uppaal supports also *committed* and *urgent* locations which must be exited immediately (i.e., without passage of time), and *urgent channels* whose synchronizations must be fired without passage of time. Committed locations, among them, can be interleaved. Similarly, urgent locations, among them, can be interleaved. However, committed locations have priority with respect to urgent locations.

The symbolic model checker of UPPAAL handles the parallel composition of the TA of a model. Parallel composition means generating all the possible action interleavings of the component concurrent processes.

UPPAAL consists of a graphical editor, a simulator and a verifier (the symbolic model checker verifyta). For exhaustive property assessment, the verifier tries to build the reachability graph of the model, where each state node holds a *data part* (variable values and location of each automaton) and a *firing domain* (time zone or clock inequalities system). The time zone implies each state graph node actually represents a *class* of equivalent states which fulfill the clock inequalities. The simulator executes a system model and visually documents the reached execution state by following a particular path in the model state graph. The simulator is useful for model debugging and to examine a diagnostic trace (counterexample) created by the verifier, e.g., when a property is not satisfied. Safety, absence of deadlocks, and bounded liveness (e.g., an end-to-end time constraint) properties can be verified by reachability analysis upon the state graph, using a subset of TCTL temporal logic formulas [10] as shown in the following:

- $E <> \varphi$ (Possibly $\psi$, i.e., a state exists where $\psi$ holds)
- $A[]\ \psi$ (Invariantly $\psi$, equivalent to: $not\ E <> not\ \psi$)
- $E[]\ \psi$ (Potentially Always $\psi$, i.e. a state path exists over which $\psi$ always holds)
- $A <> \psi$ (Always eventually $\psi$, equivalent to: $not\ E[]\ not\ \psi$)
- $\psi --> \xi$ ($\psi$ always *leads-to* $\xi$, equivalent to: $A[]\ (\psi\ imply\ A <> \xi)$)

where $\psi$ and $\xi$ are state properties (formulas), e.g., clock constraints or boolean expressions over predicates on locations.

Although min/max determinations, e.g., of a clock, can be achieved by using the above described logic queries, a shorthand notation is available as in the following:

sup{ state-predicate } : list-of-expressions
inf{ state-predicate } : list-of-expressions

These queries evaluate the superior/inferior value of the list of expressions, only in the states of the state-graph which satisfy the state predicate specified within { and }.

### A. UPPAAL Statistical Model Checker

The problem with symbolic model checking is that it could not be practically applied to realistic complex systems which generate an enormous (possible infinite) state graph, or it becomes undecidable for systems which combine in a complex way continuous time with stochastic behavior.

Property checking in these cases can only be approximated or estimated. In recent years the UPPAAL toolbox was extended to support stochastic model checking (SMC) [9]. UPPAAL SMC [11] avoids the construction of the state graph and checks properties by performing a certain number of simulation runs, e.g., in parallel on a modern multi-core machine. After that some statistics techniques are used to infer results from the simulation runs.

SMC refines and extends basic UPPAAL. Only broadcast synchronizations are allowed among stochastic TA (STA). In addition, either an invariant or the rate of an exponential distribution can be attached to a location. Stopwatches, i.e. clocks whose automatic advancement can be temporarily stopped (their first derivative is put equal to zero as an invariant of a location) can be exploited. A stopwatch resumes its advancement as soon as the automaton exits the location in which it was stopped.

UPPAAL SMC also provides floating point (double) variables which, e.g., can be assigned the value of a clock. Virtually, the symbolic model checker can be applied to a stochastic model too, in which case all doubles, exponential distribution rates etc. are simply ignored. However, on a stochastic TA model can be issued the following specific query types. Bold symbols are meta-symbols used to describe the SMC query language.

1. simulate N [ **(**clock|#|void**)** <=bound ] { Expression1, …, Expressionk }
2. Pr[ **(**clock|#|void**)** <=bound ] ( **(**<>|[]**)** Expression )
3. Pr[ **(**clock|#|void**)** <=bound ] ( **(**<>|[]**)** Expression) **(**<=|>=**)** PROB
4. Pr[ **(**clock|#|void**)** <=bound ] ( **(**<>|[]**)** Expression) **(**<=|>=**)** Pr[ **(**clock|#|void**)** <=bound ] ( **(**<>|[]**)** Expression)
5. E[ **(**clock|#|void**)** <=bound; N ] ( **(**min:|max:**)** Expression )

Expressions are state predicates without side-effects. They can specify an automaton to be in a certain location, or some constraints on data variables or clocks etc. All the queries are evaluated according to a bound which can be related to (implicit) global time or to a clock or to a number of simulation steps (#).

Query 1 makes N simulation experiments and collects information about the listed expressions. Query 2 evaluates the probability the given expression holds within the assigned bound (<>) or always holds within the bound ([]) with a confidence interval (the default 95% confidence degree can be customized by the user). Query 3 checks if the estimated probability is less/greater than a given probability value. Query 4 compares two probabilities. Query 5 estimates the minimum or the maximum value of an expression.

Responding to queries implies a certain number of simulation runs are carried out, either explicitly requested (see the parameter N in the queries 1 and 5) or implicitly defined by the query. Quantitative estimation of a query of type 2 rests on Monte Carlo-like simulations. Qualitative queries of the type 3 and 4 use sequential hypothesis testing. An important feature provided by UPPAAL SMC is *visualization* of simulation results. Following a satisfied query, the modeler can right click on the executed query and choose an available diagram (histogram, probability distribution etc.) to be plotted. At the time of this writing, UPPAAL SMC is supported by the development version 4.1.19.

## V. MAPPING TPN/sTPN ONTO UPPAAL

A TPN/sTPN model is translated into UPPAAL by associating each transition with a suitable template process and by introducing some global data and helper functions. A similar approach was adopted by authors in [16] which provides a formal correctness approach exploitable also in current work. For brevity, though, in the following only an informal semantics will be given.

### *A. TPN issues*

The structural translation adapts itself to the needs of both non deterministic analysis (TPN model checking) and the stochastic analysis (sTPN SMC). During the exhaustive verification of a TPN model, all the transitions are homogeneously modelled as timed transitions (see the tTransition automaton in Fig. 2). Immediate transitions, in particular, are expressed as timed transitions with a [0,0] static time interval. Random switches are thus replaced by non-deterministic selection (*race*) among transitions firable at the same time.

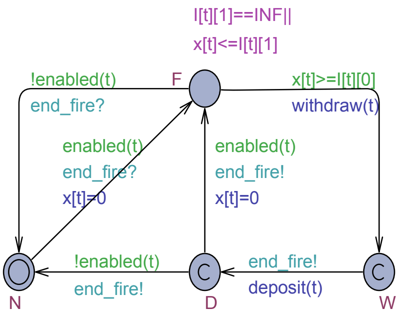

Fig. 2 The tTransition template automaton

The tTransition automaton in Fig. 2, with the sole parameter const tid t, models the generic timed transition of a TPN model. The t transition id is used to select the clock x[t] which captures the time-to-fire of the transition. The global functions enabled(t), withdraw(t) and deposit(t) assist the automaton evolution.

A timed transition starts into the N (Not enabled) location. As soon as it finds itself enabled, it resets its clock x[t] and moves to the F (Firable) location. The invariant attached to the F location states that the transition can remain in F until the latest static firing time which can be infinite. On the other hand, transition t can fire as soon as it happens its clock x[t] reaches the earliest static firing time. Bounds of the static time interval of the transition t, constrained to be positive integers (an upper bound infinite is denoted by the constant INF), are held into the global array $I: T \times 2 \rightarrow int$. $I[t][0]$ is the $EFT^s(t)$, $I[t][1]$ is the $LFT^s(t)$.

The firing process is accomplished with the help of the end_fire broadcast channel. Two broadcast synchronizations are actually used, separately triggering the withdraw-phase and the deposit-phase. Each end_fire synchronization is capable of influencing all the other transitions which are forced to re-examine their enabling status, and thus commanding a return from F to N when a firable transition detects it is no longer enabled, or moving from N to F when a not enabled transition finds itself enabled. It is worth noting that the two location W (Withdraw) and D (Deposit) are committed locations, thus ensuring the firing process is instantaneous and atomic. In the D location, a just fired transition which is still enabled, comes again into the F location and resets its clock x[t] (single server semantics). If the transition is not enabled, it reaches the default N location.

To bootstrap a TPN model, a Starter automaton (see Fig. 3) is exploited which launches an initial (fictitious) end_fire synchronization to force transitions which are enabled in the initial marking of the model, to reach the F location.

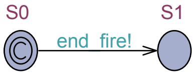

Fig. 3 The Starter automaton

Behind the design of the tTransition automaton, the following global declarations are introduced. Model topology is captured by the constants P (number of places), PRE (maximum number of input places of a transition), POST (maximum number of output places of a transition), T (number of transitions), B and F (input/output constant incidence matrices), M (marking vector), I (time intervals). Each element of the matrices B and F, purposely implemented as TxPRE and TxPOST respectively, holds the index of a place, and the weight of an input and, respectively, an output arc. Transitions are numbered from 0 to T-1. The subtypes tid and pid describe respectively the sub range types of possible transition or place ids.

### *B. sTPN issues*

The support of sTPN shares the same basic global declarations described in the previous sub-section plus some specific declarations required for statistical model checking.

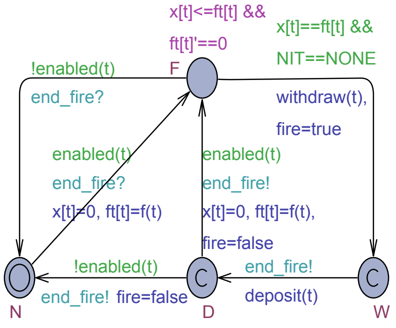

Fig. 4 The sTransition automaton

An sTPN model rests on two new timed automata shown in Fig. 4 and Fig. 5, respectively associated to a stochastic timed transition (sTransition) and to an immediate transition (iTransition).

As a matter of convention, first are numbered the stochastic transitions, from 0 to the TT-1 (TT is a model constant), then are numbered the immediate transitions (from TT to T–1). Of course, T=TT+IT. Correspondingly are defined the subtypes ttid and itid describing respectively the subranges of the stochastic and immediate transitions. An sTransition has the only the t (id) parameter of type ttid. Similarly, iTransition has the sole t parameter of type itid. All of this ensures the transition automata of a TPN/sTPN model can be implicitly instantiated at system configuration time.

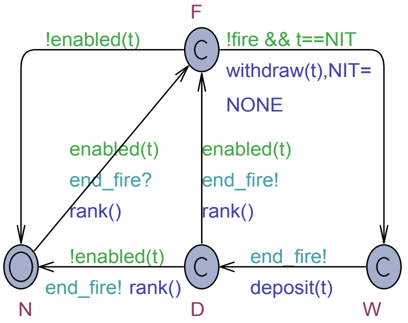

Fig. 5 The iTransition automaton

The sTransition uses two clocks: x[t] and ft[t]. The first one serves the same purposes discussed for the tTransition automaton (see Fig. 2). The second one actually stores the sampled fire time achieved (through integration of) the density distribution function (denoted by f(t)) associated to the transition. As one can see from Fig. 4, an sTransition actually fires (exiting the F location) when its time-to-fire clock x[t] equals the fire time held in the ft[t] clock. As part of the invariant attached to F, the first derivative of the clock ft[t] is put to 0 to avoid its advancement. Other details in Fig. 4 are as for the tTransition automaton.

The iTransition automaton in Fig. 5 does not use any clock. When it finds itself enabled, it moves to the committed location F. The rank() function implements the random switch and assigns to the global NIT variable (Next Immediate Transition) the id of the immediate transition probabilistically selected through the transition weights. The immediate transition that detects it is the selected NIT, instantly fires and resets NIT to NONE in preparation of a next execution of the random switch. As soon as a firable immediate transition discovers it is no longer enabled (for a conflict) it comes back to N.

Due to the committed location F in Fig. 5, and the (sub) guard NIT==NONE in Fig. 4, it is guaranteed that immediate transitions get fired before timed transitions. Moreover, the global bool fire variable in Fig. 4 and Fig. 5 ensures the fire of an immediate transition cannot actually start if the firing in progress of a timed transition is not completed.

## VI. Analysis of a TPN/sTPN Model

The structural translation from TPN/sTPN to UPPAAL described in the previous section, was applied in a case to the model presented in Section III.

### *A. Non deterministic analysis*

Here the concern was to evaluate qualitative properties of the model. Towards this timed transitions and immediate transitions are both modelled with the tTransition automaton in Fig. 2, and the exhaustive model checker of UPPAAL was used along with the construction of the (hopefully finite) state graph. The following clarifies the system configuration of the TPN model:

```
system Starter, tTransition;
```

where implicit instantiation is exploited. Due to the design of the template processes, only one instance of Starter is created, whereas T instances of tTransition (as demanded by the tid sub range type) are generated.

As a preliminary assessment of system behavior, the model was checked for the absence of deadlocks. The query was:

```
A[] !deadlock                              satisfied
```

where deadlock is a reserved keyword of UPPAAL. As a part of this first query, it was also implicitly assessed that the model is *safe*, i.e., 1-bounded. This was simply achieved by having declared the marking vector thus:

```
int[0,1] M[P]={ 1,1,1,0,0,0,0,0,0,1,0,0,0,0 };
```

and never observing an assignment out of bounds to M.

After that the model was checked for the existence of *regenerative states* [14]. A regenerative state is one where previous history of the system can be disregarded because it does not influence the future behavior.

First it was checked the property stated in [14], page 715, that repair2 cannot be persistent at each firing of start1, thus (also activating the generation of a diagnostic trace):

```
A[] (tTransition(0).W||tTransition(0).D) imply !tTransition(9).F
```

which asks if invariantly in both the intermediate marking (determined by the withdraw phase) and the final marking (determined by the deposit phase) of the firing of t0 (start1), the transition t9 (repair2) cannot be in its firable location F.

The property was found to be false as witnessed by the counterexample proposed by UPPAAL that shows effectively repair2 can be persistent to start1.

In reality, the two production cells could admit regenerative states when a *complete* processing of the second cell certainly finds the first cell in its home marking, and vice versa: when the first cell finishes its processing, the second cell *is* in its home marking. The following queries were issued to the model checker (recall places are uniquely identified by their subscripts, i.e., the numbers from 0 to P−1):

```
A[] M[5]==1 && M[6]==1 imply (M[9]==1 &&
   forall(i:int[7,13]) i!=9 imply M[i]==0)                satisfied

A[] M[12]==1 && M[13]==1 imply (M[2]==1 &&
   forall(i:int[0,6]) i!=2 imply M[i]==0)                 satisfied
```

which verify if, invariantly, each time one cell finishes its activities, i.e., a token is generated in the terminal places p5 and p6 or p12 and p13 in Fig. 1, the marking of the partner cell is surely its initial marking, meaning that no previous behavior is still in progress in the partner cell. As it was confirmed previously, e.g., at the processing end of the second cell the only possibly still pending sub activity in the second cell is the repairing of the failed res2 resource. However, satisfaction of latter queries guarantee that at each termination of the first cell, the second one always founds itself in its home marking, thus no previous behavior exists in the second cell which could interfere with new behavior.

The existence of regenerative states was a key for assessing specific behaviors of the model. For example, it was first checked about the possibility for the two resources to be failed simultaneously:

```
E<> M[3]==1 && M[10]==1                                   satisfied
```

Having found a double failed state exists, the next step was to identify *all* the possible sequences of transition firings which bring the system into the double failed state. Towards this an array s of transition ids (type tid) was introduced, together with a top variable, to memorize in the occurrence order a transition firing sequence.

The problem, obviously, was the proper dimensioning of the array s. Here it was fundamental the previous study on the regenerative states. In the light of the previous results, it was possible to create the array s with T elements, one per transition. In fact, when e.g. the second cell finishes its processing, there is no need to store again transition firings occurring in the first cell. In particular, it were also detected the instants when the array s can be safely reset in order to help model checking by forcing in s a default value. For instance, when one studies the sequence *first-cell-to-second-cell*, at the time of firing of the start1 (i.e., t0) the array s can be reset. Similarly, when the behavior *second-cell-to-first-cell* is observed, at the subsequent firing of start2 (i.e., t6) the array s can be reset.

Together with the array s, a fired(t) boolean function was introduced to check specifically for the firing of a certain transition. As an example, the existence of the double failed state was also assessed by the query:

```
E<> M[3]==1 && M[10]==1 && !fired(0)          satisfied
```

launched with the initial marking shown in Fig. 1. Now, a state with the two resources failed was checked without an intervening firing of start1, i.e., of the t0 transition, which would begin a new system execution.

Moreover, before launching the previous query, it was also asked to the model checker to generate a diagnostic trace. This way, with the property verified, it was inspected in the simulator both the sequence of events which brings the model in the double failed state, and the values of top and the first top values of s to identify the firing sequence. Therefore, as a further benefit of the previous existential query, it emerged that the sequence: t2-t4-t5-t6-t10 is capable of installing the double failed state.

The analysis was also enriched by the introduction of a global *decoration clock* y which is reset initially and at each firing of start1 (t0), and its value checked as soon as the double failed state is reached. Such a clock permits to measure the time needed, in the best and worst case, to reach the goal state. The conditional reset operation is simply added to the deposit(tid) function. An additional global decoration clock z was introduced to measure the *sojourn time* in the double failed state. The clock z is reset when the goal state is reached, and reset again as soon as the goal state is abandoned. Finding the minimal/maximal values of z provided the sojourn time. As a side benefit, watching the data and constraints (clock values) in the simulator, at the conclusion of the previous query, suggested the interval [4,9] for the possible duration of the sequence t2-t4-t5-t6-t10.

The following query was issued to find, if there are any, a new sequence:

```
E<> M[3]==1 && M[10]==1 && !fired(0) &&
!(s[0]==2 && s[1]==4 && s[2]==5 && s[3]==6 &&s[4]==10)
                                                  satisfied
```

It emerged the new sequence: t4-t2-t5-t6-t10 with a duration of [4,6] time units. The query:

```
E<> M[failed1]==1 && M[failed2]==1 && !fired(t0) &&
!(s[0]==2 && s[1]==4 && s[2]==5 && s[3]==6 &&s[4]==10) &&
!(s[0]==4 && s[1]==2 && s[2]==5 && s[3]==6 && s[4]==10)
                                                  satisfied
```

allowed to discover the third sequence t4-t5-t2-t6-t10 with duration [3,5]. Continuing with updating the query, it emerged that no more sequences exist. The sojourn time for the three firing sequences was found to be in interval [0,1].

By changing the initial marking in Fig. 1 so as to start the execution from the second cell towards the first, and repeating the work of firing sequence detection, it emerged that only other three sequences exist for this new scenario (although in [14] the existence of 7 firing paths in this second scenario was cited but not detailed). Results of the two scenarios are summarized in the Table 1 and Table 2.

As one can see from Fig. 1, a slight temporal difference exists between the first and the second cell, and is concerned with the lower bound of the time intervals of start1 and start2 which are respectively [2,3] and [1,3]. In the case both cells have the same [1,3] start interval, as expected, the paths in the two scenarios will have an identical temporal behavior. In [14] it is shown that the use of identical time intervals for start1 and start2 implies an infinite stochastic state graph which prevents the analysis. Such problems do not arise in the use of UPPAAL.

TABLE 1 FIRING SEQUENCES TO DOUBLE FAILED STATE FROM FIRST-TO-SECOND CELL

| | Firing sequence | Duration | Sojourn time |
|---|---|---|---|
| ρ0 | t2-t4-t5-t6-t10 | [4,9] | [0,1] |
| ρ1 | t4-t2-t5-t6-t10 | [3,6] | |
| ρ2 | t4-t5-t2-t6-t10 | [3,5] | |

TABLE 2 FIRING SEQUENCES TO DOUBLE FAILED STATE FROM SECOND-TO-FIRST CELL

| | Firing sequence | Duration | Sojourn time |
|---|---|---|---|
| ρ3 | t8-t10-t11-t0-t4 | [5,9] | [0,0] |
| ρ4 | t10-t8-t11-t0-t4 | [4,6] | |
| ρ5 | t10-t11-t8-t0-t4 | [4,5] | |

A further investigation was finally devoted to finding the *end-to-end* delay of a whole operation of the two production cells, i.e., measuring the min/max time required to generate the tokens in the places p12 and p13. The clock y was specialized to this new purpose: it is now reset initially and at each firing of start1 (t0) and checked when p12 and p13 have a token. The two queries:

```
inf{ M[12]==1 && M[13]==1 } : y
sup{ M[12]==1 && M[13]==1 } : y
```

furnished the time window [5,22] for the end-to-end delay.

The model checking work confirmed results achieved in [14] using the ORIS tool, but also suggested some new details.

Qualitative analysis of TPN models is rather efficient. Its scalability ultimately depends on the model topology (number of places and number of timed transitions and associated clocks) and the degree of the necessary model boundedness. As discussed in [16], what is really critical is the number of *active clocks* (i.e., the number of simultaneously fireable timed transitions) mirroring the parallelism degree of the model. An active clock is one which is growing and whose value is checked in a subsequent invariant or edge guard.

### *A. Stochastic analysis*

Whereas the non-deterministic analysis based on model checking says something can happen in the system, i.e., it predicates about qualitative concerns (properties) of the system, the stochastic analysis aims to determine a quantitative measure of the probability with which a given property can actually occur in the system.

As a concrete example, UPPAAL SMC was applied to the model in Fig. 1. To this end the system model was configured by using the sTransition automaton for the timed transitions, and the iTransition automaton for the immediate transitions (which are not used in Fig. 1).

As a preliminary step, it was checked the time limit to use for simulations. As an example, transitions start1 (t0) and start2 (t6) were monitored by cumulating their service time samples and by counting their number of firings. Then the following query was issued:

```
simulate 1 [<=100000] { t0mst, t6mst }
```

where t0mst and t6mst are decoration variables (of type double) added to the model for SMC, reflecting the monitored service time means of the two selected uniform distributions (expected values 2.5 and 2). Fig. 6 confirms that after about $3*10^4$ the mean values are reached indicating an end of transient behavior.

The following query was used to check the probability of occurrence of a single failure in the resources (time is a decoration clock mirroring system time advancement):

```
Pr[<=100000] (<>time>=30000 && (M[3]==1 || M[10]==1) )
```

UPPAAL SMC determined for the event, using 36 simulation runs, a confidence interval (CI) of [0.902606,1] with a confidence degree of 95%. Moreover, it proposed a time span like that depicted in Fig. 7 to highlight a probability distribution for the event:

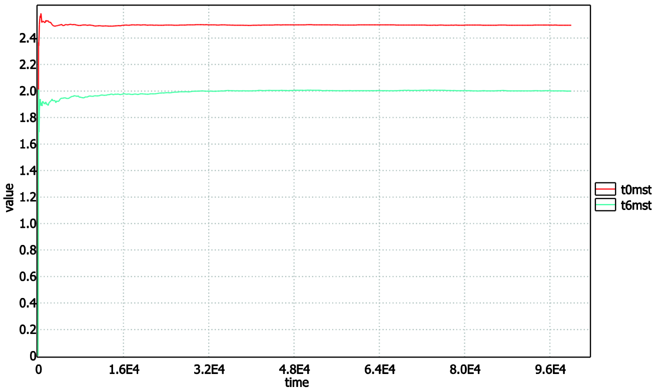

Fig. 6 Monitored values of t0 and t4 mean service time

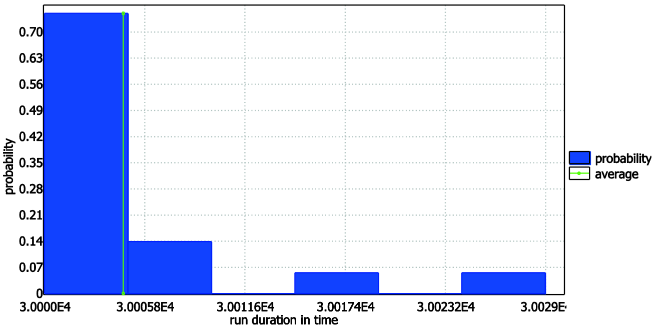

```
Parameters: α=0.05, ε=0.05, bucket width=4.831, bucket count=6
Runs: 36 in total, 36 (100%) displayed, 0 (0%) remaining
Span of displayed sample: [30000, 30028.9858340878]
Mean of displayed sample: 30004.5594488342 ± 2.39910895990846 (95% CI)
```

Fig. 7 A probability distribution for the single failure

In a similar way it was checked the probability of occurrence of a simultaneous double failure of resources:

Pr[<=100000] (<>time>=30000 && (M[3]==1 && M[10]==1))

The event has still a CI of [0.902606,1] 95%, with a suggested probability distribution depicted in Fig. 8.

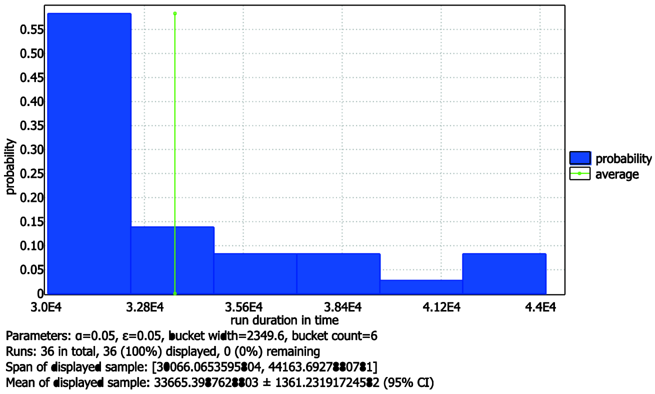

Fig. 8 A probability distribution for the double failure

All the firing sequences in Table 1 and Table 2 have a very low probability of occurrence. Each event was checked as exemplified by the following query:

Pr[<=100000] (<>time>=30000 && s[0]==2 && s[1]==4 && s[2]==5 && s[3]==6 && s[4]==10)

For all the sequence paths a CI [0,0.0973938] 95% was indicated by UPPAAL SMC.

Some experiments were specifically devoted to quantify the probability of achieving a given end-to-end delay (EED), i.e., the elapsed time from a firing of start1 (t0) to the generation of a token in both places p12 and p13 of Fig. 1. The next query was used to assess the probability of having an EED<=10:

Pr[<=100000] (<>time>=30000 && (M[12]==1 && M[13]==1) && y<=10)

Clock y is reset at each firing of t0 and measured at the end of the execution of the second cell. UPPAAL SMC proposes a CI of [0.902606,1] 95% and a cumulative probability distribution as portrayed in Fig. 9.

The probability of having an EED<=10 was checked against 80% as follows:

Pr[<=100000] (<>time>=30000 && (M[12]==1 && M[13]==1) && y<=10) >= 0.80

UPPAAL responds that such a probability is >=0.81 with 95% of confidence.

Monitored values during simulation of the end-to-end delay, collected in Fig. 10, were achieved by the query:

simulate 1 [<=100000] { EED }

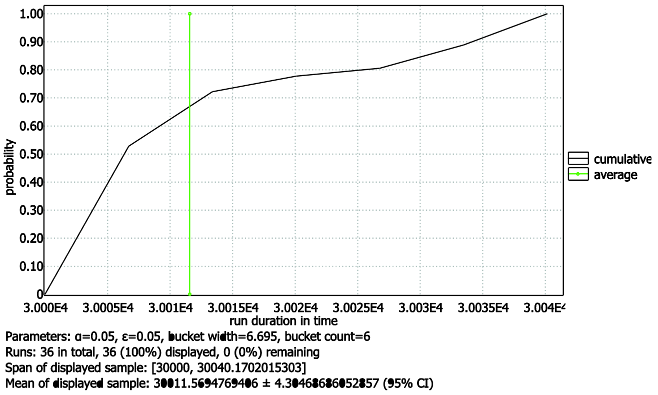

Fig. 9 A cumulative probability distribution for an EED<=10

EED is a decoration variable which receives the value of the clock y at each end of the second cell execution. From Fig. 10 it emerged an average value for the EED of about 10 tu.

Further property estimation was based on MITL formulas [11] which can provide more tight answers. The following query checks the probability that starting from the marking M[0]==1 && M[2]==1 it can follow within 3 time units a failure of res1:

Pr( M[0]==1 && M[2]==1 U[0,3] M[3]==1 )

Using 738 runs, [0,0.05] was returned as a 95% CI, indicating that the event happens with a very low probability.

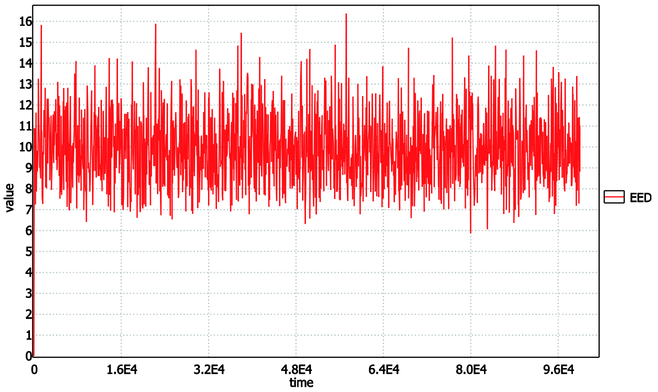

Fig. 10 Monitored EED value

The probability that within [0,1000] tu the double failure state can occur was re-checked with the query:

Pr( <>[0,1000] M[3]==1 && M[10]==1 )

which returned a [0.142412,0.242412] 95% CI. The query:

Pr( <>[0,10] M[12]==1 && M[13]==1 )

was used to evaluate the probability that within 10 tu the double cell terminates its execution. The [0.605827,0.705827] 95% CI was observed.

To check specifically the termination event within [10,22] tu it was issued the query:

```
Pr( <>[10,22] M[12]==1 && M[13]==1 )
```

which returned a [0.849729,0.949729] 95% CI to witness a very high probability of occurrence.

The occurrence probability of the firing sequences leading to double failure, was re-checked by the query:

```
Pr( <>[0,1000] top==5 && s[0]==2 && s[1]==4 && s[2]==5 &&
s[3]==6 && s[4]==10 )
```

for which (using 738 runs) a [0,0.054065] 95% CI was proposed. Similarly, for the second and third path of Table 1, it was estimated respectively a CI of [0,0.05] and [0,0.05271] 95%.

Since stochastic analysis depends on batches of simulation runs, that is UPPAAL SMC renounces to build the model state graph, there are no scalability problems when the model admits more clocks, variables etc. All of this was exploited in the case study by introducing a tailored decoration which is simply ignored when the same model is interpreted for non-deterministic analysis.

## VII. CONCLUSIONS

This paper proposes an approach to modelling and analysis of Time Petri Nets (TPN) [2]-[5] also in the presence of stochastic features (sTPN) [14].

The approach is centered on a structural translation of TPN/sTPN onto the latest version of UPPAAL which enables both qualitative non-deterministic analysis based on exhaustive model checking, and quantitative evaluation of system properties by exploiting the statistical model checker.

The UPPAAL translation makes it possible, during analysis, to reason directly in the terms of TPN/sTPN vocabulary (e.g., marking reachability and transition firings), thus simplifying its practical usage.

Prosecution of the research is directed at:

- Extending the sTPN modelling through the support of generally distributed probability functions attached to transitions.
- Improving the automatic translation of TPN/sTPN models in the context of the TPN Designer toolbox [20].
- Applying the approach, e.g., to complex maintenance procedures, phased-mission systems [17], time-constrained workflow systems.
- Experimenting the methodology with the PRISM Probabilistic Model Checker [12].
- Specializing the approach to Preemptive Time Petri Nets [18], i.e., towards the schedulability analysis of real-time tasking sets under general conditions, when the schedulability problem becomes undecidable. A preliminary framework was prototyped in [19] using UPPAAL stopwatches and over-approximation. The goal is to allow non-deterministic qualitative analysis (when possible) and quantitative analysis of task response times using the statistical model checker.

*Abstract—* **This paper proposes an original framework for modelling and verification (M&V) of starvation-free mutual exclusion algorithms based on weak semaphores, that are without a built-in waiting-process queue. The goal is to support the implementation of light-weight starvation-free semaphores useful in general concurrent systems including cyber physical systems. The M&V approach depends on UPPAAL. First known weak semaphores are modelled. Then they are exploited for model checking classic algorithms. Known properties are retrieved but subtle new ones are discovered. As part of the developed approach, a new algorithm is proposed which uses two semaphores of the weakest type, N bits (N being the number of processes) and a counter. This algorithm too is proved to be correct.**

## I. INTRODUCTION

MUTUAL exclusion is the well-known problem of synchronizing a group of concurrent processes (or threads) sharing some data variables, so as to avoid interferences on shared data. The problem is to ensure that processes can enter their critical section (i.e., a block of instructions accessing/modifying the shared data) one at a time. To be acceptable, though, a mutual exclusion algorithm should be also starvation-free, that is a process waiting to enter its own critical section should experiment a bounded waiting time. This in turn favors process fairness.

Commonly, mutual exclusion can be based on semaphores or on monitor locks. This paper focuses on starvation-free mutual exclusion algorithms based on *weak semaphores*, i.e., semaphores without an in-built process waiting queue ensuring a first-in-first-out awakening policy.

The results of this paper can be exploited for implementing light-weight starvation-free semaphores, useful in general concurrent applications and cyber physical systems (e.g., [1]), and also in distributed shared memory systems where it is challenging to build a classical queue-based semaphore when the processes belong to distinct physical computation nodes (address spaces).

The goal is to propose an original approach based on Timed Automata (TA) in the context of the UPPAAL toolbox [2], for modelling and verification through model checking [3] of any mutual exclusion algorithm designed on top of weak semaphores. The goal is similar to that described in [4] where an approach based on the use of the PVS theorem prover was developed. This paper argues that the use of a toolbox like UPPAAL can be preferable as a proving framework because it avoids the mathematical formalization necessary to specify and check properties of an algorithm. In addition the approach permits to disclose subtle aspects of a modelled algorithm, e.g., related to timing, which are normally out of reach of a theorem prover.

The modelling and verification (M&V) approach is applied to known classic algorithms, e.g. [5]-[8], of which are confirmed known properties. Nevertheless, some new properties (e.g., the existence of a zeno-cycle and of a time-sensitive behavior which affects the kind of the weak semaphores which can be used) are disclosed which were not previously documented in the literature. As a part of the accomplished work a novel algorithm based on the Morris one [5] is proposed which rests only on two weak semaphores, one counter and N bits. This algorithm too is proved to be starvation-free.

The developed proving framework can provide some new arguments on the E. Dijkstra conjecture [9] about the impossibility to build a starvation-free semaphore using only weak semaphores.

The paper is structured as follows. First an overview of the UPPAAL M&V concepts is furnished. Then the three known types of weak semaphores are introduced and modelled into UPPAAL. After that, a common vision [4] of classic starvation-free mutual exclusion algorithms is discussed. Then the developed M&V approach is applied to classic algorithms as well as to a new one proposed in this paper. A comparison of the algorithms properties is finally presented. Some indications about on-going and future work are given in the conclusions.

## II. UPPAAL CONCEPTS

UPPAAL [2] is a popular and efficient toolbox based on Timed Automata (TA) [10] suited for modelling and verification of real-time systems. A timed automaton is a finite automaton augmented with a set $C$ of real-valued variables named *clocks*. Clocks model the time elapsing and are assumed to grow synchronously at the same pace of the hidden system time. Constraints, of the form $x \sim k$ or

This work was not supported by any organization

978-83-60810-66-8/$25.00©2015, IEEE

$x - y \sim k$ where $x$ and $y$ are clocks, $k$ is a non-negative integer and $\sim \in \{\leq, <, =, >, \geq\}$, are called *clock constraints* and can be introduced to restrict the behavior of the automaton. A set of clock constraints used to label an edge it is called a *guard* and determines the possible values which can be assumed by the involved clocks for the corresponding state transition to be allowed. Clock constraints of the type $x \sim k$ can also be used to label locations and are called *invariants*. An automaton can stay in a location as long as the clocks satisfy the location invariant attached to the location. Additionally, edges can be labeled by a set of clocks, which are reset as the corresponding transition is taken, and by an *action* label.

TA can be composed to form a network of concurrent TA whose semantics is based on interleaving of actions as well as hand-shake synchronizations. UPPAAL adopts the notion of a *channel* for input and output action synchronization and uses a CSP-like notation. The edge of automaton labeled with `ch!` (output action), where `ch` is a channel, matches with an edge of another automaton labeled with `ch?` (input action). At a given time it may exist more than one pair of enabled and matched edges in which case a choice is made non-deterministically. Taking a transition (edge) in an automaton denotes an *atomic action* in the TA concurrent model. Moreover, the update of a sender is executed *before* that of a receiver.

The UPPAAL model-checker generates *on-the-fly* the state graph of a network of TA (see, e.g., [11]) for checking formulas as in the following:

- $E <> \emptyset$ (Possibly $\emptyset$, i.e., a state exists where $\emptyset$ holds)
- $A[]\ \emptyset$ (Invariantly $\emptyset$, equivalent to: $not\ E <> not\ \emptyset$)
- $E[]\ \emptyset$ (Potentially Always $\emptyset$, i.e. a state path exists over which $\emptyset$ always holds)
- $A <> \emptyset$ (Always eventually $\emptyset$, equivalent to: $not\ E[]\ not\ \emptyset$)
- $\emptyset --> \psi$ ($\emptyset$ always *leads-to* $\psi$, equivalent to: $A[]\ (\emptyset\ imply\ A <> \psi)$)

where $\emptyset$ and $\psi$ are state properties, e.g., clock constraints or boolean expressions over predicates on locations.

In addition to the support for classic TA, UPPAAL provides integer variables with a bounded set of values, arrays and structs, and a notion of automata *templates* which can be instantiated multiple times by specifying different values for their parameters.

Locations can also be labeled as being *committed* (C) or *urgent* (U) both of which must be abandoned with no time passing. Committed locations have precedence over urgent locations. UPPAAL provides also broadcast synchronizations. Channels can be declared to be urgent. An enabled synchronization on a urgent channel is required to occur without time passage.

Finally, it is worth mentioning the possibility of building a counterexample (i.e., diagnostic trace) of a not satisfied property, which can be analyzed in the simulator of the toolbox.

## III. MODELLING WEAK SEMAPHORES

A semaphore is an abstract object which hides an integer variable which can only be modified by the two atomic operations `P` and `V`. Fig. 1 shows an UPPAAL model of a basic *plain* binary semaphore, whose value can be `0` or `1`. The `P/V` operations are modelled through a matrix of channels. The first index `s` specifies the semaphore id. The second one carries the id of the requesting process. The model in Fig. 1 makes a non-deterministic selection of the requesting process at a `P` or `V` synchronization. A not chosen process rests blocked on the requesting `P!` or `V!` operation.

Of course the model in Fig. 1 is unfair: at the time of a `V`, if more processes are blocked on the `P!` synchronization on the same semaphore, one of them is chosen not-deterministically to proceed. It is also possible for the `V`-executor process to compete and reacquire immediately the semaphore. Therefore, every process can experiment an unbounded waiting. It is known that to turn an unfair semaphore into a fair one a queue can be added to the semaphore where processes which find the semaphore red (0) at the time of a `P` are stored in first-in-first-out order and then awaken in the same order at a subsequent `V`.

A challenging research goal in the literature is to achieve a fair semaphore using only a minimum number of unfair semaphores. In the case when the queue is replaced by a set, the semaphore becomes unfair and it is often referred to as a *buffered* [4] or *blocked-set* semaphore [12]. A third version of weak semaphore is the so called *polite* semaphore proposed in [4]. A *polite* semaphore is similar to a *plain* semaphore but forbids the process which executes a `V` operation to reacquire immediately the semaphore.

The three types of weak semaphores can be modelled in UPPAAL as shown in the Fig. from 2 to 4 where for generality a `P` operation is supposed to be immediately followed by a `GO` synchronization to unblock the `P`-requester process. A `V` operation, being not blocking, never requires to be followed by a `GO` synchronization.

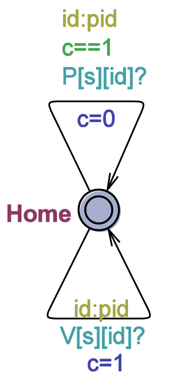

Fig. 1. A plain binary semaphore automaton

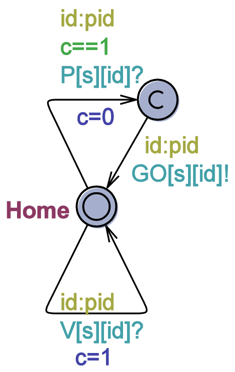

Fig. 2. Adopted `PlainBinary-Semaphore` automaton

Models in the Fig. 2 to 4 represent formal definitions of basic weak semaphores. Their correctness can be checked as follows. In the *polite* model in Fig. 3, the local variable `last` stores the id of the `V`-executor. The default value of `last` is `NONE`. At the time of a `P`, if the semaphore is green (`1`) and the process id is different from `last`, atomically the semaphore is turned to red (`0`) and the process (held in the `this` local variable) immediately receives the `GO` signal. Would the semaphore be red, or its id coincides with the `last` value, the process partially executes the `P` operation by incrementing the (local) counter `cnt` of blocked processes. A blocked process can be awaken by a `GO` synchronization raised in the right edge of Fig. 3, which completes its `P` operation by turning red the semaphore, decrementing the `cnt` variable and by assigning `NONE` to `last`. A subsequent `V` operation can (non-deterministically, as for a *plain* semaphore) unblock a waiting process, provided its id is different from `last`, or permit to a newly arrived process different from `last` to acquire the semaphore through a `P` operation.

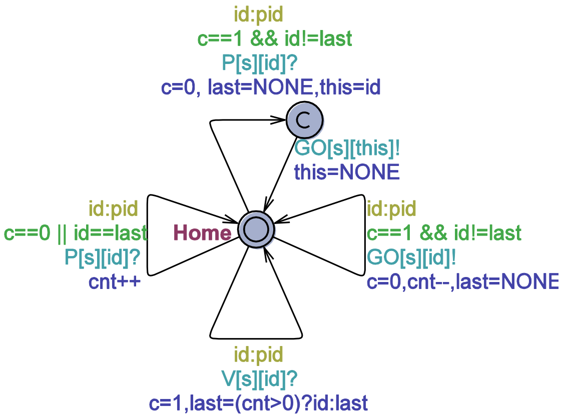

Fig. 3. `PoliteBinarySemaphore` automaton

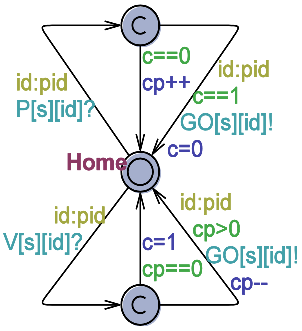

Fig. 4 `BufferedBinarySemaphore` automaton

If `s` is a *polite* binary semaphore, the following invariants hold:

1) `A[] s.last!=NONE imply s.cnt>0`
2) `A[] s.last==NONE || s.cnt>0`

Due to the invariant 1) it was omitted in the right edge with a `GO` synchronization of Fig. 3 the test `cnt>0` in the edge guard.

In the *buffered* semaphore model in Fig. 4 the buffer was purposely achieved implicitly in UPPAAL by the waiting locations of the set of processes which have just executed the `P!` operation and found red the semaphore. The number of such blocked processes is stored in the variable cp. At the time of a `V!`, if there are blocked processes, the semaphore is not turned to 1 and one of such processes is chosen non deterministically and receives the synchronization on the corresponding `GO` channel. It should be noted that both *polite* and *buffered* models exclude the `V`-executor to reacquire immediately the semaphore. But the *buffered* semaphore is stronger than the *polite* because at the time of a `V` operation, only one already blocked process can receive the semaphore pass. Fig. 5 summarizes global declarations of an UPPAAL model which makes use of any semaphore model in the Fig. from 2 to 4.

```
const int N=…;//number of processes
const int SEM=…;//number of weak semaphores
const int NONE=-1;

typedef int[0,N-1] pid;
typedef int[0,SEM-1] sid;

//semaphore IDs
…
//semaphore channels
urgent chan P[sid][pid];
urgent chan GO[sid][pid];
urgent chan V[sid][pid];
```

Fig. 5 Common global declarations for weak semaphores

Since a location without a clock invariant can disrupt liveness of an UPPAAL model being possible to remain in the location an arbitrary (potentially infinite) time, semaphore channels were declared as urgent. This way, without hurting model non-determinism, when a given operation is enabled it will be allowed to occur without time passage. This measure was adopted as a way to realize in UPPAAL the *finite delay property* [12] or *weak fairness* [4] of processes in a concurrent model, which requires a continuously enabled action eventually happens.

As a final remark, all the models in the Fig. from 2 to 4 can be implemented in a concurrent programming language (e.g., Java) using busy-waiting.

## IV. Model Checking Starvation-free Mutual Exclusion Algorithms based on Weak Semaphores

If `S` is a fair binary semaphore initialized to 1, the usual pattern for achieving mutual exclusion among `N` (>2) competing processes accessing some shared data is the following:

**process**(p)=**loop** NCS; P(S); CS; V(S); **endloop**.

A problem which has received the attention of many researchers consists in the possibility of building a sound fair semaphore using only a minimal number of weak semaphores. Starting from late seventies some starvation-free mutual exclusion algorithms were proposed, though without an adequate proof of their correctness. Recently, in [4] a very interesting proof system based on the PVS theorem prover was defined and used to establish the correctness of three fundamental algorithms proposed in [5]-[7].

This paper claims that the approach and the results described in [4] are still unsatisfactory and that some properties exist to be discovered about those and other algorithms. A fundamental step in [4] was the identification of an abstract algorithm which facilitates the interpretation and analysis of the three mentioned algorithms.

The abstract algorithm is founded on the elevator metaphor: "While there are interested processes they enter the elevator at the first floor. When there are no processes arriving anymore, the elevator goes to the second floor and lets its occupants into CS, one by one. When the elevator is empty, it goes down again. When the elevator is not at the first floor, arriving processes have to wait. After CS, the processes go down by stairs."

The abstract algorithm uses 4 integer variables: ne, nm, se and sm. The first two variables model respectively the number of processes at the first floor waiting for the elevator, and the number of occupants within the elevator. The last two variables model respectively the doors at the first and second floor. Initially all variables are set to 0 except for the se which is set to 1. The abstract algorithm is reproduced in Fig. 6 where atomic actions are enclosed within <…>.

```
process(p)=
loop
      NCS;
      <ne++>
      <await se greater-than 0; nm++; ne--;
         if ne==0 then sm++; se--; endif;>
      <await sm greater-than 0; sm--; nm--;>
      CS;
      <if nm greater-than 0 then sm++; else se++; endif;>
endloop.
```

Fig. 6 Mutual exclusion abstract algorithm

Correctness of the abstract algorithm can be verified in UPPAAL by deriving a corresponding native model like that shown in Fig. 7. Such a model only depends on the concurrency model of UPPAAL and in particular on the atomic actions labelling the various edges. The model consists of two TA: the Process(const pid p) (see Fig. 7) and the Synch(ronizer (see Fig. 8). The Process automaton embodies the mutex algorithm and is instantiated N (e.g., N=4) times.

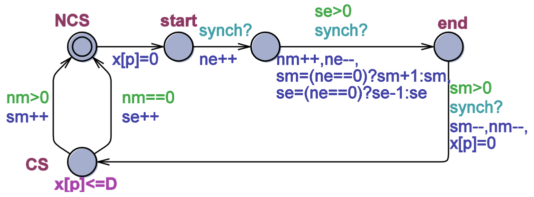

Fig. 7 UPPAAL Process automaton

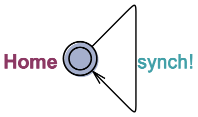

Fig. 8 The Synch automaton

All these instances share the algorithm variables, declared globally. Only one instance instead exists for the synchronizer. Each process instance p uses a clock x[p] to measure the waiting time before entering the critical section and the duration of the critical section.

The synchronizer is always ready to send a signal over the urgent unicast channel synch. Such a signal is a key to ensure progress to the model in Fig. 7 where some normal locations without clock invariants like start and end, are used.

Also the NCS location is without clock invariant, to mirror the fact that the non-critical section lasts an arbitrary number (also 0) of time units.

The entry protocol of the mutex algorithm is played from the start to the end location. The exit protocol is coded on the arcs outgoing the CS location.

The following queries were used for property checking of the abstract algorithm.

```
1)A[] !deadlock                          satisfied

2)A[] forall(i:pid) forall(j:pid)
  Process(i).CS && Process(j).CS
  imply j==i                             satisfied

3)Process(0).start --> Process(0).CS
                                     not satisfied

4)A[] forall(i:pid) Process(i).end
  imply x[i]<=2*(N-1)*D                  satisfied

5)A[] forall(i:pid) Process(i).end
  imply x[i]<=2*(N-1)*D-1            not satisfied
```

Queries 1) and 2) check *safety properties*. Query 3) verifies a *liveness property*. Queries 4) and 5) check a *bounded liveness property*.

Satisfaction of query 1) guarantees the model has no deadlock (predefined keyword in UPPAAL). Query 2) ensures only one process at a time can be in the critical section. Query 3) checks if any process which finds itself in the start location eventually reaches the CS (critical section) location. Noteworthy, this property is not satisfied. Queries 4) and 5) check about the waiting time of each process before entering CS (whose duration is supposed to be at most D time units).

Note that clock x[p] is reset on entering start and on exiting end. It is confirmed that every process p has an *overtaking factor* of 2, i.e., its blocking time is determined by all the other processes which enter two times their CS before p can enter its CS.

Absence of liveness (query 3) is a direct consequence of the fact that the model has a *zeno-cycle*, i.e., it is possible for any process to (re)enter the CS an infinite number of times before any other process can enter its CS, by consuming 0 time. The zeno-cycle mirrors the fact that the critical section as well as the non-critical section can have a 0 duration, and that nothing forbids (non-determinism) the same process to always get the synch signals.

The zeno-cycle can be eliminated by guaranteeing the critical section necessarily consumes a finite (although very small) duration (the guard x[p]>0 can be added to both edges exiting from the CS location). However, the existence of the zeno-cycle does not prevent the model checker to determine the worst-case waiting time of processes, in which case UPPAAL considers scenarios (behaviors) on the state graph where time is really advancing.

It should be noted that the presence of a zeno-cycle naturally expresses an intrinsic feature of the algorithm/model design. A different design can be without any zeno-cycle, independently from any consideration about timing.

The following invariants also hold for the model of Fig. 7:

```
A[] se==1 imply sm==0,
A[] sm==1 imply se==0,
```

which express functionality concerns of the abstract algorithm.

In [4] it is shown as some classic starvation-free mutual exclusion algorithms based on weak semaphores can be regarded as different interpretations of the abstract algorithm, where atomic operations are achieved by using a few unfair binary semaphores.

For brevity, in the following only the Morris algorithm [5] will be detailed. For the other studied algorithms, though, the experimental analysis will be synthetically reported.

### *A. Morris Algorithm*

Fig. 9 recapitulates the Morris algorithm which can be viewed as a concrete instance of the abstract algorithm of Fig. 6. The Morris algorithm uses three weak semaphores: sb, protecting specifically the ne counter holding the number of processes awaiting the elevator at the first floor, se and sm respectively controlling the door at the first and the second floor. They act as a split binary semaphore. Initially, sb and se are set to 1, sm to 0.

The initial values of the other variables are as in the abstract algorithm.

```
process(p)=
  loop
    NCS;
    P(sb); ne++; V(sb);
    P(se); nm++; P(sb); ne--;
    if ne>0 then V(sb); V(se);
    else V(sb); V(sm); endif;
    P(sm); nm--; CS;
    if nm>0 then V(sm); else V(se); endif;
  endloop.
```

Fig. 9 The Morris mutual exclusion algorithm

In Fig. 10 it is depicted an UPPAAL Process automaton corresponding to the algorithm in Fig. 9.

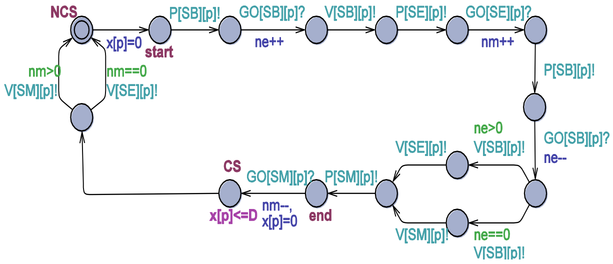

Fig. 10 UPPAAL Process model corresponding to the Morris algorithm of Fig. 9

In this case, the use of urgent semaphore channels avoids the recourse to other channels like synch of Fig. 8 in order to guarantee model progress. The model in Fig. 10 was model checked using the same queries 1) to 5) previously discussed for the abstract algorithm, and using for the se and sm semaphores the PlainBinarySemaphore template (Fig. 2) and separately checking the model behavior when the sb semaphore is implemented respectively as a *plain*, *polite*, or *buffered* binary semaphore, i.e., passing from the weakest to the strongest unfair semaphore.

In [4] a proof system was built to demonstrate that the Morris algorithm is correct, i.e., it is without deadlock, it ensures mutual exclusion and it guarantees a bounded waiting time (with an overtaking factor of 2) for the blocked processes, for the sole case sb-*buffered* semaphore, se, sm-*plain* semaphores. From our analysis based on model checking it emerged that the Morris algorithm, even with sb being a *buffered* semaphore, always has a zeno-cycle which means, under the hypothesis of zero time duration of any action in the algorithm, that the overtaking factor for a blocked process is unbounded. Only when the critical section is supposed to consume even a very small time duration, the zeno-cycle disappears. Moreover, in the presence of timing of the critical section, the overtaking factor is effectively 2 as for the abstract algorithm but for any implementation of the sb semaphore. In other words, model checking the Morris algorithm, in the presence of timing, confirmed that the algorithm is correct with three *plain* binary semaphores, contrary to what is stated in [4] and [12].

The study of the Morris algorithm suggested to us the design of a simple variation of the algorithm based on two *plain* semaphores (the se and sm semaphores of the Morris algorithm), N bits and the nm counter. The algorithm is proposed in Fig. 11 and modelled in UPPAAL as in Fig. 12. It avoids the sb semaphore and uses instead an array e of N booleans, each element being associated to a distinct process.

```
process(p)=
  loop
    NCS;
    e[p]=true;
    P(se); nm++; e[p]=false;
    if ne() then V(se);
    else V(sm); endif;
    P(sm); nm--; CS;
    if nm>0 then V(sm); else V(se); endif;
  endloop.
```

Fig. 11 Proposed variation of the Morris algorithm

The array e replaces the ne counter of the abstract algorithm. Each process p sets e[p] to true when it starts waiting for the elevator at the first floor, and resets it to false when it enters the elevator, at which time the nm counter is incremented. Since each process manages its own element in the array e, no interference can ever occur on e. The test about the existence of other processes which want to enter the elevator at the first floor, previously based on the counter ne, it is now based on checking if there are some true elements in the array e (the check is actually delegated to a function ne() which returns true if some element in the array is true, false otherwise). Of course, a true value in e can be found in the current test or it will be sensed the next time.

Model checking the model in Fig. 12 confirmed that all the five queries proposed for the abstract algorithm are now satisfied. Also the liveness property (query 3) now holds, i.e., the new algorithm is without any zeno-cycle, and correctly operates even when timing is ignored.

### B. Algorithms Comparison

During the development of the modelling and verification approach described in this paper, besides the Morris algorithm, other starvation-free mutual exclusion algorithms based on weak semaphores were studied. Model checking results summarized in the Table 1 confirm known results in the literature and in some cases are more detailed. In the column of the semaphore types, the weakest admissible types for the algorithm are shown. More stronger versions could, but unnecessarily, be used. For instance, the sb (as in the Morris algorithm) semaphore of the Udding algorithm must be *buffered*. The other two semaphores can be *plain*. The Udding algorithm is no longer starvation-free if sb is implemented with a *polite* semaphore.

Analysis results concerning the Martin & Burch algorithm [6] coincide with those formally identified in [4]. The Haldar & Subramanian algorithm which relies on two semaphores and 2 bits [8] was also investigated in [13]. The weak semaphore type the authors assumed corresponds to a *buffered* one and the overtaking factor was indicated as

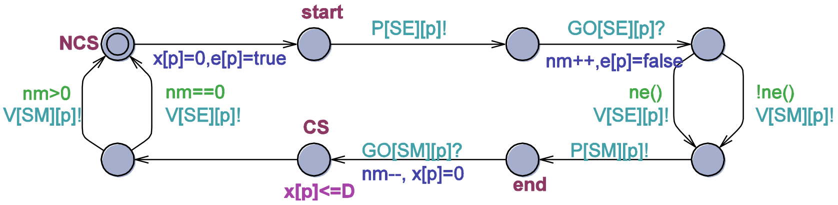

Fig. 12 Variation of the Morris algorithm based on two plain semaphores, N bits and the sole nm counter

TABLE I.
MODEL CHECKING RESULTS OF MUTUAL EXCLUSION ALGORITHMS.

| Algorithm | No of weak semaphores | Semaphore types | Zeno-cycle | Overtaking factor |
|---|---|---|---|---|
| Morris | 3 | 3 plain | yes | 2 |
| Morris variation proposed in this paper | 2 | 2 plain | no | 2 |
| Udding | 3 | 1 buffered – 2 plain | yes | 2 |
| Martin & Burch | 2 | 1 polite – 1 plain | yes | 2 |
| Haldar & Subramanian | 2 | 2 polite | yes | lesser than 2 |

being 2. However, the model checking approach developed in this work has shown that two *polite* semaphores suffice and that the waiting time of a process interested in entering its critical section is exactly 2*(N-1)*D-D, i.e., one critical section lesser than the other algorithms.

As it emerges from Table 1, the Morris variation algorithm proposed in this paper outperforms classic known algorithms. With respect to the Haldar & Subramanian algorithm, our algorithm uses only 2 binary semaphores of the weakest type (*plain*) although it uses some more memory (N bits plus the nm counter vs. 2 bits of the Haldar & Subramanian algorithm). Moreover, the proposed algorithm is the only one which is without zeno-cycles.

## V. Conclusions

The Dijkstra conjecture [9] about the impossibility of building a fair semaphore using a few weak semaphores was confuted by the development of algorithms proposed by Morris [5], Martin & Burch [6], Udding [7] etc. However the correctness proof of such algorithms was only partially provided, also considering the methodological approach proposed in [12] or the proof framework developed in [4] which does not allow a full analysis of mutual exclusion algorithms in the presence of the timing dimension.

In this paper an original proving framework based on timed automata (TA) and the Uppaal toolbox is proposed which permits modelling and full verification of the properties of starvation-free mutual exclusion algorithms based on weak semaphores, also in the presence of the timing dimension.

The approach models the three known types of weak semaphores: *plain* (the weakest type), *polite* and *buffered* (the strongest type). It is worthy of note that in its description, the Dijkstra conjecture implicitly refers to the use of *buffered* semaphores.

A key factor of the proposed approach is its modelling and analysis flexibility, being it possible to transparently replace a semaphore type with another one thus enabling a thorough study of a given algorithm.

The application of the approach confirms known properties of classic algorithms, but has the potential to discover subtle features of the considered algorithms such as the existence of a zeno-cycle or of a time-sensitive behavior which influences the kind of weak semaphores which can be actually used. All known algorithms suffer of a zeno-cycle, in the light of which the overtaking factor of a waiting process is (theorically) unbounded. However, when the critical section consumes an even infinitesimal time, the bounded waiting time and overtaking factor of the classic algorithms is effectively guaranteed. In this hypothesis the Morris algorithm is correct with three *plain* semaphores.

As part of this work, a variation of the Morris algorithm was designed which intrinsically eliminates any zeno-cycle, rests only on two *plain* semaphores and replaces a counter of the Morris algorithm with N bits. This new algorithm too was proved to be correct.

The paper contribution enables the implementation of light-weight starvation-free semaphores which can be exploited in general concurrent systems including cyber physical systems.

Prosecution of the research is geared at:

- Modelling and analysis of other mutual exclusion algorithms designed in terms of weak semaphores.
- Implementing weak semaphores and fair semaphores corresponding to mutual exclusion algorithms, in a concurrent programming language, e.g., Java.
- Experimenting with the use of weak semaphores in practical systems programming and in the development of cyber physical systems.
- Exploiting light-weight starvation-free semaphores in distributed shared memory systems, e.g., based on Java and the Terracotta middleware [14] which provides the vision of a "network heap" where shared data can be accessed by threads belonging to distributed JVMs.

***Abstract*—To improve the design of a power control unit at Philips, two Domain Specific Languages (DSLs) have been used. The first DSL provides a concise and readable notation for the essential state transitions. It is used to generate both configuration files and analysis models. In addition, we also generate instances of a second DSL which represents test traces. This second DSL is used to generate test cases for the power control unit. The use of DSLs not only improved productivity, but also the quality of the configuration files and the test set.**

## I. Introduction

THIS PAPER discusses industrial experience with the use of Domain Specific Languages (DSLs) at Philips HealthTech. We have used DSLs to develop power control units of systems for image guide therapy. These systems are used during minimally invasive medical treatments, such as the treatment of cardiology and vascular diseases. An example is the interventional X-ray system shown in Fig. 1, where X-ray images support minimally-invasive medical procedures such as placing a stent via a catheter.

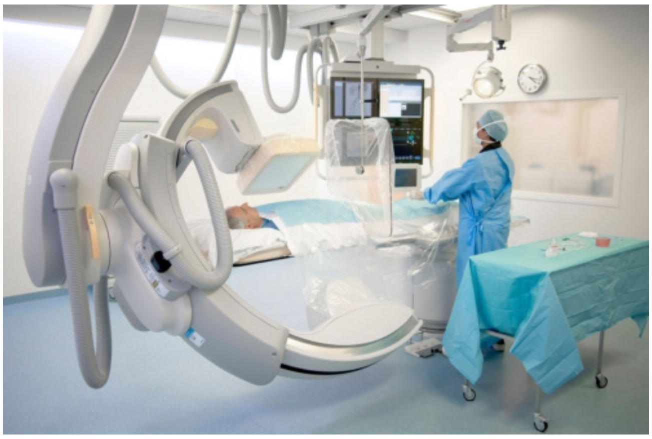

Fig. 1. Interventional X-ray System

Given the long history of these systems and the frequent need for changes to support new medial procedures, it is important to keep the software architecture and its components flexible and extensible. Hence, legacy components have to be renewed to keep them prepared for the future.

An example of such a legacy component is the power control unit. It uses low-level configuration files which are hard to read and difficult to maintain. Given the increasing number of configurations and new third-party components that have to be supported, this starts to become a potential bottleneck. In addition, only a limited set of regression tests is available.

Already long ago, DSLs have been suggested as a way to raise the level of abstraction, to deal with variability, and to improve productivity and maintainability. An early overview of terminology, techniques and applications can be found in [1]. As one of the disadvantages of DSLs this paper mentions the costs of designing, implementing and maintaining a DSL. Since then, however, large improvements have been achieved in the area of language workbenches. Such tools facilitate the efficient construction of languages, editors, and transformations [2], [3]. Examples of workbenches are MetaEdit+ [4], Rascal [5], Spoofax [6], EMFText [7], and Xtext [8].

There are a number of relevant applications in the domain of embedded systems. For instance, there is an interesting laboratory experiment of the application of MetaEdit+ to heart rate monitors of Polar [9], showing a large increase in productivity. Xtext has been used to define a DSL which models the hardware configuration of the complex lithography machines of ASML [10]. From this DSL, a simulation of hardware behaviour which enables software in the loop simulation has been generated. In [11], a DSL based on Xtext has been developed to generate code for real-time large-scale distributed data processing. By means of the MPS approach [12], an impressive extension of the C language has been constructed [13], [14].-

The aim of our work is to investigate whether DSLs could provide a solution to improve the maintainability and testability of our power control unit. We would like to get an answer to the following questions:

- How much time is needed to learn the tools and techniques?
- How much effort is needed to migrate the current legacy component to a component which is defined by a high-level human-usable DSL?
- Does the DSL approach support the combination with analysis techniques such as simulation tools and formal

This research was supported by the Dutch national program COMMIT and carried out as part of the Allegio project.

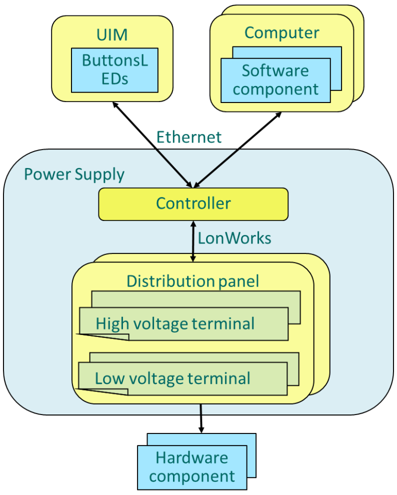

Fig. 2. Overview Power Control Unit

model checkers?

- What are the benefits of introducing these new techniques compared to the current way of working?

The paper is organized as follows. Sect. II describes our industrial case. The developed DSLs are presented in Sect. III and Sect. IV. Sect. V contains an overview of the results and an evaluation of the approach.

## II. Case: Power Control Unit

The interventional X-ray systems of Philips use a distributed architecture with a large number of hardware and software components. The system is highly configurable, i.e., customers can select a particular combination of X-ray stands, monitors, image processing capabilities, etc. Powering the hardware components, and starting up and shutting down the software components are the responsibility of the power control unit. This unit is installed in a technical room together with a number of cabinets which contain the required hardware components. The power control unit consists of a controller that has three interfaces, as shown in Fig. 2:

- An interface to a User Interface Module (UIM) that has On and Off buttons, and two LEDs for user feedback.
- An interface with software components running on computers.
- An interface with power distribution panels that are placed in the cabinets to power the hardware components installed within the same cabinet. Each power distribution panel has a number of individually switchable high and low voltage terminals that are managed by the controller.

The controller and all distribution panels have a 16 bit microcontroller running an embedded application. They communicate with each other via LonWorks [15] using a master-slave topology. LonWorks creates a communication channel superimposed on the power line with which the controller powers the distribution panels. The controller implements the system start-up/shut-down behaviour using a state machine with two parts:

- A high-level state machine that is part of the application running inside the controller.
- A configuration file that describes the low-level state behaviour of the power control unit.

The configuration file is used by the high-level state machine to perform the configuration-specific transitions. This high-level state machine is implemented with VisualState [16] and describes the main states and the associated LED behaviour when transitioning between these main states. These main states are:

- Off: the power control unit is not powered;
- Init: represents the start-up of the power control unit, in this state a Power On Self Test (POST) is executed;
- Standby: the system is off for the user, but power control unit is standby and some continuous power terminals are powered;
- Operational: the system is on for the user, typically all terminals provide power in this state;
- Emergency Power Off (EPO): the controller cuts off the power of the distribution panels immediately and thereby also all the terminals loose power (only the controller stays powered) - used when the user presses a red safety button;
- Stop: a terminal state which is entered when critical parts of the power control unit are detected to be faulty during the POST; in this state only the controller is powered to be able to diagnose the problem.

The low-level state machine for the power control unit defines the so-called recalls and the transitions between these recalls. Each recall denotes a required setting of the high and low voltage terminals, i.e., whether an individual terminal needs to provide power or not. These settings are described in a separate configuration file (not described in this paper).

To realize a particular recall, the controller compares the current status of the low- and high voltage terminals, which it has stored in volatile memory, with the desired status of the low and high voltage terminals. If the current status is different from the desired one, the controller starts communicating with the distribution panels to change the status. The transition from one recall to another may take a considerable amount of time, because of the inherently slow LonWorks communication. Depending on the chosen hardware components by the customer, there are two or three cabinets and it takes between 10 and 30 seconds to address all distribution panels.

Transitions between recalls are not atomic, that is, during such a transition a stimulus might lead to another required recall. To represent the state of these transitions, each main state consists of three substates:

- Entry: the controller compares the current status of the low and high voltage terminals with the desired recall. If they are different the next substate is Transitioning, otherwise it is Stable, except for the first recall where it stays in Entry.

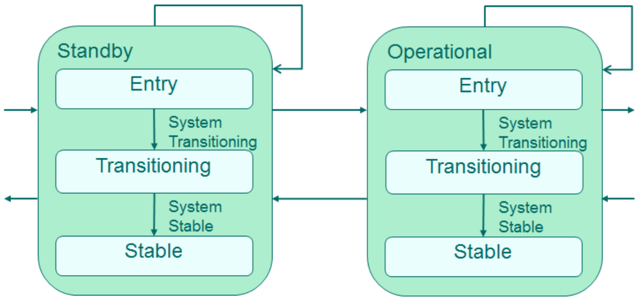

Fig. 3. Two main states and their substates

TABLE I
LINE OF A CONFIGURATION FILE FOR A LOW-LEVEL STATE MACHINE

| | |
|---|---|
| 2 2 0 00000000 00000000 112 4 2 | # < OPERATIONAL > recall 2<br># exit out of forced off |

- Transitioning: the controller is busy changing the state of the low and high voltage terminals.
- Stable: all distribution panels have reached the desired state for the low and high voltage terminals.

Fig 3 shows part of the high level VisualState state machine with two main states and their substates. The main states and substates are fixed, whereas the number of recalls is variable and defined in the configuration file. The low-level state machine and the recalls are different for every system release. The configuration file describes for each recall and stimulus, possibly with a given guard, what the next recall is and between which main states it has to transition. This is all coded in numbers. The main states are numbered, e.g., Standby = 2 and Operational = 3 and similar for the substates: Entry = 0, Transitioning = 1, and Stable = 2. Also all stimuli and all transitions between the main states have a fixed number. The recalls have a configurable number. The guard of a transition consists of two values: the relevant values of a status register and a mask. Table I shows an example of a line in the configuration file. Everything after a # is a comment.
The first three columns of Table I describe the state or -1 if it does not care.

1) The first column is the main state which is the source of the transition (in this example, state 2 denotes Standby).
2) The second column the substate which is the source of the transition (here 2 denotes substate Stable).
3) The third column the source recall (here 0 denoting that all terminals are off).

The fourth and fifth column describe the guard.

4) The fourth column describes the bits of the status register.
5) The fifth column the mask that will be applied.

The other columns have the following meaning:

6) The sixth column, describes the stimulus number (in this example, 112 denotes pushing the on button for 3 seconds).
7) The seventh column is the number of the specified transition between two main states (it might be a self-transition).
8) The eighth column describes the required recall (recall 2 in this example). By default, the substate will be Entry.

TABLE II
PART OF A TEST CASE

| | | | | | |
|---|---|---|---|---|---|
| PDS:QUE9:PAR | NoErr | 30000 | 1000 | 2000 | On Button |
| PDS:SYST? | 3:2:2 | 1000 | 1000 | 2000 | System On |

For performance reasons, this file is sorted on the sixth column. That is, the file is sorted on stimulus number and not on state, which hampers readability.

To test the state machine, there is an automated test tool running on a companion PC that connects to the controller of the power control unit via Ethernet. It can inject stimuli and ask the current state. A test case is a comma separated file. Table II shows two lines of a test case.

1) The first column is the network command that is send from the test tool to the power control unit (QUE injects a stimulus into the state machine and SYST asks the current state).
2) The second column is the expected response from the power control unit to the test tool (“NoErr” means that the command is successfully parsed and “3:2:2” is the current state, with main state 3 (Operational), substate 2 (Stable), and recall 2).
3) The third column is the time (in milliseconds) that the test tool waits before it sends the next command to the power control unit (in this example, the test tool waits 30 seconds between the QUE and the SYST command).
4) The fourth column is a time-out (in milliseconds) on the reply of the power control unit; within this amount of time the power control unit should send a message to indicate that it accepts the command.
5) The fifth column is a time-out (in milliseconds) on the response of the power control unit (as specified in the second column).
6) The sixth column contains comments.

A test case fails on a wrong response or on a time-out of the accept message or the response.

Every night a test suite is executed multiple times on two power control units with Jenkins [17] and the developers will find the results of the test execution in their mailbox. If test cases fail, a lot of time is spent investigating the cause and solving it in either the software of the power control unit or the test case. Test cases often fail because of timing issues in which the power control unit and the test tool are out of sync; this is almost always caused by the unreliable timing nature of LonWorks. The solution for such timing issues is an increase of the time bounds in the test cases. This results in long-lasting test cases with a lot of waiting time.

Concluding, the configuration file is hard to read, to change and to maintain, but has to be updated for every new system release. The same holds for the test cases which typically need to be updated manually for every new configuration file.

Fig. 4. Configuration DSL

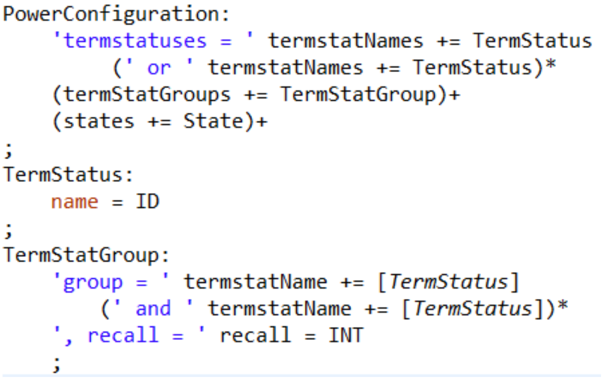
## III. Configuration DSL

To solve the problems mentioned above, we created a configuration DSL for the power control unit, using Eclipse, Xtext and Xtend [8]. This technology was chosen because the second author was familiar with it and the availability of a manual [18].

We explain the configuration DSL based on an instance fragment of the language, as shown in Fig. 4. Since the main states and their substates are always the same, there is no need to define them explicitly. The main purpose is to define the recalls and their transitions. To improve readability, the first part of the DSL instance defines meaningful names for the required status of the terminals, here called *termstatus*. Since several termstatuses might correspond to the same required settings of the terminals, the second part of the DSL groups the termstatuses and associates a recall number with each group. The third part defines the low-level state machine, where for a main state, a termstatus, and a stimulus we define the next termstatus. A transition might have a condition - indicated by the *if* keyword - on the current substate. Note that each termstatus belongs to exactly one main state, so the *next* relation implicitly defines the next main state.

The grammar for this language has been expressed in Xtext; a fragment is depicted in Fig. 5. Based on this grammar, the Xtext framework generates an editor for the language with, for instance, content assist. This makes it easy to define instances of the languages, such as the instance shown in Fig. 4.

The Xtext framework also provides suitable primitives for language validation and the generation of files from instances. In our application, the Xtend language has been used to generate a configuration file from language instances. This generator produces a line in the configuration file for every rule in the language instance. After the generator has generated all the rules, it sorts the lines on the value in the sixth column before writing it to a configuration file. A fragment of a generated configuration file is shown in Table III.



```
PowerConfiguration:
    'termstatuses = ' termstatNames += TermStatus
         (' or ' termstatNames += TermStatus)*
    (termStatGroups += TermStatGroup)+
    (states += State)+
;
TermStatus:
    name = ID
;
TermStatGroup:
    'group = ' termstatName += [TermStatus]
        (' and ' termstatName += [TermStatus])*
    ', recall = ' recall = INT
    ;
```

Fig. 5. Grammar of the Configuration DSL

The first eight columns, till the # sign, are the same as the manually created configuration file described in the previous section. In the comment part, the generator writes the first letter of the source main state, the source substate name, the stimulus, followed by the first letter of the target main state and the target substate name.

Additionally, we have generators that yield for every language instance a set of UML state diagrams, at several levels of abstraction, using PlantUML [19]. An impression of a generated diagram is given in given in Fig. 6 (not readable for reasons of confidentiality).

## IV. Test DSL

Given a formalized representation of the configuration files, we investigated the possibilities to generate test cases from this DSL. A preliminary attempt to define a generator for test cases indicated that this was possible, but became rather complex since it included strategies to define test cases as well as translations to the current test format. To separate these issues, we aimed for a more abstract representation, related to the work described in [20] concerning a tool-independent representation of test design techniques. In our context, we defined a second DSL for the definition of tests to obtain a representation of tests which is independent of the current test techniques. Fig. 7 shows the relation between these DSLs. Note that with the Xtext approach there is no separate definition of the abstract grammar with meta models.

The test DSL is explained using the instance fragment depicted in Fig. 8. Note that this instance is generated from an instance of the configuration DSL. In the first part, for each termstatus of the configuration instance three extended termstatuses are generated corresponding to the three substates, by adding *Entry*, *Transitioning*, and *Stable* behind the name. The string after keyword *code* matches the first three columns of the VisualState configuration file; it is obtained using the code of the main state of the termstatus, the code of the substate, and the recall number defined in the configuration instance.

The second part lists all possible transitions. This is used to generate a report about coverage of termstatuses and transitions and to generate additional tests for stimuli that should not lead to a transition. In the third part, one or more trace sets are defined. Each trace set has one or more traces. A trace consists of an initial extended termstatus, and a number of pairs consisting of a stimulus and a next extended termstatus. Each trace starts and ends with the same extended termstatus, which makes it possible to run a number of traces in one go. Note that this requirement makes the generation of an instance of the test DSL a bit more complicated.

The generator of the trace DSL generates a test case, as shown in Table IV, for each trace in the language instance. Every Transitioning and Stable termstatus will result in a line in the test case with a SYST command that expects the string defined after the *code* key word in the *termstatuses* part of the instance. Since Entry substates are not observable (except for the first one), they are omitted. A stimulus will result in a line in the test case with a QUE command. Note that the third column is slightly different from table II; instead of a waiting time, now also an event can be specified. Such an event is used to synchronize with the power control unit and avoids long waiting times. It makes the testing process much faster.

Additionally, we used PlantUML to generate a visualization of a test trace as a sequence diagram. An examples is depicted in Fig. 9.

TABLE IV
PART OF A GENERATED TEST CASE

| | | | | | |
|---|---|---|---|---|---|
| PDS:SYST? | 6:00:00 | 2500 | 1000 | 2000 | SystemEPOEntry |

| PDS:FWV? | 3.0.0.0 | T016_TRANS | 1500 | 2000 | SystemTransitioning |
| PDS:SYST? | 3:01:02 | 1000 | 1000 | 2000 | SystemOnTransitioning |
| PDS:FWV? | 3.0.0.0 | T017_STABLE | 1500 | 2000 | SystemStable |
| PDS:SYST? | 3:02:02 | 1000 | 1000 | 2000 | SystemOnStable |

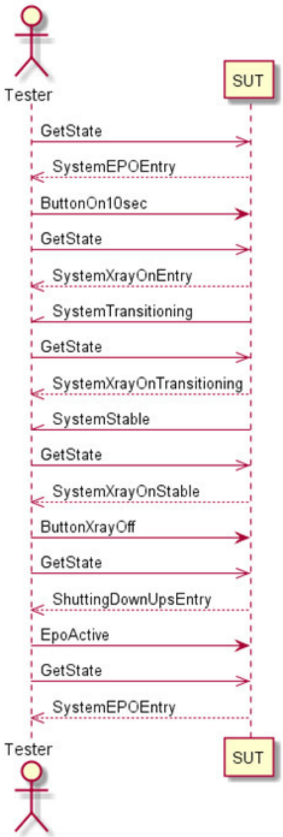

Fig. 9. Generated Sequence Diagram of a Test Case

The generator also generates a coverage file. Based on the selected termstatuses, transitions and traces, it creates a list of covered states, uncovered states, covered transitions and uncovered transitions. See Fig. 10.

Typically, we create two trace sets. The first trace set covers all transitions and is used for state and transitions coverage. A disadvantage of this set is that it also tests Emergency Power Off (EPO), which implies that only the controller of the power control remains powered; the distribution panels will lose power including the processor inside. Since this will rarely happen during normal usage, a second set is created with more realistic user scenarios where the distribution panels stay powered. Jenkins is configured to run these tests every weekend many times to test the reliability of the software running inside the power control. Outside the weekend, the full test set is run every night.

Fig. 10. Coverage File

In the work described above, we used our own algorithm to generate test cases. As a next step we investigated the use of an existing tool to generate the test cases. We selected the SAL (Symbolic Analysis Laboratory) framework [21], [22], [23] which includes an automated test generator. The generator of the configuration DSL has been extended to generate two SAL files, corresponding to the two trace sets described above. When the test generator of SAL is supplied with a test goal - in our case the goal is to cover all transitions - it will yield traces that satisfies the goal. From this information, an instance of the test DSL is generated automatically using a small script.

## V. CONCLUSION

We summarize the results in Sect. V-A. The additional generation of analysis models is described in Sect. V-B. Sect. V-C addresses the questions of Sect. I. A brief description is future work can be found in Sect. V-D.

### A. Results

We started with the configuration DSL and generated a configuration file for the current system release. This generated file was successfully tested on the target hardware. Comparing the generated file with the existing one, we found a number of issues in the existing file. It contained a non-existing transition and a number of transitions were missing. As a next step, we made a DSL instance for the next system release and generated the configuration file. The size of this new configuration file is about twice the size of the current file, which indicates the increasing complexity of our system releases.

With the generated test cases, approximately twice as much transitions are covered as the manually written tests. The manually written test cases only made transitions from the Stable substates. The generated test cases also make transitions from the Entry and Transitioning substates, which leads to twice as much transition coverage.

The manually written cases were very time-dependent, with many long waiting times. They could still fail by a slow response of hardware, which required some analysis and typically a further increase of the waiting times. By having all concepts described in a clear and concise way using DSLs, we could make the test cases much more efficient. Instead of waiting all the time, the test tool now synchronizes with the power control unit and immediately resumes the test case once the power control unit has reached the desired state.

### B. Analysis models

In addition to the generated configuration and test files, we generated a number of analysis models. From the configuration DSL we generated models for the simulation tooling of POOSL [24] and the model checker mCRL2 [25]. The generators for mCRL2 and POOSL combine the behaviour of the high-level state machine and the low-level state behaviour described by the (generated) configuration file, into one state machine describing the complete system start-up and shutdown behaviour. Implicitly, these generators define the semantics of the DSLs. The use of multiple tools increases the confidence in the correctness of the generators.

The advantage of having a separate test DSL is that we can also generate tests or checks for the analysis models. For POOSL, we generated a tester process that communicates with the generated state machine. Every test trace results in a method that applies stimuli to the state machine process and checks whether the returned responses are as expected. The results are written to a file with a test report. For mCRL2 we generated properties to express that the expected traces occur in the generated state machine. This property can then be checked by the mCRL2 tools.

Using POOSL and mCRL2, we detected problems in the DSL instance, e.g., the simulation in POOSL revealed a missing condition. Moreover, we can detect whether a termstatus occurs in multiple main states. An alternative would be to use the validation possibilities of the Xtext/Xtend framework.

### C. Evaluation

We discuss the questions listed in the introduction (Sect. I):

- *How much time is needed to learn the tools and techniques?*
  Clearly, the learning curve for new techniques depends on previous education and knowledge. The work reported here was mainly done by the first author who independently learned the DSL techniques from the manual mentioned before [18]. With a Master's in Computer Science, including course about grammars and formal techniques, the basic part of the manual requires 4 hours to install the tools and to redo the examples of the manual. This was enough to get started with the case study.
- *How much effort is needed to migrate the current legacy component to a component which is defined by a high-level human-usable DSL?*
  It took about 35 hours to create the two DSLs presented here and to integrate them with the power control unit and the test tool. This step was sufficient to demonstrate the usefulness of the approach to management. In later increments, we added the generators for the analysis models and the use of SAL for test generation. Since the adaptation of grammars and generators is relatively easy and fast, the approach supports an incremental way-of-working. The Eclipse/Xtext framework is quite mature and provides many basic features such as syntax highlighting, auto completion, and content assist.
- *Does the DSL approach support the combination with analysis techniques such as simulation tools and formal model checkers?*
  Given earlier experience with POOSL, mCRL2, and SAL, it was straightforward to write generators for these languages. For each of the three languages mentioned, this took about 5 hours. The generators to visualize the state diagram and test traces using PlantUML requires only a few hours of work.
- *What are the benefits of introducing these new techniques compared to the current way of working?*
  The complexity of our configuration files is expected to increase quickly; as already mentioned above, the file size almost doubled for a new product release. With an investment of only 35 hours, we are ready to deal with this increasing complexity. We can now create the configuration and test cases for the power control unit in a readable, easy to change and maintainable format. The tests are now 3 times faster with a double coverage. It is expected that for a new product release we need only 8 hours instead of the estimated 60 hours.

Our experience is in accordance with a recent report about the state of practice in model-driven engineering [26]. It shows that most successful applications of model-driven development use small DSLs.

### D. Future Work

Future work includes an extension of the configuration DSL such that also the configuration file which contains the details of the recalls (i.e., the required setting of the high and low voltage terminals) can be generated. Similar to the low-level state machine, also this configuration file is hard to read, to change, and to maintain.

As a next step, we intend to remove the Visual State framework, and generate the full state machine directly in the C programming language. The generators for POOSL, mCRL2, and SAL are a good indication that this will be feasible.

## Acknowledgment

We thank the anonymous reviewers for a number of useful suggestions for improvement.

***Abstract*—Reactive systems have been investigated and used for a long time. Due to new methods and new technology development, the reactive systems needs their redefinition. These systems are currently an interesting topic for IT (Information Technology) solution providers. In this paper the authors try to define a new view of the architecture of reactive systems, because reactive systems are evolving and there is no clear definition of them. The starting point of the investigation was the reactive manifesto which defines reactive systems by four main features (quality attributes): responsiveness, resilience, elasticity and message driven interoperability. The mentioned quality attributes are the basis for developing a system solution. For each of the quality attributes, a set of tactics are proposed to maintain attribute required behavior. The suitability of the proposed tactics was investigated for Reactive Sensor Middleware which is part of a CoS (Cloud of Sensors) in the PaaS (Platform as a Service) layer. A cloud of sensors for pollution monitoring in urban areas was used as an example. Verification of the tactics has confirmed that some of the proposed tactics are suitable for the selected CoS subsystem.**

***Index Terms*—Keywords Reactive systems, reactive manifesto, software architecture, quality attributes, tactics, cloud of sensors, pollution sensing**

## I. Introduction

IN THIS paper an approach is presented for the purpose of defining a software architecture model for a class of systems. The class considered here are reactive systems. In the classic book [1] on reactive systems design, systems are described by their characteristics: highly interactive, nonterminating process, interrupt driven, state-dependent response, environment-oriented response, parallel processes, usually stringent real-time requirements. The starting point of the analysis of reactive systems was the reactive manifesto [2], which defines reactive systems by its features. The manifesto stated that "a coherent approach to systems architecture is needed, and we believe that all necessary aspects are already recognized individually: we want systems that are responsive, resilient, elastic and message driven". The systems described by these features are called reactive systems. The reactive manifesto went through two revisions. The scalable and event driven traits from the previous version are replaced by elastic and message driven in the current version. We found this clarification interesting, especially when observing changes in dependency diagram which is part of both revisions. In the previous version the traits are all connected bidirectional lines, suggesting that all of them depends on each other, which was not very informative. That changed in Reactive Manifesto 2.0. The current iteration contains far more interesting inner dependencies. Message Driven pattern was defined as basis for all other traits. Responsiveness seems to be the main goal of reactive systems, because all other traits depends on it.

The goal of this paper is to develop an system solution based on selected quality attributes responsiveness, resilience, elasticity and message driven pattern. For the predefined set of quality attributes architectural tactics are proposed. The tactics will be used in determining architectural models. The approach is based on the classic software architecture development process proposed by Software Engineering Institute [3][4]. In the literature different solutions are proposed in the field. In [5] a general approach is proposed for embodying nonfunctional requirements (NFRs) into software architecture using architectural tactics. In [6] the influence of quality properties on decision making regarding software architecture was investigated.

## II. Quality Attributes of Reactive Systems

Quality attributes are referred to as Non Functional Requirements (NFR) and represent a desirable behavior of the system and are key success factors in developing software architecture. In next subsections three quality attributes are considered: elasticity, resilience and responsiveness.

### A. Elasticity

Elasticity is the ability of a system to scale resources up or down with minimal latency for different environment behavior during system runtime for different time periods. The ability can be reached manually or automatically. For the reactive systems the following sub attributes can be distinguished:

Consistent System Load. The load of IT systems can be not evenly distributed. The system should be able to scale both up and down - changing dynamically and automatically the amount of resources allocated. The goal is to handle user requests in a predictable, consistent manner. Attribute metrics should represent a standard level of usage of resources. It‘s lower boundary should not be set too low (the system is wasting resources, over-provisioned) while it‘s upper boundary

978-83-60810-66-8/$25.00 ©2015, IEEE

should not be set to high - in this case, we are in constant risk of throttling the system at any moment (under-provisioning).

Latency in allocating and deallocating resources. The system should be able allocate resources to achieve elasticity corresponding to the current load. Due to that time is a critical criteria - the amount of time needed to set up an additional application process should be as short as possible. The application should be small and granulated and it‘s startup time really quick beginning from the “cold” system and ending with the ability of handling user requests. The criteria chosen are time of allocating and de allocating new resources. The attribute metrics are numeric - startup time from the state before allocating new resources to the moment, when new resources are able to handle new users.

Scalability. An elastic system should be scalable in a predictable way. Its performance should improve proportionally to added resources. The overhead of adding new application instance should be as small as possible. It is desirable to achieve linear proportion between those two values (performance to capacity of added resources).

### B. Resilience

A resilient system is one that delivers a service that can be justifiably trusted when facing changes [9]. Resilience is related to a system’s ability of maintaining service provision without deviating from the fulfillment of system goals, despite changes that might affect the system or its environment. An example of resilience evaluation is presented in [7]. For description of resilience the following sub attributes are selected based on the “technologies” defined in [9].

Evolvability. It is ability to respond effectively to change. Within evolvability, an important topic is adaptivity, i.e., the capability of evolving while executing and retaining the notion of justified confidence.

Assessability. It is based on verification and evaluation. Classically, verification and evaluation are performed offline in a pre-deployment stage. In reactive systems assessment and evaluation has to be performed at run-time, during operation.

Usability. Computing systems have already pervaded all activities of our life, hence the importance of usability.

Diversity. Diversity should be advantageous in order to prevent vulnerabilities, e.g. have single points of failure.

From our perspective, there are additional sub attributes which resilient system should have:

Automaticity. Reactive systems, due to constant changes, should not be administrated by people only. A system should react automatically on changes in it (e.g. a situation when a given service is down or a new deployment is ready) and perform a predefined strategy, mitigating the occurrence of human errors which could cause the system to close down. In a resilient system, infrastructure should automatically resize itself to keep required quality.

Rationality. The system should be able to provide value even when it is partially inaccessible. In that case the system is built from the isolated micro services, it shouldn‘t happen that the system is not responding when one trivial part is not able to respond (e.q. we have parts of system unaccessible due to power blackout). This feature cannot be easily added to the system in the later stages and should be taken into account during the design process. A system should know which parts are important and cannot be missed (responding to a failure) and which parts are trivial (it’s just add value). Rational systems don‘t fail if there is no reason to do that.

### C. Responsiveness

Responsiveness refers to the ability of a system to fulfill assigned tasks within a given time as seen by the user.

Consistent response time. It is important to achieve consistent response time for a system request. Typically, mean response time is used as a metrics. Unfortunately, it doesn‘t say much about a time consistency of a request. Two systems with exactly the same mean can have a highly different pattern of behavior. One system can be predictable and consistent, the other may have quick as well as slow response times. For both systems their mean metrics will still be similar. Consistency increase user trust in the system reliability. The attribute metrics may be a standard deviation of response time for a full request-response loop. It describes how a system behaves in the long term in a given time and presents information about the best and worst cases.

Adapting data processing to the given usecase. Data from the system should be accessible as fast as they bring the value for the end client. Topic becomes more important when we are talking about communication between systems which are better adapted to fast data acquisition and usage. Internet of Things presents both new opportunities and challenges, that’s why Fast Data term becomes more and more important in synergy with Big Data systems.

## III. Tactics for Reactive Systems

A tactic is a design decision that aims to improve one specific design concern of a quality attribute [5]. Software architects utilize a rich set of proven architectural tactics and patterns to help satisfy specific quality concerns. Architectural patterns have an overarching impact on a software system, and are typically selected early in the design process. They determine the overall style of the design and include well-known solutions schemes [8]. Tactics and patterns are known architectural concepts; the work [9] provides more specific and in-depth understanding of how they interact. In the next subsections tactics are proposed for a previously selected set of quality attributes.

### A. Elasticity

*1) Ability to scale part of a system independently:* If we want to achieve usage of resources in a sufficient way, we need the ability to scale a different part of the system in response to its growing demand. Today, applications no longer rely on monolithic architecture. Parts of the system are developed in different technologies and they can have a very distributed necessity of system resources.

Sharding. Sharding is a specific type of database partitioning and its role is to split a database into smaller pieces, called shards, which are easier to manage, faster and less vulnerable to problems of global locking, meanwhile being easier to replicate due to its reduced size. Shards shouldn't share information between them, giving the ability to spread data between different physical instances and scale them independently, without the necessity of maintaining high-end, high-power systems. A common strategy is e.g. sharding data geographically, where we can take into account problem of latency too.

*2) Decrease overhead of single components:* Starting the executing of software components is the biggest factor in system latency. Below, are some tactics proposed, which are used to reduce software overheads

Containerization. Containerization and Software Containers are not new topics. However, they gain attraction in recent years, thanks to the support of IaaS Providers. In contrast to virtual machines it uses the kernel of the host machine and runs on isolated user space instances. Containers can be prepackaged and quickly distributed, with a minimal starting time of a single instance. It's worth to mention that there are particular Operating System Solutions created directly to work with Containerized software.

Lightweight technology stack. The bigger codebase, the longer load time can be felt by user. Splitting application into smaller pieces can drastically shorten time needed to run the new instance. Due to that fact, when want to achieve ability to run application instances dynamically on demand, we shouldn‘t relay on heavyweight enterprise technologies with huge amount of dependencies. Each application should have as little dependencies as possible and use external libraries/framework only when it‘s necessary.

*3) Allowing for Resource Balancing:* In the system which rely on the input from user, who can join or disconnect in any moment, amount of received data can vary dramatically over time. Having that in mind system should have ability for automatic resources balancing. Humans are error prone and too to slow to react while working with rapidly changing load. System should be able to allocate and deallocate resources to maximize ratio between throughtput and economic cost.

Implementing Backpressure. Backpressure in terms of responsive systems means the ability to acquire a feedback message from request passed through the system, e.g. by passing the message through the queue. Acquiring feedback is necessary to scale software in the correct way, e.g. the utilization of component resources. The implementation of backpressure is a nontrivial problem due to the asynchronous model of the communication. However, it is especialy important while dealing with the everlasting stream of data - there is possibility that the system under load will be overloaded by the incoming data.

Resource Managing based on Kernel Sharing Layer. An approach is used based on kernel features to provide the abstraction and isolation of system resources, instead of them on system-level defined rules, rather than monitoring the application and pooling its state through metrics values, such systems respond to application demands, by increasing its resources and spawning new instances (e.g. Apache Mesos [10] with Apache Aurora). It's solution fitted for Server Racks and Clusters to hide abstraction of multitenancy systems.

Immutable Designing. The less mutable state inside application, the easier application is to scale. In that case instances can‘t be easily replicated and a client can be served only by the instance with which started communicating. If the application is stateless, the load balancer can pass user input to whatever instance of application has free resources at the moment. The Domain Driven Design methodology is a good tool to evaluate which part of the application should be mutable and which not. Using good suited tools, such as functional programming languages or using message driven approach can be also benefitial.

### B. Resilience

The resilience of the system is an offshoot of both dependability and availability, defined to better suit the demands of an architecture based on micro services. Lack of availability of microservices sums up. The important thing is to design a system in such way that when one of the elements fails it will not bring down the whole application functionality.

*1) Replication:* The most obvious way to achieve high availability of all systems parts is to provide redundancy. This is especially preferable when a considered system is stateless and every request can be processed by any instance.

Bulkhead. Bulkheads are used in ships to create separate watertight compartments which prevents the ship from sinking. The idea can be effectively used in computer systems. In a similar manner, a computer system should have redundant components which are easily replicable whenever something happens to the system and one of its counterparts.

*2) Delegation:* In contrast to the classic synchronous method calls, a reactive system cannot use exception and exception handling due to its isolated nature. Thrown exceptions don‘t have a chance to reach component which is able to handle it. Information about failure should be delegated to another component able to resolve it.

Feedback supervisor. In the reactive system a supervisor should exist, which is a special component existing outside the standard flow of the systems and has information about the whole system. Whenever a failure occurs, corresponding information with the whole bounded context should be send to the supervisor. It‘s a great way to decouple the standard flow of the system from the failure support and error handling mechanism (e.g. Netflix‘s Hystrix).

*3) Isolation:* The main problem of distributed systems is the possibility of partial failure. We don‘t want errors propagate over the systems, dragging whole infrastructure down. Isolation is an important trait of the system created from the micro services, which assures that failure of one part does not spread over whole system.

State and behavior containment by Bounded Context. Every component should be as small as possible and enclose specific problem domains inside the bounded context. Boundaries are connected by messaging protocols. This ensure that the system architecture reflects the problem domain making it easy to evolve. It also promote component composability and modularization on the architectural level.

Containment of failures. It should be possible to contain a failure inside the block where it occurred. The failure shouldn't be promoted to the next block, inhibiting "disease spreading". No error should be able to cascade through the system. Whenever we do not provide the fallback, we should fail-fast to not saturate system resources and pass failure to the supervisor.

### C. Responsiveness

The responsiveness of the systems was investigated for a long time. In [5] six general principles for the synthesis of responsive software systems are presented: fixing, locality design, processing versus frequency tradeoff, shared resources, parallel processing, and centering. In the current systems developing a new approach for responsiveness tactics is essential.

*1) Deferred data validation:* The biggest difference between local software and software working throughout the network is the fact, that the distributed software has a far much longer feedback loop for each request. Whenever a user performs any action, it needs to wait to validate it on the server side, which can be a long operation striking user out of context. That's why it is important to sustain for the user an illusion of local work.

Normalization of data. System need to be able to cope with different type of inputs communicating on both a different protocols and data quality. That bring a necessity of bringing normalization layer which is able to retrieve common values from system, marking all data with an input specific metadata which can be used to additional analytics.

Data store synchronization. Thanks to better technology, it is possible to use data storage both on the client as on the server side. During work with web applications the user has feeling to work with native application by providing him with two data stores, a local and remote one. This is especially handy when both client and server are written in the same technology, sharing a common codebase. The user is working on the local copy bringing a short feedback. The local copy synchronization is performed in the background. The user is informed only whenever conflict happens.

Multiplayer game style data validation. To achieve smoothness of experience, programmers introduced a sophisticated system of the multiplayer game. Each player plays in his local environment and information about his actions is passed to the server, which confirms if its actions are possible to be done. The server has godlike power over each player and if he finds conflicts, resolves them and informs players about a verdict. Thanks to that each player has his own smooth experience.

*2) Sustaining consistent response time:* It is necessary to receive data as soon as they are able to be processed by system and end user. Synchronization should be done in the background. If our system responds to fast, responses it will be placed inside a buffer which should be maintained. If it will be too slow, we risk lowering the consistency of the overall system.

Streaming based data store To suit needs of the Fast Data system, our technology stack need to be adapted to processing not only huge amount of data, but also need to be able to process them in the fast way. Such a system needs to be able to combine storing huge amount of data from the many different concurrent inputs as a data warehouse, it also need to be able to deliver stream result in a quick way with a most current results for a waiting clients. An example of such a solutions can be Apache Storm and Apache Spark.

Non-blocking client-server communication. Communicating in a synchronous way is the biggest issue when trying to achieve consistent response times. A server communicating in a synchronous way is always waiting for a response and a one long request can delay a whole queue of operations. Each request should be responded to in the deferred way.

Worst case scenarios designing. To ensure that a response will be produced in reasonably, consistent time, it is important to use algorithms with low complexity. To provide a good level of stability in distributed systems, we need to bound a system with realistic timeouts. It is important not to break connections in case the data are processed correctly, but too long.

## IV. A Cloud of Sensor with Reactive Sensor Middleware

The proposed tactics for the reactive system will be verified for RSM (Reactive Sensor Middleware) which is part of a CoS (Cloud of Sensors) in the PaaS (Platform as a Service) layer.

The proposed RSM is very important because it is assumed that the number of sensors will increase rapidly. The physical sensors and a well-defined communication interface will be delivered by sensor providers. The sensor providers will deal with service installation, sensor infrastructure maintenance, and the sensor data offering to sensor service consumers over the Internet. The service consumers can use the sensor data with their own or other providers' applications, which are integrated with the physical sensors. The described solution is known as a CoS (Cloud of Sensors). This makes it possible for users to lease the sensing hardware and associated applications instead of buying the complete infrastructure.

There are similar solutions to CoS such as cyber physical cloud (CPC), the Internet of things (IoT) or Fog Computing [11], which is a paradigm that extends Cloud computing to the edge of the network and services can be hosted at end devices. All these solutions [12] have sensors and a cloud as an integral part of their architecture. CPS consists of computer (cyber) systems that interact with the physical world. CPC is simply a CPS with cloud integration. Thus, CPC is CPS with a cloud as its backbone for computation and communication. In contrast, the Internet of Things (IoT) enables pervasive and ubiquitous interconnection in near real-time on a massive scale with different remote devices (mostly sensors) that can be uniquely identified, located, and communicated with. Cost effective and scalable IoT solutions can be achieved using cloud-centric architecture.

Cloud of Sensors Solution Architectures Existing research into CoS and related architectures proposes various solutions.

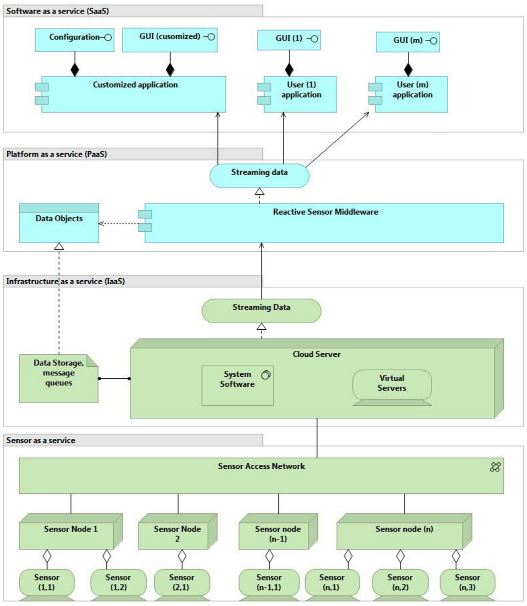

Fig. 1. CoS structure with Reactive Sensor Middleware located in PaaS layer

Some interesting examples are given below.

Paper [13] presents the design and evaluation of a Data Quality-Aware Sensor Cloud (DQS-Cloud) which is based on a cloud-based sensor data services infrastructure. The objective of the paper is to make a DQ as a multidimensional space in which all sensor devices produce multiple quality parameters or metadata such as accuracy, delay, frequency, latitude, longitude, sensor type, etc. Paper [14] proposes a new infrastructure called Sensor-Cloud infrastructure which virtualizes a physical sensor as a virtual sensor using cloud computing. An important issue is the developing of mathematical models (e. g. [15]) for the virtualization of sensor node resources. In [16] two alternative architectures for service management in IoT and sensor networks are discussed: based on Open Service Gateway (OSGi) framework and Remote Services for OSGi (R-OSGi) bundle.

For CPS systems other solution architectures are more suitable. In [17] a unified 5-level architecture is proposed as a guideline for implementation of CPS (Cyber Physical Systems). CPS solutions can be extended using SOA (Service-Oriented Architecture) solutions.

The CoS solution used for tactics verification of reactive systems, using cloud-centric architecture with Reactive Sensor Middleware in the PaaS layer is outlined on Fig. 1.

Pollution Monitoring in an Urban Area A cloud of sensors may have very broad applications. As an example an atmospheric pollution monitoring system was chosen in the paper. The goal of such a system is on-line pollution monitoring for decision making and the development of environmental policies, with the goal of reducing the impact of pollution on ecosystems and human health.

Some distinguished examples are given here. In [18] an interoperable system for air quality information management is proposed. The system is based on open-source standards-compliant tools and designed to develop a Spatial Data Infrastructure (SDI). In [19] a Pollution-Sense system for air pollution monitoring and control is presented. Participatory sensing combines the use of everyday mobile devices, such as cellular phones, GPS technology and location-based services, and sensors, to form interactive, bidirectional mobile sensing information systems. The system should provide large amounts of pollution data in time and space with different granularities. In [20] a method is described for the automatic detection of air pollution and fog using sensors mounted on vehicles. The described system consists of sensors which acquire their primary data from cameras and Light Detection and Recognition (LIDAR) instruments. In [21] a sensor cloud based on WSN (Wireless Sensor Networks) is proposed which virtualizes the wireless sensors and provides sensing as a service to users.

Different users of pollution monitoring systems can be distinguished. Some examples of users of such systems are: (1) Single persons or families (e.g. planning an excursion in an urban area); (2) People with allergies or breathing problems like asthma (e.g. planning to go outside); (3) Schools (e.g. planning different sport activities outside for children); (4) Early warning systems for municipal operation; (5) Urban planning used for air pollution reduction.

There are different types of pollution sensors which can be wearable, mounted on vehicles or UAVs, or installed in fixed positions (buildings, weather stations, etc.). The specialization of pollution sensors may differ significantly: (1) Personal environmental sensors, which are wearable sensors connected to or integrated with smart phones; (2) Pollution sensor stations installed on fixed points or on vehicles measuring air pollutants; (3) LIDAR (Light Detection and Recognition) used to detect small concentrations of air pollutants.

From the above discussion it is clear that providers of the sensor as a service layer can be individual persons or organizations with the motivation to receive payment for service proportional to sensor usage. The presented discussion aims only to be an overview of possible pollution system monitoring solutions, and is not intended to demonstrate the full picture.

## V. Verification of Tactics

The proposed set of tactics will be verified for an RSM which is part of a CoS placed in the PaaS layer. Of course not all of the proposed tactics for reactive systems will be suitable for RSM. Only the tactics most useful while building the aforementioned system will be selected.

**Elasticity** is a very important aspect of a system based on dynamically attached external data sources (in our case sensors). We do not know in advance the size of the streams of data that our application will be exposed to. For this reason correctly implemented resource balancing needs to be a core part of the infrastructure. Proper implementation of backpressure tactics is especially important as the system needs to be able to control the flow of data. A perfect solution would appear to involve quickly running and disabling new application instances when there is an urgent load increase or decrease, in order to setup and disable containers on the shared Resource, especially when the application is stateless and implemented using a light technology (a good example of such a stack is Node.js Amazon Lambda). In this case, for a cloud of sensors a sharding tactic should be proposed. Usually data received from sensors are closely related to geographical locations or data sensor types, therefore the data should be logically grouped to ensure processing efficiency. This makes it possible to easily separate data in order to mitigate latencies during querying of the data store.

**Resilience** is defined as the time taken by a system to return to an acceptable state after failure. The investigated cloud of sensors is highly dependent on the external data, therefore constant supervision is essential. A component which monitors the behavior of intermediate elements is needed, and this can be achieved by using a feedback supervisor tactic. A good level of isolation in the system should be provided as data can be acquired from different inputs and the instances collecting the data are independent. A containment of failure tactic can be used to prevent the failure of one instance impacting others. All instances should not be deployed in a single cluster, instead the system should use a bulkhead tactic which splits it into different physical locations, thereby mitigating the potential for a critical situation in which the system is unresponsive as a whole.

An important aspect of the design of the discussed sensor cloud from a **responsiveness** perspective is the use of a normalization of data tactic. This ensures that the data store always has data in a proper, common format and is able to execute all necessary analytic operations quickly and responsively, without intermediate steps. Also, providing non-blocking client-server communication is important if we want to achieve consistent response times for clients of our cloud solution.

## VI. Summary

The current reactive system's needs must be examined from different perspectives due to the emergence of new system solutions and new technologies. One such factor is the big data processing issue, caused by the need for real time data stream acquisition and visualization, which makes it important to perform architecture refactoring of reactive systems. The approach presented, which starts with the analysis of quality attributes and their tactics, seems proper at this stage of development. The investigation of the suitability of the proposed tactics for Reactive Sensor Middleware which is a part of CoS (Cloud of Sensors) placed in the PaaS (Platform as a Service) confirms the approach. The next stage will be experimentation on other real system examples, analyzing suitable architecture patterns and finally defining a reference architecture model for reactive systems.

# 8th International Symposium on Multimedia Applications and Processing

## ORGANIZED BY

SOFTWARE Engineering Department, Faculty of Automation, Computers and Electronics, University of Craiova, Romania "Multimedia Applications Development" Research Centre

## Background and Goals

Multimedia information has become ubiquitous on the web, creating new challenges for indexing, access, search and retrieval. Recent advances in pervasive computers, networks, telecommunications, and information technology, along with the proliferation of multimedia mobile devices - such as laptops, iPods, personal digital assistants (PDA), and cellular telephones - have stimulated the development of intelligent pervasive multimedia applications. These key technologies are creating a multimedia revolution that will have significant impact across a wide spectrum of consumer, business, healthcare, educational and governmental domains. Yet many challenges remain, especially when it comes to efficiently indexing, mining, querying, searching, retrieving, displaying and interacting with multimedia data.

The Multimedia - Processing and Applications 2015 (MMAP 2015) Symposium addresses several themes related to theory and practice within multimedia domain. The enormous interest in multimedia from many activity areas (medicine, entertainment, education) led researchers and industry to make a continuous effort to create new, innovative multimedia algorithms and applications.

As a result the conference goal is to bring together researchers, engineers, developers and practitioners in order to communicate their newest and original contributions. The key objective of the MMAP conference is to gather results from academia and industry partners working in all subfields of multimedia: content design, development, authoring and evaluation, systems/tools oriented research and development. We are also interested in looking at service architectures, protocols, and standards for multimedia communications - including middleware - along with the related security issues, such as secure multimedia information sharing. Finally, we encourage submissions describing work on novel applications that exploit the unique set of advantages offered by multimedia computing techniques, including home-networked entertainment and games. However, innovative contributions that don't exactly fit into these areas will also be considered because they might be of benefit to conference attendees.

## Call for Papers

MMAP 2015 is a major forum for researchers and practitioners from academia, industry, and government to present, discuss, and exchange ideas that address real-world problems with real-world solutions.

The MMAP 2015 Symposium welcomes submissions of original papers concerning all aspects of multimedia domain ranging from concepts and theoretical developments to advanced technologies and innovative applications. MMAP 2015 invites original previously unpublished contributions that are not submitted concurrently to a journal or another conference.

Papers acceptance and publication will be judged based on their relevance to the symposium theme, clarity of presentation, originality and accuracy of results and proposed solutions.

## Topics

Topics of interest are related to Multimedia Processing and Applications including, (but are not limited) to the following areas:

- Audio, Image and Video Processing
- Animation, Virtual Reality, 3D and Stereo Imaging
- Big Data Science and Multimedia Systems
- Cloud Computing and Multimedia Applications
- Machine Learning, Data Mining, Information Retrieval in Multimedia Applications
- Multimedia File Systems and Databases: Indexing, Recognition and Retrieval
- Multimedia in Internet and Web Based Systems
- E-Learning, E-Commerce and E-Society Applications
- Human Computer Interaction and Interfaces in Multimedia Applications
- Multimedia in Medical Applications
- Entertainment and games
- Security in Multimedia Applications: Authentication and Watermarking
- Distributed Multimedia Systems
- Network and Operating System Support for Multimedia
- Mobile Network Architecture
- Intelligent Multimedia Network Applications
- Future Trends in Computing System Technologies and Applications

## Best Paper Award

A best paper award will be made for work of high quality presented at the MMAP Symposium. The technical committee in conjunction with the organizing/steering committee will decide on the qualifying papers. Award comprises a certificate for the authors and will be announced on time of conference.

## Steering Committee

**Amy Neustein,** Boston University, USA, Editor of Speech Technology

**Lakhmi C. Jain,** University of South Australia and University of Canberra, Australia

**Ioannis Pitas,** University of Thessaloniki, Greece

# Shape and colour recognition of dishes for the purpose of customer service process automation in a self-service canteen

Tomasz Kryjak, *Member IEEE*
AGH University of Science and Technology
al. Mickiewicza 30, 30-059 Krakow, Poland
Email: tomasz.kryjak@agh.edu.pl

Damian Król
Email: damians.krol@gmail.com

***Abstract*—In the article a vision system for shape and colour recognition of dishes (plates, bowls, mugs), which can be used to automate the process of customer service in a self-service canteen is described. In consists of three basic components: object segmentation using so-called background model subtraction, shape recognition using geometric invariant moments and SVM classifier, as well as colour recognition using a Gaussian model. In addition, recognition in case of close or abut objects using a distance transform like approach is presented. The solution was evaluated on a dedicated test stand with controlled LED lightning. A 98% accuracy was obtained on over 100 test images, which indicates that the solution could be used in business practise.**

## I. Introduction

IN TODAY'S world a rapid automation of customer services in different areas can be observed. Among numerous examples worth to mention are: the growing number of vending and ticket machines, automatic cash registers in supermarkets or recently emerging touch-screen kiosks for ordering and paying in fast food restaurants.

The customer service process in a self-service canteen can also be subjected to automation. This topic is particularly relevant in the context of the currently ongoing economic and social changes. The model, which assumes eating lunch or dinner after work at home changes to dining in canteens, lunch-bars or restaurants. Therefore, an increasing number of various types of self-service restaurants can be observed. There, the customer takes a tray, collects the meals and proceeds to the cash desk, where the content of the tray is priced by the cashier and the payment is made.

The automation of the described process requires the use of two modules: the pricing of products on the tray and the payment collection. The second issue is already well know and applied on a large scale: payment terminals (with PIN based authentication and so-called contactless cards) and CDMs (cash deposit machines). However, the automatic pricing of meals or dishes is still a challenge.

The topic of vision based food classification is addressed in several research papers. It should be noted that the issue is very challenging due to the great variety of possible meals, which are often quite similar. Another big problem is the segmentation of a particular food type on a plate.

In the work [1] the GrabCut segmentation is used to extract individual food types, as well as SURF features and SVM classifier. The accuracy of the system is more than 81%. In paper [2] the concept of using local and global features is described. Additionally, the results from several individual classifiers are combined to improve the accuracy, which for the system is about 80%. Similar results were obtained in the work [3]. The authors of the work [4] used a combination of deformable part-based and a texture model. For particular food recognition a multi-view multi-kernel SVM was utilized. The accuracy of this system reaches 90%.

This short analysis reveals that the topic of food recognition is up to date and intensively researched. However, the high complexity limits the accuracy of the systems to about 90%. This is insufficient for an automated pricing system in a self-service canteen. It is also worth noting, that for similar systems several patents can be found – for example from the SRI company [5]. In addition, an interesting system to automate the pricing of bakery products developed by Brain Corporation is presented in a video available at [6].

In this paper a pricing system based on video analysis of the shape and colour of dishes is presented. To the best knowledge of the authors, this is the only described in the literature vision system operating on this principle. The input to the system is a photo (single video frame) of a tray with one or more dishes (plates, bowls, mugs). Then, the individual objects are extracted and their shape and colour is determined. To use this information in the pricing task it has to be assumed that on a given day, on a particular dish (defined by shape and colour) and single meal is served. For example: on a *large round, green* plate pork chop with french fries and on a *large round, red* plate fish with potatoes is served. It is worth noting that such a system quite strictly defines the operation rules of the canteen. The meals have to be placed by the staff on appropriate dishes. This can be done on a regular basis (applying to the customer's request) or prepared in advance (the problem of keeping the meal warm). In addition, it should

be assured that the boarder of the dish is free form parts of the meal.

The remainder of this paper is organized as follows. Section II contains a general overview of the proposed vision system. Detailed information about particular modules i.e. object segmentation, shape recognition, colour recognition and close or abut object recognition are given in Sections IV, V and VI. Evaluation of the system is presented in Section VII. The paper ends with a summary and indication of future research directions.

## II. Overview of the proposed vision system

This section provides basic information about the discussed vision system. Is has been implemented in C++ programming language using the OpenCV image processing library [7] and the Qt GUI library [8].

The designed and implemented algorithms were evaluated on a specially constructed test stand, which consisted of:

- digital camera – a typical USB camera with resolution 640 × 480 pixel was used (Logitech Webcam Pro 9000),
- illuminator – in order to provide good lighting conditions for image acquisition, a LED based illuminator was developed. It was a source of strong, white and diffused light. This reduced the problems of shadows and disturbances caused by external lightning,
- housing – to partially isolate the workspace from external lighting. It was also the mounting point of the illuminator and the camera,
- worktop – it was used for proper tray positioning.

In the application image processing and recognition was performed in two modes:

- continuous (for every frame) – tray and hand presence detection, background model acquisition and update,
- on-demand (at user request) – object segmentation and recognition followed by item pricing.

### A. Continuous mode

In order to provide proper classification, it is necessary to correctly place the tray in the field of view of the camera (i.e. in the workspace). It was assumed that the positioning in the axis perpendicular to the typical tray movement will be forced by two guide-rails (movement to and from the user), while in the other axis will be controlled by automatic detection of square markers. The markers are placed in the workspace, in a distance corresponding to the tray width. Using information about their visibility, the presence and position of the tray can be determined.

The second module working in the continuous mode is the detection of the so-called empty workspace i.e. a situation when in the camera's field of view there are no objects: plates, tray or even dirt. It such case, the current image is saved and than used in the segmentation phase as a background model (details in Section III).

The third module is responsible for detecting the presence of objects that have a common part with the boarder of the workspace. This prevents from starting the image analysis, when the user still holds the tray or has his hand in the camera's field of view. A detailed discussion of the three modules is presented in the work [9].

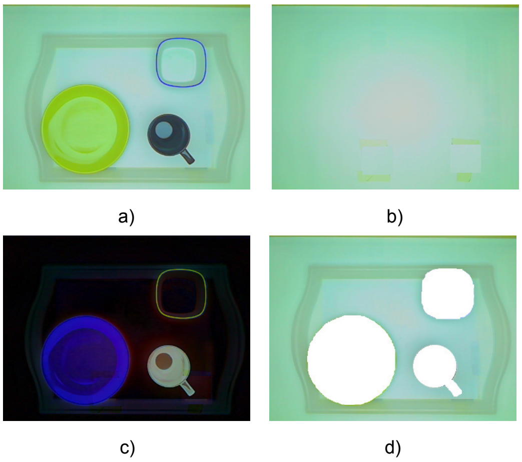

Fig. 1. Object segmentation using background subtraction. a) current workspace image, b) background model (image of an empty workspace), c) differential image, d) thresholding result overlaid on the input image (with same additional post-processing)

### B. On demand mode

When the tray is correctly positioned and the user has removed his hand from the workspace, the analysis can be started by pressing a button. It consists of the following steps:

- object segmentation,
- object shape recognition (also for close or abut objects),
- object colour recognition.

These steps will be discussed in detail later in the paper. The final result is the information about detected objects – their shapes and colours. On this basis, it is possible to price the tray.

## III. Object segmentation

The segmentation of objects (i.e. dishes/plates) is one of the most important elements of the described vision system. On its accuracy, to a large extent, depend the further processing steps: shape and colour recognition.

Taking into account the specificity of the task, the purpose of segmentation is to isolate:

- the correct shape of the objects – for classification,
- continuous edges of the objects, thick enough to retrieve colour information – the interior of the dishes can not be considered as a reliable source of information about colour, as it usually contains meals.

In addition, the method should reduce the possibility of connecting separate objects due to occurring shadows and have a tolerance to variable lighting conditions.

In the proposed solution object segmentation is based on the so-called background subtraction approach. From the current image with tray and plates, a background image is subtracted (view of an empty workspace). Thresholding the differential image allows to extract individual objects. The concept is illustrated in Figure 1. It is worth noting that in Figure 1b there are no markers visible on the worktop. This is due to a marker removal procedure, that involves replacing the marker's ROI with a workspace image from another location. This allows to obtain correct segmentation of the tray content, because markers are not detected.

The method has two main advantages. Its concept and the obtained results are easy to interpret i.e. all detected objects are regarded as dishes. Furthermore, it is very efficient. It should also be noted, that the empty workspace detection and background model update procedures allow to compensate lighting changes (e.g. naturally occurring during the day), which could affect the segmentation accuracy.

Limitations include: the need that objects or at least their boarder, have a colour different from the workspace and the requirement that the tray has the same colour as the workspace background – the tray should be transparent for the segmentation procedure.

In the current version of the algorithm, the segmentation is carried out in the RGB colourspace. First, the absolute value of the difference between the current image and the background model is computed – separately for each component. Then the maximal difference is selected and compared with a thershold. The obtained object mask is post-processed using morphological closing with a $5 \times 5$ square structuring element. Finally, a hole filling procedure is applied to eliminate the influence of the plate content on the segmentation result. A detailed description of the segmentation procedure is presented in the work [9].

## IV. Object shape recognition

The object shape recognition is a two-step process. First, a feature vector, which describes each shape, is generated. Then, this vector is assigned to a pre-defined class (i.e. classified). The input to this procedure is a binary object mask (containing a single object) and the output the class to which this object belongs.

### A. Feature vector

To describe the shape of an object (i.e. to generate a feature vector) a common approach involves the use of shape descriptors. This task is not easy, because on one hand a good differentiation of shapes is required (e.g. squares, circles, ellipses, etc.) is required. On the other hand the description must be insensitive to scaling, translation, rotation, affine transformations and some disruptions (e.g. "ragged" shape edge). In the literature a lot of different shape descriptors are described. They can be roughly divided into contour based (only the edge is analysed) and area based (the whole object is analysed). In the paper [10] four of them were evaluated: Fourier descriptors, curvature scale space descriptor, angular radial transform and image moments. The experiment showed that the geometric moments are a good solution for shape description. Furthermore, their are implemented in the popular image processing library OpenCV [7].

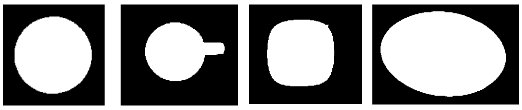

Fig. 2. The used shapes: circle, mug, rsquare, elipse

In the described system geometric invariant moments, also often referred to as Hu moments, are used. They have been proposed in the work [11] and are the basis of many shape recognition approaches. For example, in [12] they are utilized for human action recognition.

### B. Classifier

As a classifier the Support Vector Machine (SVM) algorithm was used. It was originality proposed by Vladimir Vapnik [13] and is one of the most popular machine learning algorithms. This is due to: intuitiveness of the method, good accuracy, high computational efficiency and quite simple and quick learning procedure (possible to automate because of small number of parameters).

In the basic version, the SVM is a binary linear classifier. However, a modification was proposed (so-called kernel trick), that allows the classification of non-linear problems. It involves the transformation of the feature vectors to a new space with higher dimensionality. Often as the kernel the Gaussian radial basis function (RBF) is used (the default solution in OpenCV library).

To enable the classification of more than one object type the multi-class problem is transformed into multiple binary classifications. For example, for three shapes $S_1, S_2, S_3$ three classifiers are required: $C_1$ to distinguish $S_1$ from $S_2$ and $S_3$, $C_2$ to distinguish $S_2$ from $S_1$ and $S_3$ and $C_3$ to distinguish $S_3$ from $S_1$ and $S_2$.

### C. Training dataset preparation

The use of a machine learning approach requires the preparation of three datasets: training, validation and test. The first is used to train the classifier i.e. to obtain the required parameters. The second to test various options (e.q. SVM parameters or number of used features). The last to asses the final solution. Typically, the input dataset is divided at a ratio of 60%, 20%, 20%.

In the current version of the system the following shapes are used:

- circle (big plate, small plate, bowl),
- mug (circle with a handle),
- rounded square (rsquare) (plate, small bowl),
- elipse (platter).

The used shapes are presented in Figure 2. Using these templates three datasets: training, validate and test were generated. For this purpose the templates were: scaled, rotated, subjected to affine transform, disturbed.

A template and exemplary samples (rotated and disturbed) are presented in Figure 3.

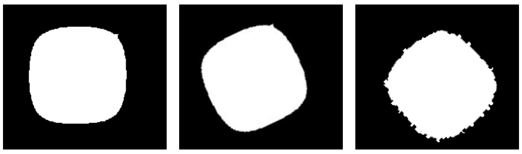

Fig. 3. Shape template (*rsquare*) and two samples: rotated and disturbed

Finally, the training dataset consisted of 2696 samples (673 for each shape), the validation dataset of 748 samples (187 for each shape) and test dataset of 876 samples (219 for each shape). For each sample the first three Hu moments were computed. They formed a feature vector used in training and evaluation of the classifier. The features were subjected to normalization given by: $s_n = (s - f_{min})/(f_{max} - f_{min})$, where $f_{max}$ and $f_{min}$ are respectively the largest and smallest value of the feature (particular Hu moment).

### D. Classifier training and evaluation

Training and evaluation of the classifier was performed on the prepared training, validation and test datasets. The SVM with RBF kernel available in OpenCV was used. The classifier was trained with the `train_auto` function, which performs a multiple cross-validation procedure to select the best SVM parameters.

During the experiments, the impact of number of used Hu moments on the classification performance was evaluated. The accuracy $ACC = TD/(TD + FD) * 100\%$ measure was utilized, where $TD$ – number of correct classifications, $FD$ – number of incorrect classifications.

The obtained results are summarized in Table I. The analysis indicates that using only the first two Hu moments should allow to obtain very good classification accuracy. For this case an experiment on the test dataset was carried out and the following results were achieved: *circle* – 100%, *elipse* – 100%, *mug* – 100%, *rsquare* – 100%.

### E. Results and comments

The proposed shape recognition method achieved almost 100% accuracy. It turned out, that Hu moments are well suited for distinguishing simple geometric shapes. For the considered application the use of the first two invariants resulted in satisfactory performance. The SVM classifier is very easy to use (lots of libraries, available in OpenCV and Matlab) and fast during classification. The solution was designed to allow a simple extension of the feature vector – for example adding other Hu moments or shape descriptors. It is also worth to notice, that the automatic generation of training samples significantly facilitated the evaluation of the approach.

## V. Object colour recognition

Colour, next to shape, is the second feature which is used to identify a particular dish in the system. In this section the method of obtaining colour samples, evaluation of various colour models, as well as the used solution is presented. In the current version of the system colours: blue, orange, green, brown[1] are recognized.

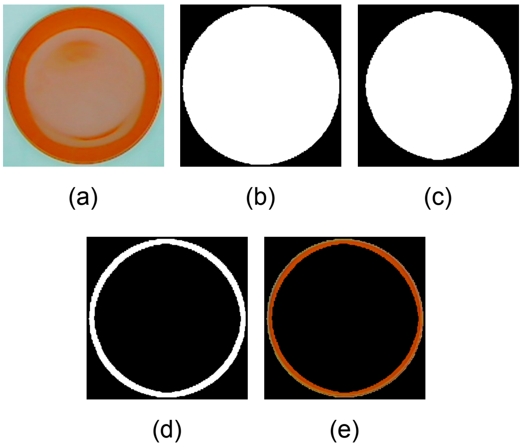

Fig. 4. Edge extraction demo. (a) current image, (b) object mask, (c) mask after erosion, (d) subtraction of (b) and (c), (e) the extracted edge

### A. Obtaining colour samples

The process of obtaining samples used to build the colour model is an element of the system calibration procedure. During its course, the dishes with particulars colour are placed in the workspace. Then object segmentation and edge extraction are performed. Reliable colour information can be only obtained from a narrow edge of the dish, mainly due to presence of meals in its central part.

The edge is extracted using a morphology-based approach. First, the input mask (obtained in the segmentation stage) is subjected several times to erosion with a square structural element of size $3 \times 3$ . Then the input mask and erosion result are subtracted. Finally, the edge with colour samples is obtained. Examples of this procedure is presented in Figure 4.

### B. The analysed colour models

In this subsection the analysed colour spaces and colour models (Gaussian and histogram based) are described.

*a) Colour spaces:* In the experiments several common colour spaces were used:

- RGB (*Red, Green, Blue*) – the basic colour space used in input (cameras) and output (displays) devices,
- YCbCr – a colourspace with a luminance (Y) and two chrominance (Cb, Cr) components. It is used in image and video stream compression (JPEG/MJPEG),
- CIE Lab – colour space similar to YCbCr, but defined to be perceptually uniform i.e. the distance (Euclidean) between two colour samples corresponds with the difference noted by a human.

The HSV (Hue, Saturation, Value) colour space was not analysed, because of the angular coordinates of the H component, which causes some difficulties in models using mean and standard deviation.

[1] This colours were available in the used dish set

TABLE I
CLASSIFICATION RESULTS FOR DIFFERENT FEATURE VECTORS

| | circle | | elipse | | mug | | rsquare | |
|---|---|---|---|---|---|---|---|---|
| Hu moments | Train | Validate | Train | Validate | Train | Validate | Train | Validate |
| 1 | 99.9629 % | 99.8656% | 89.9703 % | 90.5914 % | 89.8217% | 89.7849 % | 99.9629 % | 100 % |
| 1,2 | 100 % | 100 % | 100 % | 100 % | 100 % | 100 % | 100 % | 100 % |
| 1,2,3 | 99.9629 % | 100 % | 100 % | 100 % | 100 % | 100 % | 100 % | 100 % |

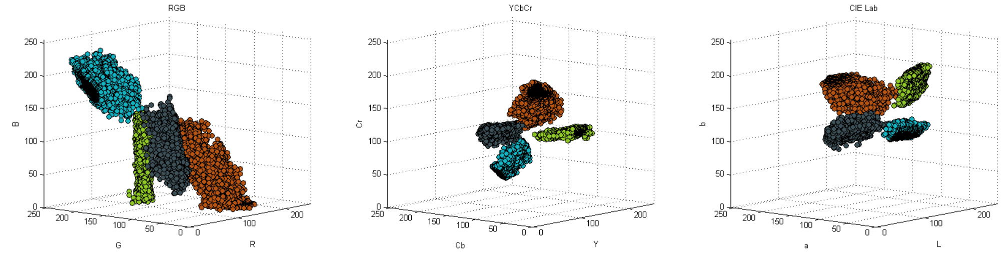

Fig. 5. Colour model samples displayed on a 3D scatter plot. From left: RGB, YCbCr, CIE Lab

TABLE II
STANDARD DEVIATION ANALYSIS FOR USED COLOUR SPACES

| Colour | RGB | YCbCr | CIE Lab |
|---|---|---|---|
| orange | 14352,61 | 2282,61 | 2351,64 |
| blue | 4030,69 | 932,80 | 150,01 |
| green | 3966,19 | 569,31 | 230,09 |
| brown | 11199,39 | 424,27 | 679,77 |

In the first step, the used colour samples were displayed on a 3D plot – Figure 5. On this basis it can be concluded that for the YCbCr and CIE Lab colour spaces the samples are more separated from each other than for RGB. This observation is also confirmed by calculating the standard deviations of the individual components of the samples. In Table II the product of standard deviations for each component is presented. It illustrates the dispersion degree of samples around the mean value. The analysis confirms the earlier observation that YCbCr and CIE Lab have better properties than RGB. It should also be noted that YCbCr and CIE Lab are quite comparable, with a slight indication of the latter. However, due to much more efficient conversion between RGB and YCbCr comapring to RGB and CIE Lab in the further analysis the YCbCr colour space is used.

The obtained colour samples are used to create a representation (model) for classification. In this work models based on Gaussian distribution, 1D histograms and 3D histograms were evaluated. More advanced approaches like Gaussian Mixture Models [14], artificial neural networks [15] or typical machine learning [16] approach were not considered. However, if in future versions of the system, more, especially quite similar, colours should be recognized, than this methods could provide better performance and reliability.

*b) Gaussian distribution model:* For each vector of training samples assigned to a particular colour, mean and standard deviation can be computed. On that basis a Gaussian model can be build. However, there are two options available. In general, it is assumed that the individual colour components are interdependent. Then the probability that a given pixel belongs to a particular model is given by:

$$p(x|\theta) = \frac{1}{(2\pi)^{n/2}\sqrt{(det\Sigma)}} e^{-\frac{1}{2}(x-\mu)^T \Sigma^{-1}(x-\mu)} \quad (1)$$

where: $x$ – given pixel, $\theta$ – given colour, $n$ – number of colour components $(3)$, $\Sigma$ – covariance matrix, $\mu$ – mean value vector.

It can be also assumed that the components are independent, which simplifies the equation:

$$p_c(x|\theta) = \frac{1}{\sqrt{(2\pi S)}} e^{-\frac{(x-\mu)^2}{2S}} \quad (2)$$

where: $S$ – standard deviation.

In this case the probability is obtained separately for each component. Therefore, to define it for a pixel, the particular results should be summed up: $p(x|\theta) = p_{c1}(x|\theta) + p_{c2}(x|\theta) + p_{c3}(x|\theta)$.

Thus, for a given pixel the probability of belonging to a particular colour model is obtained. The computations are performed for the whole edge of the dish. At this point, there are two possibilities. First, individual decisions about colour assignment for each pixel can be made. Than the obtained "votes" can be summed up to perform a final classification. Another way involves the summing up of the probabilities and making the decision for the entire image. In the experiments, the second approach was used.

*c) 1D histogram model:* Another common used colour model is a histogram. It can be one-dimensional or three-dimensional (described in the next paragraph). In the first case the given colour is described by three separate histograms, one for each colour component. An important parameter of the method is the number of histogram bins. If the value is less than 256 (assuming that the colour component values are in range 0-255), then nearby values are aggregated.

Colour classification can be performed in two ways. In the first, using the pixel values as an "address" – the corresponding histogram values are obtained and summed. The resulting number is a measure of probability that the pixel has a given colour (histogram normalization is assumed). The numbers, like in the Gaussian model, should be summed up for the whole image. Following this procedure for each colour model (i.e. $4 \times 3$ histograms) and then selecting the maximal value allows to perform the recognition.

In the second approach, a histogram is computed for edge pixels. Then it is compared with the model using a distance measure between two histograms. The most common are correlation, intersection and Bhattacharyya distance.

*d) 3D histogram model:* A three-dimensional histogram can also be used as a colour model. A certain disadvantage of this approach is its high memory complexity – in the default case the histogram has $256^3$ bins. Therefore, aggregation (bin number reduction) is frequently used. The classification can be done in two ways – analogous to those described above for the 1D histogram.

### C. Evaluation and results

When evaluating different colour models, two aspects should be addressed. Firstly, high classification accuracy is required. This means that for each test image the correct result should be obtained. Unfortunately, during research it turned out that this is not a sufficient criterion. The test image database does not include all possible cases that may occur during operation of the system. This applies particularly to potential changes in lightning. Therefore, it is advisable to propose and use an additional measure that will determine which model is better, even in the case when more than one has 100% accuracy on the test dataset.

In this research a classification certainty factor was used. For methods with a probability output the following coefficient can be computed: $cS = \frac{P(m)}{\sum P(c)}$, where: $P(c)$ denotes the probability than an object (i.e. a dish edge) belongs to the colour class $c$ and $P(m)$ is the maximum of this factor. In the ideal case this value should be one, which indicates that all pixels were correctly classified.

For methods based on histogram comparison this coefficient should be modified. In case of correlation, a positive value is obtained when the classification is correct (positive correlation). For other colours the value is usually negative. Therefore, it seems to be eligible to use the absolute value and repeat the above described scheme. When using the histogram intersection, the $cS$ coefficient can be used directly. However, for the Bhattacharyya distance it is necessary to subtract the final values from 1 ($cS = 1 - cS$).

The finally implemented model was selected after a series of experiments. A dataset of 64 images containing dishes in different workspace locations and orientations was used. Additionally, possible lightning conditions were simulated: brightening, darkening and adding gradient (using appropriate gamma correction).

In the first stage, the models with 100% classification accuracy on the test dataset were selected. This were the Gaussian model with dependencies between components and 3D histogram. However, it is worth noting that the remaining models obtained results ranging from 97% to 99%.

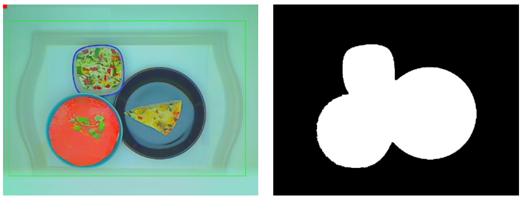

Fig. 6. Example of abut objects. On the left the input image, on the right the corresponding object mask

In the second stage the classification certainty coefficient was evaluated. For the Gaussian model the value $cS = 0.99$ was obtained. Similarly for the probability version of 3D histogram, as well as correlation, intersection and Bhattacharyya histogram distance (using 256, 128 and 64 bins). Therefore, all this approaches should be regarded as very robust.

It should be noted that there was no significant impact of the number of histogram bins on the classification performance. This could be due to the considered colours, which were quite different from each other (separated in the colour component space). Finally, the Gaussian model was used because of its lower memory complexity.

## VI. Close or abut object recognition

In this section a procedure of shape and colour recognition for close or abut objects is described. An example of such a situation is presented in Figure 6.

It should be noted that in the initial vision system specification it was assumed that objects should be placed apart from each other i.e. on the object mask each of them should appear separately. Therefore, when close or abut object are detected, a message for the user is generated: "Please correct the positioning of the dishes". However, to speed-up the service and increase system capabilities an automatic procedure for this case was developed. The issue is quite complex and at least two main problems have to be addressed and solved:

- determining that two or more objects are segmented as one (are close or abut) – distinguishing this situation from typical arrangement of dishes on the tray,
- detecting abut objects with the same colour. In a general case the information about colour can not be used in this procedure, also due to possible influence of food or meal colour on the segmentation results.

### A. Abut objects detection

A situation in which two or more objects are close or abut can be detected by analysing:

- object's shape – there is no recognition by the SVM classifier (i.e. the abut objects form a new shape, which is not similar to any other recognized by the system),
- object's size – it is larger than other recognized by the system.

Thus, if during the shape analysis an object with unrecognised shape and large area appears, it is regarded as a collection of abut or close objects. Here it is assumed, that several small objects can not "form" a large, recognized object (e.g. a big plate formed by several small mugs). Correct recognition in this case seems to be very difficult and would require more sophisticated segmentation algorithms.

### *B. Different concepts of separating objects*

During preliminary research different methods of separating abut objects were analysed. The most straightforward solution is the use of information about edges, because this allows a human to correctly recognize connected objects. Unfortunately, the approach of: detecting edges using Sobel or Canny, thickening them and subtracting from the input mask does not allow to properly separate objects. Mainly due to discontinuities of detected edges and disturbances caused by meals or non-uniform lightning. Furthermore, the obtained object masks are usually smaller then the input ones, which causes difficulties during colour sample extraction.

Another promising solution is the Hough transform, but it has a quite high computational complexity, especially for shapes, whose analytical description requires multiple parameters (circle, ellipse) and it can not be used for all kind of shapes (non-analytical curves).

However, the use of some kind of "knowledge" about the recognized shapes seems to be the key to proper connected object segmentation. This is the result of the observation that knowledge of how the objects look like, in combination with edges and colour information make the task of separating objects quite easy for a human. Therefore, basing on the results published in [17] a distance transform (DT) based solution was used in the proposed system.

### *C. The proposed shape recognition method*

The starting point for the shape recognition algorithm development was the analysis of the distance transform method described in [17]. It uses two of the mentioned observations: object edge analysis and pattern detection (i.e. knowledge).

In the first step of the method, for the input image edges are determined. The resulting binary edge mask is used to compute the so-called distance transform (DT). It is an image in which a pixel value represents the distance (Euclidean, chessboard, Manhattan, quasi-Euclidean) to the nearest edge. An example is presented in Figure 7c.

In the developed algorithm, extracting individual objects requires the use of shape templates in the form of an edge mask and a binary mask. The template is moved across the DT image using a sliding window approach. For each location, the following factor is computed:

$$D_{coef} = \frac{1}{|T|} \sum_{t \in T} DT(t); \tag{3}$$

where: $|T|$ – number of pixels for a given template, $DT(t)$ – distance transform value for pixel $t$ from template $T$. The location with the best match for a given template is characterized by the smallest $D_{coef}$ value.

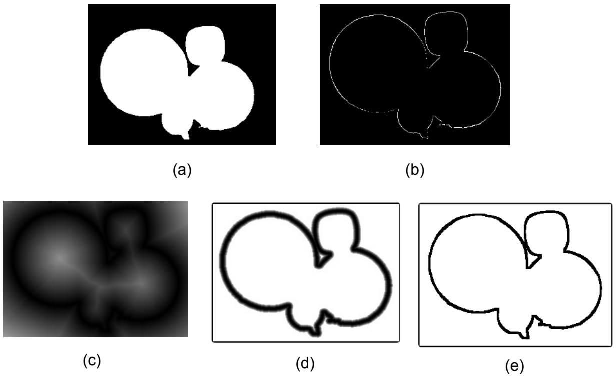

Fig. 7. Distance transform example: (a) input image – object mask, (b) binary edge mask, (c) DT result, (d) modified DT result, (e) binary DT result

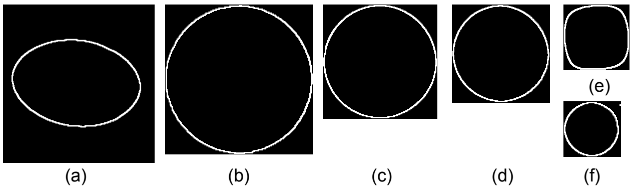

Fig. 8. Used shape templates: (a) – elipse, (b) – big plate, (c) – small plate, (d) – bowl, (e) – small bowl (rounded square), mug (without handle)

In the general case, to ensure proper operation for this type of algorithm, template modifications like translation, scaling and rotation are required. Translation is "built-in" in the sliding window approach. Scaling is not required, because the distance between the camera and object is fixed. However, rotating the template is necessary for selected, asymmetrical shapes like an ellipse.

The used shape templates are presented in Figure 8. It should be noted, that for the *mug* template the shape was simplified to a circle (the handle was omitted). This eliminates the rotation necessity, but does not affect the recognition performance, as there are no objects of similar size and shape in the system.

During preliminary research three variants of the DT based approach were considered: basic DT, modified DT and DT reduced to a binary mask. In the modified version the initial DT image was transformed according to the following formula: $DT(i,j) = DT(i,j)^{\alpha}$ (during tests $\alpha = 2$). Such an approach promotes locations with good template match. An example image is presented in Figure 7d.

A further simplification is the assumption that the DT image has a binary form – in a small neighbourhood of the edges the DT values are set to 0 and in the remaining part to a maximal value. This further enhances the promotion of good-match locations. An example is presented in Figure 7e. It is worth noting, that in this case computing the "DT" image involves only performing a morphological dilation of the edge mask,

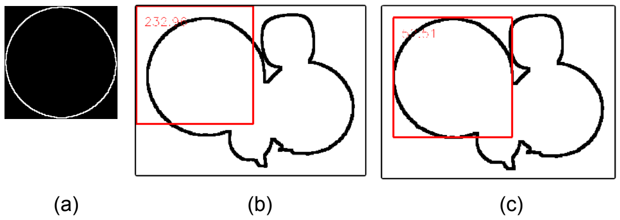

Fig. 9. Template search with sliding window approach: (a) template, (b) initial situation ($D_{coef} = 232.96$), (c) best match ($D_{coef} = 52.51$)

which greatly improves the computational efficiency.

Initial experiments demonstrated a similar performance of the three described DT variants. Therefore, in the final version of the system, the binary DT approach was used, since it is most computationally efficient. However, it is worth considering why such a simple solution obtains comparable results with the "full" DT transform. First, in the described system, the algorithm operates only on the object's outer edge mask, whereas the original solution used all edges of the input image. This significantly limits the number of edges that could potentially affect the shape recognition. Second, the used templates are quite simple, rigid, with well defined size and only slight variation caused by perspective issues. Finally, due to strictly controlled lighting conditions the object's boarder segmentation is very reliable.

### D. Shape recognition procedure for connected objects

During designing the solution, the primary goal was to ensure high recognition reliability. Therefore, an iterative search procedure was proposed. In a single iteration one most probable shape is found.

First, the edge mask and the DT binary image are computed. Next, for each shape template the sliding window procedure is applied and the best location (lowest $D_{coef}$) stored. At the configuration stage, it can be determined if a particular template should be rotated. In the current version of the system, the rotation is only performed for the *ellipse* with 30° step, which results in 5 different templates. For the non-symmetrical template *rsquare* it turned out that no rotation is necessary. Example of the search procedure is presented in Figure 9.

After obtaining the $D_{coef}$ (compare Equation (3)) values for all used shape templates, the minimum is selected. In this way, the most probable shape is detected.

In the next step this shape is removed from the object mask. The new mask is subjected to filtration. This involves the removal of connected components with area smaller than a preset threshold (so-called area open) and morphological processing. An example in shown in Figure 10. The described iteration is repeated until all object are removed.

*a) Template localization improvement:* During experiments it was noted that the obtained, in the above described procedure, shape locations are not very accurate. This has a great impact on the subsequent colour extraction method, particularly for dishes with narrow edge like a bowl. In order to compensate this error a simple template position improvement method was proposed. First, using the initial location estimate, a ROI from the input object mask is extracted. It size is slightly bigger than those of the considered template. Next, in this ROI a sliding window approach is used to find the location, where subtracting the template mask from the object mask results in removing maximal number of pixels. This is then regarded as the improved object location.

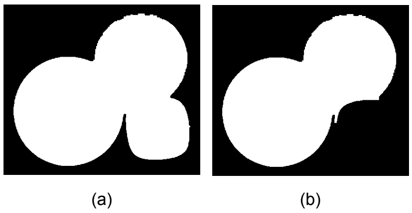

Fig. 10. Shape removal example: (a) – input mask, (b) – mask after shape removal (*rsquare*).

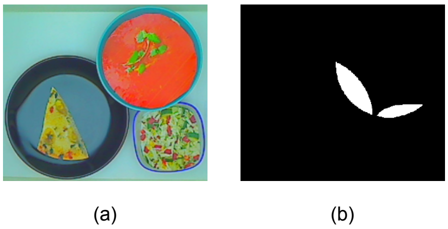

Fig. 11. Example of obscuration area detection: (a) – input image, (b) – obscuration mask.

*b) Analysis of the detected objects:* The result of the above described procedure is the information about all detected objects i.e. their shape and location. For the purpose of colour recognition edge extraction should be performed. However, in case of close or abut objects often some obscuration occurs. For example a bowl could cover a part of a plate. Extracting colour samples in this areas could lead to errors.

Therefore, such regions should be detected and excluded from further analysis. This is done using a so-called obscuration mask – example presented in Figure 11.

In the next step, for the detected objects, edge masks are obtained. This is done in three steps:

- determining the logical AND (intersection) of the objects mask and template mask,
- extraction the edge of this object (using the described prior morphological approach),
- determining the logical AND of the edge mask with the negation of the obscuration mask.

The obtained masks are used in the colour recognition procedure. An example of the described approach is presented in Figure 12. It is worth to notice, that despite some minor errors in determining the localization, the final detection is correct.

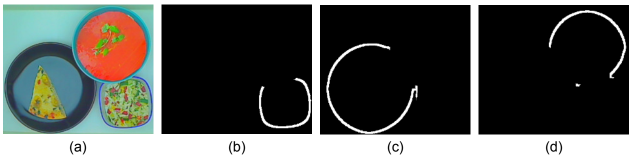

Fig. 12. Example of abut objects splitting. (a) – input image, (b), (c), (d) – edge masks for the detected objects

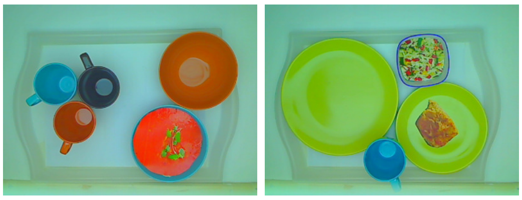

Fig. 13. Examples of test images used in evaluation of the close or abut object recognition procedure

### E. Evaluation and parameter selection

The impact of different parameters on the connected object separation procedure was evaluated. For this purpose 30 test images with different close or abut objects were used. Two examples are presented in Figure 13.

The accuracy of the procedure was evaluated by comparing the returned shape and colour recognition with reference ground truth (more details in Section VII). The following parameters of the method were analysed: template edge thickness, image resolution, sliding window step.

For the first parameter it was observed, that above a certain edge thickness value, the obtained results were incorrect. Finally, for edge extraction an erosion with 7 × 7 square structuring element was used. This results in 3-4 pixels thick edges. In case of reducing the input image resolution, the size of structuring element should also be reduced.

The resolution of the analysed image (object mask) has a great impact on the performance of the described procedure. This is directly related to the sliding window approach and $D_{coef}$ calculation. Therefore, reducing the image size brings significant acceleration to the entire vision system. In the experiments it was determined that changing the size from 640 × 480 to 192 × 144 (30% of the input value) does not result in loss of accuracy – all objects present on test images were correctly recognized.

The sliding window step value is a compromise between template location accuracy and calculation speed. During experiments it was determined, that the value 4 pixel (vertical and horizontal) is suitable for the used resolution of $192 \times 144$.

Additionally, in an experiment is was proved that switching off the template localization improvement procedure leads to errors in colour classification for the bowl shape.

## VII. Vision system evaluation

The developed vision system was subjected to a series of test on the designed stand (compare Section II). Their goal was to evaluate basic functionalities like:

- proper tray position detection,
- empty workspace detection,
- presence of hand in the workspace detection,
- object segmentation,
- shape and colour recognition,
- recognition of close or abut objects.

In addition, elements of the algorithms that require further improvement and modification were identified.

Evaluation of the first three functionalities were conducted on-line i.e. the system behaviour was observed during real-time analysis of the video stream acquired by the camera. The tray position was detected correctly. The only potential problem that occurred was the partial visibility of a marker (the marker was not fully covered by the tray). However, even if it was detected as an object, due to small size it was excluded from further analysis. In addition, it is assumed that the user will co-operate i.e. place the tray as accurate as possible (supported by the feedback provided by the system).

The empty workspace detection module worked correctly in case of proper camera placement and marker position calibration. However, it should be noted that presence of some kind of dirt in the workspace may cause errors – be recognized as an object. Consequently, the background model update mechanism will fail. It is worth mentioning that a frequent background model update is necessary for proper segmentation. During experiments, despite the used LED illuminator, the external lighting changes had impact on the segmentation.

The presence of hand in the workspace detection works correctly. The only exceptional case is when the user wears a sweater or sweatshirt with long sleeves in colour similar to the workspace. In the future, skin-colour regions segmentation could be considered. Whereby, the result interpretation could be quite difficult – some food could have colour similar to skin.

Other functionalities were tested both on-line and off-line on selected test images.

### A. Test images annotation

In order to automate the vision system evaluation and parameter selection process a tool for object annotation was designed. Each object (dish) present on a test image can be described by: location (rectangle inscribed in the object), shape, colour.

For the purpose of frame annotation, a simple GUI application was created. It allows to browse a directory with images and set information about location, shape and colour of different dishes.

### B. Object segmentation evaluation

The used segmentation method worked correctly when the background model was up to date. The only observed problems occurred when cast shadows, present due to specific dish location, caused incorrect operation of the abut object recognition procedure.

TABLE III
SHAPE AND COLOUR OF DISHES USED IN THE EVALUATION.

| Shape name | C 1 | C 2 | C 3 | C 4 |
|---|---|---|---|---|
| `circle_huge` [big plate] | brown | blue | green | |
| `circle_big` [small plate] | brown | blue | green | orange |
| `circle_small` [bowl] | brown | blue | green | orange |
| `mug` [mug with handle] | brown | blue | | orange |
| `rsquare` [small bowl, plate] | —- | | | |
| `elipse` [platter] | —- | | | |

### C. Object shape and colour recognition evaluation

Evaluation of the object shape and colour recognition process was performed by comparing the results returned by the application with prepared manual annotation (ground truth). A series of test scenarios was prepared: from simple one with one dish, to complex involving close or abut objects, as well as presence of additional objects (like napkins or cutlery). The used dishes – they shapes and colours – are summarized in Table III.

For the test procedure 81 images with single dish, 9 with multiple dishes (not close) and 33 with close or abut dishes were prepared. The current version of the system returned an incorrect result in 2 out of 123 cases (accuracy 98%). Both errors were related to a quite significant shape change due to location far from the centre of the camera's optical axis. This could be eliminated by proper camera calibration.

## VIII. Conclusions

In this paper a vision system able to recognize the shape and colour of objects was described. It can be used to automate to process of customer service in a self-service canteen. It is built of four main modules: object segmentation, shape classification, colour classification and recognition of close or abut objects. When designing each module, different possibilities were considered and those with high efficiency and low computational complexity were selected. The final system meets the design constrains i.e. accuracy above 95% and computing time < 1s on an typical PC.

The solution can be further developed in several directions. One of them is the broadly understood relaxation of restrictions. A good example is the use of tray with colour different than the workspace (i.e. not "transparent" for the segmentation). Another one would be the determination of the minimum edge thickness required for proper colour recognition. This would allow to use dishes with only a thin colour boarder instead of "full" colour and therefore use more different colours.

In addition, the use of a lens distortion correction module or another camera should be considered. In a long term perspective, a food recognition module could also be added. An interesting and promising direction is the development of a smart camera vision system to perform the described image processing, analysis and recognition.

## Acknowledgements

The work presented in this paper was supported by the Malopolska Regional Development Agency under the program "Knowledge, Practice, Experience – the key to success in business" in cooperation with Qumak S.A., Kobierzynska 2, 30-363 Krakow

The authors wish to thank Qumak S.A. Krakow company, and particularly Mr. Konrad Pogódź for supporting this research, as well as Dr. Zbigniew Mikrut for help and many valuable comments.

***Abstract*—In this paper, the problem of segmentation of 3D Computed Tomography (CT) brain datasets is addressed using the fuzzy logic rules. In particular, a new method which combines Fuzzy C-Means clustering and the idea of super-voxels is introduced. Firstly, the method applies the extended Simple Linear Iterative Clustering (SLIC) method to divide image into super-voxels, which are next clustered by Modified Fuzzy C-Means algorithm. The method deals with 3D images and performs fully three dimensional image segmentation. Ten samples are supplied proving that our Modified Fuzzy C-Means (MFCM) together with super-voxels are apt to take into account a large diversity of special domains that appear and which are inappropriate solved adopting classical Fuzzy C-Means approach. The results of applying the introduced method to segmentation of the Cerebro-Spinal Fluid (CSF) from the brain ventricles are presented and discussed.**

## I. Introduction

DIVIDING an image into coherent regions, that are somehow homogeneous and uniform leads to image segmentation.

One of the most popular clustering algorithms used for image segmentation is the Fuzzy C-Means (FCM) approach [1]. Since the method has a lot of advantages (e.g. it provides the best results for overlapped data sets of pixels) it is especially popular when the segmentation of medical images is required [2]. In particular, there was a significant number of attempts to apply FCM clustering for brain segmentation [3], [4], [5]. These works however consider mainly MRI datasets. To the best of our knowledge, there are only few works regarding brain segmentation from CT datasets.

Despite its popularity, the FCM algorithm has also some disadvantages, which limit its application to segmentation of 3D CT medical datasets. The main limitation of the algorithm is in particular its high computational complexity, intensive memory workload and unacceptably long time of computations. These result from the necessity of processing billions of voxels contained within a scan.

Therefore, the most of the existing FCM-based algorithms dedicated to 3D image segmentation are in fact 2.5D approaches. This means that they perform FCM segmentation slice-by-slice and then compose 3D result by combining 2D results obtained from single slices [6], [7].

To overcome the above mentioned limitations of FCM algorithm and make the the method available also in the case of 3D images this paper proposes a solution which incorporates the idea of super-voxels into the Fuzzy C-Means clustering approach. In particular the proposed approach extends the idea of super-pixels into supre-voxels. The Super-voxels are next clustered using FCM algorithm according to statistical features extracted using the co-occurrence matrix.

The proposed approach is next applied to extract the CSF from 3D CT datasets of brain.

The following part of this paper is divided into five sections. Firstly, in Section II, the technical background and a brief review on super-voxels and Fuzzy C-Means techniques is presented. Next, in the Section III datasets used in this paper are characterised. This is followed in Section IV by the description of the introduced approach. The results of the method are presented and discussed in Section V. Finally, Section VI concludes the paper.

## II. Theoretical Background and Related Works

### A. Fuzzy C-Means Clustering

FCM is an algorithm proposed by Bezdek [8] as an alternative for K-means clustering [9]. According to FCM algorithm, each datum point is a part of a cluster whose degree is governed by its membership grade.

What is distinct about FCM is that it divides a collection of $N$ vectors into $c$ fuzzy groups with a cluster centre for each group. It is worth noting that a datum point may be a part of many groups and it gets a membership grade ranging between 0 and 1.

The role of FCM revolves around having $c$ as the number of clusters, $c_i$ as the cluster centre of fuzzy group $i$ and the parameter $m$ as the weighting indicator for every fuzzy integrating group. Through optimizing the function of FCM, the fuzzy subdivision can be conducted.

978-83-60810-66-8/$25.00©2015, IEEE

The membership $J_{FCM}(U,V)$ and the cluster centres are determined according to the following equation [9]:

$$J_{FCM}(U,V) = \sum_{k=1}^{n}\sum_{i=1}^{c}(u_{ik})^m d^2(x_k, v_j) \tag{1}$$

where: $u_{ik}$ is a matrix of size $(c \times d)$, $d = \| x_j, v_i \|$ is the Euclidean distance between the centroid $v_i$ and each pixel $x_j$, $U = u_{ik}$ represents the matrix of fuzzy partition, $V = v_1, v_2, ..., v_n$ is are class centres, $m$ is the fuzzy factor with $m > 1$ and $c$ is the class number.

Because of its advantages, FCM approach has been widely applied in segmentation of medical images. Application of the method to brain segmentation is especially popular. Additionally, numerous improvements to the FCM method have been proposed.

One of the major proposals in the medical image segmentation is concerning the adoption of the spatial distance into the clustering based segmentation as initiated by Tolias and Panas [10], [11], [12]. Furthermore, Liew [13] proposed an automatic segmentation of 3D dimensional Magnetic Resonance Imaging (MRI) brain images. They used a local spatial distance into the FCM algorithm adopting a new dissimilarity index instead of the standard Euclidean distance. In addition, they created a cluster prototype with variation of 3D multiplicative bias field [14].

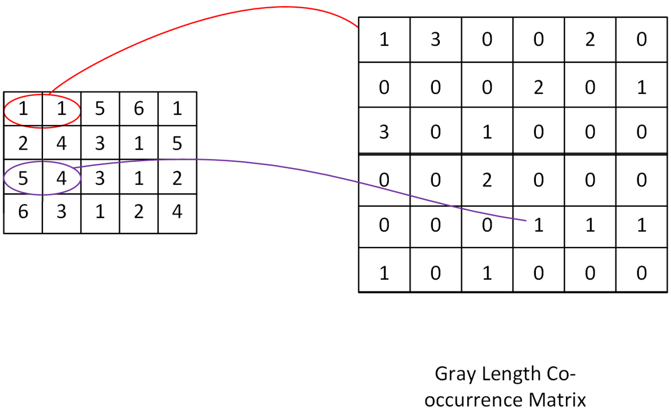
In the same context, there is an approach which provides the extraction of some features. It can incorporate the intensity information for the voxels neighbours [15]. Moreover, the fuzzy logic supply to segment 3D image under the consideration of the following three information: position, boundary and intensity knowledge [16]. This method aims to extract the three portions of the brain such as the left cerebral hemisphere, right cerebral hemisphere, cerebellum and brain stem. One popular technique involves adopting Fuzzy C-Means stand on the local spatial continuity [14]. It takes into account the voxel neighbour information and the intensity variation.

Regarding to other methods, [17] adopted a new method for segmentation of 3D datasets, based on Fuzzy C-Means. This approach is applied only to the three views; sagital, coronal and axial. Furthermore, the extraction of CSF is reported in [6]. This approach is based on the fuzzy inference rules. It is focused on the information obtained by the fuzzy information granulation.

The use of the Fuzzy C-Means may present some constraints, especially, when applied to brain segmentation. Brain image segmentation from CT scans faces the numerous numbers of challenges due to the characteristics of the images: poor image contrast, high-level speckle noise, weakly defined boundaries and boundary gaps. The traditional Fuzzy C-Means method is often unable to perform adequately on these images complex extension. Therefore, to overcome the above drawbacks, this paper proposes a new method based on the second statistic feature by the use of the co-occurrence matrix.

## B. 3D Co-occurrence Matrix

The co-occurrence matrix stores information about the occurrence of couples of pixels in the image. It takes into consideration the neighbouring pixels and the spatial relationship of pixels. In the case of intensity images, the co-occurrence matrix is also called grey-level spatial dependence matrix or grey level co-occyrence matrix (GLCM). This matrix is determined based on pixel intensity values. The idea of the GLCM determination is explained in figure 1. In particular, the (5×4) matrix shown on the left represents image with pixel intensities represented by numbers, while the (6×6) matrix on the right represents the corresponding GLCM.



| | | | | |
|---|---|---|---|---|
| 1 | 1 | 5 | 6 | 1 |
| 2 | 4 | 3 | 1 | 5 |
| 5 | 4 | 3 | 1 | 2 |
| 6 | 3 | 1 | 2 | 4 |

| | | | | | |
|---|---|---|---|---|---|
| 1 | 3 | 0 | 0 | 2 | 0 |
| 0 | 0 | 0 | 2 | 0 | 1 |
| 3 | 0 | 1 | 0 | 0 | 0 |
| 0 | 0 | 2 | 0 | 0 | 0 |
| 0 | 0 | 0 | 1 | 1 | 1 |
| 1 | 0 | 1 | 0 | 0 | 0 |

Fig. 1: The idea of the gray level co-occurrence matrix determination: the input image (on the right) and the corresponding co-occurrence matrice (on the left).

The GLCM was introduced to describe two dimensional images. However, in the literature, there are approaches which concentrate on using the 3D co-occurrence matrix which involves a good description of the image information. For the first time GLCM was adopted to extract important features using the texture, called the second order statistics [18]. These include the homogeneity, the angular second moment, the entropy and the contrast. After that, the 2D Haralick texture feature was applied to medical images and extended to 3D domain [19]. Furthermore, it is adopted for the hyperspectral imagery as an image cube [18].

In the same context, the self organizing map (SOM) is a kind of artificial neural network founded on competing as well as unsupervised learning. The combination of SOM and FCM with the GLCM is assumed to extract the first and the second statistical features preceded by a segmentation of the input image [19]. The main inconvenient of 3D image segmentation performed in this way is that it involves only the 2D images, performing image segmentation slice-by-slice [6] [7].

## C. Super-voxels

A super-pixel can be defined as a set of connected pixels that posses similar attributes. Most commonly, pixel intensity or colour is regarded [20]. Figure 2 shows the super-pixel principle. The top image represents an input 2D image, while the bottom image is an output image after image division into super-pixels.

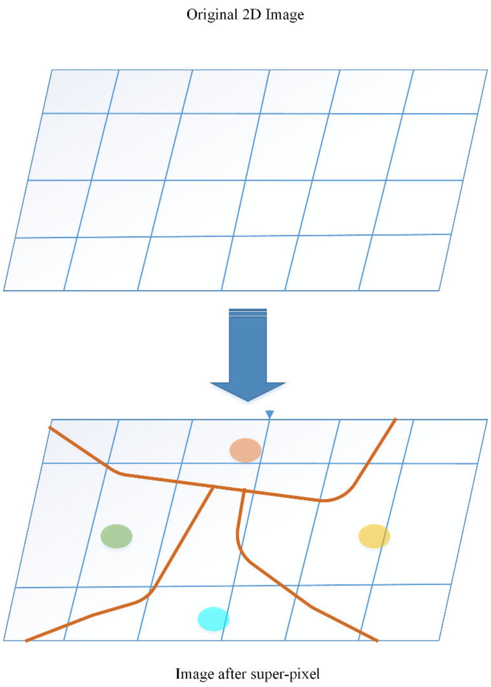


Fig. 2: A model of image segmentation using super-pixels algorithm.

The state-of-the-art is replete with approaches for image division into super-pixels, which have been proposed for 2D images. These include SLIC approach [21], [20] which uses linear iterative clustering, Turbo-pixels [22] which use curve evolution, NC super-pixels [23] based on the normalized graph cuts, FH super-pixels which use greedy segmentation proposed in [24] or methods based on energy minimisation framework as proposed in [25].

There are also some approaches which extend the idea of super-pixels into 3D images. For example, the approach proposed in [26] aims to divide a three dimensional image into blocks. Other method uses the super-voxel technique for processing a Voxel Of Interest (VOI) [27] instead of the whole voxels of the image. In [28], the convexity is considered as a metric for the super-voxel extraction. Moreover, a method of super-voxel combined with a clustering approach has been reported in [29] in order to extract statistical features. The same problem is treated in [30]. It aims to determine the region of interest adopting shift followed by the super-pixel algorithm. Its advantage is that it is applicable not only for 3 dimensions, but also from 1 to $N$ dimensions.

The method proposed in this paper extends Zero version of Simple Linear Iterative Clustering (SLICO) approach into three dimensions. SLICO method is widely used in the literature. It aims to divide the input image into a super-pixels, that commonly have a uniform and compact shape with better boundary stickiness. In this paper, we adopted the SLICO technique because it is fast to compute, memory efficient, and simple to use. The memory efficiency and low computational cost is especially important when segmentation of 3D images is considered.

Figure 3 shows the application of SLICO approach to a sample CT brain slice. In particular, the figure (3-a) represents the input 2D image, while the figure (3-b) shows the result of SLICO method.

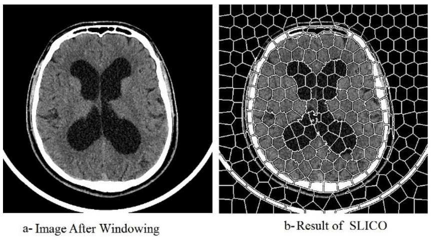

Fig. 3: SLICO approach for 2D image super-pixel segmentation: a- Image after windowing, b- Result of SLICO algorithm.

To the best of our knowledge the combination between the FCM and super-pixel is concerned only in [31] and [32]. The first work takes into account the super-pixel technique as a clustering objects in spite of the classical super-pixel. The second approach inspects a different strategy. An additional feature of segmentation is added (eg. extraction of CSF, white matter and gray matter). Both methods however are dedicated only to segmentation of 2D brain images.

## III. Input Data

Ten CT brain scans in Digital Imaging and Communications in Medicine (DICOM ) format were used in this paper. All of them present brain with the ventricular system enlarged due to the hydrocephalus. The images were adopted in order to extract the CSF contained within the brain ventricles, to test the proposed approach and to evaluate its performance in comparison to other methods. The average number of slice in the dataset was 215. Each slice had the spatial resolution of $512 \times 512$, the bit resolution of 12 and the slice thickness equal to 1.5000. In addition, the spacing between slices has $0.7500mm$.

The figure 4 shows 2D the selected slices composing a sample 3D CT brain scan. The slices are after intensity windowing.

## IV. Proposed Method

The Modified Fuzzy C-Means algorithm based on super-voxels is our proposed approach. The main idea behind this approach is to perform image division into super-voxels using the extended SLICO approach and then cluster the resulting regions using FCM algorithm.

The proposed method contains three main steps, namely: image pre-processing followed by an application of the super-voxels technique and finished by using the modified Fuzzy C-Means algorithm.

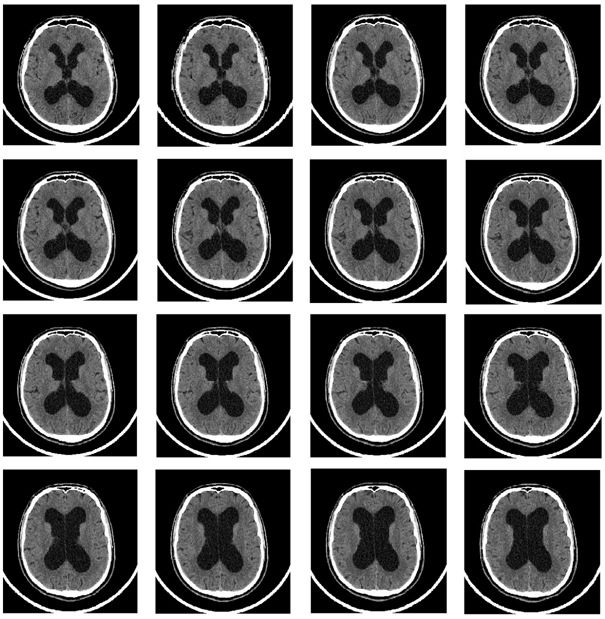

Fig. 4: Sample CT brain slices after pre-processing step.

The block diagram of the introduced approach is shown in figure 5. The details regarding each step of the introduced approach are given in the following subsections.

### A. Image pre-processing

The pre-processing is the fundamental task for the introduced approach. It is mainly operated by window and contrast adjustment. The modification of the window as well as the contrast values depends on the input image and the region of interest. The information about the desired window is usually given in the DICOM header.

In the preprocessing step, firstly image intensities are linearly transformed according to the rescale intercept and slope as described in equation ( 2).

$$New_{HU} = (RPV \times R_S) + R_I \qquad (2)$$

where: RPV is the raw (original) pixel value, $R_S$ is the rescale slope and $R_I$ represents the rescale intercept.

After applying the rescale/intercept transformation, image windowing is performed. Generally, crucial brain regions such as the cerebrospinal fluid, the white matter and the grey matter drop within the interval from 0 to 150 under Hounsfields Units (HU). Accordingly, the windowing procedure has to be achieved to highlight intensities within the region of interest. In particular, the original pixel values declined over the range are threshold to black or white. To obtain this, the window centre $W_C$ is set to 40, while, the window level $W_L$ is set to 80. Finally, the images converted to 8-bit grey scale format, where intensities range from 0 (black) to 255 (white). This procedure is described by equation ( 3).

$$GrayImage = 255\frac{W_{Max} - W_{Min}}{New_{HU} - W_{Min}} \qquad (3)$$

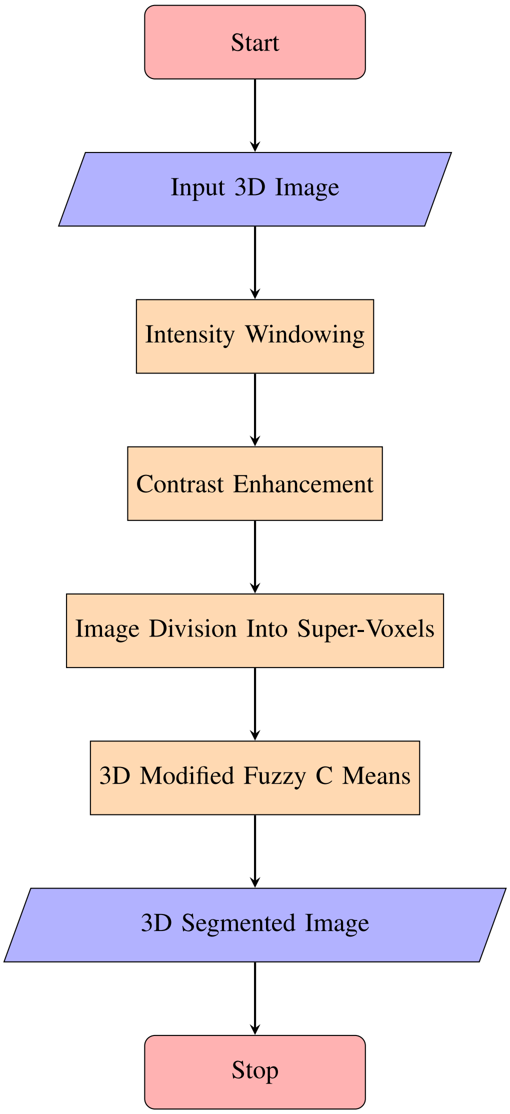

Fig. 5: The block diagram of the proposed method.

where: $W_{Max} = W_C + W_L/2$ and $W_{Min} = W_C - W_L/2$.

Figure 6 illustrates the original image and the image after the windowing. In particular, sub-figures 6 a and 6 c show sample images before windowing, while sub-figures 6 b and 6 d correspond to images after this procedure.

After intensity transformation, intensities corresponding with brain region and CSF region are highlighted.

### B. Super-voxels algorithm

In this paper, the SLICO super-pixels algorithm is extended to be adequate with three dimensional images and greyscale super-voxels. In order to do this, the initialization of the cluster is required. Thus, we called SLICO technique a super-pixel clustering. The second step is to calculate the spatial distance between the cluster centre and each voxel in the window of size $(7 \times 7 \times 7)$. Eventually, the new cluster centres have to be updated relatively to the spatial distance.

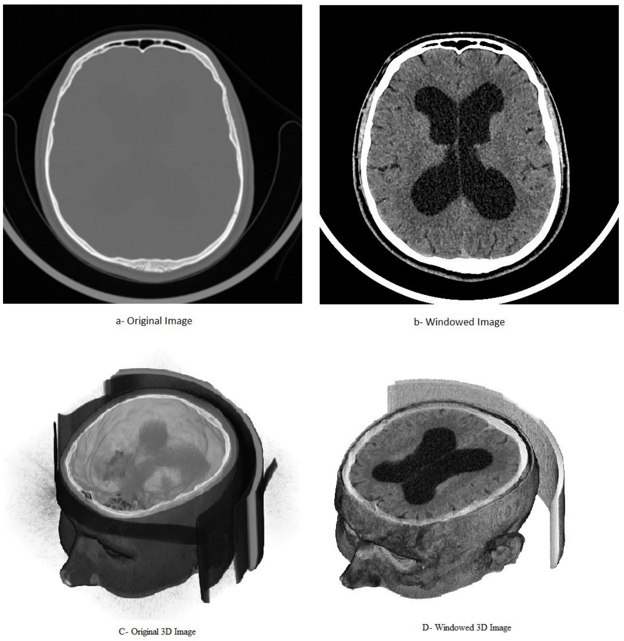

Fig. 6: Image windowing: a- 2D original image, b- 2D windowed image, c- 3D original image, d- 3D windowed image.

The proposed method presents several advantages compared to existing ones. Simple linear iterative clustering (SLICO) is an adaptation of k-means for super-voxels generation, with two important distinctions:

- The number of distance calculations in the optimization is greatly decreased. This reduce is due to the limiting the search space to a region proportional to the super-voxels size. This minimizes the complexity to be linear in the number of pixels $N$ and also independent of the number of super-voxels $k$.
- While simultaneously a providing control over the size and compactness of the super-voxels, a weighted distance measure combines colour and spatial proximity. SLICO is similar to the approach described in [17]. This latter is used as a pre-processing step for depth estimation, which was not fully explored in the context of super-voxel generation.

The algorithm 1 can be described step by step as follows [33]:

1) Use the vector $[lx, ax, bx, cx, xk, yk, zk]$ to represent each voxel, $[lx, ax, bx, cx]$ for the voxel colour vector (in the case of greyscale image, this vector = [0,0,1] ), $[xk, yk, zk]$ is the voxel position, then the voxel of our colour similarity and distance to produce super-voxels. The grid interval is $(S = \sqrt[N/K]{2})$; initialize the $K$ clusters centres.
2) In the area of where $(n*n*n)$, find the minimum gradient position $I(xk, yk, zk)$ is $(xk, yk, zk)$ position of the voxel $[lx, ax, bx]$ vector, $||.||$ is the norm.
3) Perform the following steps to know the cycle $E$ (residual error) $< a$ threshold:
   Each cluster centre $C_k$ is designed for $(7S \times 7S \times 7S)$ voxels area. The most appropriate voxel allocated to this cluster is for the greater value of $m$ .
4) After the clustering is complete, recalculate the cluster centres and $E$;
5) Connect similar regions.

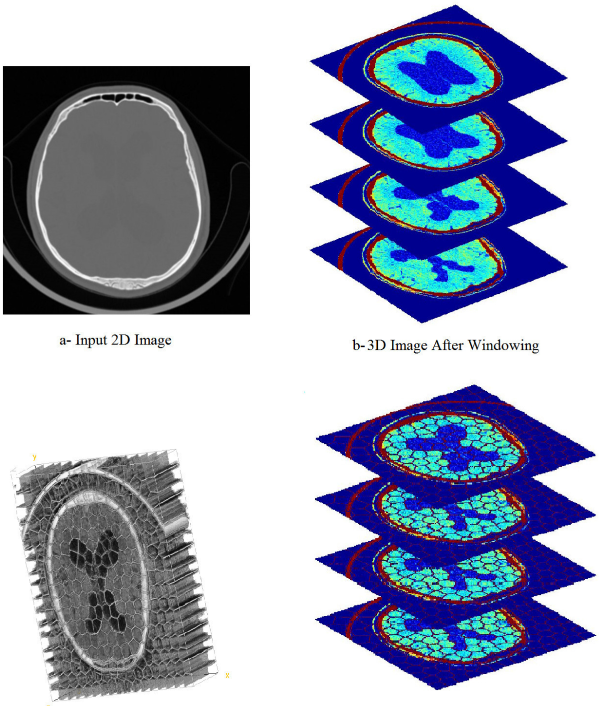
The adopted technique is described by Algorithm 1.

The improved SLICO technique adopts the typical compactness parameters (chosen as an initialization) applied to all super-voxels in the 3D image. In the case of a high smoothness in some regions with a high texture for the others, the SLICO provides a smoothness repeatedly super-voxels in the weak regions and extremely intermittent super-voxels in the textured regions.

SLICO is an improvement of SLIC proposed in [33] to solve that problem effectively. The compactness parameter must not be initialized by the user. SLICO precisely selects the compactness parameter adequate for each super-voxel separately. This achieves ordinary shaped super-voxels for both textured and non textured parts in the image.

The figure 7 represents the application of SLICO algorithm after its extension to three dimensions as proposed in this paper. The figures 7-a and 7-c show the original 2D and 3D images after windowing, while, the figures 7-b and 7-d show the 3D image after division into SLICO super-voxels.



a- Input 2D Image
b-3D Image After Windowing
c-After SLICO Super-voxels
d- 3D Image After SLICO

### C. Modified Fuzzy C-Means

The modified Fuzzy C-Means is a combination between a creation of the co-occurrence matrix and the standard Fuzzy C-Means algorithm.

Conventionally, many approaches of 2D image segmentation take into account the two specified parts: the segmentation technique and the representation system. Throughout this structure, the proposed approach is defined as an amendment of the Fuzzy C-Means algorithm, established on a co-occurrence matrix [34]. The Fuzzy C-Means algorithm can be adopted to compute the membership degree for each super-voxel. However, the FCM algorithm involved only the grey level and does not include the super-voxels spatial information with consideration of each other. For this reason, we determined the statistical attributes of the image after applying the super-voxels technique. This combination may help to impress this inconvenient.

The steps of 3D Modified Fuzzy C-Means method are specified as follows [34]:

1) Choose our input image after super-voxel technique.
2) Set the size of the sliding window.
3) Calculate of the co-occurrence matrix for the sake of extracting a peculiar image.
4) Perform the standard Fuzzy C-Means algorithm which is applied to the attribute image to attain the final segmented one.
5) Adopt the standard Fuzzy C-Means technique in order to extract the region of interest (CSF).

*1) Spatial feature correlation method:* In this paper, we used the co-occurrence matrix [35] as it is related to the presence of a voxel pair from the given image $I$. The co-occurrence matrix is made of important data that restore the class bias of $I$. Consequently, the proposed co-occurrence matrix performs a major role in image dividing.

The co-occurrence matrix, known also as spatial feature correlation method, describes the occurrence of voxel pairs in the distance denoted $d$ in a certain direction in accordance to the following equation:

$$Cooc(i,j,k,R) = card\left\{ \begin{array}{r} ((x,y,z),(x',y',z') \in D, checking\ R(d,\theta) \\ I(x,y,z) = i; I(x',y',z') = j \end{array} \right. \tag{4}$$

where $card(A)$ denotes the cardinality of the subset $A$, *checking* $R(d,\theta)$ expresses the relation between two voxels, $d$ is the Euclidean distance between two voxels. $\theta$ is the angle that describes the orientation of the two voxels among the horizontal direction. This angle can be equal to $0°$ or $45°$ or $90°$ or $135°$. Every element of the co-occurrence matrix $Cooc(i,j,k,R)$ conforms to the number of voxel pairs $(i,j,k)$. It expresses the number of occurrence of a voxel which has a gray-level value $j$. Therefore, this occurrence have to be related to a horizontal adjacency. Subsequently, the evaluation of the regions within the image is made through the use of the co-occurrence matrix. Therefore, the removal of the second statistical features will be simple. These features are the mean $Me$ (Eqn. 5), the variance $V$ (Eqn. 6), the Skinewski $Sk$ (Eqn. 7) and the Kurtosis $Ku$ (Eqn. 8).

$$Me = \frac{1}{M \times N \times S} \sum_{k=1}^{s} \sum_{i=-\frac{w-1}{2}}^{\frac{w-1}{2}} \sum_{j=-\frac{w-1}{2}}^{\frac{w-1}{2}} I(n+i, r+j, t+k) \tag{5}$$

$$V = \frac{1}{M \times N \times S} \sum_{k=1}^{s} \sum_{i=-\frac{w-1}{2}}^{\frac{w-1}{2}} \sum_{j=-\frac{w-1}{2}}^{\frac{w-1}{2}} (I(n+i, r+j, t+k) - Me)^2 \tag{6}$$

$$Sk = \frac{1}{M \times N \times S} \sum_{k=1}^{s} \sum_{i=-\frac{w-1}{2}}^{\frac{w-1}{2}} \sum_{j=-\frac{w-1}{2}}^{\frac{w-1}{2}} (I(n+i, r+j, t+k) - Me)^3 \tag{7}$$

$$Ku = \frac{1}{M \times N \times S} \sum_{k=1}^{s} \sum_{i=-\frac{w-1}{2}}^{\frac{w-1}{2}} \sum_{j=-\frac{w-1}{2}}^{\frac{w-1}{2}} (I(n+i, r+j, t+k) - Me)^4 \tag{8}$$

where $I$ denotes the image and $(M \times N \times S)$ represents the size of $I$, $(w \times w \times w)$ is the sliding windows as shown in the figure 9. The four features are obtained from the windows size $(7 \times 7 \times 7)$, described by the figure 8.

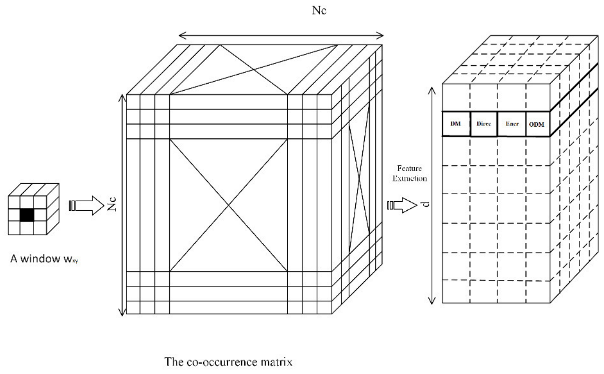

Fig. 8: A sliding window for statistical features extraction.

The window is centered at the voxels $(n, r, t)$ in order to extract a centred window around every voxels. Hence, in the figure 8, the vector that contains the statistical features (DM, Direc, Ener, ODM) is classified adopting the C-Means algorithm into $c$ classes.

The segmentation based on the C-Means algorithm divides the image in $c$ regions (classes). The dimensional scanning plan of an image is implemented voxel by voxel.

*2) Standard Fuzzy C-Means Algorithm:* After applying the SLICO super-voxels algorithm for dividing the image into super-voxels, we extracted the attribute image (Means, Variance, Skinewski and Kurtosis). The third step of the proposed method is to adopt the Fuzzy C-Means algorithm to each super-voxels of the obtained image.

The Fuzzy C-Means aims to minimize the weighted within class sum of squared error objective function [3] :

$$J_{FCM}(U,V) = \sum_{l=1}^{s} \sum_{k=1}^{n} \sum_{i=1}^{c} (u_{lik})^m \|x_k - v_i\|^2 \tag{9}$$

where $x = [x_1, x_2, x_3, \ldots, x_n]^T$ is the data set, $U$ is composed by memberships $u_{ilk}$ of $k^{th}$ bit in the $i^{th}$ class and $m$ is the fuzzy factor with $m > 1$.

The proposed solution of the objective function can be attained using an iterative process, that is performed as follows:

1) Input of the original image which has a size $(M \times N \times D)$,
2) Initialize the parameters: the fuzzifier and the centres of classes,
3) Initialize the partition matrix $U^{(0)}$ based on random variables between 0 and 1,
4) Calculate of the Euclidean distance referring to the following equation :

$$d(x,y,z) = \sqrt{(z_2 - z_1)^2 + (y_2 - y_1)^2 + (x_2 - x_1)^2}, \tag{10}$$

where: $(x_1, y_1, z_1)$ are the coordinates of the first voxel, while $(x_2, y_2, z_2)$ are the coordinates of the second voxel.

5) Update of the prototype using the equation as follows:

$$b_i = \frac{\sum_{k=1}^{n} U_{ik}^m \times x_k}{\sum_{k=1}^{n} U_{ik}^m} \tag{11}$$

6) Calculate the partition matrix $U^{(k)}$ according to equation:

$$U_{lij} = \left[ \sum_{l=1}^{s} \sum_{k=1}^{c} \left( \frac{d^2(x_j, b_i, z_l)}{d^2(x_j, b_k, z_l)} \right)^{\frac{2}{(m-1)}} \right]^{-1} \tag{12}$$

7) Convergence test: repetition of the 4, 5 and 6 steps described by the following equation:

$$||U^{(k+1)} - U^{(k)}|| < \varepsilon \tag{13}$$

where $\varepsilon$ is the tolerance. It converges to zero.

## V. Experimental results

This section presents the results of applying the introduced approach to 10 sample CT images of brain. In particular, a region of CSF is extracted by the proposed method.The sub-figure (10-a) is the windowed 3D image, the sub-figure (10-b) is the result after applying the SLICO algorithm. The sub-figure (10-c) shows the image after applying the SLICO algorithm combined with the mathematical morphology (10-d) is the image after Modified Fuzzy C-Means algorithm. The Figure 11 presents an the results shown in 3D. While, the figure 12 represents the sample slice overlayed.

The proposed approaches were compared in terms of the accuracy and the execution time with the following approaches: Modified Fuzzy-C Means, the combination between SLIC and MFCM and the combination between SLICO and MFCM.

The results of accuracy comparison (in percentage) are given in the Table I. It was measured as follows :

$$Accuracy = \frac{\text{Number of correctley classified pixels}}{\text{Total number of pixels}} \times 100\% \tag{14}$$

The first column shows the case ID. This is followed by the accuracy of the MFCM. The third column represents the accuracy of SLIC combined with the MFCM and the last column shows the accuracy percentage of our proposed method (SLICO+MFCM). While Table II presents comparison of execution time between the Modified Fuzzy C Means, the combination between the Modified Fuzzy C-Means, the Modified Fuzzy C Means combined with the SLIC super-voxels algorithm and the the combination between SLICO and MFCM.

The execution time is given in the table II. Tests were

performed on a PC computer with an Intel Core (TM) i5-3450 CPU 3.10 GHz, a 32 GB of RAM and a CUDA for Graphic Processing Unit using Graphic Parallel Unit Toolbox under Matlab 2013a version.

We can interpret the figure 12 and 13 that the two classes are correctly extracted for 2D and 3D images. The first class is the CSF region and the second one if for the rest of the image.

In our paper, we are interested in the CSF region. So, the figure 13 takes into account the region of Interest (CSF). It is clear that, our SLICO technique combined with the Modified Fuzzy C Means is more efficient than the SLIC technique combined with the Modified Fuzzy C-Means.

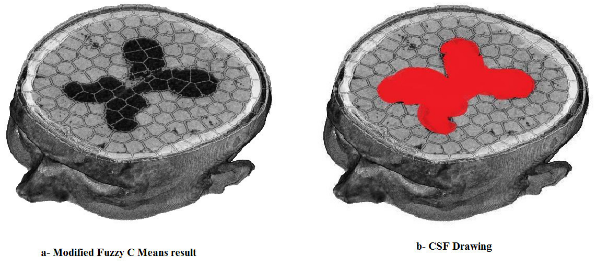

Fig. 12: Sample slice overlayed.

From the Table I, we can say that the 3D Modified Fuzzy C Means takes much time than the ameliorated version based on the GPU. Otherwise, the MFCM combined with SLICO technique is faster than the SLIC technique combined with the MFCM algorithm. The average time of the combination between SLICO technique and Modified Fuzzy C-Means is about 20.94 s. Althought, for The average time of the combination between SLIC technique and Modified Fuzzy C-Means is about 29.10.

Furthermore, the Table II demonstrates that the ameliorated MFCM combined with the SLICO is more accurate than the combination between the MFCM algorithm and SLIC supervoxels technique.

The extracted CSF from three dimensional image is showed in the figure 13. As can be seen in this figure, the visualization of the (VOI)Volume Of Interest using our prposed method (MFCM+SLICO) is more consistent than the Modified Fuzzy C-Means combined with the SLIC technique.

## VI. Conclusion

The segmentation method proposed in this article, is a novel region segmentation method based on the super-voxel technique and the modified Fuzzy C-Means algorithm while the Cerebro-Spinal Fluid (CSF) part has a good consistency. This method consists of three steps. In the first step, the intensity windowing and contrast enhancement are applied

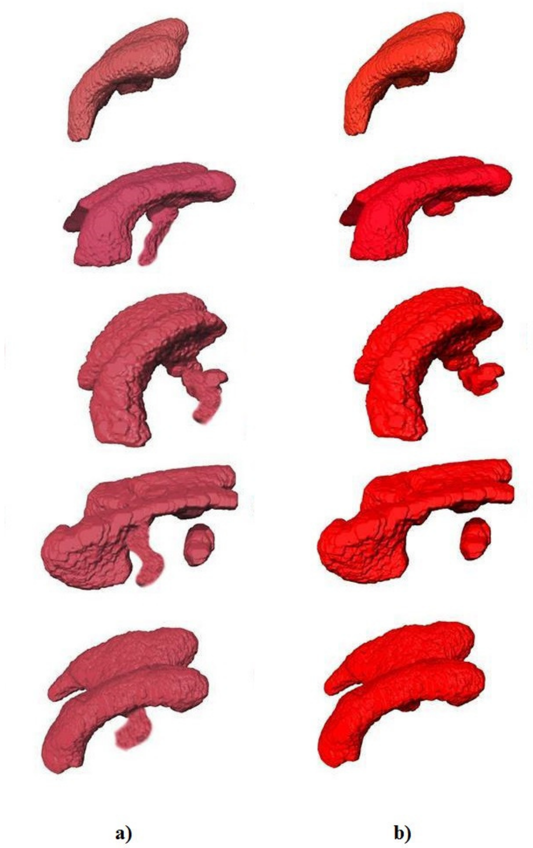

Fig. 13: CSF Visualization: a) SLIC combined with MFCM, b) SLICO combined with MFCM results.

TABLE I: Comparison the accuracy between original MFCM, SLIC algorithm combined with MFCM and SLICO algorithm combined with MFCM.

| Case ID | Accuracy MFCM (%) | Accuracy SLIC+MFCM (%) | Accuracy SLICO+MFCM (%) |
|---|---|---|---|
| 01 | 93,12 | 96,13 | 97,50 |
| 02 | 92,60 | 93,15 | 98,27 |

| 09 | 1119,35 | 11,90 | 12,27 |
| 10 | 1127,14 | 11,94 | 12,68 |

to the input 3D CT image. In the second step, we adopted an image division into super-voxels. Then, a segmentation modified Fuzzy C-Means approach is applied in order to segment the image into two classes. Considerable evaluation results have demonstrated great potential on our new approach.

Regarding to the main objective of this research paper, there is no exist method suggested the combination of fuzzy logic rules with a super-voxel technique. Furthermore, the proposed method considers the neighbouring membership degree among the voxels of the images during the determination of a final classification which can be unable with traditional segmentation methods.

*Abstract*— **Today, the most of the video streaming system provides quality adaptation and prefers to send their packets over HTTP. MPEG group has standardized Dynamic Adaptive HTTP Streaming (DASH) regarding this tendency on the adaptive HTTP streaming. Besides providing quality adaptation with a non-scalable codec, DASH standard also allows Scalable Video Coding (SVC) to adapt quality. Software Defined Networks (SDN) is a recently emerged networking paradigm. SDN enables to separate control and data plane of computer networks and hence provides flexibility to network operators to implement their own routing approaches. In this paper, we propose a system for increasing Quality of Experience (QoE) of SVC-DASH clients by utilizing SDN. Our experimental results show that the proposed system provides an increase in received video quality and decrease in outage duration and startup delay when compared to the performance of the client running over todays Internet implementing shortest path routing.**

## INTRODUCTION

CISCO estimates that IP video traffic will be up to 80% of global Internet traffic in 2018 [1]. The huge demand on IP video lead researches to develop video streaming applications providing high Quality of Experience (QoE) to the clients [2]. Video streaming applications need to adapt their bitrate according to the underlying network conditions to provide good performance in terms of QoE. Popular video streaming applications such as Youtube [3], Microsoft Silverlight [4], Apple HLS [5] send video packets over HTTP and perform quality adaptation by sending HTTP requests for receiving the video partitions with different qualities. HTTP protocol is preferred since it reduces the server load by HTTP caches while providing reliable data transfer.

In HTTP adaptive streaming, video files encoded at various rates are stored in the server. Each video file, i.e. representations, is separated into the small partitions called segments. The clients observe several parameters giving indication about underlying network capacity, such as buffer level or download duration to transfer the recent segments. As a result of observed parameters, the clients send their request indicating the selected representation for each segment. Hence, the selection of video quality changes over time regarding the client requests. Recently, MPEG group has standardized Dynamic Adaptive HTTP Streaming (DASH) [6]. DASH standard defines the formats of the segments and document containing the segment information.

With a non-scalable codec, video file should be separately encoded in order to obtain different representations having different quality. If scalable video coding (SVC) is used, video file is encoded once and video sequences with different quality can be extracted from this encoded file [7]. Hence, SVC provides the storage advantage. If SVC is used with HTTP streaming, storage advantage provides cache efficiency and optimizes the bandwidth usage since only one encoded video sequence is send to the HTTP cache for a video file [8]. Using SVC with DASH allows producing video sequences with large range of representations while providing cache efficiency [8].

Software defined networking (SDN) technology decouples the control and data plane of computer networks [9]. This separation allows network operators to implement different routing algorithms designed by considering specific application needs. In an SDN domain, a centralized device, called controller, has the network topology view. The controller determines the routing paths and sends related information to the forwarding elements. SDN paradigm offers a flexible platform to implement various routing algorithms designed for different network applications.

In this study, we propose a system for improving the performance of SVC-DASH clients running over SDN. We use quality of experience parameters such as received video quality, buffer underruns -i.e. outage durations-, and startup delay to measure the performance. SDN architecture enables to select different streaming path to transfer different video layer flows. We define a method for controller to learn which layers are streamed to which clients without communicating with the clients and the server, and provide path assignments using this information. We also give the design guideline of a SVC-DASH client running over SDN.

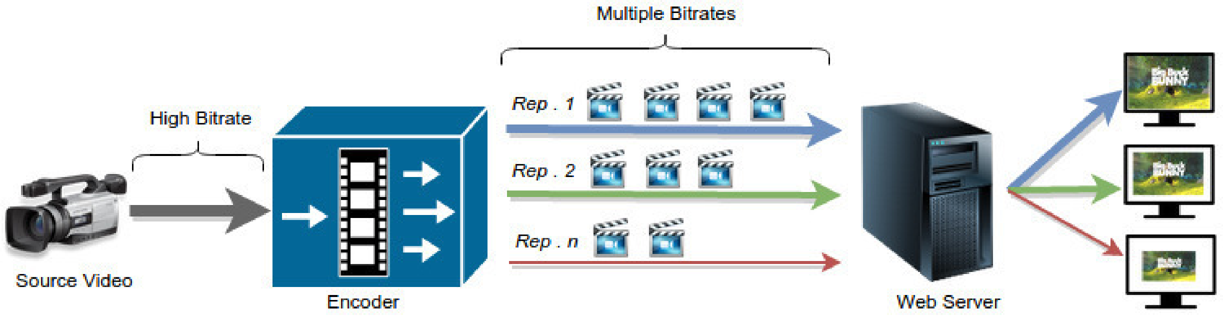

Fig. 1 DASH diagram showing different representations of the same video content.

The rest of the paper is organized as follows. In section two, the background of SDN and SVC-DASH are given with the related work proposed in the literature. In section three, the design of the proposed system is detailed. The performance of the proposed system is reported in section four. Finally, the conclusion is given followed by the references.

## BACKGROUND

### A. Dynamic Adaptive Video Streaming over HTTP

In DASH standard, more than one video file encoded at different bitrates for the same content is stored in a web server. In Fig. 1, a DASH diagram is given where a video content is encoded at three different bitrates with different resolutions.

In the server, each video sequence is separated into the segments. The segments can be independently decoded and has the data of fixed time interval. Information about the segments such as representation ID, URL address and bitrate are kept in Media Presentation Description (MPD) file. DASH standard defines MPD document and segment formats [6]. When a client connects to the DASH server, it gets the MPD file after establishing TCP connection between itself and the server. The quality adaptation is performed by client requests via selecting the segments with different qualities. Hence the complexity is given to the clients. DASH client decides which representation to be selected in each request. The clients adapt the video rate by changing the representations over time and send request to the server to get current segment of selected representation.

Rate adaptation algorithm is the algorithm that determines the policy of representation selection. The rate adaptation algorithms of DASH clients differ according to the parameter which is taken into account when selecting the next segment. This parameter can be measured bandwidth [10, 11] or the level of buffer fullness [12]. Some client algorithms use both of them to decide representation [13].

SVC provides to produce video sequences with various qualities in one file. The video content is encoded so as to consist of one base layer and one or more enhancement layers with SVC. While base layer can be decoded independently, it is required to base and *n*-1 enhancement layers to decode $n^{th}$ enhancement layer. Base layer has the minimum quality and each enhancement layers increase the quality. In SVC-DASH or Advanced DASH, each layer corresponds to one representation. The layer dependencies are defined in MPD. Hence, when a client requests for a segment, it may also request segments of lower layers according to the dependencies given in MPD document.

### B. Software Defined Networking

SDN paradigm enables to separate control and data planes of computer networks. This approach moves the intelligence from forwarding elements to an external device, called controller. Network operators can implement novel routing strategies taking requirements of network applications into account by programming the controller. The controller sends commands containing forwarding rules to the forwarding elements, i.e. switching devices. Another advantage that SDN provides is that the controller can have the network topology information such as traffic amount on the links, packet loss ratio or drop packets by communicating with the switches. The SDN architecture is given in Fig. 2.

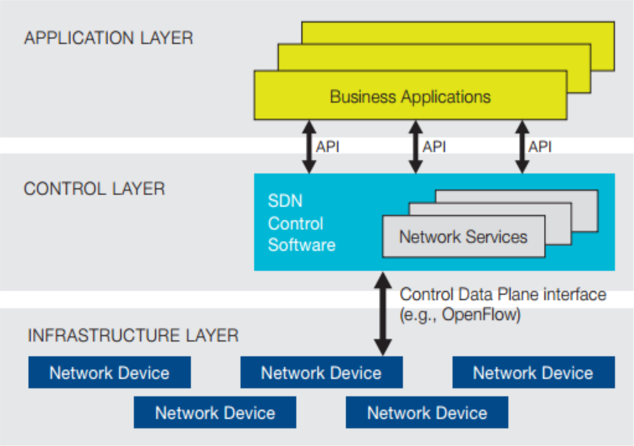

Fig. 2 SDN architecture showing decoupled structure of control plane and the data plane [9].

OpenFlow is the first protocol designed for providing communication between the controller and the switches. OpenFlow opens a secure communication channel. Switches update their forwarding tables according to the messages of the controller, sending via using OpenFlow protocol. When a switch gets a packet, it checks the header information of the packet, and performs an action regarding the defined rule for that information. In other words, the switches implements a <match, action> processing for each packet. Forwarding a packet, discarding a packet, or querying controller for asking the rules of a packet can be given as action examples.

### C. Related Work

Since both DASH standard and SDN paradigm have gained great attention from the academia and market, researchers has proposed several studies related on these topics recently.

In [14], dataset for SVC-DASH is presented. HTTP cache efficiency of SVC-DASH is discussed in [8]. In this study, it is shown that if SVC-DASH is used, then network traffic reduces when compared to the traffic amount of MPEG-DASH.

The performance in terms of QoE of DASH clients can be improved by utilizing SDN capabilities. In [15], the authors aim the provide fairness among DASH clients. For this purpose, the controller communicates with the clients and sends commands indicating which representation should be selected. This selection is determined according to the network topology information and client type. Since SDN provides controller to decide forwarding rules, different selection strategies for the flow routes between server and the clients is also proposed in several studies to increase QoE of DASH clients. In [16], a traffic shaping policy is determined for OpenFlow enabled switches, which gives priority to the HTTP flows. This approach provides DASH clients to achieve higher performance when compared to the case that HTTP flows has no priority. QoE centric path assignment over SDN networks for DASH clients is proposed in [17]. The controller communicates with DASH clients and if the performance decreases in terms of QoE parameters, the bottleneck point is detected by the information obtained from the switches. If the problem is in SDN network, then a different path is selected, otherwise the server is changed [17]. Path assignment by considering the bitrate of the segments and path capacities for increasing DASH clients' performance running over SDN networks is proposed in [18]. The server signals the controller to give information about the bitrate of the current segment and the paths are changed if the capacity of the current path is not enough to convey that segment packets.

Path assignment capability of SDN networks brings a natural approach to send packets of scalable coded video by sending base layer video over a different path. In [19], base layer video packets is send over a lossless path while the remaining traffic is send over the shortest path over SDN network. Besides sending base layer video packets over lossless path, forwarding enhancement layer packets over another path is proposed in [20]. The flow routes of base and enhancement layers packets are determined according to the output of an optimization model by considering packet loss and delay variation [21]. Quality adaptation techniques and flow route decisions considering the quality adaptation are not briefly discussed in these studies.

To the best of our knowledge, there is one approach proposed in the literature to route HTTP flows for SVC-DASH clients running over SDN. In [22], the path that has the smallest load is assigned to route base layer packets. Similar to base layer path assignments, the paths determined for enhancement layers are done based on layer priority; the packets of enhancement layer having higher priority are sent over a path having smaller load. The SVC-DASH client always requests all enhancement layers for each segment, i.e. it has no rate adaptation algorithm. Since rate adaptation is not implemented in that client software, there is no strategy defined for selecting the representation to be requested. The client sends requests in every 2 seconds [22].

In this study, we propose a system for SVC-DASH streaming over SDN. In the system, we think each video layer packets as a separate flow and assign streaming paths considering the bitrate of the layers. The paths of each layer can be the same if the available bandwidth is enough, but can be different, otherwise. Our approach differs from the studies in the literature in the following aspects. First, the controller does not communicate with the server or the clients to get information about the client requests. Second, we utilize different OpenFlow message types to detect received quality. And finally, we give an implementation guideline for SVC-DASH clients running over SDN.

## Flow Route Assignment for SVC-DASH over SDN

In this section we give the details of the proposed system for improving the performance of SVC-DASH clients running over SDN and give the details of SVC-DASH client implementation in the proposed system.

### D. SDN for SVC-DASH Clients

In the proposed system, flow routes i.e. streaming paths between the server and the clients are determined by the controller. The controller communicates with the switches in both proactive and reactive manner. It queries the switches periodically in order to obtain traffic information as proactive behavior. The controller calculates the available bandwidth of each path in the network by using the traffic information. Whenever the controller receives a message from a switch querying for a flow, it sends the forwarding rule to that switch. This is the reactive part.

Since the controller determines the paths for video flows between server and the clients, the switches need to communicate with the controller to learn the forwarding rules. The controller determines the paths for video layer packets; and then sends the forwarding rules related to the assigned path. Note that, the controller has to send the message containing forwarding rules to all switches along the chosen path.

As a path assignment strategy, the controller can assign the path having maximum available bandwidth for the newly joined client. Although the path having maximum available bandwidth is selected as streaming path for that client, sending each video layer packets over the same streaming path may decrease the capacity utilization. For example, suppose we have two paths where the capacity of first and second path equal to bitrate of base and first enhancement layer, respectively. In this case base layer packets can be sent over the first path and enhancement layer packets can be sent over the second path. But capacity of each path is not enough to transfer both layers packets.

Because of capacity utilization problem, we advocate to assign different streaming paths for the video layer packets requested by the same client for maximizing the network capacity utilization. For capacity utilization maximization, the best solution is to assign paths regarding the bitrate of the layers being sent. When a client joins the system, the controller makes system-wide path assignment for each client in the system by taking capacity of the paths and bitrates of the video layers into account.

In order to assign paths for the video layers packets of the clients, one approach is for controller to communicate with the clients or the server, to obtain requested layer information and to assign path according to the retrieved layer information. However, this reactive approach brings extra message complexity to the system. Instead of communicating with the server or the clients, we propose a method for controller to have the requested layer information without introducing extra messaging burden. We provide that the server sends each layer from a different TCP port and put this port information of video layers into the MPD file. The clients send video layer requests according to the given information in the MPD file. For example, if a client requests base and one enhancement layer, it sends these requests to defined ports of base and first enhancement layers, not the same port on the server. Hence, the switches look for a match of the tuples (client IP address, server IP address, port number) when receiving request messages of the clients. If this match does not present in its flow table, the switches sends a query containing the tuple.

SVC-DASH client establishes a TCP connection between the server and itself after connecting to the system. The first message of the TCP connection establishment is TCP SYN message being sent by the client. The OpenFlow enabled switch that newly joined client is connected to sends a PACKET_IN message to the controller after receiving TCP SYN message. The controller assigns paths upon getting a PACKET_IN message. Since the controller has not the information of what representation, i.e. which layers will be requested by the client; it determines the paths for base layer packets and for enhancement layer packets in case of there is enough network capacity.

```
Procedure Path_Assignment

1:  $c_i$: $i^{th}$ online client
2:  N: number of online clients
3:  $cp_p$: the capacity of path p

4:  $i = 0$;
5:  while $i$<N
6:      $p$: the path having max available bandwidth
7:      assign $p$ for the base layer packets of client $i$
8:      $cp_p = cp_p$ – bitrate of base layer;
9:      $i$++;
10: end while

11: $i = 0$;
12: current enhancement layer = first enhancement layer;

13: while current enhancement layer ≠ NULL && there
    exist any $p$ with $cp_p \geq$ bitrate of current enhancement layer

14:     while $i$<N
15:         $p$: the path having max available bandwidth
                                            (i.e. capacity)
16:         if ($cp_p \geq$ bitrate of current enhancement layer)
17:             assign $p$ for the current enhancement layer
                                packets of client $i$
18:             $cp_p = cp_p$ – bitrate of current enhancement layer;
19:         end if
20:         $i$++;
21:     end while

22:     if (current enhancement layer =
                                highest enhancement layer)
23:         current enhancement layer = NULL
24:     else
25:         current enhancement layer = next enhancement
                                                layer;
26:     end if
27: end while
```

Fig. 3 Path assignment algorithm running by the controller. The output of the algorithm determines the paths for all clients

The path assignment algorithm is given in Fig. 3. As given in the algorithm, the controller first assigns the paths having maximum available bandwidth for transferring base layer packets of all clients between the 5th and 10th lines of the algorithm. Since base layer packets are crucial, the controller has to assign paths for them even if the capacity of the network is not enough to send these packets properly. Upon completing the path assignment for the base layer packets, the controller assigns the paths for enhancement layer flows starting from the first enhancement layer for all clients in the while loop starting at line 14. But this time, if the network capacity is not enough to transfer the packets of an enhancement layer, then this assignment procedure is stopped. In other words, the paths for enhancement layer packets are assigned if and only if there is enough capacity.

After determining the paths for transferring the packets of video layers, the controller sends related flow information to the switches. The switches overwrite new forwarding rules to the existing entries in their flow tables. Note that at this point, although the switches have the information of rules for forwarding base and one or more enhancement layer packets, the clients may not request to receive any enhancement layer, in turn, these rules may not be used. Here, the controller determines the paths in proactive manner.

As defined in HTTP adaptive streaming, the clients request for a representation after it joins the system and gets MPD file from the server. Besides that, online clients continue to request representations according to their rate adaptation algorithms. At this point, there are three possible cases for a client:

(*i*) The controller may have assigned the paths for exactly same number of enhancement layers with the number of enhancement layers that a client requests to.

(*ii*) The controller may have assigned paths for *i* enhancement layers but the client requests more than *i* enhancement layers packets.

(*iii*) The controller may have assigned paths for *i* enhancement layers but the client requests less than *i* enhancement layers packets.

Clearly, for the first case, the forwarding rules for the requested representations, i.e. video layers flows are already determined on the flow tables of the switches.

In the second case, the switch gets a packet (or more than one packet) which flow information does not present in its flow table. It sends a PACKET_IN message to learn what to do with the received packet. This case occurred when the client measures available bandwidth and decides that it can receive more enhancement layers, which shows that the available bandwidth of at least one of the paths assigned for that client is higher than expected. Suppose the client receives video packets over n paths. The controller assigns the path having maximum available bandwidth among these n paths for the requested flow.

In the third case, the switches have more forwarding rule entry than it is required to. In this case, there are unused flow entries in the flow tables of the switches. The same situation can happen when a client decreases the quality by requesting less number of enhancement layers than that of it requested in previous period. In the OpenFlow protocol, each flow entry has an idle timeout which is determined by the controller. The switch removes a flow which has no matching packets in idle timeout and informs controller by sending FLOW_REMOVED message. In this work, the flow of base layers has no idle timeout where the enhancement layers is set to a certain threshold called flow timeout. When controller receives a FLOW_REMOVED message, it determines the path having minimum throughput among the paths which are assigned to transfer video layer packets for that client. The controller changes this path to a new path having maximum available bandwidth and sends related forwarding rules to the corresponding switches. The controller performs the second step in order to find better path which can be provide to increase the quality received by the client.

There is one thing left subtle but important. As stated in previous section, DASH clients request for the segments consecutively. If a segment is downloaded fast, the client waits for a while before it sends the request for the next segment. In other words, it enters the successive downloading and waiting periods. This phenomenon is known as on/off behavior [23]. On/ off period cause a traffic measurement problem if the controller measures of a current flow traffic when the client is in off period. If the client is in off period, then the controller measures the current traffic on that path as zero. In order to prevent that misconclusion, we have conducted a set of experiments and determine maximum length of off periods. Then we set idle timeout of the flows to a value higher than maximum off period length. Hence, we provide that the controller to sense traffic if there is at least one client receiving packets over corresponding path.

### *E. An Implementation of SVC-DASH Client Running over SDN*

Typically, two parameters are determined regarding the output of the rate adaptation algorithm: which representation (if SVC is used, which enhancement layers) will be requested and when it will be requested. In this section, we give the details of the implemented SVC-DASH client software.

When a client joins the system, it requests MPD file from the server as stated in DASH standard. Since we added the port information in MPD file, the client extracts the port information for each video layer from the MPD document besides the information of the bitrate of each video layer. The client also estimates the available bandwidth by calculating the download rate of the MPD document. Based on this calculation, the client determines the number of video layers to be requested for the first segment.

In SVC-DASH client implementation given in [22], the client requests base and enhancement layers segments consecutively. For example, if client decides to request video segment of second enhancement layer after executing rate adaptation algorithm; it sends request for base layer packets first. Upon receiving the base layer packets, it requests for the first enhancement layer packets, and after receiving first enhancement layer packets, it requests second enhancement layer packets.

Since the controller can assign different paths to the video layer flows in SDN network, the clients does not have to request video layers sequentially. In our SVC-DASH client implementation, the client requests video layers simultaneously after deciding which layers will be requested. Suppose the client decides to request one base and two enhancement layers. The clients send an HTTP GET message to the corresponding ports of the server at the same time. Hence, the client throughput is maximized since it does not have to wait downloading packets of a video layer to request the next layer packets for a segment.

In order to calculate throughput, we need a new method since each video layer packet transmitted over a different path. Suppose the client request base and $n$ enhancement layers. Let $t_{dt}$ represents the total time to download base and these $n$ enhancement layers. Then $t_{dt}$ and the throughput for the requested segment are calculated according to the formula given in (1) and (2), respectively. In the formulas, $e_i$ represents the $i^{th}$ enhancement layer, $b$ represents base layer. $t_x^{last}$ is the receiving time of the last packet of $x^{th}$ layer, $t_{request}$ is the sending time of the request and $br_x$ is the bitrate of the $x^{th}$ layer.

$$t_{dt} = \max(t_b^{last}, t_{e_1}^{last}, \ldots, t_{e_n}^{last}) - t_{request} \qquad (1)$$

$$\frac{br_b + \sum_{i=1}^{n} br_{e_i}}{t_{dt}} \qquad (2)$$

After calculating the throughput, the client selects the representation which has the maximum bitrate value lower than the throughput. The client sends next HTTP GET message upon downloading the requested layers packets of current segment.

## PERFORMANCE EVALUATION

### F. Experimental Setup

The experiments have been performed over a test bed shown in Fig. 4. SDN environment including OpenFlow-enabled switches and hosts that run SVC-DASH clients and SVC-DASH server are emulated using Mininet [24] software. SDN controller is implemented using Floodlight [25] software.

In the experiments, Big Buck Bunny video [14] which has one base layer and three enhancement layers are served by the SVC-DASH server. The bitrates of the video layers are given in Table 1. Note that the bitrates given in the table are cumulative because of inter-layer dependency. The video is divided into 300 segments each with a length of 2 seconds. Therefore the experiments last for 600 seconds. The clients join the system with interval of 30 seconds and never exit during the experiments. Flow idle timeout is set to 20 seconds.

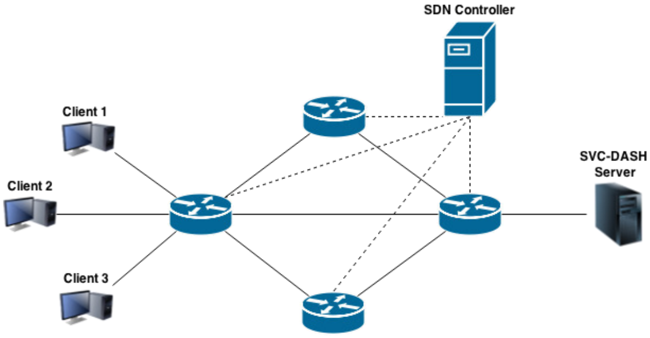

Fig 4. Experimental Testbed

TABLE I.
THE BITRATE DISTRIBUTION OF VIDEO LAYERS

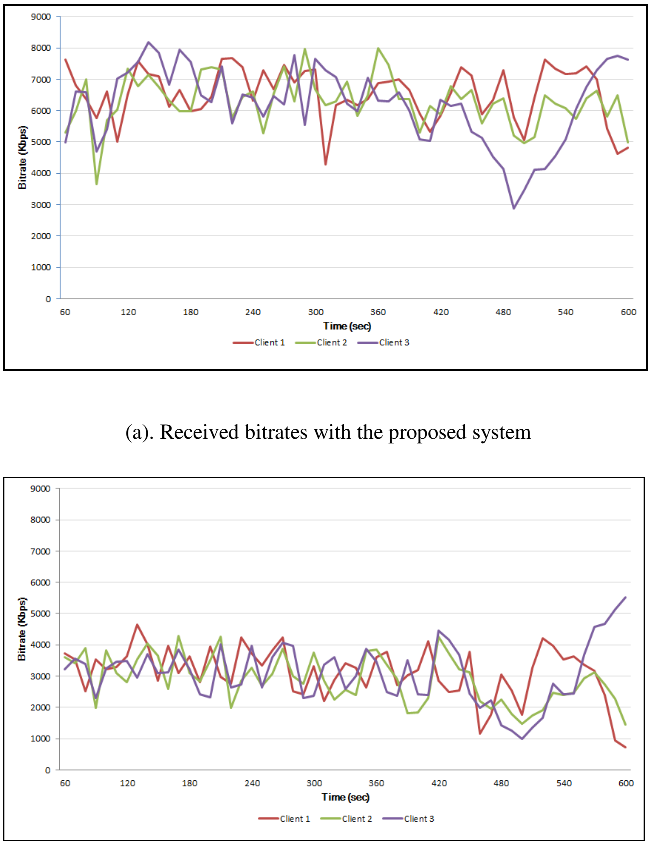
| Video Layer | *Bitrate* |
|---|---|
| Base | 1555 Kbps |
| Base + Enhancement 1 | 2700 Kbps |
| Base + Enhancement 1 + Enhancement 2 | 4547 Kbps |
| Base + Enhancement 1 + Enhancement 2 + Enhancement 3 | 6857 Kbps |

As seen from Fig. 4, there are three different paths between server and the clients in the network topology. The capacity of each path in the network equals to 6000 Kbps. This means that although the network capacity is enough to send base layer to each client, there is not enough capacity to send the highest enhancement layer to all clients in the system.

### G. Experiment Results

In order to show performance of the proposed system, we observe several QoE parameters: received bitrate, received video quality and, number and length of durations. We also perform experiments with same set of parameters by using traditional Internet shortest path routing and give the results comparatively. The topology includes only one shortest path with the length of one hop. Hence, the video packets are streamed over the same path with shortest path routing. Each experiment is repeated 10 times; averaged results are obtained and shown in the graphs.

In Fig. 5a and Fig. 5b, the average bitrates received by each client in the proposed system and in the system with shortest path routing are given as a function of time, respectively. While the averaged received bitrate values for the clients are in the range of 5000 Kbps and 8000 Kbps, these values are in the range between 2000 Kbps and 4000 Kbps with shortest path routing. In both approaches, the clients can achieve bitrate higher than the capacity of the paths. The main reason of that is on/off period pattern of the clients. A client may even use the full capacity of a path if other clients using that path are in their off periods.



(a). Received bitrates with the proposed system

(b). Received bitrates with the shortest path routing

Fig 5. Averaged received bitrate as a function of time

In order to show the quality of the received video, we measured the total length of the video segments that received from each layer and give the results in Fig. 6. In the figure, base and enhancement 3 denotes the minimum and maximum quality, respectively. During the streaming session, the clients in the proposed system experience the video quality provided by the enhancement 2 most of time, where the clients receive the base layer quality in the shortest-path approach. Furthermore, the clients in the shortest-path approach never experience the quality provided by the enhancement 3. Note that, the values given in the graph are cumulative. In other words, if receiving an enhancement layer is shown in the graph, it means base and all enhancement layers below the received enhancement layer are also received.

When the bandwidth is not enough to send the selected representation, the clients may drain their buffers and then start to experience outages. In Fig. 7, average durations in seconds observed in the proposed system and the shortest path approach are given. As it is seen, the proposed system has a lower number of outages. The reason of this is that the proposed system dynamically changes the paths and provides to increase network capacity utilization. Thus the clients get the maximum available bandwidth. But in the shortest path approach, the clients always use the same path. So their share of bandwidth decreases which causes outages to increase. In Fig. 8, CDF graph of total outage durations is given in order to show the distribution of outage durations.

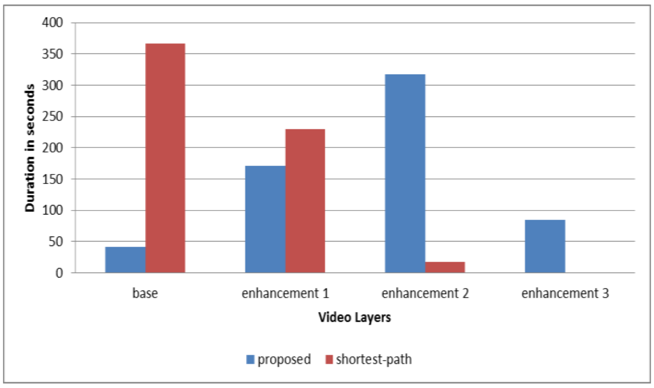


Fig 6. Received video quality in terms of layers

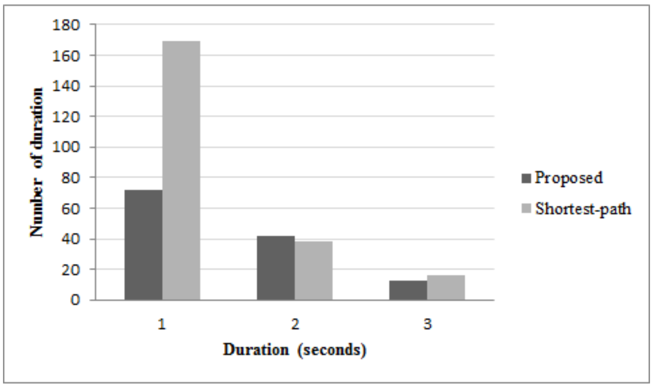

Fig 7. Total duration values of outages measured in the experiments

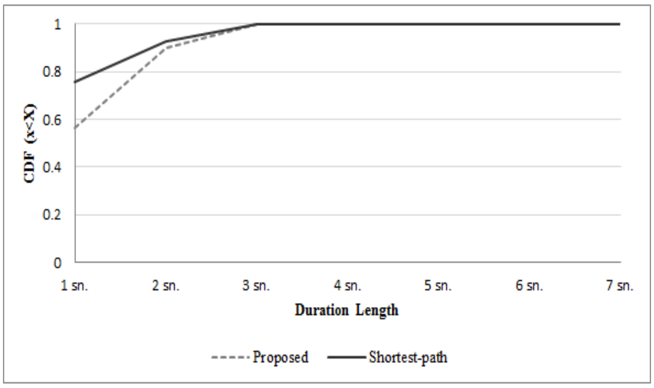

Fig 8. CDF graph of observed duration of outages

In Table 2, averaged startup delays experienced by each client are given. Startup delay equals to the elapsed time from requesting the first segment to playing the video. As seen from the table, limited capacity causes an increase in startup delays. The clients experience longer startup delay with shortest path routing.

TABLE II. STARTUP DELAY VALUES IN SECONDS

| | ***Proposed system*** | ***Shortest-path routing*** |
|---|---|---|
| Client 1 | 10 sec | 10 sec |
| Client 2 | 11 sec | 12 sec |
| Client 3 | 11 sec | 17 sec |

## CONCLUSION

In this paper, we propose a system for increasing QoE SVC-DASH client running over SDN. For this purpose, we think each layer of the video as a separate flow and assign paths by taking path capacity and the bitrate of the layers into account.

Our system differs from the similar studies in the literature as the controller does not communicate with the server and the clients to detect which video layers are sent to the clients. In order to detect requested number of enhancement layers, we utilize PACKET_IN and FLOW_REMOVED messages sent by the switches to the controller. The controller decides system wide re-routing of flows or change the path of a flow according to the received message type and capacity of the paths.

The performance of the proposed system is measured by considering the QoE parameters such as received video quality, outage duration and startup delay. When we compare the achieved performance of the proposed system with the traditional shortest-path routing of today's Internet, our system provides to yield better performance for each QoE parameter.

In the future, we are planning to measure the performance of the proposed system with larger number of clients, different types of video resolutions and with different types of network topologies.

***Abstract*—The multimedia databases are becoming more and more popular nowadays. One of their main problem is a huge data amount storage. Another problem with multimedia databases is querying. Traditional approaches, based on textual keywords are not sufficient. More advanced techniques, incorporating image content features, should be used. In this paper we propose new multimedia database structure with ability of Content Based Image Retrieval which is based on our previous work: Query by Shape method (QS). Query by Shape is a method which is based on decomposing an object into features. Each feature may consists of shape primitive, a color or a texture. In this paper we only use shape primitives. In order to achieve high scalability and workload control, we propose a modified Scalable Distributed Two-layer Data Structure, as a storage. The modification incorporates adding tree structure, comparing algorithm and returning a set of results to the client.**

## I. Introduction

THE MULTIMEDIA databases are becoming more and more popular nowadays. There are many applications where they are needed, like social media portals (e.g. Facebook, Instagram, Flickr and Google+) or monitoring systems. Because modern cameras produce high resolution images, the amount of data which has to be stored is very huge. Another problem with multimedia databases is their querying. Traditional approaches, based on textual keywords are not sufficient. More advanced techniques incorporating image content features should be used.

In this paper we propose the idea of a multimedia database structure with ability of Content Based Image Retrieval which is based on our previous work described in [1], Query by Shape (QS). Query by Shape is a method which is based on decomposing an object into features [1]. Each feature may consists of shape primitive, a color or a texture. In this paper we only use shape primitives. As a data structure for storage we use a modified Scalable Distributed Two-layer Data Structure which is highly scalable, distributed data store [2]. The modification incorporates adding tree structure, comparing algorithm and returning a set of results to the client.

This paper is organized as follows. The Section II presents the survey of image retrieval algorithms. The Section III contains a short review of NoSQL data stores. The idea of Scalable Distributed Two-layer Data Structures is described in the Section IV. The Section V shows the motivation of our research. The idea of our database structure is presented in the Section VI. The conclusion of the research is given in the Section VII.

## II. Image Retrieval algorithms

In the area of multimedia databases, three types of retrieval algorithms can be distinguished: Keyword-Based Image Retrieval (KBIR), Content-Based Image Retrieval (CBIR) and Semantic-Based Image Retreival(SBIR).

The first group, KBIR, is based on the relational database approach, where images are stored in the database and they are described using keywords. During the query, the proper keywords should be given. The database structure is very simple but strongly relies on the textual annotations given by a human. This approach is prone to mistakes because of the subjective kind of descriptions [1]. Moreover it is very hard to cover the whole information, present in the image, using textual description [3], [4].

The CBIR algorithms are based on different approach than KBIR. Image features are used to index images and perform queries [1]. All algorithms in this group could be divided into two categories: low-level and high-level algorithms. The low-level algorithms process images globally, extracting features from the whole frame, using e.g. a normalized color histogram [5], a spatial domain [6], a difference moment and entropy [7] or an MPEG-7 image descriptors like shape and texture [8]. The low-level features used by CBIR algorithms are easy to compute but they are insufficient if the query is oriented on searching for similar objects rather than whole images, which incorporates separating the object from the background.

The high-level CBIR algorithms provide more reliable and precise results in this situation. The major part of the algorithms from this group are based on the regions extraction and graphs matching. A region is a group of similar pixels, most often grouped by colors. There are also methods which uses during region extraction: a set of primitives [9] or fuzzy pattern [10] detection, moment-based local operators [11] or parallelograms, ellipses, corners and arcs detection [12]. After region extraction, a graph is being constructed in order to store the relations between them [1]. During the multimedia database query, the graph-subgraph matching is performed

978-83-60810-66-8/$25.00©2015, IEEE

e.g. using the classic Ullman algorithm [13] or more advanced ones. There are algorithms that are automatic or semi-automatic with ability to present preliminary results to the user who may choose important regions and repeat the query [14]. Another group of CBIR algorithms allows queries without full knowledge about searched images or objects. One of the first and most successive approaches in this area uses a human drawn sketches which are compared with the corresponding sketches in the database, globally for the whole image [15]. Another example is Query by Shape method [1], which is our previous research and which is used as a base of this paper. The idea of the algorithm is to decompose objects into features like shape primitives or color features. The features are not used for region extraction but for constructing an object's sketch or skeleton which is strictly a graph. Also the matching algorithm is proposed which uses the $similarity$ coefficient. The $similarity$ informs how similar two graphs are. If they are the same, the $similarity$ is equal to 1, if they are completely different, it takes 0 value. All intermediate values indicates that graphs are partially similar.

The SBIR algorithms are algorithms that try to overcome the "semantic gap", which is the difference between what is present on the image and what a human could interpret [4], [16]. Most SBIR algorithms are based on textual description which, in contrast to the KBIR algorithms, is a much longer phrase. The phrase is easy to create, use and understand by the human, the example could be "the sunrise in the mountains". The textual descriptions are not used directly, but they are mapped onto semantic features and then a query is performed [17].

All groups of algorithms need efficient data storage methods. One of the most often used structure is a cell or a tree, because it can store the relations between similar images [8]. There are also approaches that joins both data structures. One of the example is [18] which is based on gathering similar records in the same cells. Additionally, some biological processes are added, like mitosis, when the similarity between items in the same cells is below the specified level.

## III. The NoSQL data stores

The multimedia databases very often stores millions of photos or images. Because there has to be stored and processed very huge amount of data, with high availability and workload management, the traditional SQL-based databases may not be sufficient. Much better results are obtained using NoSQL databases. The NoSQL databases may be classified into the following groups: Graph databases, Key-Value data stores, Document data stores and Column-based data stores [19].

The Graph databases provides similar features as relational databases but they are not well-prepared to store huge amount of data because of the problems with scalability [19]. Key-Value data stores use an unique single key (e.g. a number) for storing data (value). Most often they have only two operations: inserting and retrieving data [20]. The examples of such data stores are Dynamo data store by Amazon which uses single integer key [20] or Apache Hbase which identifies the data by a timestamp, column name and row name [21]. The Document data stores use textual data interchange formats, like JSON or xml to store data. The most popular document data store is MongoDB [19].

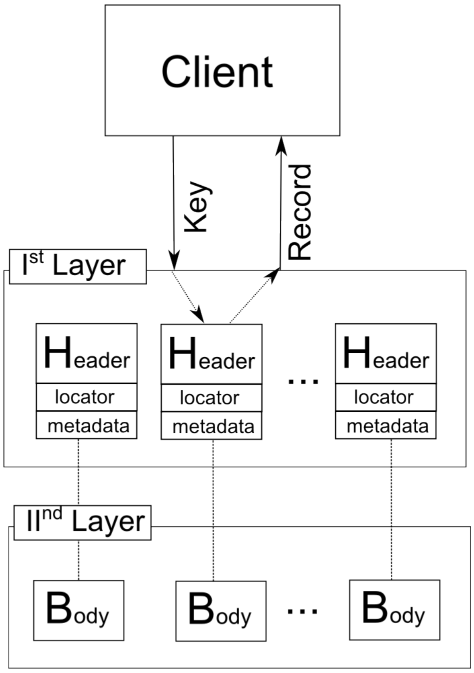

Fig. 1. The SD2DS structure overview.

The NoSQL data stores were successfully adapted to store images. As an example the Apache Hbase may be given, which was used to store Google Earth images [21].

## IV. The SD2DS data stores

Scalable Distributed Two-layer Data Structures (SD2DS) are one of variants of Scalable Distributed Data Structures (SDDS) [2], which may be classified as an distributed NoSQL data store. They stores data using a key and a value in so-called "buckets". Each bucket has storage limit and when it is reached a split is performed. Buckets may be distributed through many machines, e.g. nodes on the multicomputer. The SD2DS stores data in two separate layers. The first layer contains only data headers which consists of the data locator and metadata. The data locator is used to locate the stored data in the second layer. The metadata is an additional information connected with the actual data and may contain optional information e.g. the data length, a checksum, insertion date or data description. The second layer contains only the actual data, called body [2]. That structure maintains data more efficiently, because both layers are independent of each others and may be stored on different machines. Moreover the data store is highly scalable, without theoretical limitations and may contain as many data as is needed. The SD2DS allows also to use as a second layer other solutions, even without buckets. The SD2DS structure is presented in the Fig. 1.

The SD2DS may be easily extended e.g. by adding throughput adjustment [22] which highly improves the data access time.

## V. Motivation

The problem of multimedia database querying is very complicated. As a continuation of the previous research [1], we would like to propose the Content Based Image Retrieval Database incorporating Query by Shape Method. The database has to store a very huge amount of data. Simple records table, a tree or a cell would be not sufficient. Because of that, more advanced data stores, especially NoSQL-based should be used. In order to obtain very high scalability and availability, as a base for our system the Scalable Distributed Two-Layer Data Structures should be used. As a result of our research we would like to create the system which will fulfil the following requirements:

- queries using a graph of features e.g. primitives,
- similarity control for graphs comparison, the similarity should be set by the client,
- client feature: graphical queries easily drawn by a human (without drawing skill), e.g. using predefined shapes,
- client feature: automatic image transformation into a graph, used for a query,
- very fast data access,
- scalability without turning off the system,
- easy addition of the new hardware used for storage,
- good performance for the very huge data workload stored in the database.

## VI. The system overview

The proposed system extends the SD2DS data store structure. The classical approach consists of two layers with the first layer containing record's headers, the second with their bodies and the client which uses single key to retrieve the single record. In order to provide features mentioned in the previous section, some modifications have to be made. The system overview is shown in the Figure 2.

### A. The Client

The client should query the data store by a graph, instead of a standard key. Moreover it has to be able to receive the result of a query which may consists of many records. Therefore, the following messages are defined:
Messages send by the client:

- record (graph and image) insertion (GI) - a message used to insert a new record containing a graph and an image into the database,
- query (SQ) - a query after which all result records are sent by the database in a one message,
- distributed query (DQ) -a query after which result records are sent gradually with one message per one record, allowing e.g. to show progressively results for a user,
- get record (GR) - a message used to retrieve the record using its key.

Messages received by the client:

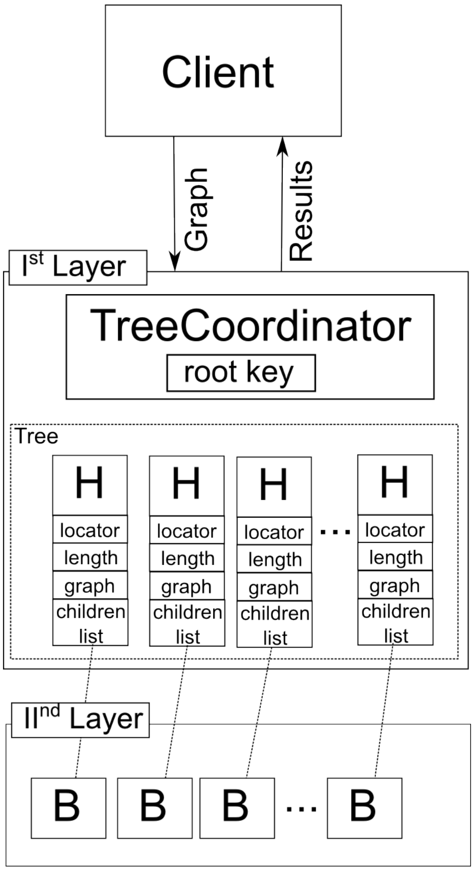

Fig. 2. The proposed system overview.

- result of the insertion (RI) - sent by the database as a response to GI message, returning the failure code or new node's record key,
- not found (NF) - sent by the data store when there are no similar graphs/images in the data store, returned for both SQ and DQ messages,
- results (RR) - contains list of similar records, returned only as a response to SQ message,
- single result (SR) - contains only one similar record, returned only as a response to DQ or GR messages.

All sent messages contain the query graph and the minimal similarity which is used during comparisons. Moreover the messages may define if as a result full record or only a header should be returned.

### B. The First Layer

The first layer of the data store was redesigned into two sub-layers: the Tree Coordinator and the Tree. The Tree sublayer consists of the standard SD2DS record headers. Each record header is treated as a one tree node, containing as a metadata a graph and a list of children nodes (a list of records keys). The Tree Coordinator is responsible for communicating with the clients and the logic of the tree: storing the tree root record key, adding new nodes, traversing tree and making queries. Moreover it is able to execute queries in two ways, analogously to the SQ and DQ messages. In order to improve the performance, some of the Tree Coordinator features, like comparing graphs and tree traversing may be implemented as a part of buckets. Also the $DQ$ message could be directly sent by the bucket.

*1) The tree structure:* The tree nodes used in the database are stored in the first layer using standard SD2DS headers records. The graphs are inserted into the tree hierarchically, storing its common parts in parent nodes. Because of that, the root node may contain a graph with only one shape or an empty graph. The example tree structure with scooter, bicycle and car objects is shown in the Fig. 3. Moreover, because there are indirect nodes which stores only graphs without connection to any images, the SD2DS modification allows records headers in the first layer with empty bodies.

*2) Record Insertion:* after receiving the GI message the Tree Coordinator compares the graph with graphs stored in the tree, starting from the root node using the Query by Shape comparison algorithm (QS) [1] and the minimal similarity parameter extracted from the GI message. The algorithm is presented in the Alg. 1. The Tree Coordinator retrieves the record using similar procedures as the client in the standard SD2DS. Then children nodes are extracted from the record and used for the next records retrieval.

*3) Querying:* The querying algorithm is very similar to the insertion of a node. The algorithm is shown in the Alg. 2. During the query, the results could be sent immediately to the client or stored in the Tree Coordinator temporary buffer before completion and then sent.

### *C. The Second Layer*

The second layer has not been modified. Because of the tree structure, there may be less bodies than records in the first layer. The images are retrieved during querying, but the client in the $SQ$ or $DQ$ could force the database to only send headers from the first layer or even only the keys.

## VII. Experimental results

The presented tree-based structure has been evaluated using experimental implementation written in C++. The results were compared with the linear SD2DS QS system and are shown in the Tables I and II. The linear SD2DS QS system uses also first SD2DS layer to store graphs, but without tree structure. During the query, all elements has to be compared with the query graph. In order to evaluate algorithms performance, the precision and recall coefficients were used [1]:

$$precision = \frac{number\ of\ relevant\ results\ images}{total\ number\ of\ results\ images} \tag{1}$$

$$recall = \frac{number\ of\ relevant\ results\ images}{total\ number\ of\ relevant\ images\ in\ the\ database} \tag{2}$$

As a number of relevant results images we assume the number of images which are from the same class as the query image. For the tests, about 117 real life images of different objects classes were used.

**Algorithm 1** Inserting new node to the tree

```
Require: $graph$ and $image$ extracted from the $GI$ message
  if tree is empty then
      add record as a root node, store its key as a Root Key;
      send $RI$ message with the key to the client;
  else
      add Root Key to the FIFO queue;
      while FIFO queue is not empty do
          $key \leftarrow$ pop first element from FIFO;
          $treeNode \leftarrow$ get record with key == $key$;
          compare $graph$ with $treeNode$ using QS;
          if $treeNode$ is not a root node then
              if graphs similarity $\leq$ similarity of $graph$ and $treeNode$'s parent then
                  add $graph$ as a child of $treeNode$'s parent;
                  send $RI$ message with the $graphs$'s key to the client;
              end if
          else
              add $graph$ as a new root node;
              add $treeNode$ to the $graph$'s children list

          end if
          if graphs similarity $\geq$ highSimilarity then
              add record as a child to $treeNode$;
              send $RI$ message with the record's key to the client;
          else
              if $treeNode$ does not have any children then
                  add $graph$ to the tree;
                  add the common part of $graph$ and $treeNode$ as their parents;
                  if $treeNode$ is a root node then
                      the Root Key $\leftarrow$ common part's key
                  end if
                  send $RI$ message with the $graph$'s key to the client;
              else
                  add each $treeNode$ children to the FIFO queue;
              end if
          end if
      end while
  end if
```

The test results shows that for most queries the tree structure increased the precision comparing to the previous, linear structure. This is due to the additional steps during the query algorithm (Alg. 2) which omits the whole sub-tree with too low precision and check if the precision is increasing in children nodes. Moreover, the lower precision in the automated queries was caused by some failures of shape detection algorithms.

The recall measurements shows that for the manual queries more relevant results were returned by the tree algorithm version. The automatic query was problematic for same cases for tree version because of occurrence of many unconnected

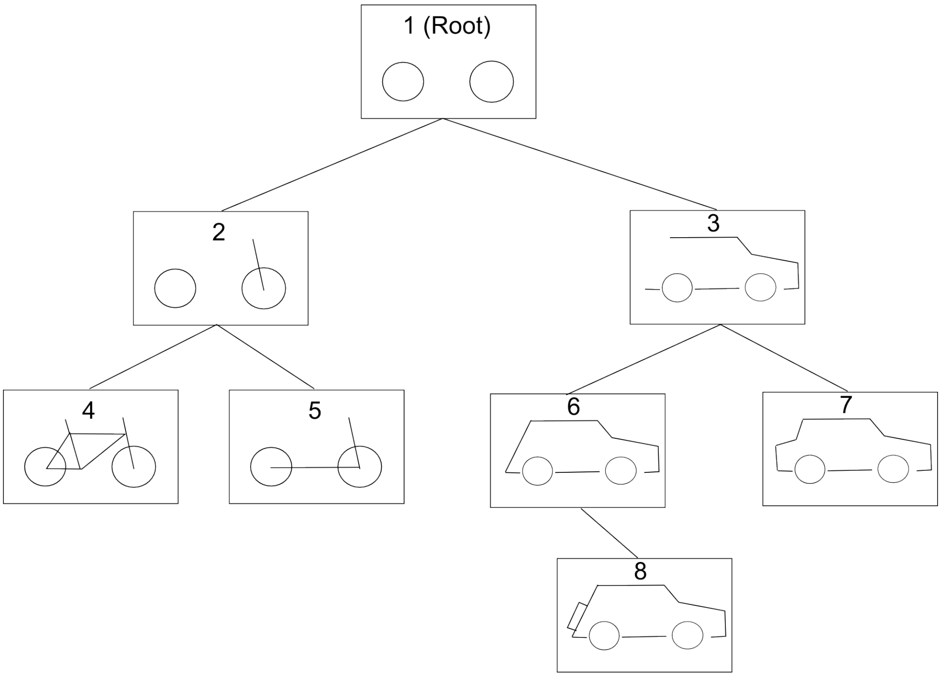

Fig. 3. The example of the tree with bicycle (node 4), scooter (node 5) and 3 cars graphs (nodes 6-8). The shape sizes were omitted during tree construction in order to show the main idea and simplify the structure.

TABLE I
THE PRECISION RESULTS FOR THE EXAMPLE BICYCLE AND CAR QUERIES

| | **Manual queries** | | **Automated queries** | |
|---|---|---|---|---|
| | **Tree-based** | **Linear** | **Tree-based** | **Linear** |
| bicycle no. 1 | 0.7708 | 0.6065 | 1 | 0.9 |
| bicycle no. 2 | 0.8529 | 0.5714 | 1 | 0.8 |
| car no. 1 | 1 | 0.7059 | 0.4182 | 0.5658 |
| car no. 2 | 1 | 0.8 | 0.5902 | 0.5428 |

TABLE II
THE RECALL RESULTS FOR THE EXAMPLE BICYCLE AND CAR QUERIES

| | **Manual queries** | | **Automated queries** | |
|---|---|---|---|---|
| | **Tree-based** | **Linear** | **Tree-based** | **Linear** |
| bicycle no. 1 | 0.9737 | 0.9737 | 0.3023 | 0.2093 |
| bicycle no. 2 | 0.7636 | 0.8421 | 0.2558 | 0.0930 |
| car no. 1 | 0.5814 | 0.5581 | 0.5 | 0.86 |
| car no. 2 | 0.7209 | 0.4651 | 0.72 | 0.76 |

nodes in skeletons. This caused problems with inserting them in the proper sub-tree.

The performance of the structure is dependent on the number of elements. During our experiments using SD2DS, to up to 1000 elements there were very small difference between tree and linear version. For higher number of elements, the tree structure was becoming more and more faster. We also implemented version which uses as a storage vector array. During experiments the tree version occurred to be up to 2x faster than linear version.

## VIII. CONCLUSION

In this paper a new Content Based Image Retrieval database structure was presented. The main idea of our research is to apply our previous research results, Query by Shape method [1], into Scalable Distributed Two-layer Data Structure. The modification of data store included redesigning it to store records in a tree. Also a Tree Coordinator was added to the first layer in order to communicate with the client and perform tree queries.

The future research includes implementing the version of the algorithm with comparison algorithm moved to buckets. We expect that it should improve the querying time as well as allows to use buckets and nodes more efficiently. Moreover the throughput adjustment may be added in order to improve the image data access time.

Another direction of research will concern the Query by Shape method in order to improve the results precision. This may include e.g. adding other primitive types and color features. Moreover more advanced graph matching algorithms should be applied, as well as some optimization methods should be evaluated, e.g. [23].

***Abstract*—New e-book readers and multifunctional mobile tablet devices are currently emerging, so bringing about a transition from printed to the electronic books. It is important to learn how usable these mobile devices are, by testing them on real users from various backgrounds. The paper presents a study which explores the perceived usability of two electronic reading devices, one dedicated reader and one multifunctional device. More specifically, the study employs eight tasks which users were required to complete within a specific time with two devices. Our results show that users functioned better on the multifunctional device in terms of performance measures, such as navigation, task difficulty and satisfaction.**

## I. Introduction

Electronic reading devices, including e-readers and tablet computers, are becoming popular so rapidly today, that it is vital to understand how the users themselves perceive the usability of such devices. An e-reader is designed for displaying electronic books, magazines, and periodicals. Various e-readers use various formats. For example, ibooks are produced for the iPad, whilst AZW, TXT and KF8 formats are mostly used by the Kindle. E-books are frequently available in PDF format, which is common for popular computer operating systems.

New opportunities for e-reading appeared, when lighter devices with better screens, such as the Amazon Kindle, appeared in late 2000 and the content available to devices increased at the same time. A vital question is why one should use an electronic reader, when one can use a net-book, tablet or a smart phone. The fundamental advantage of the electronic reader lies in its display. Thanks to the materials from which the display is manufactured, its appearance resembles that of paper, which means that the user does not have to strain his or her eyes when reading. Making objects more usable and accessible is part of the larger discipline of User-Centered Design, which employs various methods and techniques [1]. Usability testing is a method employed to evaluate a product by testing it on representative users. Greenberg and Buxton point out that “Usability evaluation is valuable for many situations, as it often helps validate both research ideas and products at varying stages in its lifecycle” [2]. The purpose of our study was to explore user experience with two e-reading devices. One was dedicated e-reader device, the Cybook Odyssey and the other was a multifunctional device, the Apple iPad. The main criterion for selecting these mobile devices was their availability on the Greek market at the time, November 2013. Despite the best efforts of designers, new technologies often fail to meet basic human needs and desires [3].

We start our paper with a review of the literature, which establishes the theoretical background to our study. We then describe the research methodology employed, discuss the results and offer some conclusions.

## II. Background

### A. E-readers

An e-reader, also called an e-book reader or e-book device, is a mobile electronic device designed primarily for the purpose of reading digital e-books. New opportunities for e-reading emerged when new lighter devices, such as the Amazon Kindle, that had better screens, appeared at the end of 2000 and the available content for devices increased at the same time. E-readers reproduces the appearance of a printed book.

Thus an e-reader should ideally offer readability, be able to host extensive texts, be portable, allow one to read anywhere and possess a long-lasting battery. It should also offer the ability to create bookmarks, to add notes on the book and to highlight passages as desired. The most important part of an e - reader is the screen. Unlike the majority of displays with which we interact on daily basis, paper is a reflective medium. As Zehner notes, a reflective display has an inherent advantage in terms of readability, because the brightness of the display naturally adapts to the ambient lighting conditions [4]. E-paper displays are expected to provide the user with a more paper-like reading experience that does not cause eye strain and that possess the contrast and reflection of real paper [5].

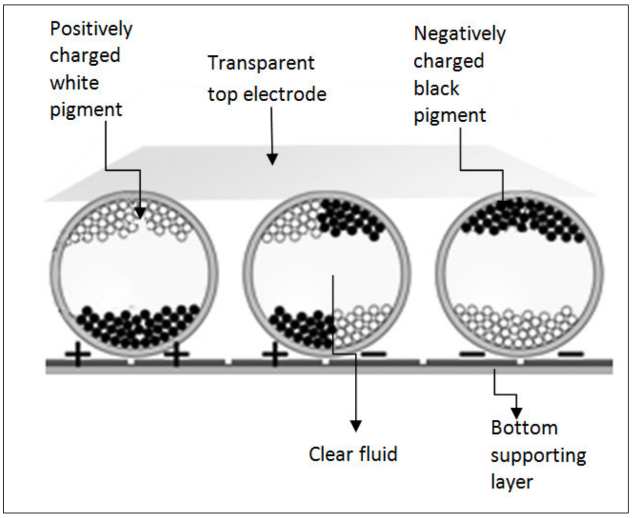
### *B. E-Ink technology*

E-Ink is a bistable display technology that creates a near-paper-like reading experience and requires minimal battery power [6]. Electronic ink is made up of millions of tiny microcapsules only 100 microns in width. Every microcapsule contains positively-charged white particles and negatively-charged black particles suspended in a clear fluid. When a positive or negative electric field is applied, the chips will either rise to the top or be pulled to the bottom, where they become visible to the viewer [7]. This makes the surface appear either white or black at the spot in question. Patterns of white and dark can then be created to form words and sentences (Fig.1). E-Ink displays do not need any background lighting and are easy to read, even in direct sunlight. Although E Ink technology devices require energy for turning pages, they do not consume much battery power. This means that a device, when fully charged, can be used for several thousand pages or several weeks.



Positively charged white pigment
Transparent top electrode
Negatively charged black pigment
Clear fluid
Bottom supporting layer

Fig. 1 Scheme of electronic ink technology.

### *C. iPad*

The iPad is a tablet computer. Its basic technology differs from that of dedicated e-readers, in that it has a colour screen which does not employ the eye-friendly E-Ink technology and it is multi-functional. The iPad has been found to compete well with dedicated e-readers. Probably the most comprehensive iPad usability studies are those carried out by by Nielsen and Budiu in 2010 and 2011 [8,9]. Their findings are summarized below:

*Read-tap asymmetry*
Content was large enough to read, but too small to tap.
*Accidental activation*
This was a particular problem in apps lacking a back button.
*Too small touchable areas too close together*
This lead to accidental activation.
*Users disliked typing*
They thus avoided the registration process
*Splash screens*
A compulsory introduction screen bothers users.
*Information squeezed into too small areas*
This made the content harder to perceive and manipulate.
*Too much navigation*
The large number of navigation options gives one less space.

### *D. E-readers and Usability*

Nielsen did a within-subjects study employing 32 competent adult readers. The text was a Hemingway short story in several formats, namely printed book, personal computer, iPad and Kindle. The iPad gave a 6.2% lower reading speed than the printed book, whereas the Kindle gave a speed 10.7% slower than print [10]. However, the difference between the two devices was not statistically significant, because of the fairly high variability of the data.

Clark et al., reported that 36 Kindle users at the University of Texas thought that the limited content availability, the inconsistent pricing of titles, poor graphics resolution and other functions were barriers to the wider acceptance and use of the device [11].

### *B. Usability testing*

The term *"usability"* is frequently employed in the field of human-computer interaction (HCI). Nielsen describes usability as an issue related to the broader issue of acceptability [12]. In his view, *"Usability is a quality attribute that assesses how easy user interfaces are to use"*. Usability is a significant part of the user experience and therefore of user satisfaction. A formal definition of usability is given in the ISO standard 9241–11 : *"...the extent to which a product can be used by specified users to achieve specified goals with effectiveness, efficiency and satisfaction, in a specified context of use"*. Effectiveness is defined as the accuracy and completeness with which users achieve specified goals and efficiency as the resources expended in relation to the accuracy and completeness with which users achieve goals. Satisfaction is defined as the freedom from discomfort, and positive attitude to the use of the product, whilst the context of use is defined as users, tasks, equipment and the physical and social environments in which a product is used [13].

Usability testing is a method employed in user-centered design to evaluate product design by testing it on representative users. Such users thus yield quantitative and qualitative data in that they are real users performing real tasks [14].

Dumas & Redish argue that usability testing is a *"a systematic way of observing actual users trying out a product and collecting information about the specific ways in which the product is easy or difficult for them"* [15].

## III. RESEARCH METHODOLOGY

To examine how users conceptualize interaction with e-readers, we created a user test involving two e-reading devices. We compare one dedicated e-reader with one multifunctional device (Fig.2).

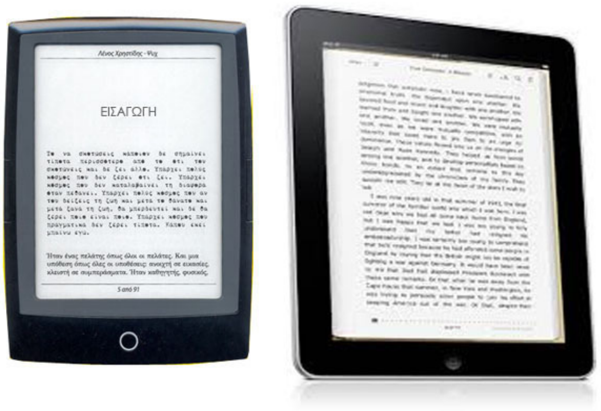


Fig. 2 The two mobile devices compared in the study: The Cybook Odyssey and the Apple iPad.

Nielsen [16] argues that five participants will discover 80% of the problems in a system. In any case, a small quantity of users, that is, generally fewer than 10 subjects, is sufficient, for any formative evaluation of usability [17]. On the other hand, Spool and Schroeder [18] state that five users identified only about 35% of the problems in a website. The research by Turner et al. implies that a group size of seven may be optimal, even when the study is fairly complex [19].

According to Sauro and Lewis “the most important thing in user research, whether the data are qualitative or quantitative, is that the sample of users you measure represents the population about which you intend to make statements” [20].

### A. Participants

Our session was designed specifically to include a representative pool of the potential users of e-readers. Twelve participants (N=12) aged between 18 - 65 (mean age = 36.08, SD = 14.47, years), seven of whom were males and five females, participated in the session. Using either a skilled participant or an under-qualified one will bias the outcomes of usability testing. All participants were novices as regards e-reading devices, but were fond of reading. On the other hand, all of them had used a digital device (e.g. PC or mobile phone) prior to this study, to read news, information or academic content online. The participants received short instructions on how to turn their device on and off, but were not instructed in how to operate it. This was designed to test the usability of the devices and to examine how intuitive the interface was for the participants. Participants did not suffer from any visual or cognitive impairment and were educated to at least high school level. Participants gave written informed consent prior to participation.

### B. Material

Two mobile devices, the Apple iPad, a multifunctional e-reader and the Cybook Odyssey, a dedicated e-reader, were compared in the study. Devices were chosen on grounds of anticipated availability on the Greek market. A Panasonic HDC-SD40 digital camera was used to create a complete record of all user interactions with the e-readers. Technical specifications for the mobile devices are provided in Table I.

TABLE I.
TECHNICAL SPECIFICATIONS OF THE TWO COMPARED DEVICES.

| **Thechnical Specifications** | **Cybook Odyssey** | **Apple iPad (3rd generation)** |
|---|---|---|
| Intro year | 2013 | 2012 |
| Display size | 6" | 9.7″ |
| Display type | I-ink HD | LCD screen |
| Rresolution | 758x1024 | 2048 x 1536 |
| Weight | 180 g | 652 g |
| Touch screen | Multi touch | Multi touch |
| Memory | 2GB iNAND+ MicroSDHC up to 32GB | 16GB |
| Content ebook formats | EPUB, PDF, Adobe DRM, HTML, TXT, FB2 | Ibooks, ePub, PDF |
| Content picture formats | JPEG, PNG, GIF, BMP, ICO, TIF, PSD | JPEG, GIF, TIF, PSD |
| Battery life | Up two weeeks | Up to 10 hours |

### C. User Tasks

For the usability test, the participants were required to read a segment of the text from an e-book on Greek mythology on the two e- reading devices and to complete eight tasks given in Table II. The tasks were chosen as being representative and as covering as many as possible of the features of the e-reading devices. Task success (whether or not a participant successfully completed a task) was recorded. Participants were allowed up to two minutes to complete each task.

TABLE II
PARTICIPANTS TASKS

| **Tasks** | **Task Description** |
|---|---|
| **Task 1** | **Open the book** “Mythology” |
| **Task 2** | **Go to page** 26 |
| **Task 3** | **Change the page** to landscape format |
| **Task 4** | **Highlight** the first two sentences of the page |
| **Task 5** | **Delete the highlighted** sentences |
| **Task 6** | **Make a note** of the first paragraph of the page |
| **Task 7** | **Increase the font size** |
| **Task 8** | **Add bookmark** |

### D. User Performance

User performance was recorded in terms of the effectiveness, efficiency and ease of use of e-reading devices. In order to evaluate task effectiveness, we measured the percentage of tasks successfully completed within the time limit. Task completion time refers to the time needed to accomplish the task. To evaluate efficiency, we recorded the time needed to process a task. To measure user satisfaction, we asked users to complete a post-test questionnaire SUS (system usability scale). A SUS questionnaire gives ten statements regarding different aspects of usability. Users mark their agreement with the statements on a five-point Likert scale.

### *E. Post -test Questionnaire*

The aim in administering a written questionnaire after the test (post-test questionnaire) is to record participants' preference, in order to identify any potential problems with the product. Information collected usually includes opinions and feelings regarding any difficulties encountered in using the product. Our questionnaire was based on the System Usability Scale (SUS) developed by Brooke [21], since this is the most precise type of questionnaire for a small number of participants, as is shown by Tullis and Stetson's study [22]. SUS employs a "quick and dirty" approach in evaluating the overall subjective usability of a system (Appendix A). While the SUS was originally intended to be used for measuring perceived usability, i.e. measuring a single dimension, recent research shows that it provides an overall measure of satisfaction of the system [22],[23],[24]. In addition to these advantages over other systems, the SUS is a powerful and multifunctional instrument [25].

### *F. Test protocol*

Participation in the study lasted approximately 40 minutes for each participant and was conducted in an isolated room in our Faculty. Participation consisted of the series of tasks mentioned above. Participants were informed for the process of the test and all participants were tested individually.

After being welcomed by the experimenter, participants were told that they were to take part in a usability test and were to interact with two e-reading devices. Participants were reminded to note the instruction for gestures on the desk on their left. In addition participants gave their permission to be recorded on video. Subsequently participants completed our eight tasks. Finally there was a question about what readers considered the most important features in eReaders

## IV. Results And Discussion

The main factors to be examined when testing usability are effectiveness, efficiency and user satisfaction. Effectiveness refers to how "well" a system does what it supposed to do. In order to evaluate task effectiveness, we measured the percentage of steps successfully negotiated within the time limit (2min). Efficiency refers to how quickly a system supports the user in what he wants to do. To evaluate efficiency, we recorded the time needed to process the task. Satisfaction refers to the subjective view of the system on the part of the user [1]. Qualitative and quantitative data were collected from each participant. Qualitative data included the participants' verbal protocol as recorded in video recording.

Problems of usability were identified and categorized. We also collected comments on e-reading devices and preference data and evaluations in the form of the SUS data questionnaire completed by the users after the test. Any user action that did not lead to the successful completion of a task we defined as error.

Table III
Tasks completion rates

| | Cybook | iPad |
|---|---|---|
| **Task1** | 11/12 | 12/12 |
| | **91%** | **100%** |
| **Task2** | 9/12 | 11/12 |
| | **75%** | **91%** |
| **Task3** | 8/12 | 9/12 |
| | **66%** | **75%** |
| **Task4** | 7/12 | 8/12 |
| | **58%** | **66%** |
| **Task5** | 7/12 | 11/12 |
| | **58%** | **91%** |
| **Task6** | 2/12 | 7/12 |
| | **16.7%** | **58%** |
| **Task7** | 9/12 | 10/12 |
| | **75%** | **83.3%** |
| **Task8** | 10/12 | 11/12 |
| | **83.3%** | **91%** |

### *A. Effectiveness.*

The percentage of users that manage to complete a task successfully thus becomes a measure of the effectiveness of the design. The number of errors made on the way to completing a task is an example of a performance measure [1],[12].

Errors were classified into two main categories, navigation errors and comprehension errors. Navigation errors occurred when partcipants did not move as expected. Comprehension errors occured when participants did not understand the design of the interface. (Table IV).

Table IV
Types of errors by e-reader device

| **Type of error** | **Cybook** | **iPad** |
|---|---|---|
| **Navigation** | 3 | 4 |
| **Comprehension** | 5 | 3 |
| **Total** | 8 | 7 |

### *B. .Efficiency - Task Completion Time*

Efficiency is a measure that is highly dependent on the time spent on completing the task. We recorded the total amount of time required to complete each task on mobile devices. Table V shows information on the mean time spent by the participants. The results thus indicate that participants spent more time on task completion when using the Cybook.

TABLE V
AVERAGE TIME IN SECONDS FOR COMPLETING ALL GIVEN TASKS

| Tasks | Task Description | Cybook | iPad |
|---|---|---|---|
| **Task 1** | **Open the book** "Mythology" | 29,7 | 24,2 |
| **Task 2** | **Go to page** 26 | 63,7 | 48,3 |
| **Task 3** | **Make a note** of the first paragraph of the page | 78,2 | 65,1 |
| **Task 4** | **Highlight** the first two sentences of the page | 67,3 | 52,6 |
| **Task 5** | **Delete the highlighted** sentences | 42,3 | 38,2 |
| **Task 6** | **Change the page** to landscape format | 27,2 | 14,1 |
| **Task 7** | **Increase the font size** | 35,6 | 17,2 |
| **Task 8** | **Add bookmark** | 48,7 | 29,7 |
| | **Average Time** | **49,1** | **36,2** |
| | **Standard Deviation** | **18,8** | **18,1** |

However with the respect of the amount of time that participants spend on Cybook was higher than iPad. The expectation was, however, that participants would interact more efficiently with a dedicated e-reader than with a multi-functional device when reading a book (Fig.3).

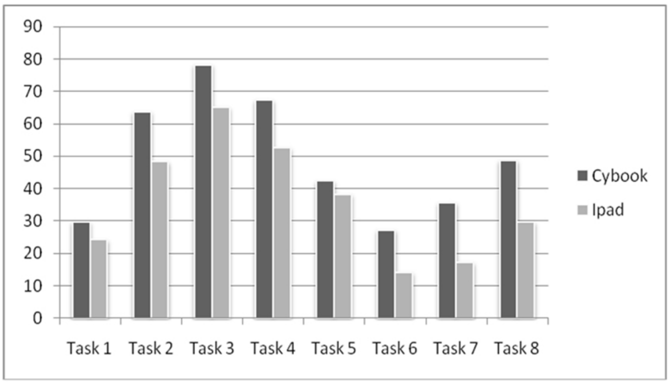

**Fig.3** Task completion time per e-reader device.

### *C. User satisfaction*

We. are aware that time-on-task measures can be useful for collecting data on the efficiency of a system. On the other hand, such data does not give any information on overall satisfaction on the part of the user. User satisfaction may be an important factor in motivating people to use a product and may affect user performance. Thus, as a final point, we decided participants should complete the System Usability Scale (SUS) questionnaire which has ten item attitude Likert-scale which measures the view of subjective assessments of usability and explore users' experiences with the two mobile devices. A crucial feature of the SUS lies in the fact that asks the user to evaluate the system as a whole, rather than specific aspects.

All 10 questionnaire statements having been processed, the overall SUS score for each prototype is that given in Table VI. To calculate the SUS score, first we summed the score contributions of items 1, 3, 5, 7 and 9 (Appendix A). The score contribution of these items are their scale position minus one. We then summed the score contributions of the other items: five minus their scale position. Finally, we multiplied the sum of the scores by 2.5, to obtain the overall score with a range between 0 to 100.

The study results showed the overall level of satisfaction. Sauro reports that a mean value over 74 is level B, value above 80.3 is level A [25]. An average value of below 51 is level F (fail). The iPad, which was given an average value of 79.3, is to be placed on level B, and Cybook, with an average value of 70.8, level B. It can be remarkable to notice that none of the e-Readers had an extremely high satisfaction score, meaning that users preferences were ambiguous.

TABLE VI
OVERALL SUS SCORE

| Participants | Cybook | iPad |
|---|---|---|
| P1 | 80.0 | 80.0 |
| P2 | 70.0 | 87.5 |
| P3 | 82.5 | 90.0 |
| P4 | 77.5 | 90.0 |
| P5 | 55.0 | 82.5 |
| P6 | 70.0 | 77.5 |
| P7 | 75.0 | 65.0 |
| P8 | 70.0 | 75.0 |
| P9 | 72.5 | 82.5 |
| P10 | 70.0 | 82.5 |
| P11 | 72.5 | 70.0 |
| P12 | 55.0 | 70.0 |
| **Mean** | **70.8** | **79.3** |

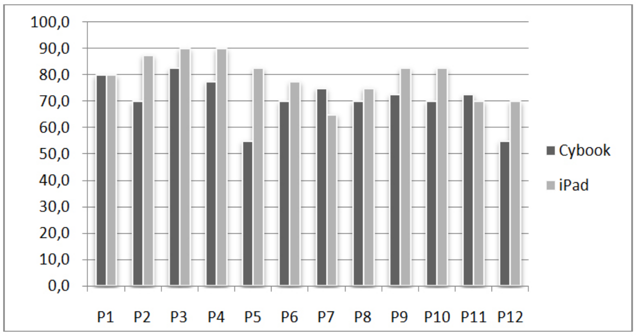

**Fig.4** Overall SUS score.

### *C. Overall user experience*

Overall users liked the process and regarded their interaction with the devices positively. Nevertheless, in some cases, the participants were apprehensive. Uncertain in their selections, they demanded greater confirmation and reassurance about the actions they were to take. In such cases, it is important for the researcher to motivate participants, encouraging them discreetly to investigate alternative directions, while simultaneously recording any mistakes made. Participants reported that the task in which one had to make a note was difficult to perform on the Cybook, as the keypad was complicated in comparison to that of the iPad.

Overall, participants had a preference for the iPad when highlighting and making notes. Additionally, the ability to change font size on the Cybook means that the device uses location numbers, rather than page numbers. The following conclusions can be drawn from the results derived from our group of participants, but one should avoid making any generalizations based on them. (Fig.4)

Participants complained of

- Poor page navigation
- Difficulty in turning the page
- Slowness in adapting to non-linear reading and
- The environment

On the other hand, participants reported that :

- In the case of the dedicated device (the Cybook), the menu allowed users to find some functions easily,
- older participants liked the ability to adjust font size,
- the portability and lightness of the devices was appreciated and that,
- when users read a narrative on an e-book sequentially from beginning to end, they found e-ink technology more friendly than the corresponding technology employed on the other device *(iPad)*.

### *D. Limitations*

The results of the study should not be generalized to all e-readers mobile devices. The small sample size (n = 12 ) limited the ability to acquire a more comprehensive view of the effects of various reading formats. Some e-readers are very similar in format to traditional print books. Reading on a very small screen device, however, like reading on a smartphone or online reading in a personal computer, with its links, multiple pages, and sometimes distracting graphics, raises various issues [26].

Another important reason was that participants read a narrative book, rather than a text offering information.

## V. Conclusion

The aim of our study was to explore user experience with two e-reading devices. One was a dedicated e-reader device, the Cybook Odyssey and the other was a multifunctional device, the Apple iPad. We tested our empirical methodology on twelve individuals, all of them novices in terms of e-reader use. The goal of our user study was to gain knowledge on the readability and usability of two different e-readers devices in a specific context. As a consequence of the small sample size (n=12), we evaluated our data on the basis of descriptive statistics. Eight tasks were selected in order to elicit user experience.

The results of the study show that both in terms of usabillity and overall impression, the iPad was the preferred device. This was somewhat surprising, as the lightness, long battery life and portability of the Cybook was greatly liked by the participants in the study. Additionally the testing material was a black and white book on Greek mythology and not a multi color magazine which is better for iPad use.

However, we feel that our paper, which focuses more on the users and their cognitive abilities, offers a new insight into how users perform tasks with e-readers devices and conveys their overall impressions. Long battery life and portability are advantages for any use, but the inability to facilitate easy browsing and navigation make the devices slow to use for any non-linear reading. In addition, from users' comments there emerged additional issues regarding digital rights management (DRM), and storage which should be explored in future studies. We believe that successful e-reading use depends on the integration between reading device, content providers and service platform.

## Appendix

Appendix **A** *System Usability Scale*

| | Strongly agree | | | | Strongly disagree |
|---|---|---|---|---|---|
| 1. I think I would like to use this device frequently | 1 | 2 | 3 | 4 | 5 |
| 2. I found the device unnecessarily complex. | 1 | 2 | 3 | 4 | 5 |
| 3. I thought the device was easy to use. | 1 | 2 | 3 | 4 | 5 |
| 4. I think that I would need the support of a technical person to be able to use this device. | 1 | 2 | 3 | 4 | 5 |
| 5. I found the various functions in this device were well integrated. | 1 | 2 | 3 | 4 | 5 |
| 6. I thought there was too much inconsistency in this device. | 1 | 2 | 3 | 4 | 5 |
| 7. I would imagine that most people would learn to use this device very quickly. | 1 | 2 | 3 | 4 | 5 |
| 8. I found the device very cumbersome to use. | 1 | 2 | 3 | 4 | 5 |
| 9. I felt very confident using the device. | 1 | 2 | 3 | 4 | 5 |
| 10. I need to learn a lot of things before I could get going with this device. | 1 | 2 | 3 | 4 | 5 |

## ACKNOWLEDGMENT

We express our gratitude to the participants, who enthusiastically gave their time to allow us to understand the value of their experiences.

# Augmented Reality Using Optical Flow

Konrad Koniarski
System Research Institute,
Polish Academy of Science,
ul. Newelska 6, 01-447 Warsaw, Poland
Email: konrad.koniarski@gmail.com

***Abstract*—The paper deals with the application of Lucas-Kanade optical flow algorithm to develop an augmented reality (AR) system. Merging of a live view of the physical real world with context-related computer-rendered images to create a mixed image is a challenging problem. A virtual object has to be located in the correct pose and position in real time and perspective. Besides the occlusion problem need to be taken into consideration.**

**In the paper a computer-vision based method for AR systems based on the fiducial marker matching is proposed. For simplicity black square was used as the marker. This method consists of two main steps. The initial step uses Hough's transformation to detect the marker initial position and to select the marker tracked points. In the second step for each image frame these selected points are being tracked using Lucas-Kanade optical flow method. The positions of the selected points are used for calculating the pose and position of a virtual object. Unlike existing method proposed system using optical flow to increase speed performance. The examples of AR applications using the proposed algorithm are provided and discussed.**

## I. Introduction

THE Augmented Reality (AR) is a technology supplemented people's perception of real world by using virtual world. It consists in the integration of the computer generated virtual information such as sound, video or graphics with the real-world environment. This technology is characterized by using real-virtual combinations, 3D registration as well as the real-time interaction. AR interfaces superimpose in real-time textural or pictorial virtual information onto real-world scenes registered in 3D and allow users to interact with real and virtual element simultaneously. The technical challenges in AR technology lie in determining in real-time which image elements should be shown, where and how. Since AR proposes that the user has not to be able to distinguish between real and virtual information it requires that the virtual elements show both geometric as well photometric consistency with the real part of the image. Geometric consistency includes correct placement and size of the virtual element as well as the identification of occlusions. Photometric consistency means suitable shadowing, mutual reflections, chromatic adaptation to scene illumination. The solution of these problems even under simplified assumptions is not trivial.

AR technology appeared in the 1990s. It finds a wide variety of applications like education, entertainment, architecture, medical, machinery manufacturing and maintenance, military, regional planning and many other fields. The implementation of AR technology significantly depends on the used devices and/or user interfaces. The main devices for AR are head mounted or handheld displays, wireless wristbands or gloves as input devices, digital cameras or wireless sensors as tracking devices and powerfull CPU with considerable amount of RAM memory to process camera images. The appropiate techniques for intuitive interaction between the user and the virtual content of AR applications are one of the most important aspects of AR. These techniques include tangible, collaborative, hybrid or multimodal AR interfaces.

Correctly positioning of virtual objects relative to the real enironment is called registration. AR image registration uses different computer vision methods consisting usually from two steps: tracking and reconstruction or recognizing. Tracking is based on the detection in the camera images fiducial markers, optical images or other interest points. To interpret camera images tracking can make use of feature or edge detection methods or other image processing methods. Most of the available tracking techniques can be separated into two classes: feature-based and model-based methods [18]. Feature based methods consists in discovering the connection between 2D image features and their 3D world frame coordinates. Model based methods make use of model of the tracked object's features such as CAD models or 2D templates of the items based on distinguishable features. Once a connection is made between 2D image and 3D world frame it is possible to find the camera pose by projecting the 3D coordinates of the feature into the observed 2D image coordinates and by minimizing the distance to their corresponding 2D features. The constraints for camera pose estimation are most often determined using point features. The reconstruction or recognizing stage uses the data obtained from the firts stage to reconstruct a real world coordinate system. There are different tracking technologies available, including among others optical, magnetic, movemnent, ultrasound sensors or thermal imaging. They capture features from the real world and based on this information the AR system determines when, where and how the virual scene should be merged with a real one.

Due to low cost, accuracy as well as robustness requirements optical tracking is mostly used in AR applications. Two types of optical tracking are usually used: marker based and markerless. The first approach makes use of known artificial patterns, called markers, placed along the real environment in order to perform camera pose estimation. Markers are designed to be easy to recognize and the camera matrix can be recovered from the detected marker pose. The position of the virtual object is

978-83-60810-66-8/$25.00©2015, IEEE

computed using a camera matrix and a detected marker pose for correct virtual object projection. Marker based tracking is a more established approach for registration [15]. Marker based AR consists in the identification of their location with respect to camera as well as in the calculation of the projection and transformation matrices used to correct positioning and integrating of the virtual object with the real environmemt. The position of the virtual object is calculated based on the marker information. On the other hand markerless tracking differs from the former one by the method to place virtual objects in the real scene. In markerless AR natural objects in the real scene are used as markers. This approach exploits natural features of the real environment to perform tracking. Since markerless AR is based on natural features rather than on fiducial markers there are no ambient intrusive markers that are not really part of the world. Moreover markerless AR counts on specialized and robust trackers as well as provides possibility of extracting from the surroundings characteristic information that may be later used by the AR system for other purposes. Markerless AR is subject of intensive research in the last years and still presents important challenges to be overcome [18].

## II. Related Work

In this paper marker based AR is adopted to estimate the pose and position of the virtual object. Marker based AR has been investigated by many authors [3], [4], [17], [18], [19], [20], [21], [22], [23], [24]. The most frequently used method has been proposed by Kato in [3] where the matching technique for detection and tracking the square marker is developed. Kato's method has been implemented in the form of computational library ARToolKit. In ARToolKit marker position is computed for every frame of video sequence and that lower real time performance of Kato's method. Since Kato's method appeared sensitive to perturbations it has been improved in [4] where vision-based corner tracker has been used. Paper [23] presents many different types of fiducial markers in AR applications designed for having many image features that are easy to track by optical flow alghoritms [4]. Eleven criterias for robustness and usefulness of marker are indicated where the most important are: false positive recognition, intermarker confusion, immunity to lighting connditions, immunity to occlusion and speed performance. New types of markers used for AR are proposed in [24]. For details concerning the construction and the application of markerless methods see [18]. Different aspects of using AR are indicated in [19], [20], [21], [22]. Paper [14] is concerned with the developement of AR environment without specialized hardware or pre-calibration. AR environment is built using SURF method combined with bi-directional optical flow alghoritm. In [14] Herakleous estemate SURF method as not sufficent for real time performance giving only 10 frames per second. Applying bi directional optical flow Herakleouts improve performance of SURF for 50 percent. Paper [14] is not dealing with immunity of linght conditions and immunity of occlusion.

This paper deals with the development of a marker based approach to AR. A new hybrid algorithm combining camera calibration, the selection of characteristic points on the marker surface as well as tracking the movement of these points using the optical flow technique and the estimation of the position pose of the virtual object is proposed and tested. As a initial step the camera calibration process is performed using moving plane techniques [8]. That step is done only once. Next step is to find marker position. Hough transformation [16] is used for the detection of the marker pattern features. For simplicity marker containt only one black square, but any recognizable pattern could be applied. Next block of presented method is tracking loop. A key elememt of the algorithm is the application of Lucas Kanade optical flow method [2] to track the movement of the selected marker points. Finally the pose of the virtual object is estimated using the updated camera projection matrix. The proposed algorithm has been programmed in C++ enviroment and tested. The obtained results are provided and discussed. They indicate that the proposed algorithm is robust and efiicient tool in realizing AR applications.

## III. Proposed Algorithm

The proposed approach consists from two steps. At initial step camera is calibrated and marker is detected. In main part selected marker points are tracked using Optical Flow method and virtual object pose and position are calculated. Furthermore virtual object is rendered in front of image from camera. System overview diagram is presented on Fig. 1.

### A. Camera calibration

The aim of camera calibration is to determine the extrinsic and intrinsic parameters of the transformation between an object in real 3D space and the 2D image observed by the camera based on visual data acquired from the images. The extrinsic transformation parameters includes the rotation and the translation matrices of the camera. The coordinates of the principal point, the scale factors along the axes and the skew of the two image axses are called intrinsic camera parameters. These parameters, i.e., six extrinsic and 5 intrinsic are assembled in the form of the $3 \times 4$ camera projection matrix.

In this paper Zhang method based on moving planes technique is used [8] to calibrate and rectify the camera. This algorithm consist of the following key steps:

1) The printed pattern is attached to a planar surface.
2) A few images is of the model plane is taken under different orientations due to the movement either the camera or the plane.
3) The feature points in the images are detected.
4) Estimate all the parameters using the homography between the model plane and its image.
5) Estimate the coefficients of the radial distortion by solving the linear least-square problem.

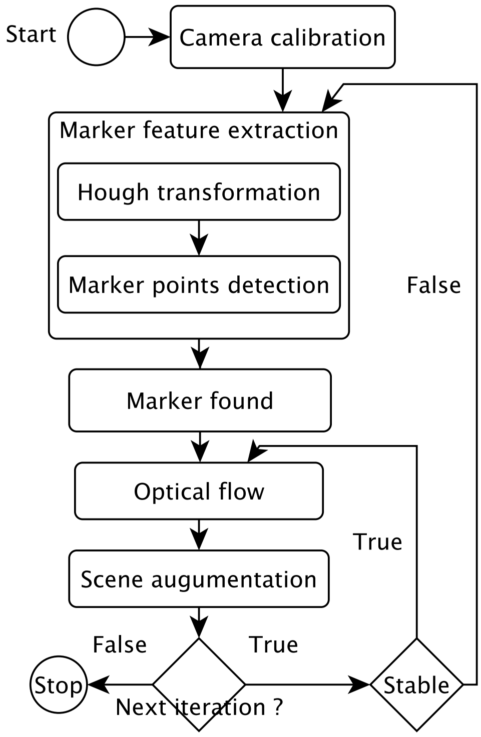

Fig. 1: System overview diagram.

6) Refine all parameters including the lens distortion parameters by minimizing the distances between the image points and their predicted positions.

Remark the pattern could be anything as long as we know the metric on the plane. If pixels are square the minimum number of orientations is two but for better quality it should reach 4 or 5 different orientations. Either camera or the planar pattern can be moved. There is no need to know the motion but a pure translation should be excluded.

Figure 2 presents detection of marker pattern while Figure 4 shows rectified image.

### B. Tracking points selection

Since we confine to the fiducial marker based AR let us choose a pattern of a marker. In literature [3], [17] there exists many examples of marker selection.A marker that is simpe black square was chosen. The black square corners are perfect candidates for tracking points. For that alghoritm any recognizable marker pattern can be used, but that required different method of selecting tracking point then applied Hough trasformation. For details see Fig. 5. In second step of our algorithm our aim is to select the characteristic points of the fiducial marker allowing to determining its initial position and tracking it in the optical flow step.

First having acquired marker image we determined its edges using method of [10]. Next Hough method [16] is used to detect square edges characterizing the marker. Hough transform is recognized as a powerful tool to extract parametrized curves. The idea behind the method is simple: parametric shapes in an image are detected by looking for accumulation points in the parameter space. If a particular shape is present in the image then the mapping of all of its points into parameter space must cluster around the parameter values which correspond to that shape. Usually this method consists from the following phases: voting, peaks localization, determining the actual parameters and verification. In our case black square generate 4 lines.I assume that in the initial position of the marker these lines are perpendicular. For our marker these set of lines is displayed in Fig. 5. Having known the parameters of each line I solve the system of linear equations to find their intersection points. Among these intersection points I choose square corners. These points are stable for Lucas-Kanade alghoritm [2], i.e., such points where the image function takes minimum and maximum values with respect to black and white colours, respectively. The selected points are feature points, deployed

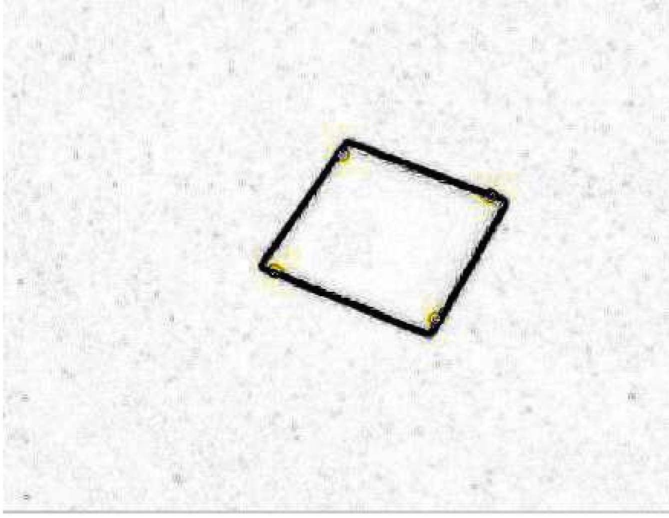

Fig. 5: Marker detection. Black lines are detected by Hough line detector.

at squares corners, which improve tracking stability during the next optical flow step.

### C. Lucas-Kanade Optical Flow

The core area of computer vision is the analysis of the sequence of images to approximate motion of 3D objects. Optical flow field is a convenient and useful image motion representation. It is used to approximate the movement of 3D objects based on a sequence of 2D images [12]. I expect that optical flow is not too different from the motion field. The optical flow calculations are based on two main assumptions: the image brightness constancy and the small motion. The first assumption means that while the object may change the position in short time interval the reflectivity and illumination will remain constant. The second assumption means that the movements less than one pixel are considered. There are numerous methods to calculate optical flow. These methods include differential-based methods, frequency-based methods, correlation techniques, multiple motion methods, feature based method, as well as hierarchical approaches [12]. Optical flow approach is widely used for object tracking, camera stabilization, image mosaics, 3D shape reconstruction or obtaining a structure form motion. Since tracked features points can move in any direction or be obscured by other scene objects, tracking is a chalenging investigation problem.

The optical flow methods are very often used in Augmented Reality applications to track the movement of the extracted features points [2], [14], [15]. Lucas and Kanade's local differential algorithm is one of the most popular method for optical flow computations [13]. This method is based on the assumption that in a given pixel the flow vector will be similar to a small neigbourhood surrounding this pixel. A weighted least square method is used to approximate the optical flow at a given pixel. For each pixel an optical flow vector consistent with the neighbouring spatial and temporal gradients is found. This method is very popular these days, but it still has some drawback. The first disadvantage of this method is challenging computational problem and result image is not dense. Only selected points can be computed for the real time applications. The selected points for tracking can't be placed on edges or low textured regions where this method doesn't give stable results. The best candidates for tracking are points in high textured regions. Lucas-Kanada's optical flow method use correlation window for tracking near pixel movement. For point movement tracking Gaussian pyramid with different scales of images is used [9].

The Lucas-Kanade's Optical Flow algorithm [2] is used for tracking the marker feature points in camera captured images. This method is faster than detection image features analyzing all pixels. Consider small window $\Omega \subset D \subset R^2$ occupied by the pixels $\mathbf{p}$ of an image $D$. The pixel image $p$ is characterized by $p = [x, y]$ where $x, y$ denotes coordinates of a point in $\Omega$.I denote the intensity of the image at position $(x, y)$ and at time $t$ by $I(x, y, t)$ as well as the velocity $v$ of the image pixel $p$ by

$$\dot{p} = v = (v_x, v_y) = (\frac{dx}{dt}, \frac{dy}{dt}) \tag{1}$$

Based on the brightness constancy assumption of the pixel $p$ during the time increament $dt$ I can write

$$I(x + v_x dt, y + v_y dt, t + dt) \approx I(x, y, t) \tag{2}$$

If the brigthness changes smoothly with $x, y, t$ I expand the left-hand side of (2) by a Taylor series and obtain

$$\begin{aligned} I(x + v_x dt, y + v_y dt, t + dt) = I(x, y, t) + \\ \frac{\partial I}{\partial x} v_x dt + \frac{\partial I}{\partial y} v_y dt + \frac{\partial I}{\partial t} dt + O(dt^2), \end{aligned} \tag{3}$$

where $\frac{\partial I}{\partial x}$ denotes the first derivative of the function $I$ with respect to $x$ and $O(dt^2)$ denotes the higher order terms. Due to the small motion assumption I ignore in (3) the higher order terms. Substitutting (3) into (2) I obtain optical flow constraint equation

$$\nabla I \cdot v + I_t = 0 \tag{4}$$

where $\nabla I = (\frac{\partial I}{\partial x}, \frac{\partial I}{\partial y})$ denotes a spatial gradient, $I_t = \frac{\partial I}{\partial t}$ is a temporal gradient and $v = (v_x, v_y)$ denotes the optical flow vector.

Remark, for each pixel, the equation (4) provides only a single constraint for the two components of the optical flow vector $v_x$ and $v_y$. Only the component of the vector in the direction of the spatial gradient is provided. It means that I cannot determine optical flow uniquely only from such optical flow constraint equation.We need some other constraints.

Lucas-Kanade's local differential technique is one of the most popular methods to calculate the optical flow. This method assumes that the flow is essentially constant in a local neighborhood of the pixel under consideration and solves the basic optical flow equation (4) for all the pixels in that neighborhood. Therefore we obtain the system consisting from many equations (4) where the number of unknowns is lower than the number of equations. The least square method is used to find a solution to this system of equations. The optical flow is a field which describes the movement of pixels between two frames, often used for image sequences like movies. It often forms the lowest level for motion analysis and is used as input to higher level systems like segmentation and tracking for interpretation. This system follows the same approach. The optical flow field is determined for each frame of the movie and is used to segment the frame into separate regions. These regions are fed as input to an object tracking system which determines information about the regions in the image and matches them with regions seen in previous frames. This allows us to track various objects through the scene.

Let $\Omega$ denotes a surrounding neighbourhood of a pixel $[x, y]$ under consideration of size $N$ where each neighbour pixel is represented as $p_i$ and $\mathbf{p} = (p_1, ..., p_N)$. Let us define a window function $W(\mathbf{p})$, $\mathbf{p} \in \Omega$. We let the weight of the center bigger than others, i.e., the window function favors the center. Usually $W(\mathbf{p})$ is assumed to be Gaussian window. The size of the window $W$ is $5 \times 5$, i.e., usually $N = 25$ pixels are used. Let us introduce the error function for the optical flow vector $v$ for a pixel $[x, y]$

$$E(v) = \sum_{\mathbf{p}\in\Omega} W^2(\mathbf{p})(\nabla I(\mathbf{p}) \cdot v + I_t(\mathbf{p}))^2 \tag{5}$$

This function simply sums the error of applying the flow vector $v$ to the spatial and temporal gradients of all surrounding neighbours usin the optical flow equation (4). The error is higher if the consider flow vector is not consistent with the spatial and temporal gradients for the surrounding pixels. The weights are used to diminish the importance of distant neighbours. We are looking for $v$ minimizing the error function (5), i.e.,

$$\min_v E(v) = E(v^\star) \tag{6}$$

Differentiating the error function (5) with respect to $v_x$ and $v_y$ we get the following necessary optimality condition to the minimization problem (6)

$$\frac{\partial E}{\partial v_x} = \sum_{\mathbf{p}\in\Omega} W^2(\mathbf{p})(\frac{\partial I}{\partial x}(\mathbf{p})v_x + \frac{\partial I}{\partial y}(\mathbf{p})v_y + \frac{\partial I}{\partial t}(\mathbf{p})\frac{\partial I}{\partial x} = 0 \tag{7}$$

$$\frac{\partial E}{\partial v_y} = \sum_{\mathbf{p}\in\Omega} W^2(\mathbf{p})(\frac{\partial I}{\partial x}(\mathbf{p})v_x + \frac{\partial I}{\partial y}(\mathbf{p})v_y + \frac{\partial I}{\partial t}(\mathbf{p}))\frac{\partial I}{\partial y}(\mathbf{p}) = 0 \tag{8}$$

Let us introduce notation:

$$W = diag(W(p_1), ..., W(p_N))_{N\times N}, \quad v = [v_x, v_y]^T \tag{9}$$

$$A = \begin{bmatrix} \frac{\partial I}{\partial x}(p_1) & \frac{\partial I}{\partial y}(p_1) \\ \vdots & \vdots \\ \frac{\partial I}{\partial x}(p_N) & \frac{\partial I}{\partial y}(p_N) \end{bmatrix}_{N\times 2} \tag{10}$$

$$b = -\begin{bmatrix} \frac{\partial I}{\partial t}(p_1) \\ \vdots \\ \frac{\partial I}{\partial t}(p_N) \end{bmatrix}_{N\times 1} . \tag{11}$$

Using this notatiotion the system (7)-(8) can be written in the matrix form

$$A^T W^2 A v = A^T W^2 b \tag{12}$$

So, assuming the matrix

$$A^T W^2 A = \begin{bmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{bmatrix}_{2\times 2} \tag{13}$$

$$\begin{aligned} a_{11} &= \sum_{\mathbf{p}\in\Omega} W^2(\mathbf{p})(\frac{\partial I}{\partial x}(\mathbf{p}))^2 \\ a_{12} &= \sum_{\mathbf{p}\in\Omega} W^2(\mathbf{p})\frac{\partial I}{\partial x}(\mathbf{p})\frac{\partial I}{\partial y}(\mathbf{p}) \\ a_{21} &= \sum_{\mathbf{p}\in\Omega} W^2(\mathbf{p})\frac{\partial I}{\partial x}(\mathbf{p})\frac{\partial I}{\partial y}(\mathbf{p}) \\ a_{22} &= \sum_{\mathbf{p}\in\Omega} W^2(\mathbf{p})(\frac{\partial I}{\partial y}(\mathbf{p}))^2 \end{aligned}$$

is invertible, the flow $v$ for the image pixel $p$ equals

$$v = (A^T W^2 A)^{-1} A^T W^2 b \tag{14}$$

### D. Pose estimation of the augmented object

In the last step of the proposed method the projection matrix of the augmented object is computed using the approach from section III-A. However here this matrix projects [8] 3D virtual object points positions on the 2D image plane in global coordinates. First based on the intrinsic camera parameters and the homography matrix the estimations of the rotation and translation matrices as well as the projection matrix are calculated. The homography matrix is calculated using

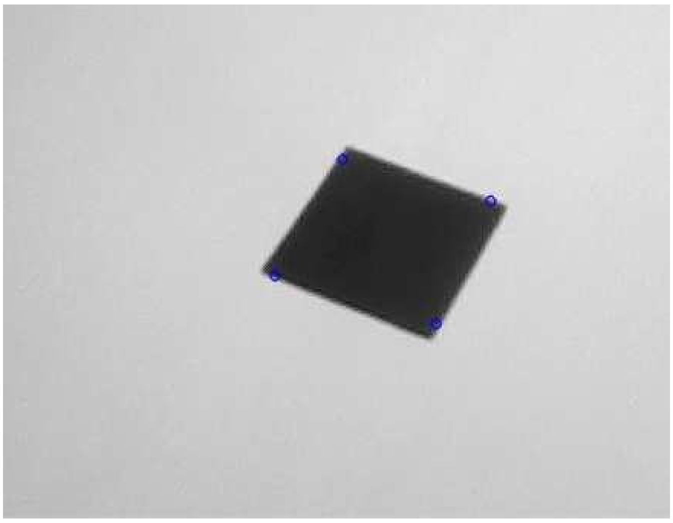

Fig. 6: Blue circles marked tracked marker points.

maximum likelihood criterion and the coordinates of the model and image points. For details see [8]. Next the components of the projection matrix are refined by minimizing the square of the Euclidean norm distance between the positions of the geometric reference points on the marker and the positions of the tracked marker points.

## IV. Results

The algorithm has been implemented in C/C++ and MinGW environments. Moreover OpenCV 2.4 development library was used for image processing and manipulations [11]. Then OpenGL library is used for rendering 3D objects and composing it into real scene. All tests were run on 8GB RAM machine equipped with Intel i7 2640M 2.80GHz processor. The processed images have 640 by 480 pixels resolution.
The marker presented in Fig. 4 was printed and displayed on flat moving surface. Webcam was static. Results are presented on Fig. 7. Right part of images show tracked marker, left part present marker and the virtual object - standard openGL teapot. All of those images presents marker from different perspective and proper projection of virtual object.

## V. Evaluation

For evaluation of proposed method five criterias were used: false/positive recognition, marker confusion, immunity of light conditions, immunity of occlusion and speed performance.

1) False/positive recognition: This criteria indicate sensitiveness for not recognize marker. First step of the presented method detects marker tracking points and passing marker points as input for second stage. If second stage loose it's stability in tracking marker points methods fallback to detection stage. This robust solution works stable until brightness constraint is violate or view angle is to acute.
2) Marker confusion: indicates sensitiveness if marker is recognized correctly. In presented case marker have four symmetric points any of them can be used as first feature to track.
3) Immunity of light conditions: Lucas-Kanade method use brightness constraint to track pixel movement between two frames. This constraint is also required for presented method. Selected marker has big contrast, so small changes in image brightness not disturb stability of presented method.
4) Immunity of occlusion: Optical flow is sensitive on occlusion. When tracking point is vanished by to acute angle or by other item occlusion Lucas-Kanade method is not stable and observed point usually move to other local minimum. Proposed method using only 4 points to track marker and if any of them is not tracked correctly methods loose stability. That triggers step back to marker detection block.
5) Speed performance: One of the most important criteria

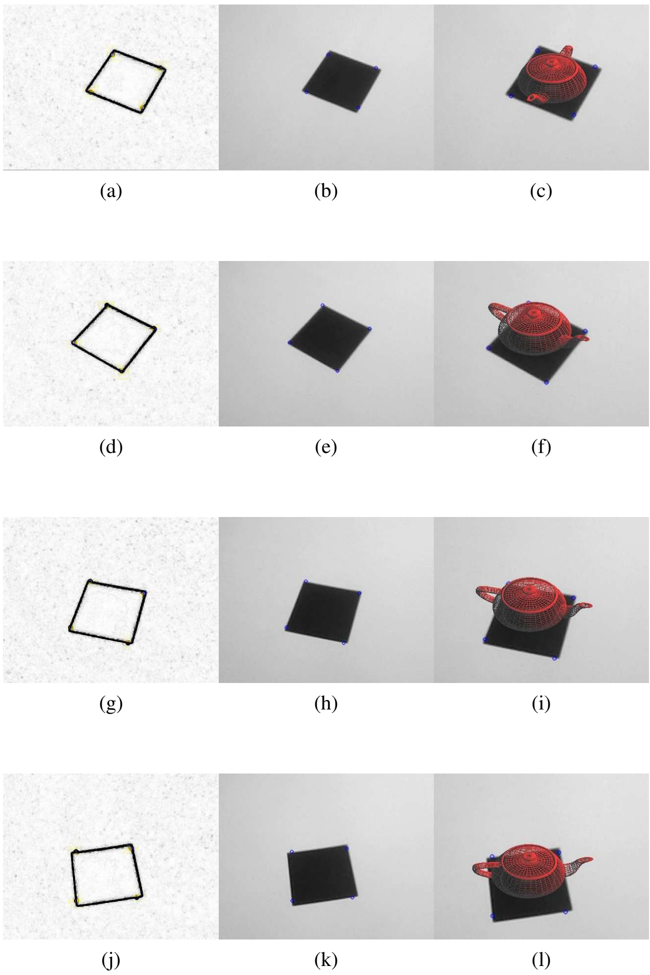

Fig. 7: Augmented virtual image - First column - marker detection. Middle column marker points tracking. Right column augumented virtual image

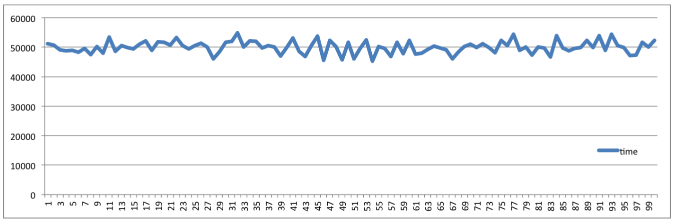

Fig. 8: Time in microseconds.

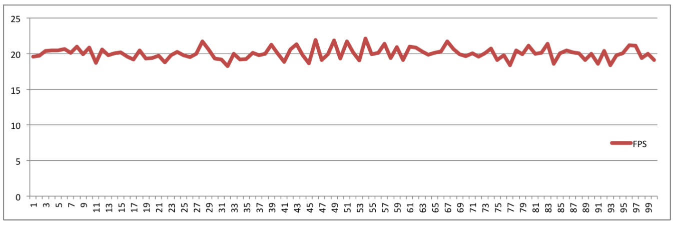

Fig. 9: Frames per second.

for AR is real time performance. Figure 8 presents time in microseconds to render each frame for 100 frames video. Figure 9 showing that system works with average 20 frames per second. That is comparable with real time performance.

## VI. Conclusion

This paper presents a new approach for Augmented Reality system based on Optical Flow method. The presented method uses a marker for obtaining the position, scale and pose of the virtual object. The proposed method runs in real time. The marker is detected correctly when there is no brightness change between image frames. All part tracking point from the marker must be visible during tracking otherwise method become unstable. The performed experiment shows that method is working correctly when marker was moved.

Using Optical Flow method for Augmented Reality is considered by the author as the natural step forward in combining marker and markerless method, and it will certainly become much popular in the near future.

## VII. Future work

As presented methods gives good results in Augmented Reality application, the next step should improve alghoritm stability when one of tracked points is obscured. This method is also sensitive to changing light conditions. Future work should improve presented mehtod to be less sensitive for changing light conditions.

***Abstract*—The paper presents unsupervised method for word detection in recorded spoken language signal. The method is based on examining signal similarity of two analyzed media description: registered voice and a word (textual query) synthesized by using Text-to-Speech tools. The descriptions of media were given by a sequence of Mel-Frequency Cepstral Coefficients or Human-Factor Cepstral Coefficients. Dynamic Time Warping algorithm has been applied to provide time alignment of the given media description. The detection involved classification method based on cost function, calculated upon signal similarity and alignment path. Potential false matches were eliminated in the algorithm by comparing costs of the path subsequences to a threshold value. The results of the work could provide incentives to build affordable commercial or non-commercial solutions for specific and multilingual applications.**

## I. Introduction

CURRENTLY one can observe increasing use of methods and techniques of digital processing of sound information for simple daily tasks. Many of these methods and techniques have been implemented in various types of mobile devices, having as a matter of principle, relatively small memory resources and being not efficient enough to fulfill their requirements to full extent. Two common tasks in this field are connected with speech recognition and speech synthesis. Due to the limited resources two models, especially in recognition, are being observed: low quality local processing for specific usage, high quality remote (Internet service-oriented) processing[1] for wider usage. Regarding the described trend, in this paper the combination of both approaches were being adopted to word detection in recorded speech task.

Word detection relates to problem of searching for a given word in a speech medium (container or stream). In this paper only the solid container, such as: WAV, MP3 is concerned. The detection is usually given by the two [1] coupled values: position in medium (i.e. time code) and quality ratio. This problem is also recalled in contemporary literature as "keyword spotting[2]" (KWS) [2], [3] or "spoken term detection" [4] and usually refers to continues, unconstrained vocabulary speech.

Classical solutions to this problem address two-step-supervised approach where models such as hidden Markov model (HMM) or support-vector machine (SVM) are trained like in a typical automatic speech recognition (ASR) system, using Large Vocabulary Continuous Speech Recognition (LVCSR) methods [5] at the first step [6]. At this step the speech signal is divided into segments of equal-size, from which speech features are extracted. At the second step, appropriate algorithm is employed to determine the type of signal present in each segment.

Different approaches like this described in [1] base on the fact that for some applications it is not possible to have model trained, either due to lack of relevant training data or due to time-specific limitations. Moreover as maintains [7] by exploiting the structure of repeating patterns within the speech signal, unsupervised recognition task is made possible directly from an un-transcribed audio stream.

Under the concept of the unsupervised matching process lay suitable speech features and a classification strategy. Speech signal cepstrum-based features like Mel-Frequency Cepstral Coefficients (MFCC) are those used extensively in nowadays ASR [8]. Interesting study on MFCC and its two siblings can be found in [9]. However that work hasn't considered Human-Factor Cepstral Coefficients (HFCC), which had been introduced in [10] one year later. In [1] HFCCs are described as the closest to human perception system and therefore seen as more robust in this task.

Concerning classification strategy mainly two are considered: HMM with Viterbi algorithm [2] and Dynamic Time Warping (DTW) [1]. Advantages and disadvantages of

This work was supported by Cybernetics Faculty (Military University of Technology, Warsaw, Poland) under the grant no. RMN/953/2014

[1] See: www.nuancehealthcaredeveloper.com, as an example of speech recognition/synthesis service and www.shazam.com, as an example of music excerpts recognition service. For legal notice see footnote 3.

[2] Spotting task is strictly connected with pattern matching but usually without explicit requirement for further (a posteriori) verification. The word "keyword" usually occurs within a clause (not alone) or/and describes its context.

978-83-60810-66-8/$25.00©2015, IEEE

these approaches are discussed in [11]. Further in this paper the approach based on Dynamic Time Warping (DTW) for pattern matching has been chosen, as it does not require any modeling or training as compared to the HMM, but still enables one to mitigate temporal differences.

## II. PROBLEM STATEMENT

### A. Scenario and speech features

In the paper the following scenario is considered. To an operator (a user) a container with recorded speech is provided. The operator has to search the speech content for the existence of specific words. The words are either not known in advance or are changing frequently. Moreover the recorded voice origin and its language is out of operator's knowledge. The sound quality is low and its characteristics (especially the environment) are changing during analyzed period like in live telephone conversation. Still the detecting process is time-sensitive as the existence of specific words will result in more detailed examination and perhaps in appropriate human activity (like calling police or fire brigade).

The presented scenario provides considerably limited usage of classical LVCSR methods because of too little knowledge of speech signal. The approach speculated here is directed to unsupervised methods, resulting in coarse detection, connected either with user interaction (i.e. hearing) or involving precise detecting methods.

Proposed approach applied to the scenario has been taken from [1] but the innovative reference queries strategy has been proposed in this paper. The approach assumes at this point the choice of appropriate speech signal features. In the research two types of feature vectors have been used:

- Mel-Frequency Cepstral Coefficients (MFCC),
- Human-Factor Cepstral Coefficients (HFCC).

MFCCs has been computed according to the following algorithm:

1) given signal $S$ has been windowed by Hamming window resulting in $N$ segments, $s_1 ... s_N$ ;

2) each segment has been processed by short-time Fourier transform (STFT) with length of 51 ms and step size of 10 ms;

3) then the triangular filter bank has been developed with 40 equally spaced mel-scale center frequencies $f_i$, $i = 1,...,40$ and with uniform bands controlled by the neighbor center frequencies $f_{i \pm 1}$ (see Fig. 1);

4) in this step the actual filtering (or spectral smoothing) has been done, by multiplication of each STFT segment (representing magnitude spectrum) with magnitude spectrum of bands for MFCC;

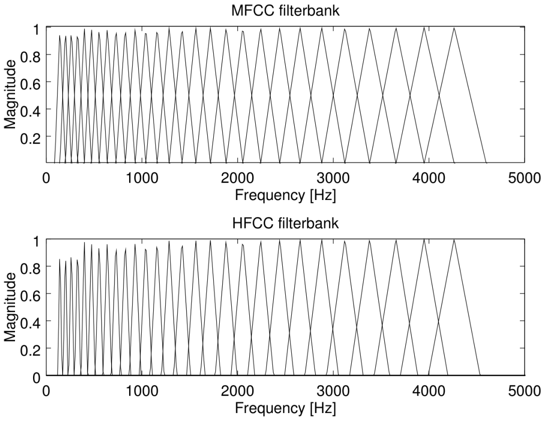

Fig. 1. Exemplary filter banks for MFCC and HFCC. HFCC filters corresponding to MFCC filters have narrower bandwidth, determined by (1).

5) the result has been then decorrelated using Discrete Cosinus Transform (DCT). Finally only 15 the most decorrelated vectors (MFCC coefficients) have been kept.

The concept of Human-Factor Cepstral Coefficients introduced in [10] employs congenial algorithm to the abovementioned. The essence of HFCC lays in filter design stage. In MFCC filter bands are determined by the spacing of the center frequencies which are equally distributed in mel frequency scale. In HFCC design filter center frequencies are still equally spaced in mel frequency scale, but unlike in MFCC filter bandwidth is treated as a parameter. This parameter determines filter bands' endpoints (cut-off frequencies) using the following measure, called Equivalent Rectangular Bandwidth (ERB) [10]:

$$ERB(f) = 6.23 f^2 + 93.39 f + 28.52 \text{ Hz} \qquad (1)$$

where $f$ states for filter center frequency, expressed in kHz.

As a result of using the approach, HFCCs are perceived as a better approximation of human auditory model [1], [10] than MFCCs and by incorporating appropriate scaling to ERB, by some factor, HFCC-based speech recognition can be under some circumstances treated as robust speech features to chosen applications [12].

### B. Textual query

For the recalled scenario two reasonable approaches are emerging:

1) Profile (or design and implement new) ASR system: write down a set of words likely to be searched for, gather relevant training set, then prepare, train and verify model of each word, according to chosen pattern learning method. Set the system to recognize only selected words from the trained set. In case of positive recognition register the time of related speech segment.

2) Exploit Text-to-Speech (TTS) system to generate synthetic voice from the text (query). Transform the produced speech query to chosen speech feature's space (the query becomes a pattern). Read a chunk of speech signal from the given source, transform it to the same speech feature space and apply appropriate classification strategy.

In case of detection (pattern matched) of the given word register the time of related speech segment.

These approaches shall be amplified (or duplicated) to reflect language variations assumed in the scenario. Implementation of the selected approach could then take advantage of parallel processing techniques and search for the same word, translated to several languages, in the given speech signal.

The second approach makes impression of being much more innovative and promising than the first one. While using TTS there is rather no limitation in producing new query, in ASR-based approach this task will be probably the most demanding, and resource consuming. Supporting argument is the existence of publicly available, free of charge online translators with speech synthesis features and accessible APIs, e.g.[3]: Google Translate, Bing Translator, Yandex Translate, etc. Based on this argument several queries can be created in less than a second.

### C. Similarity and alignment path

Dynamic Time Warping is a known and still used with success speech classifier [3]. It is popular for readability of implementation and analysis as well as for relatively high recognition accuracy similar to HMM.

In the overall look on DTW used in speech recognition it is to compare two feature vectors of different length (analyzed voice and the reference pattern) and to find an optimal alignment path $P$ of both by stretching them with respect to time. $P$ is usually calculated upon the local distance matrix (similarity matrix) from lower left corner to upper right corner of the matrix. Optimal means here the lowest cost path $P$ for passing from one point of matrix to another within given constraints. Application of DTW to exemplary speech features vectors is presented in Fig. 2. The similarity refers to speech signal of the same phrase, spoken by the same speaker. Double reduced utterance tempo is observed in analyzed voice part.

Building similarity matrix $D_{A,R}$ where $A$ stands for analyzed voice feature vector and $R$ stands for referenced pattern feature vector, is the first step considered in speech classification. Feature vector consists for either MFCC or HFCC coefficients computed for segments $s_1 \ldots s_N$. Individual element $d(a,r)$ of similarity matrix, where $a,r$ stands for specific element of vector $A$ and vector $R$ respectively, is given by inner product [6]:

$$d(a,r)=\frac{\langle A_a, R_r\rangle}{\|A_a\|\|R_r\|} \tag{2}$$

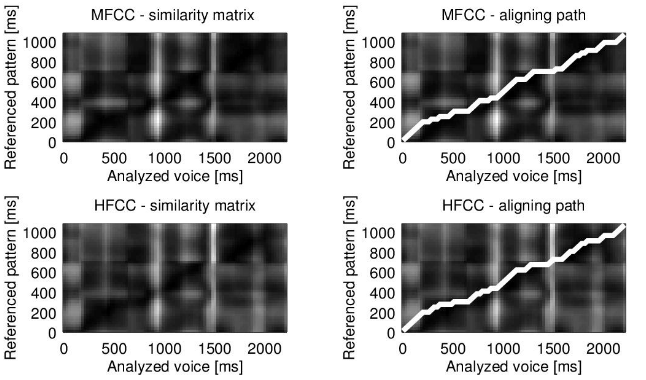

Fig. 2. Exemplary similarity matrices for MFCC and HFCC as well as corresponding aligning paths, received after applying DTW. The difference in image contrast between MFCC and HFCC indicates a higher MFCC features fuzziness.

In the following step DTW algorithm is exploited to perform cost path computation. The algorithm is two-staged[4]. At the first stage the calculation of an accumulator $C_{A,R}$ is performed (where $C$ is of size $D$). The accumulator is a structure that contains at each of its point $c(a,r)$ the value of accumulated lowest transition cost to this point from its neighbors, including the cost of lowest transition to the neighbors from theirs consequent neighbors until the starting point $c(1,1)$, retaining directional constraints, according to the recursion:

$$c(a+1,r+1)=d(a+1,r+1)+\min\begin{cases} c(a-1,r) \\ c(a,r) \\ c(a,r-1) \end{cases} \tag{3}$$

where: $a,r \geq 1$ and $c(1,1)=d(1,1)$.

At the second stage the optimal aligning path $P$ is created. Its creation is based on accumulator traceback, starting from its last point $c(N_A,N_R)$ and ending in point $c(1,1)$ recursively by searching across all allowable predecessors to each point. Because each point holds the value of the lowest transition cost to itself, the actual calculation of the path is based on choosing the next point upon the minimal value.

Presented algorithm is a type of conventional Dynamic Time Warping and it is regarded as slow and memory consuming [11], especially for aligning large sequences, therefore a practical usage could engage its specific modifications, like a multiscale approach [14]. Nevertheless in this for DTW has been used in the research described in the paper.

### D. Classification and verification

DTW presented in preceding paragraph refers to global alignment of one feature vector to another (in time domain), such as these presented in Fig. 2 (on the right). In general this is not enough to classify the part of analyzed voice as detected word, with regard to referenced pattern. Moreover

[3] Author of the paper would like to strongly accent having nothing in common with the companies whose products were listed. The author is far from rating, comparing and criticizing these products. Names of the products have been presented in this paper only in relation to the contemporary, publicly available technology, not for marketing purposes.

[4] The DTW algorithm used in the reported research, is based on the code originated with the project described in [13].

as commonly $N_A >> N_R$ holds, additional matching procedure shall be applied. The matching procedure is presented in figure Fig. 3.

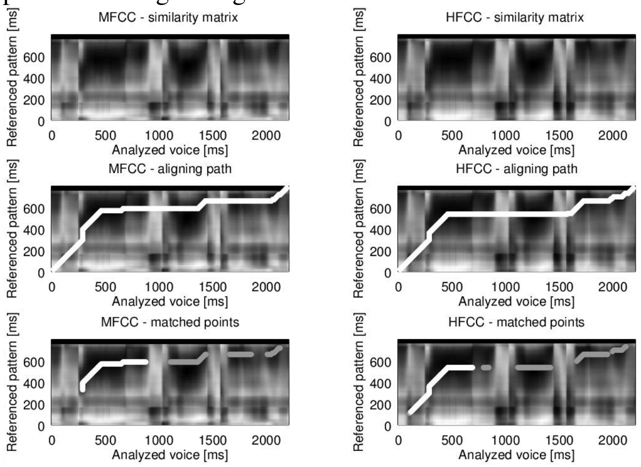

Fig. 3. Pattern matching procedure. Upper images present computed similarity between the pattern (the word “school” - synthesized woman’s voice) and analyzed voice (recorded man’s voice “school is closed today”). Images in the middle present global alignment path. Bottom images present resultant match: white strip is for the best match, gray strips are for remaining matches.

After computation of aligning path $P$, the points $p_1 ... p_{N_P}$ lying on the path are being assigned weight values $v$ based on referring points of matrix $D_{A,R}$ and a path threshold $T_P$, satisfying inequality (4).

$$T_P \leq v := 1 - d \leq 1 \tag{4}$$

$T_P$ controls the number of points suspected to indicate detected words. In Fig. 3 they are presented in the bottom images (as gray strips). As there could be several alleged word occurrences detected, indicated by subsequences: $p_{k_1}^{(l)} ... p_{k_{N_P}}^{(l)}$, $l = 1,2...$, the verification step is executed. This step consists of computing Longest Common Subsequence (LCS) with maximization criterion of cumulative weights of subsequences, i.e. the longest subsequence with the highest weights sum wins. It is worth noting that the minimal cumulative cost for a subsequence should be restricted by the second threshold value (called here sequence threshold), controlling the number of possible word reoccurrence.

As a result of matching procedure, assuming only one occurrence of the searched word, the best match is projected to the analyzed voice time domain (see white strips in the bottom images of Fig. 3) and, according to the scenario assumed in research, presented to the operator as a speech signal.

## III. UNSUPERVISED KEY DETECTION

### A. Algorithm

On the basis of literature search, especially [1], [2], [3], [11], [12] and performed experiments, the following algorithm has been proposed to unsupervised key detection.

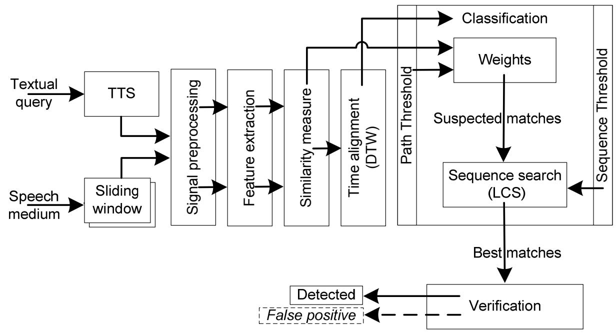

Fig. 4. Unsupervised key detection algorithm.

Description of respective processing blocks, presented in Fig. 4 is the content of the previous paragraphs, except of the sliding window and signal preprocessing. Sliding window block represents the abstract of feeding the model (or the program etc.) with respectively short signal, which the model is able to process. The size of the window is to be determined before the start of examination. It is assumed to be the function of size of the query.

Signal preprocessing is understood as applying standard digital signal processing techniques, at least but not limited to: silence cancellation, resampling and pre-emphasis filtering.

### B. Experiments

A series of preliminary experiments have been conducted on the basis of methods and techniques of speech signal processing addressed in the paper, with regard to the presented algorithm. The target was to detect a word in a given speech medium by examining signal similarity of two analyzed media description: registered voice and referenced pattern, where the descriptions were given by a sequence of MFCC or HFCC coefficients.

Dedicated research material has been prepared, which consists of five short (from 1 – 5 seconds) sentences in English language: spoken by one man (natural speech) and synthesized by six (free of charge) TTS systems with fourteen men voices, and nine women voices. This material has been stored on a hard drive in the WAV containers.

The queries have been produced online by three TTS systems, different from these used in preparing research material. One TTS was the part of local operating system while two others were available through the World Wide Web via HTTP protocol. Nevertheless query generation was taking less than one second.

The research material as well as the queries were of the following (different[5]) properties: PCM (lossless) codec, one channel, 16 bits per sample, sampling frequency: 8000 – 22050 Hz, bit rate: 256 – 352 kbps. During examination all used sounds were resampled to 8000 Hz. The model (Fig. 4) was configured according to the guidelines from paragraph II.A. For HFCC ERB scaling factor of value 3 was used.

[5] During material acquisition (except of the natural voice recording) there was not possible to influence sound properties.

Experiments have been conducted according to the following strategy: selected word to find (textual query) has been sent to the TTS system to obtain speech signal, the signal then has been read by program and compared with the entire research material according to the algorithm (Fig. 4). This has covered both situations: the existence and inexistence of the word in the examination set.

### C. Results

Overall results have been presented in Table 1. "No detection" phrase used in the results means the percent of false negatives (lack of detection, when the word actually existed in the analyzed signal). Higher detection rate for HFCC, as well as lack of false negatives for these features is noticeable. Nevertheless MFCC present lower false detections.

TABLE 1. OVERALL RESULTS BY SPEECH FEATURES

| | Detected words | No detection | False positive |
|---|---|---|---|
| MFCC | 82,43% | 4,05% | 13,51% |
| HFCC | 85,14% | 0,00% | 14,86% |

The results showed that the unsupervised detection of word in a given set is possible with relatively high detection rate. It is worth noting the lack of "no detection" results when using HFCC.

In Table 2 the discrimination on the basis of speech source has been presented. The results give the overview that either male or female synthesized voice can be with success use to detect words in speech.

TABLE 2. MEAN RESULTS BY SPEECH SOURCE

| | Detected words | No detection | False positive |
|---|---|---|---|
| Real speech | 95% | 0% | 5% |
| TTS (male) | 80% | 15% | 15% |
| TTS (female) | 70% | 12,5% | 17,5% |

HFCC based detection gives better overall results in comparison with the MFCC method, but the results of the research don't allow to make general statement for this.

## IV. CONCLUSION

Results of the work presented in this paper are satisfactory, but still far from industrial standard. It is difficult to make direct comparisons with other related works as this work has been conducted partly on synthesized material. The following work shall be considered: (1) applying multiscale approach (like presented in [13]) for bypassing fully different signal parts, and analyzing these initially consonant parts on higher resolution, (2) parallel processing: for searching the multilingual queries, as well as increasing detection reliability based on information fusion.

Moreover additional study on less speaker-dependent features should be done, to limit the number of false positives.

The main problem in the approach (especially while applying DTW and LCS) that cannot be fully circumvent is the determination of the threshold values. The mitigation of the problem could employ computation of the values based on query or signal properties.

In general view of this work, its results could provide incentives to build affordable multilingual commercial or non-commercial solutions for specific applications.

## ACKNOWLEDGMENT

Author would like to thank the team (of the year 2010) of KOM department, Fraunhofer FKIE, Wachtberg, Germany, especially Dirk, Frank and Paul (NUWC), who gave me the inspiration of the topic, as well as the leader of the department Dr. Markus Antweiler, who enabled my scientific internship at FKIE.

***Abstract*—The HUGO project, published at 2010, can be considered as one of the most promising direction in the design of highly undetectable steganography. The main idea of that approach is to minimise the embedding impact from the steganalysis point of view. This goal is achieved by using trellis codes in the embedding procedure, the Viterbi algorithm (VA) and the SPAM features. But the optimality of VA was kept still unclear because a generic purpose of VA is to correct errors with trellis codes instead of embedding secret information. The first goal of the current paper is to prove the optimality of VA application in its generalised form proposed about 30 years ago by one of the authors of this paper. The second goal is to optimise the parameters of the trellis code check matrix for better undetectability of stegosystems.**

***Index Terms*—stegosystem, images, HUGO project, trellis codes, generalised Viterbi algorithm.**

## I. Introduction

STEGANOGRAPHY (SG) is the information hiding technique that embeds the hidden information into an innocent *cover object* (CO) under conditions that CO is not corrupted significantly and that the presence of the additional information in CO may not be detected. This goal entails an obvious requirement: the embedding impact has to be minimised from the steganalysis point of view. Moreover, it does not mean that the number of changes into CO just after embedding should be minimised because the changes “weights” may differ, hence a minimisation of changes into CO does not necessary results in the minimisation of SG detectability.

The assumed most effective stegoanalytic method is the so called *blind steganalysis* based on the transition probabilities of the *Subtractive Pixel Adjacency Matrix* (SPAM) features model between neighboring pixel of the image and CO along 8 different directions [1], [2].

Let $X \in \mathbb{R}^{n_1\times n_2}$ be a grey scale cover image and let $Y \in \mathbb{R}^{n_1\times n_2}$ be the resulting image after embedding using some stego-algorithm. Let $D(X,Y)$ be the distortion of the stegoimage and the cover image, in the sense of ability of the SPAM stegoalgorithm to distinguish $X$ and $Y$. Up to an enumeration of the pixel array, any image $X$ can be regarded as an array $\mathbf{x} = (x_i)_{i=1}^n$, with $n = n_1 n_2$.

The additive distortion function chosen for SPAM and *Highly Undetectable steGO* (HUGO) [3] is

$$(X,Y) \mapsto D(X,Y) = \sum_{i=1}^{n} \rho_i \left|x_i - y_i\right| \tag{1}$$

where, $\rho_i \in \mathbb{R}^+ \cup \{+\infty\}$ is the weight coefficient (the cost of changing the $i$-th pixel), $x_i, y_i$ are the values of the $i$-th pixel at $X$ and $Y$ respectively. All changes are restricted to $\pm 1$ increments, so that the following inequality holds after $\pm 1$-embeddings in LSB:

$$\forall i \text{ with } 1 \leq i \leq n: \ |x_i - y_i| \leq 1.$$

The additive form of (1) means that detectability of SG does not depend on the correlation between the embedded bits. That assumption holds when the changed pixels are located sufficiently far from each other, which in turn holds when the embedding rate is relatively low.

Two immediate problems arise in the design of effective SG:

1) How to choose adequately the weights $(\rho_i)_{i=1}^n$?
2) What is the best coding method for changing pixels according to their weights?

In order to find the pixel weights to be used at (1), for each $i \in \{1,\dots,n\}$, let $Y^{(i)}$ be the image $X$ with the $i$-th pixel changed. Then, $\forall j \in \{1,\dots,n\}: \ |x_j - y_j^{(i)}| \leq 1$. Let us pick $\rho_i = D(X, Y^{(i)})$.

The weight $D(X,Y)$ can be calculated as proposed in [3], as the addition of two sums:

$$\sum_{d_1,d_2=-T}^{T} w(d_1,d_2) \left| \sum_{k\in U} \left(C^k_{d_1 d_2}(X) - C^k_{d_1 d_2}(Y)\right)\right| + \\ \sum_{d_1,d_2=-T}^{T} w(d_1,d_2) \left| \sum_{k\in V} \left(C^k_{d_1 d_2}(X) - C^k_{d_1 d_2}(Y)\right)\right| \tag{2}$$

where the map $C^k_{d_1 d_2}$ is calculated, in line with the SPAM features, as the Markov transition probabilities for the eight directions at $U \cup V$, with

$$U = \{\leftarrow, \rightarrow, \uparrow, \downarrow\} \text{ and } V = \{\searrow, \nwarrow, \nearrow, \swarrow\}.$$

978-83-60810-66-8/$25.00©2015, IEEE

In particular, for the case of the horizontal direction (→), for any integers $d_1, d_2 \in [-T, T]$:

$$C^{\rightarrow}_{d_1 d_2}(X) = \Pr\left(D^{\rightarrow}_{i,j} = d_1 \ \& \ D^{\rightarrow}_{i,j+1} = d_2\right) \tag{3}$$

where for $1 \le i \le n_1$ and $1 \le j \le n_2 - 1$,

$$D^{\rightarrow}_{i,j} = X_{i,j} - X_{i,j+1}.$$

As in [3], we consider a weight function of the form:

$$w(d_1, d_2) = \left[\sqrt{d_1^2 + d_2^2} + \sigma\right]^{-\gamma} \tag{4}$$

for some optimised parameters $\sigma > 0$ and $\gamma > 0$. It is well known [1] that in order to minimise the number of changes among pixels of the CO, a *syndrome coding* may be used:

$$H\,\mathbf{y} = \mathbf{m} \tag{5}$$

where $\mathbf{y}$ is the block of stego-image bits of length $n = n_1 n_2$, $\mathbf{m}$ is a block of information bits of length $k$ that should be embedded into $\mathbf{y}$ and $H$ is a $(k \times n)$-matrix chosen for encoding. Next, among all the solutions $\mathbf{y}$, for given $\mathbf{m}$ and $H$, it is necessary to select those providing minimum number of changes between $\mathbf{y}$ and its CO block $\mathbf{x}$. At [1], a technique to solve this problem was presented, and it is especially simple for the Hamming code with a specific check matrix $H$. But in our case it is necessary to minimise not the number of changes in CO but the distortion function $D : (X, Y) \mapsto D(X, Y)$ given by (1). It seems to be similar to a transition from hard decoding to soft decoding in communications where trellis codes using Viterbi algorithm for decoding can be more favorable than block codes, using some algebraic decoding algorithms. Nevertheless there exists a significant difference in the solution of the matrix equation (5) with respect to $\mathbf{y}$ given $\mathbf{m}$ with minimising the distortion function $D$ given $\mathbf{x}$ as a CO and the solution of the error correction procedure equation $H\,\mathbf{m} = \mathbf{y}$, given some distance between $\mathbf{y}$ and $\mathbf{x}$. Fortunately, there exists the so called *generalised Viterbi algorithm* (GVA) proposed in 1984 [4], [5] that is able to describe both error correction and also steganographic embedding problem in analytic form without execution on trellis graphs.

This method of stegosystem design based on trellis codes and GVA becomes clearer and gets a strict justification. We describe GVA and its application to steganographic problem design in the Section II.

Results of matrix optimisation, which are obtained by simulation with the use of GVA, are presented in Section III. Section IV concludes the paper.

## II. Application of GVA to the SG system design problem

Let us state a problem that results in a natural solution within GVA [4], [5].

**Problem.** Find

$$\tilde{\mathbf{x}}_N = \arg\min_{\mathbf{x}_N} \Lambda_N(\mathbf{x}_N) \tag{6}$$

where

$$\begin{aligned} \Lambda_N(\mathbf{x}_N) &= \sum_{k=1}^{N} \lambda(\xi_k) \quad \text{with} \\ \xi_k &= \begin{cases} (x_1, x_2, \dots, x_\nu) & \text{if } k \le \nu \\ (x_{k-\nu}, x_{k-(\nu-1)}, \dots, x_k) & \text{if } k > \nu \end{cases} \end{aligned}$$

where $0 \le \nu \le N - 1$, each entry $x_j$ is in the set $X$, $\operatorname{card}(X) = r$, and $\lambda$ is a real function defined on the set of finite length real sequences. Here, the goal at (6) is to minimise, but it can be to maximise, as well.

The stated problem can be solved through an algorithm introduced at [5]:

1. Find $\tilde{x}_1 = \arg\min_{x_1} \Lambda_{\nu+1}(x_1, x_2, \dots, x_{\nu+1})$.
2. Find $\tilde{x}_2 = \arg\min_{x_s} \Lambda_{\nu+2}(\tilde{x}_1, x_2, \dots, x_{\nu+2})$.

$\vdots$

$s$. Find $\tilde{x}_s = \arg\min_{x_s} \Lambda_{\nu+2}(\tilde{x}_1, \dots, \tilde{x}_{s-1}, x_s, \dots, x_{\nu+s})$.

$\vdots$

$N-\nu$. Find $(\tilde{x}_{N-\nu}, \dots, \tilde{x}_N) = \underset{(x_{N-\nu}, \dots, x_N)}{\arg\min} \Lambda_{\nu+2}(\tilde{\mathbf{x}}_N)$, where $\tilde{\mathbf{x}}_N = (\tilde{x}_1, \dots, \tilde{x}_{N-\nu-1}, x_{N-\nu}, \dots, x_{\nu+s})$

It is easy to see that for all steps, except the last one, the number of calculations for every argument is at most $r^{\nu+1}$ and the last step requires at most $r^\nu$ operations.

We note that the conventional VA is a particular case of GVA with $\nu = 1$. Then we get:

$$\Lambda_N(\mathbf{x}_N) = \lambda(x_1) + \lambda(x_1, x_2) + \cdots + \lambda(x_{N-1}, x_N). \tag{7}$$

If we assume now that each $x_k$ in (7) is the state of trellis on the $k$-th step and $\lambda(x_k, x_{k+1})$ is the length of branch from the state $x_k$ to the state $x_{k+1}$, then the decoding problem for convolutional code presented by trellis diagram is equivalent to a minimisation of (6). But fortunately, GVA can be used also for a situation of embedding problem for SG given by (5) that seems to be at a single glance completely different than correction of errors by convolutional codes.

Let us consider a matrix $H$ in (5) that has the "step-wise" sliding form based on a submatrix $\tilde{H}$ of order $t \times w$ pictured at Fig. 1.

In order to simplify further the description, let us consider the particular case of $t = 2$, $w = 2$, and $\tilde{H} = [h_{ij}]_{1 \le i,j \le 2}$. Let us assume also $k > 0$, and $n = 2k$. Then equation (5) can be written as follows:

$$\begin{bmatrix} h_{11} & h_{12} & 0 & 0 & \cdots & 0 & 0 \\ h_{21} & h_{22} & h_{11} & h_{12} & \cdots & 0 & 0 \\ 0 & 0 & h_{21} & h_{22} & \cdots & 0 & 0 \\ \vdots & \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & 0 & 0 & \cdots & h_{11} & h_{12} \end{bmatrix} \mathbf{y} = \mathbf{m} \tag{8}$$

with

$$\begin{aligned} \mathbf{y} &= [y_1 \ \cdots \ y_{2k}]^T \\ \mathbf{m} &= [m_1 \ \cdots \ m_k]^T \end{aligned}$$

$$H = \begin{bmatrix} h_{11} & h_{12} & \cdots & h_{1w} & 0 & 0 & \cdots & 0 & \cdots & 0 & 0 & \cdots & 0 & 0 & 0 & \cdots & 0 \\ h_{21} & h_{22} & \cdots & h_{2w} & h_{11} & h_{12} & \cdots & h_{1w} & \cdots & 0 & 0 & \cdots & 0 & 0 & 0 & \cdots & 0 \\ \vdots & \vdots & & \vdots & h_{21} & h_{22} & \cdots & h_{2w} & \cdots & 0 & 0 & \cdots & 0 & 0 & 0 & \cdots & 0 \\ h_{t1} & h_{t2} & \cdots & h_{tw} & \vdots & \vdots & & \vdots & & \vdots & \vdots & & \vdots & \vdots & \vdots & & \vdots \\ \vdots & \vdots & & \vdots & h_{t1} & h_{t2} & \cdots & h_{tw} & & \vdots & \vdots & & \vdots & \vdots & \vdots & & \vdots \\ \vdots & \vdots & & \vdots & \vdots & \vdots & & \vdots & & h_{11} & h_{12} & \cdots & h_{1w} & 0 & 0 & \cdots & 0 \\ 0 & 0 & \cdots & 0 & 0 & 0 & \cdots & 0 & \cdots & h_{21} & h_{22} & \cdots & h_{2w} & h_{11} & h_{12} & \cdots & h_{1w} \end{bmatrix}$$

Fig. 1. $H$ as a step-wise sliding matrix.

determining the equation system

$$\begin{array}{rcl} h_{11}y_1 + h_{12}y_2 & = & m_1 \\ \forall j = 2, \ldots, k-1 : & & \\ h_{21}y_{2j-3} + h_{22}y_{2j-2} + h_{11}y_{2j-1} + h_{12}y_{2j} & = & m_j \\ h_{11}y_{2k-1} + h_{12}y_{2k} & = & m_k \end{array} \tag{9}$$

It is possible to apply GVA to solve the system (9) given the column vector $M$ and $X$ providing a minimisation of the weight

$$D(X, Y) = \sum_{j=1}^{2k} \rho_j \, |x_j - y_j|.$$

This algorithm can be performed through the following steps:

1) Build the Table of variants $(\hat{y}_1, \hat{y}_2)$ for all possible tuples $(y_3, y_4)$ satisfying equation (9), for $j = 2$, and minimise the function
$$\Lambda_1 = \rho(x_1, \hat{y}_1) + \rho(x_2, \hat{y}_2),$$
where $\rho(x_i, y_i) = \rho_i |x_i - y_i|$.
2) Build the Table of variants $(\hat{y}_3, \hat{y}_4)$ for all possible tuples $(y_5, y_6)$ satisfying equation (9), for $j = 3$, and minimise the function
$$\Lambda_2 = \rho(x_1, \hat{y}_1) + \rho(x_2, \hat{y}_2) + \rho(x_3, \hat{y}_3) + \rho(x_4, \hat{y}_4),$$
where $\rho(x_i, y_i) = \rho_i |x_i - y_i|$.

Proceed similarly up to the last equation at (9).

**Example.** Let $k = 3$, $\rho_i = 1$ for $i = 1, \ldots, 6$, $\mathbf{x} = 101110$ and $\mathbf{m} = 100$. Then the matrix $H$ is

$$\begin{array}{rcl} H & = & \begin{bmatrix} h_{11} & h_{12} & 0 & 0 & 0 & 0 \\ h_{21} & h_{22} & h_{11} & h_{12} & 0 & 0 \\ 0 & 0 & h_{21} & h_{22} & h_{11} & h_{12} \end{bmatrix} \\ & = & \begin{bmatrix} 1 & 0 & 0 & 0 & 0 & 0 \\ 1 & 1 & 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 1 & 1 & 0 \end{bmatrix}. \end{array}$$

In line with (8) we have

$$H\mathbf{y} = \mathbf{m} \tag{10}$$

where

$$\begin{array}{rcl} \mathbf{y} & = & [y_1 \;\; y_2 \;\; y_3 \;\; y_4 \;\; y_5 \;\; y_6]^T \\ \mathbf{m} & = & [1 \;\; 0 \;\; 0]^T \end{array}$$

| $y_1$ | $y_2$ | $y_3$ | $y_4$ | (*) | $\Lambda_1$ |

| 0 | 1 | 1 | 1 |
| 1 | 0 | | |

TABLE II
ADMISSIBLE TUPLES $(y_1, y_2, y_3, y_4)$.

1) In order to satisfy the first equation in (9) we get two possibilities $(y_1, y_2) = (1, 0)$, and $(y_1, y_2) = (1, 1)$.
2) For all possible pairs $(y_3, y_4)$ and $(y_1, y_2)$ which are obtained in the Step 1) we get the possibilities to satisfy the second equation in (9) shown at Table I.

In Table I there are presented also the calculation results of the values $\Lambda_1$ for "survived" strings (with an asterisk). Next in Table II we present all possible pairs $(y_3, y_4)$ satisfying to the corresponding equation in (9) for every pair $(y_5, y_6)$.

By combining the Tables I and II, we get Table III presenting all possible$(y_1, y_2, y_3, y_4)$ tuples for every pair $(y_5, y_6)$ and corresponding to them, the values $\Lambda_3$.

Now it is possible to minimise $\Lambda_3$ by selecting a pair $(y_5, y_6)$. This gives two optimal tuples $\mathbf{y} = 101100$ and $\mathbf{y} = 101010$. It is easy to see that each of these tuples requires one change of the tuple $\mathbf{x}$ and satisfies the equation (10).

This approach can be extended to any "step-wise" matrix generated by shifting the $(t \times w)$-submatrix $\tilde{H}$. Then the

| $y_1$ | $y_2$ | $y_3$ | $y_4$ | $y_5$ | $y_6$ | $\Lambda_3$ |
|---|---|---|---|---|---|---|
| 1 | 1 | 0 | 0 | 0 | 0 | 4 |

complexity for GVA will be of the order $O(kwt\,2^{wt})$ with respect to operations.

## III. OPTIMISATION OF $\tilde{H}$ BY SIMULATION WITH GVA

Let us consider initially the case with $\rho_i = 1$, for $i = 1, \dots, n$. This means that we try to minimise the number of changes into the image pixels after embedding against the sizes $t$ and $w$ of a randomly chosen submatrix $\tilde{H}$. The results of simulation are shown in Fig. 2 where relative changes

$$\nu = \frac{\text{card}\left(\{i|\ x_i \neq y_j\}\right)}{n}$$

are presented on the vertical axis.

From Fig. 2 it can be seen that it is sufficient to bound the sizes of the submatrix $\tilde{H}$ as $t \leq 15$, $w \leq 10$, at least for the case $\rho_i = 1$, for $i = 1, \dots, n$.

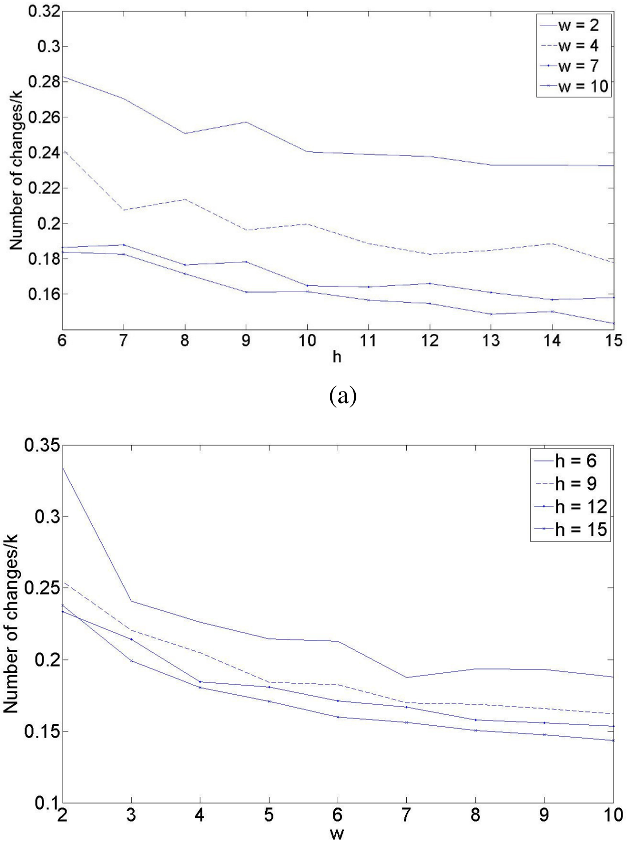
But it is more interesting to investigate the undetectability of SG based on syndrome embedding under the condition that the SG detection is performed by blind SVM-based steganalysis with the use of SPAM features (see (2)-(4)). The experiment has been arranged as follows: The image base was taken similar to those considered in [6]. Since the embedding procedure is very time-consuming the images were reduced to lesser sizes. The weight coefficients $\rho_{ij}$ in (1) were calculated by (2), (3) with the weight function (4) after optimization of parameters $\sigma$ and $\gamma$. At the training SVM stage both 500 images with and without embedding were used. During the testing SVM stage, there were executed 500 images with and without embedding. This HUGO-based algorithm was compared with conventional ±1 embedding algorithm taken with the same embedding rate $R = \frac{k}{n}$, where $k$ is the number of embedded bits and $n$ is the number of image pixels. As a criterion of stegosystem undetectability, it was used (in line with a recommendations [1]) the averaged error probability

$$P_e = \frac{1}{2}\left(P_m + P_{fa}\right)$$

where $P_m$ is the probability of SG missing and $P_{fa}$ is the probability of SG false alarm. The value $P_e$ has been minimised at the cost of SVM threshold optimization.

The results of simulations are shown in Tables IV and V.

We can see from these Tables that the use of the HUGO trellis code-based SG offers some advantages in undetectabilities against a conventional ±1 in LSB embedding SG.



(a)

(b)

Fig. 2. Relative changes of image pixels after embedding based on trellis codes with $n_1 n_2 = 10^5$. (a) against the matrix parameter $t$ given $w$, and (b) against the matrix parameter $w$ given $t$.

| Image size | Embedding rate $R = \frac{k}{n}$ | $P_e$ |
|---|---|---|
| $16 \times 16$ | 0.4 | 0.27 |
| $64 \times 64$ | 0.4 | 0.176 |
| $128 \times 128$ | 0.2 | 0.1780 |
| $128 \times 128$ | 0.4 | 0.123 |
| $256 \times 256$ | 0.4 | 0.099 |

TABLE IV
THE PROBABILITIES OF INCORRECT ±1 SG SYSTEM DETECTION ($P_e$) FOR DIFFERENT IMAGE SIZES AND EMBEDDING RATES $R$.

It is worth to note that the undetectability of SG, even in the case of a trellis code-based embedding (used with the HUGO project), depends significantly on the image texturing. We have found that the greater is the degree of texture, the most frequent undetectability of the corresponding image. Qualitatively, image texturing means that the image has a presence of precise contours, while not texture images have sliding luminance changing and noisy background. Numerically image texture can be estimated by the parameter [1]

$$t_n = \frac{1}{n_1 n_2} \sum_{ij} \left( \max_k B_{ij}^k - \min_k B_{ij}^k \right) \qquad (11)$$

| Image size | $R = \frac{k}{n}$ | SPAM parameters | | | $P_e$ |
|---|---|---|---|---|---|
| | | $T$ | $\sigma$ | $\gamma$ | |
| $16 \times 16$ | 0.4 | 10 | 10 | 4 | 0.337 |
| $64 \times 64$ | 0.4 | 10 | 10 | 4 | 0.24 |
| $128 \times 128$ | 0.4 | 10 | 10 | 4 | 0.162 |
| $128 \times 128$ | 0.2 | 10 | 10 | 4 | 0.269 |

TABLE V
THE PROBABILITIES OF INCORRECT HUGO SG SYSTEM SPAM-BASED DETECTION ($P_e$) FOR DIFFERENT IMAGE SIZES AND EMBEDDING RATES $R$

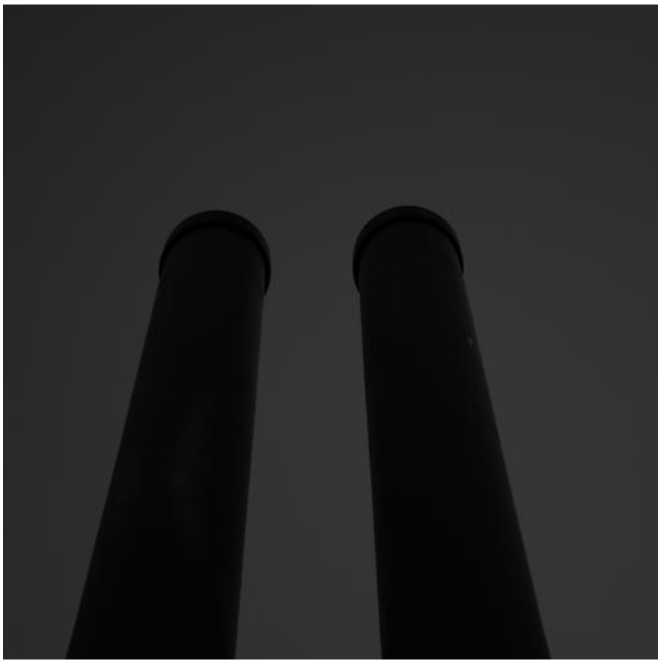


Fig. 3. Example of a low texture image.

where $B_{ij}^k$ is a $(2 \times 2)$-pixel block with $(i, j)$-coordinates and $k$ is the $k$-th pixel of this block.

On Fig's. 3 and 4 there are shown examples of images with low and high texture coefficient $t_n$, respectively.

As it can be seen by (11), in order to calculate a measure of image texture $t_n$ it is necessary to divide the image on disjoint $(2 \times 2)$-blocks and next to calculate for every block the difference between maximum and minimum pixel luminance of this block.

In Table VI there are presented the averaged error detecting probabilities for HUGO-based SG after embedding of messages into the images with different texturing. For both SVM training and testing phases 500 images from different image sets were used.

We can see from this Table that, in fact, the level of image texturing affects very significantly on SG system detectability. It seems to be recommended to select for SG embedding such images, which have large texture level. But on the other side it can be looking suspiciously with point of steganographic usage view. Maybe it is better to embed the amount of secret bits depending on the level of image texture.

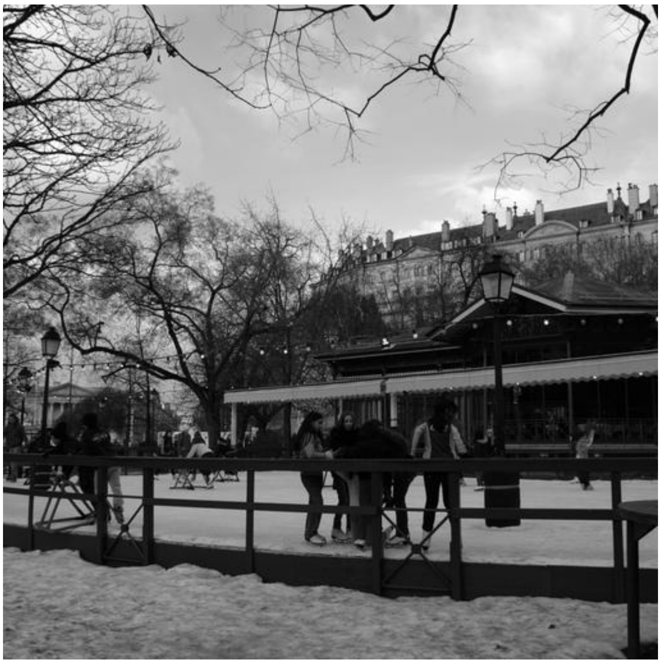

Fig. 4. Example of a high texture image.

| Image size | $t_n$ | $R = \frac{k}{n}$ | SPAM parameters | | | $P_e$ |
|---|---|---|---|---|---|---|
| | | | $T$ | $\sigma$ | $\gamma$ | |
| $64 \times 64$ | $< 0.194$ | 0.4 | 3 | 10 | 4 | 0.012 |
| $64 \times 64$ | $> 5.28$ | 0.4 | 3 | 10 | 4 | 0.391 |

TABLE VI
THE ERROR DETECTING PROBABILITIES FOR HUGO-BASED SG AFTER EMBEDDING OF MESSAGES INTO THE IMAGES WITH DIFFERENT TEXTURING.

## IV. CONCLUSION

A new generation of stegosystems with the use of trellis code-based embedding is very promising because this approach minimises an embedding impact with the point of view blind SVM-SPAM based steganalysis. This is the so called HUGO project developed recently [3].

But our main contribution into this direction is to make more clear and to prove rigorously that the use of generalised Viterbi Algorithm is in fact the optimal embedding procedure jointly with trellis codes.

With the use of this method we have shown experimentally that HUGO-based SG has significant advantage against simple stegosystems (like LSB or ±1 algorithm). We have found also that the level of image texturing is very important in a choice of images intended for embedding of hidden messages with high undetectability.

We agree with the importance given to “Open Problem 1” in [7], namely the design of effective coding schemes for non-additive distortion function.

***Abstract*—Nowadays the effective and fast detection of fruit defects is one of the main concerns for fruit selling companies. This paper presents a new approach that classifies fruit surface defects in color and texture using Radial Basis Probabilistic Neural Networks (RBPNN). The texture and gray features of defect area are extracted by computing a gray level co-occurrence matrix and then defect areas are classified by the applied RBPNN solution.**

***Keywords*-Co-occurrence Matrix, Texture Analysis, Pattern Recognition, Probabilistic Neural Network.**

## I. Introduction

IN ORDER to ensure the quality standard required in orange production lines, companies need trained people to inspect the fruits while they move in a conveyor belt. These experts classify oranges according to several categories based on visual features. However, for fast and precise quality standards, this approach is not competitive and sometimes unreliable. Therefore is paramount to use of an automatic system based on intelligent methods [1], [2], [3], [4], [5], [6]. The aim of this paper is to investigate the applicability of the Artificial Intelligence (AI) methods based on soft computing for detection of external defects of the fruits. Several methods based on more specific image acquisition are reported in [7], [8], [9], [10], [11], [12], [13]. Wen and Tao developed a near-infrared vision system for automatic apple defect inspection, see [14], While some recent advances in feature extraction for images and biometrics are reported in [15], [16], [17], [18], [19]. Zion et al. introduced a computerised method to detect the bruises of Jonathan, Golden Delicious, and Hermon apples from magnetic resonance images by threshold technique. The algorithm was only able to discriminate between all-bruised and non-bruised apples and was not applicable to on-line detection. Pla and Juste presented a thinning algorithm to discriminate between stem and body of the apples on monochromatic images. However, the task of classifying the calyx and defected parts in real-time was missing. Yang and Marchant used the ‘flooding’ algorithm for initial segmentation and ‘snakes’ algorithm for refining the boundary of the blemishes on the monochromatic images of apples. Miller et al. in [20] compared different neural network models for detection of blemishes of various kinds of apples by their reflectance characteristics.

From the said research, and according to the current literature, we can conclude that Multi-Layer Back Propagation (MLBP) gives proper recognition rates and also that increased complexity of the neural network system did not yield to better results [21]. Leemans, segmented defects of ‘Golden Delicious’ apples by a pixel-wise comparison method between the chromatic (RGB) values of the related pixel and the color reference model. The local and global approaches of comparison were effective, but more research was needed. In his further research work, Leemans [22] used a Bayesian classification method for pixel-wise segmentation on chromatic images of ‘Jonagold’ apples. Machine vision systems are successfully used for recognition of greenhouse cucumber fruit using computer vision [23]. A method for the classification and gradation of different grains (for a single grain kernel) such as groundnut, Bengal gram, Wheat etc., is described in [24]. The effect of foreign bodies on recognition and classification of food grains is given in [25]. Some researchers have used a neural network approach to the color grading of apples [26]. All these studies show that it is hard to define geometric or spectral properties for the fruit skin.

Most of the industry treatments such as washing and packing are highly automated, while the most important verification steps (e.g., inspection and grading in quality) are still performed manually, around the world. For this reason, we propose an efficient classifier based on fruit skin texture analysis, which can be implemented in manufacturing expert systems [27]. A new automatic classifier of oranges defects based on co-occurrence matrix and probabilistic neural networks is presented in the following sections. Orange is an important fruit of Mediterranean countries and it is well-known for its considerable anti-microbial, anti-viral, potent anti-oxidant properties. High-quality products are the basis for the success in today’s highly competitive market. Currently, manual inspection is being used in order to determine the orange quality. The increasing demand for quality assurance

978-83-60810-66-8/$25.00©2015, IEEE

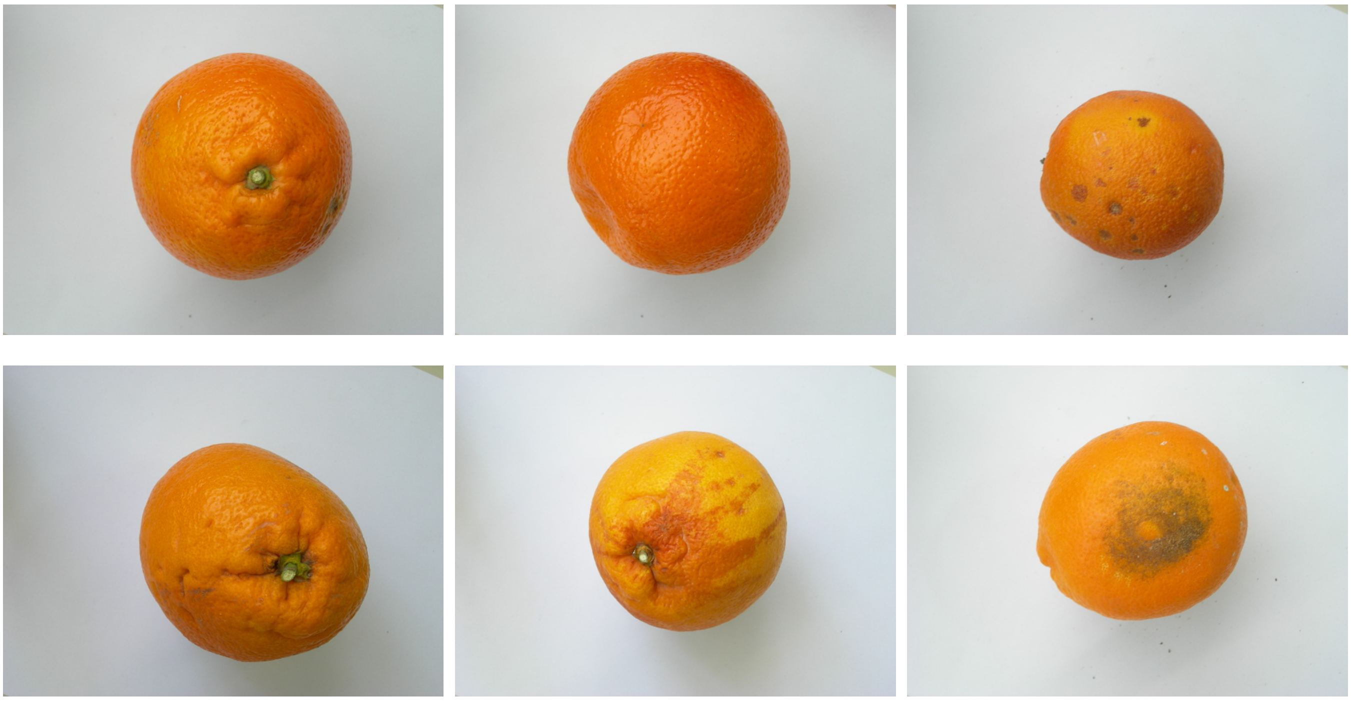

Fig. 1. Different sample of oranges used for this work. From left to right and top to bottom: Two normal oranges, an orange with several surface defects, a morphology defect, an orange with color defect, and an orange affected by a black mould.

requires simple and reliable sorting methods. The use of computer vision systems enables the detection of external quality defects. The objective of this study was to investigate the applicability of a method for detection of external defects and an automatic orange's classification system. For this purpose, the development of a classifier based on textural features of images, captured with a digital camera, was evaluated. The proposed technique is very robust and can identify specific defects like: surface defect, morphological defect, color defect, black mould or recognise a normal fruit. In fact, our RBPNN model is able to correctly attribute the samples to the correct defect groups with an overall error of $2.75\%$.

## II. Fruit classification Technique

In previous years, several types of image analysis techniques are applied to analyse the agricultural images such as fruits and vegetables, for recognition and classification purposes. The most popular analysis techniques that have been used for both recognition and classifications of two dimensional (2D) fruit images are color-based and texture-based analysis methods.

### A. Fruit classification based on shape

Shape based classification of fruits is based on various features like area, perimeter, major axis length and minor axis length. For calculating shape features an RGB image is converted into a gray scale image. After conversion into gray scale, the image represents a luminance intensity scale. There is a difference in intensity values for an object to be classified and its background, hence a threshold value is used to separate an object from its background. According to this threshold value, a gray scale image is converted into a binary image in which the value greater than the threshold is $1$ and the value lower than the threshold is $0$. With the help of this binary image different shape features are computed. The most common shape features are computed from the image area, perimeter, major axis length and minor axis length.

### B. Fruit classification based on color

RGB color space is converted into another color space such as HSV and for all the converted color space values, the mean and standard deviation are calculated. Each fruit image gives different values of mean and standard deviation, therefore assisting its classification.

*1) HSV Color Space:* HSI stands for hue, saturation and intensity. Then, for an image the color attribute is given by hue and the amount by which the pure color is diluted by white is given by saturation. The RGB components are separated from the original image, and the Hue (H), Saturation (S) and Intensity (I) components are extracted from RGB components. Equations (1), (2) and (3) are used to evaluate Hue, Saturation and Intensity of the image samples.

$$H = \begin{cases} \theta & B \leq G \\ 360 - \theta & B \geq G \end{cases}$$

$$\theta = cos^{-1}\left\{\tfrac{1}{2}\left(\tfrac{\lfloor (R-G)+(R-B) \rfloor}{\lfloor (R-G)^2+(R-B)\sqrt{G-B} \rfloor}\right)\right\} \tag{1}$$

The saturation component is given by:

$$S = 1 - \left(\frac{3}{R+G+B}\right)[min(R,G,B)] \tag{2}$$

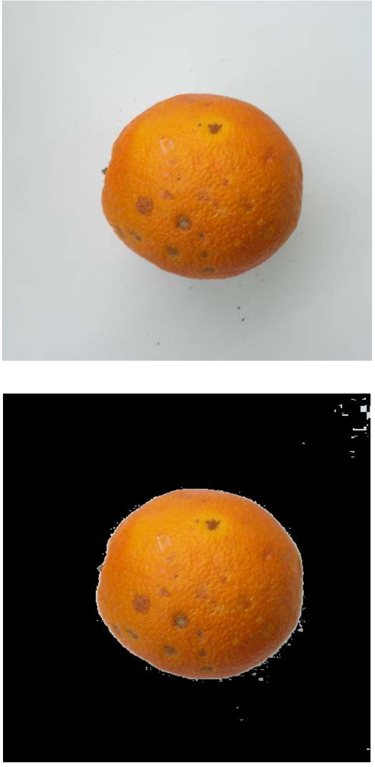

Fig. 2. An orange with some surface defects and the segmentation preprocessing result: the background is removed in order to analyse the orange surface only.

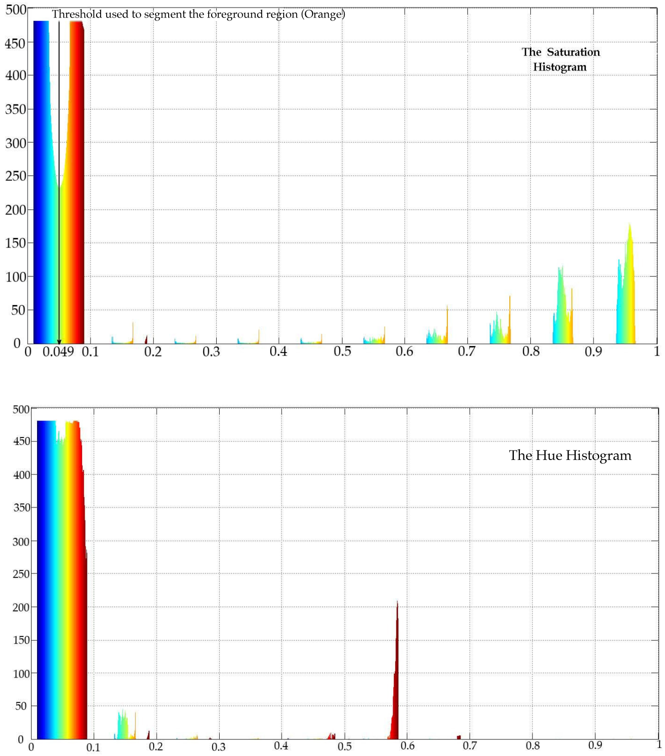

Fig. 3. The saturation (above) and hue (below) histogram related to the orange depicted in Fig. 2. The result shown in Fig. 2 is obtained by thresholding the saturation histogram shown here.

The intensity component is given by:

$$I = \frac{1}{3}(R + G + B) \tag{3}$$

### C. Fruit classification based on texture
